Skin lesions occur in 10% of cases. Sarcoidosis is the most common cause of erythema nodosum (see p. 1250). The association of bilateral symmetrical hilar lymphadenopathy with erythema nodosum occurs only in sarcoidosis. A chilblain-like lesion known as lupus pernio is also seen, as are skin nodules (see p. 1253).

Ocular and associated effects. Anterior uveitis is common and may present with misting of vision, pain and a red eye, but posterior uveitis may present simply as progressive loss of vision. Although ocular sarcoidosis accounts for about 5% of uveitis presenting to ophthalmologists, evidence of asymptomatic uveitis may be found in up to 25% of patients with sarcoidosis. Conjunctivitis may occur and retinal lesions have also been reported. Uveoparotid fever is a syndrome of bilateral uveitis and parotid gland enlargement together with occasional development of facial nerve palsy and is sometimes seen with sarcoidosis.

Keratoconjunctivitis sicca and lacrimal gland enlargement may also occur.

Metabolic manifestations. It is rare for sarcoidosis to present with problems of calcium metabolism, though hypercalcaemia is found in 10% of established cases. Hypercalcaemia and hypercalciuria can lead to the development of renal calculi and nephrocalcinosis. The cause of the hypercalcaemia is due to an increase in circulating 1,25-dihydroxyvitamin D₃ with 1α-hydroxylation occurring in sarcoid macrophages in the lung in addition to that taking place in the kidney.

The central nervous system. Involvement of the central nervous system (CNS) is rare (2%) but can lead to severe neurological disease (see p. 1159).

Bone and joint involvement. Arthralgia without erythema nodosum is seen in 5% of cases. Bone cysts are found, particularly in the digits, with associated swelling. In the absence of swelling, routine X-rays of the hands are unnecessary.

Hepatosplenomegaly. Sarcoidosis is a cause of hepatosplenomegaly, though it is rarely of any clinical consequence. A liver biopsy is occasionally performed when the diagnosis is in doubt and shows granulomas.

Cardiac involvement is rare (3%). Ventricular dysrhythmias, conduction defects and cardiomyopathy with congestive cardiac failure are seen.

Fig. 14.39 CT scan in sarcoidosis. Note enlarged glands at the hilum (black arrow) and nodular shadowing, particularly in right middle lobe (white arrow).
Investigations

- **Imaging.** Chest X-ray (see above). High resolution CT is useful for assessment of diffuse lung parenchymal involvement, and multislice CT detects and characterizes small nodules.
- **Full blood count.** There may be a mild normochromic, normocytic anaemia with raised ESR or CRP.
- **Serum biochemistry.** Serum calcium is often raised and there is hypergammaglobulinaemia.
- **Transbronchial biopsy** is the most useful investigation, with positive results in 90% of cases of pulmonary sarcoidosis with or without X-ray evidence of lung parenchymal involvement. Pulmonary non-caseating granulomas are found in approximately 50% of patients with extrapulmonary sarcoidosis in whom the chest X-ray is normal.
- **Serum level of angiotensin-converting enzyme (ACE)** is raised by two standard deviations above the normal mean value in over 75% of patients with untreated sarcoidosis. Raised (but lower) levels are also seen in patients with lymphoma, pulmonary tuberculosis, asbestosis and silicosis, limiting the diagnostic value of the test. However, the test is useful in assessing the activity of the disease and therefore as a guide to treatment with corticosteroids. Reduction of serum ACE during treatment with corticosteroids does not, however, imply complete resolution of the disease.
- **Lung function tests** show a restrictive lung defect in patients with pulmonary infiltration. There is a decrease in TLC, a decrease in both FEV₁ and FVC, and a decrease in gas transfer. Lung function is usually normal in patients who present with extrapulmonary disease or who only have hilar adenopathy on chest X-ray.

Treatment

Both the need to treat and the value of corticosteroid therapy are contested in many aspects of this disease. Hilar lymphadenopathy on its own with no evidence on chest X-ray of involvement of the lungs or decrease in lung function tests does not require treatment. Persisting infiltration visible on the chest X-ray or abnormal lung function tests are unlikely to improve without corticosteroid treatment. If the disease is not improving spontaneously 6 months after diagnosis, treatment should be started with prednisolone 30 mg for 6 weeks, reducing to alternate-day treatment with prednisolone 15 mg for 6–12 months. Although there have been no controlled trials of corticosteroids, it is difficult to withhold them when there is continuing deterioration of lung function. Eye involvement or persistent hypercalcaemia are definite indications for systemic steroids.

If the erythema nodosum of sarcoidosis is severe or persistent it will respond rapidly to a 2-week course of prednisolone 5–15 mg daily, as will patients with uveoparotid fever. Myocardial sarcoidosis and neurological manifestations are also treated with prednisolone.

Prognosis

Sarcoidosis is a much more severe disease in certain racial groups, particularly American blacks, where death rates of up to 10% have been recorded. It is probable that the disease is fatal in fewer than 5% of cases in the UK, most often as a result of respiratory failure and cor pulmonale and rarely, from myocardial sarcoidosis and renal damage. The chest X-ray provides a guide to prognosis. The disease remits in 2 years in over two-thirds of patients with hilar lymphadenopathy alone, in approximately one-half with hilar lymphadenopathy plus chest X-ray evidence of pulmonary infiltration, but in only one-third of patients with X-ray evidence of infiltration without any demonstrable lymphadenopathy. Lung function tests are the most useful way to monitor progression.

GRANULOMATOUS LUNG DISEASE WITH VASCULITIS

The classification of pulmonary vasculitis and granulomatous disorders is unsatisfactory. In broad terms it is reasonable to consider two main groups: the respiratory manifestations of systemic diseases, and disorders associated with the presence of anti-neutrophil cytoplasmic antibodies (ANCAs).

**Anti-neutrophil cytoplasmic antibodies** (ANCAs) (see also pp. 504 and 596) are found in the acute phase of vasculitides, particularly Wegener’s granulomatosis, Churg–Strauss syndrome and microscopic polyangiitis (polyarteritis) associated with neutrophil infiltration of the vessel wall. Two major ANCA reactivities are recognized: proteinase-3 (PR3) ANCA and myeloperoxidase (MPO) ANCA. Approximately 10% of all vasculitis patients are ANCA-negative: this is more common in Wegener’s granulomatosis limited to the upper respiratory tract. Ten to fifteen per cent of cases of progressive glomerulonephritis with anti-glomerular basement membrane (GBM) antibodies are MPO ANCA-positive and these are the most likely to suffer pulmonary haemorrhage.

Wegener’s granulomatosis (see p. 551)

This granulomatous disease of unknown aetiology is one of the primary systemic vasculitides in which the small arteries are predominantly affected (the other is Churg–Strauss syndrome, see below). It is characterized by lesions involving the upper respiratory tract, the lungs and the kidneys. Often the disease starts with severe rhinorrhoea with subsequent nasal mucosal ulceration followed by cough, haemoptysis and pleuritic pain. Occasionally there may be involvement of the skin and nervous system. A chest X-ray usually shows single or multiple nodular masses or pneumonic infiltrates with cavi- tation. The most remarkable radiographic feature is the migratory pattern, with large lesions clearing in one area and new lesions appearing in another. The typical histological changes are usually best seen in the kidneys, where there is a necrotizing microvascular glomerulonephritis. This disease responds well to treatment with cyclophosphamide 150–200 mg daily. Rituximab is also being used. A variant of Wegener’s granulomatosis called ‘midline granuloma’ affects the nose and paranasal sinuses and is particularly mutilating; it has a poor prognosis.

Churg–Strauss syndrome

This condition occurs usually in males in their fourth decade, who have a triad of rhinitis and asthma, eosinophilia and systemic vasculitis. The aetiology is uncertain, with some believing that it represents an unusual progression of allergic disease in a subset of predisposed individuals. Others believe it is a primary vasculitis which presents like asthma because of the involvement of eosinophils.
The pathology of this condition is dominated by an eosinophilic infiltration with a characteristic high blood eosinophil count, vasculitis of small arteries and veins, and extravascular granulomas. Typically it involves the lungs, peripheral nerves and skin, but kidney involvement is uncommon. Transient patchy pneumonia-like shadows may occur, but sometimes these can be massive and bilateral. Skin lesions include tender subcutaneous nodules as well as petechial or purpuric lesions. ANCA is usually positive. The disease responds well to corticosteroids. Occasionally Churg–Strauss syndrome may be revealed when oral steroids are withdrawn in patients being treated for asthma. There is no reason to think that other anti-asthma drugs precipitate the condition.

Microscopic vasculitis (polyangiitis)
This involves the kidneys and the lungs where it results in recurrent haemoptysis. ANCA is usually positive. In the early literature there was confusion between this condition, Churg–Strauss syndrome and polyarteritis nodosa. The latter, however, is ANCA-negative and rarely involves the lungs.

Pulmonary autoimmune rheumatic disease
Rheumatoid disease (see also p. 527)
The features of respiratory involvement in rheumatoid disease are illustrated in Figure 14.40.

- **Pleural adhesions, thickening and effusions** are the most common lesions. The effusion is often unilateral and tends to be chronic. It has a low glucose content but this can occur in any chronic pleural effusion.

Several forms of parenchymal disease can occur in patients with rheumatoid arthritis. These include fibrosing alveolitis, rheumatoid nodules, cryptogenic organizing pneumonia, lymphoid interstitial pneumonia and bronchiectasis; other pulmonary problems include pulmonary hypertension, fibrosis and others shown in the figure. Moreover, some patients will have modified presentations because they are already on disease-modifying drugs such as prednisolone or methotrexate for their arthritis.

- **Fibrosing alveolitis** occurring in rheumatoid arthritis can be considered as a variant of the cryptogenic form of the disease (see p. 872). The clinical features and gross appearance are the same but the disease is often more chronic.

- **Rheumatoid nodules** appear on the chest X-ray as single or multiple nodules ranging in size from a few millimetres to a few centimetres. The nodules frequently cavitate. They usually produce no symptoms but can give rise to a pneumothorax or pleural effusion.

- **Obliterative disease of the small bronchioles** is rare. It is characterized by progressive breathlessness and irreversible airflow limitation. Corticosteroids may prevent progression.

- **Cicatrycinoid joint involvement** by rheumatoid arthritis gives rise to dyspnoea, stridor, hoarseness and occasionally severe obstruction necessitating tracheostomy.

- **Caplan’s syndrome** is due to a combination of dust inhalation and the disturbed immunity of rheumatoid arthritis. It occurs particularly in coal-worker’s pneumoconiosis but it can occur in individuals exposed to other dusts, such as silica and asbestos. Typically the lesions appear as rounded nodules 0.5–5.0 cm in diameter, though sometimes they become incorporated into large areas of fibrosis that are indistinguishable radiologically from progressive massive fibrosis. There may not be much evidence of simple pneumoconiosis prior to the development of the nodule. These lesions may precede the development of the arthritis. Rheumatoid factor is always present in the serum.

Drugs used in the treatment of rheumatoid arthritis cause many pulmonary problems: pneumonitis, e.g. methotrexate, gold, NSAIDs; fibrosis, e.g. methotrexate; bronchospasm, e.g. NSAIDs, aspirin; infection, e.g. corticosteroids, methotrexate. With the use of anti-TNF therapy, reactivation of tuberculosis can occur.

Systemic lupus erythematosus (see also p. 543)
Pleurisy is the most common respiratory manifestation of this disease, occurring in up to two-thirds of cases, with or without an effusion. Effusions are usually small and bilateral. Basal pneumonitis is often present, perhaps as a result of poor movement of the diaphragm, or restriction of chest movements because of pleural pain. Pneumonia also occurs, because of either infection or the disease process itself. In contrast to rheumatoid arthritis, diffuse pulmonary fibrosis is rare.

Systemic sclerosis (see pp. 545 and 1252)
Autopsy studies have indicated that there is almost always some diffuse fibrosis of alveolar walls and obliteration of capillaries and the alveolar space. Severe changes result in nodular then streaky shadowing on the chest X-ray, followed by cystic changes, ending up with a honeycomb lung. Lung function tests reveal a restrictive defect and poor gas transfer. Pneumonia may occur owing to aspiration from the dilated oesophagus (see p. 254). Breathlessness may be
worsened by restriction of chest wall movement owing to thickening and contraction of the skin and trunk.

**IDIOPATHIC INTERSTITIAL PNEUMONIAS (IIP)**

A recent international classification is shown in Box 14.7. IIP is characterized by diffuse inflammation and fibrosis in the lung parenchyma.

**Idiopathic pulmonary fibrosis (IPF)**

This is also known as *usual interstitial pneumonia* (UIP) and was previously known as cryptogenic fibrosing alveolitis (CFA).

It is relatively rare with a prevalence of up to 20 per 100,000 population, a mean onset in the late sixties and is more common in males. The cause is unknown but cigarette smoking, chronic aspiration, antidepressants, wood and metal dusts and infections, e.g. Epstein–Barr virus, may play a part.

**Pathology**

A patchy fibrosis of the interstitium (often with intervening normal lung), subpleural and paraseptal changes, minimal or absent inflammation, acute fibroblastic proliferation and collagen deposition (fibroblastic foci) and honeycombing are the key features.

**Pathogenesis**

There are many hypotheses but the epithelial/mesenchymal hypothesis (Fig. 14.41) suggests that injury results from repeated exogenous and endogenous unknown stimuli. Disruption of the alveolar epithelium and basement membrane activates inflammatory cells, which release proinflammatory cytokines and chemokines, pro-fibrogenic growth factors and endothelin-1 from endothelial cells. Fibroblasts differentiate into myofibroblasts, synthesize collagen and aggregate to form ‘fibrotic foci’.

**Clinical features**

The main features are progressive breathlessness, a non-productive cough and cyanosis, which eventually lead to respiratory failure, pulmonary hypertension and cor pulmonale. Gross finger clubbing occurs in two-thirds of cases and fine bilateral end-inspiratory crackles are heard on auscultation. An acute form known as the Hamman–Rich syndrome occurs in a small proportion of cases. A number of autoimmune diseases are seen in association with this condition (see also Box 14.6). IPF has also been reported in association with coeliac disease, ulcerative colitis and renal tubular acidosis.

**Investigations**

- **Chest X-ray** initially shows a ground glass appearance, followed by irregular reticulonodular shadowing (often maximal in the lower zones) and finally a honeycomb lung.

- **High-resolution CT scan (HRCT)** shows characteristic bilateral changes involving mainly the lower lobes (Fig. 14.42). There are subpleural reticular abnormalities with minimal or no ground glass changes, honeycombs, i.e. thick-walled cysts (Table 14.14) 0.5–2 cm in diameter in terminal and respiratory bronchioles, and traction bronchiectasis with a diagnostic accuracy of approximately 90%.

- **Respiratory function tests** show a restrictive ventilatory defect – the lung volumes are reduced, the FEV₁, to FVC ratio is normal to high (with both values being reduced), and carbon monoxide gas transfer is reduced. Peak flow rates may be normal.

- **Blood gases** show an arterial hypoxaemia caused by a combination of alveolar–capillary block and ventilation–perfusion mismatch with normal or low $P_{CO_2}$ owing to hyperventilation.
- **Blood tests.** Anti-nuclear antibodies and rheumatoid factors are present in one-third of patients. The ESR and immunoglobulins are mildly elevated.
- **Bronchoalveolar lavage** shows increased numbers of cells, particularly neutrophils and macrophages.
- **Histological confirmation** is necessary in some patients. Transbronchial lung biopsy is rarely diagnostic, but can exclude other conditions which present similarly, e.g. sarcoidosis or lymphangitis carcinomatosa. A video-assisted thoracoscopic lung biopsy is performed to obtain a larger specimen, which will allow a clear histological diagnosis to be made.

**Differential diagnosis**

The diagnosis of IPF is usually made in a patient presenting with the above signs and characteristic HRCT changes. The differential diagnosis of the chest X-ray appearance includes extrinsic allergic alveolitis, bronchiectasis, chronic left heart failure, sarcoidosis, industrial lung disease and lymphangitis carcinomatosa.

**Prognosis and treatment**

The median survival time for patients with IPF is approximately 5 years, although mortality is very high in the more acute forms. Treatment with prednisolone (30 mg daily) is usually prescribed for disabling disease. Azathioprine or cyclophosphamide may be added if there is no response. A number of treatments have been tried, including N-acetylcysteine, warfarin, interferon, endothelin-1 antagonists (bosentan) and monoclonal antibodies, with variable results. New randomized controlled trials are awaited. Supportive treatment includes domiciliary oxygen therapy. In severe disease, single lung transplantation can be offered.

**Desquamative interstitial pneumonia (DIP)**

This occurs mainly in middle-aged male smokers and is less severe but similar to usual interstitial pneumonia (UIP). Pathologically there are more mononuclear cells than in UIP, due to smoking (pigmented macrophages). The prognosis is good with corticosteroid therapy.

**Respiratory bronchiolitis interstitial lung disease (RBILD)**

Clinically, RBILD is like DIP. Pathologically, pigmented macrophages are seen in the lumen of respiratory bronchioles. It has a better prognosis than UIP.

**Acute interstitial pneumonia (AIP)**

There is a very acute onset of pneumonia, often preceded by an upper respiratory tract infection, and progressive respiratory failure. Diffuse alveolar damage (DAD) is seen on lung biopsy. The prognosis is poor.

**Non-specific interstitial pneumonia (NSIP)**

The onset is subacute with a fever in 30%, a lack of finger clubbing and no male preponderance. It is unlike the other interstitial pneumonias histologically as there is a chronic interstitial pneumonia with mononuclear inflammatory cells and some fibrosis. Prognosis is variable (depending on amount of fibrosis).

**Cryptogenic organizing pneumonia (COP)**

This condition, previously called bronchiolitis obliterans organizing pneumonia (BOOP), is an organizing pneumonia of unknown aetiology. No infective agent has been described. Typically, patients present with single or recurrent episodes of malaise associated with cough, breathlessness and fever. Pleuritic chest pain is sometimes present but finger clubbing is very rare. Chest X-rays show confluent bilateral parenchymal shadowing. Lung function tests may show a restrictive defect. The white blood count is normal, but the ESR may be raised. Open lung biopsy will reveal characteristic buds of connective tissue (Masson’s bodies) in respiratory bronchioles and in alveolar ducts. These are diagnostic, but the diagnosis is usually made on history and X-ray appearances. The disease responds rapidly to corticosteroid treatment but may recur episodically, especially in older women.

**Lymphoid interstitial pneumonia**

This condition is more common in children than in adults and is characterized by infiltration with lymphocytes, plasma cells
and immunoblasts. It is thought to be a viral pneumonia and causes diffuse reticulonodular infiltrates on the chest X-ray. Corticosteroid therapy appears to be of benefit, as is zidovudine.

**Drugs**

Drugs causing diffuse parenchymal lung disease are shown on page 877 and in Table 14.17.

### OTHER TYPES OF DIFFUSE LUNG DISEASE

**Langerhans’ cell histiocytosis (LCH)**

This rare disease (a prevalence of 1 per 50,000) is characterized histologically by proliferation of Langerhans’ cells identified by the presence of Birbeck granules on electron microscopy or the CD1a antigen on the surface of the cells. There is a wide variation in clinical presentation, from unifocal bone lesions in older children (which may regress spontaneously), to more disseminated disease in younger children (with a high mortality). Pulmonary LCH occurs almost exclusively in smokers. Chest X-rays (and HRCT) show multiple small cysts (honeycomb lung), fibrosis or widespread nodular shadows. **Treatment** is with stopping smoking, corticosteroids and immunosuppressive therapy. For advanced progressive disease, lung transplantation is the only option. Five-year and 10-year survivals are 75% and 65% respectively.

**Goodpasture’s syndrome** (see also p. 595)

The disease often starts with symptoms of an upper respiratory tract infection followed by cough and intermittent haemoptysis, tiredness and eventually anaemia, although massive bleeding may occur. The chest X-ray shows transient blotchy shadows that are due to intrapulmonary haemorrhage. These features usually precede the development of an acute glomerulonephritis by several weeks or months. The course of the disease is variable: some patients spontaneously improve while others proceed to renal failure.

The disease usually occurs in individuals over 16 years of age. It is due to a type II cytotoxic reaction driven by antibodies directed against the basement membrane of both kidney and lung. It has been proposed that there may be a shared antigen. ANCA may be positive. An association with influenza A2 virus has been reported.

**Treatment** is with corticosteroids, but in some cases dramatic improvement has been seen with plasmapheresis to remove the autoantibodies.

**Diffuse alveolar haemorrhage**

This is clinically similar to Goodpasture’s syndrome, but there are no anti-basement-membrane antibodies and the kidneys are less frequently involved. Most cases occur in children under 7 years of age. The child develops a chronic cough and anaemia. The chest X-ray shows diffuse shadows that are due to intrapulmonary bleeding, and eventually miliary nodulation. Characteristically, haemosiderin-containing macrophages are found in the sputum. There is an association with a sensitivity to cow’s milk, and an appropriate diet is usually tried.

The prognosis in general is poor and treatment with corticosteroids or azathioprine is usually given.

**Lymphangioleiomyomatosis**

This is a rare disorder of young women with hamartomatous smooth muscle infiltration of the lungs. Patients present with dyspnoea, chyloous pleural effusions, haemoptysis and pneumothorax. Treatment is with hormones/oophorectomy. Prognosis is variable.

**Pulmonary alveolar proteinosis**

This is a rare disease in which there is accumulation of lipoproteinaceous material within the alveoli. It can be congenital, but most cases are acquired and appear to have an autoimmune basis, with antibodies directed against the cytokine GM-CSF. The disease mostly affects men and presents with progressive exertional dyspnoea and cough. Inspiratory crackles are present in only about 50%. Diagnosis is made by bronchial lavage, which reveals a milky appearance and many large, foamy macrophages but few other inflammatory cells.

**Further Reading**

**PULMONARY INFILTRATION WITH EOSINOPHILIA**

The common types and characteristics of these diseases are shown in Table 14.15. They range from very mild, simple, pulmonary eosinophilias to the often fatal hypereosinophilic syndrome.

**Simple and prolonged pulmonary eosinophilia**

Simple pulmonary eosinophilia is a relatively mild illness with a slight fever and cough and usually lasts for less than 2 weeks. Occasionally, the disease becomes more prolonged, with a high fever lasting for over a month. There is usually an eosinophilia in the blood and this condition is then called prolonged pulmonary eosinophilia. In both conditions the chest X-ray shows either localized or diffuse opacities. The simple form is probably due to a transient allergic reaction in the alveoli. Many allergens have been implicated, including *Ascaris lumbricoides*, *Ankylostoma*, *Trichuris*, *Trichinella*, *Toxocara*, *Strongyloides*, *Wuchereria*, *Babesia*, *Plasmodium*, *Pneumocystis*.

*Taenia* and *Strongyloides*. Drugs such as aspirin, penicillin, nitrofurantoin and sulphonamides have been implicated. Often, no allergen is identified. The disease is self-limiting and no treatment is required, apart from treating the cause. In the more chronic form all unnecessary treatment should be withdrawn and, where appropriate, worms are treated. Corticosteroid therapy is indicated, with resolution of the disease over the ensuing weeks.

**Asthmatic bronchopulmonary eosinophilia**

This is characterized by the presence of asthma, transient fleeting shadows on the chest X-ray, and blood or sputum eosinophilia. By far the most common cause world-wide is allergy to *A. fumigatus* (see below), although *Candida albicans* and other mycoses may be the allergen in a small number of patients. In many, no allergen can be identified. Whether these cases are intrinsic or driven by an unidentified extrinsic factor is uncertain.

**Diseases caused by Aspergillus fumigatus**

The various types of lung disease caused by *A. fumigatus* are illustrated in Figure 14.43.

The spores of *A. fumigatus* (diameter 5 mm) are readily inhaled and are present in the atmosphere throughout the year, though they are at their highest concentration in the late autumn. They can be grown from the sputum in up to 15% of patients with chronic lung disease in whom they do not produce disease. They are a cause of extrinsic asthma in atopic individuals.

**Allergic bronchopulmonary aspergillosis**

In this rare disease, *Aspergilloma* actually grows in the walls of the bronchi and eventually produces proximal bronchiectasis. There are episodes of eosinophilic pneumonia throughout the year, particularly in late autumn and winter. The episodes present with a wheeze, cough, fever and malaise. They are associated with expectoration of firm sputum plugs containing the fungal mycelium, which results in the clearing of the pulmonary infiltrates on the chest X-ray. Occasionally the large mucus plugs obliterate the bronchial lumen, causing collapse of the lung.

Left untreated, repeated episodes of eosinophilic pneumonia can result in progressive pulmonary fibrosis that usually affects the upper zones and can give rise to a chest X-ray appearance similar to that produced by tuberculosis.

The peripheral blood eosinophil count is usually raised, and total levels of IgE are usually extremely high (both that specific to *Aspergillus* and non-specific). Skin-prick testing to protein allergens from *A. fumigatus* gives rise to positive immediate skin tests. Sputum may show eosinophils and mycelia, and precipitating antibodies are usually, but not always, found in the serum.

Lung function tests show a decrease in lung volumes and gas transfer in more chronic cases, but there is evidence of reversible airflow limitation in all cases.
Treatment is with prednisolone 30 mg daily, which causes rapid clearing of the pulmonary infiltrates. Frequent episodes of the disease can be prevented by long-term treatment with prednisolone, but doses of 10–15 mg daily are usually required. Several antifungal agents have been tried in the past without success, but there is evidence that treatment with itraconazole improves pulmonary function. The asthma component responds to inhaled corticosteroids, although they do not influence the occurrence of pulmonary infiltrates.

**Aspergilloma and invasive aspergillosis**

Aspergilloma is the growth of *A. fumigatus* within previously damaged lung tissue where it forms a ball of mycelium within lung cavities. Typically the chest X-ray shows a round lesion with an air ‘halo’ above it. Continuing antigenic stimulation gives rise to large quantities of precipitating antibody in the serum. The aspergilloma itself causes little trouble, although occasionally massive haemoptysis may occur, requiring resection of the area of damaged lung containing the aspergilloma. Antifungal agents, such as amphotericin, have been tested in aspergilloma, but with little success. Invasive aspergillosis is a well-recognized complication of immunosuppression and requires aggressive antifungal therapy usually with i.v. amphotericin (250 μg/kg daily). Itraconazole or voriconazole is used if amphotericin is ineffective, and caspofungin may also work.

**Tropical pulmonary eosinophilia**

This term is reserved for an allergic reaction to microfilaria from *Wuchereria bancrofti*. The condition is seen in the Asian subcontinent and presents with cough and wheeze together with fever, lassitude and weight loss. The typical appearance of the chest X-ray is of bilateral hazy motting that is often uniformly distributed in both lung fields. Individual shadows may be as large as 5 mm or may become more confluent, giving the appearance of pneumonia.

The disease is characterized by a very high eosinophil count in peripheral blood. The filarial complement fixation test is positive in almost every case, although the microfilaria are seldom found. The treatment of choice is diethylcarbamazine (see p. 163 for details).

**The hypereosinophilic syndrome**

This disease is characterized by eosinophilic infiltration in various organs, sometimes associated with an eosinophilic arteritis. The heart muscle is particularly involved, but pulmonary involvement in the form of a pleural effusion or interstitial lung disease occurs in about 40% of cases. Typical features are fever, weight loss, recurrent abdominal pain, persistent non-productive cough and congestive cardiac failure. Corticosteroid treatment may be of value in some cases.

### EXTRINSIC ALLERGIC ALVEOLITIS

In this disease there is a widespread diffuse inflammatory reaction in both the small airways of the lung and the alveoli. It is due to the inhalation of a number of different antigens, the most common being microbial spores contaminating vegetable matter (e.g. straw, hay, mushroom compost). Some examples are illustrated in Table 14.16. By far the most common of these diseases world-wide is farmer’s lung, which affects up to 1 in 10 of the farming community in disadvantageous, wet communities around the world. Cigarette smokers have a lower risk of developing the disease due to decreased antibody reaction to the antigen.

**Pathogenesis**

Histologically there is an initial infiltration of the small airways and alveolar walls with neutrophils followed by T lymphocytes and macrophages, leading to the development of small non-caseating granulomas. These comprise multinucleated giant cells, occasionally containing the inhaled antigenic material. The allergic response to the inhaled antigens involves both cellular immunity and the deposition of immune complexes causing foci of inflammation through the activation of complement via the classical pathway. Some of the inhalant materials may also lead to inflammation by directly activating the alternative complement pathway. These mechanisms attract and activate alveolar and interstitial macrophages, so that continued antigenic exposure results in the progressive development of pulmonary fibrosis.

**Clinical features**

Typically fever, malaise, cough and shortness of breath come on several hours after exposure to the causative antigen. Thus, a farmer forking hay in the morning may notice symptoms during the late afternoon and evening with resolution by the following morning. On examination, the patient may have a fever, tachypnoea, and coarse end-inspiratory crackles and wheezes throughout the chest. Cyanosis caused by ventilation-perfusion mismatch may be severe even at rest. Continued exposure leads to a chronic illness characterized by severe weight loss, effort dyspnoea and cough as well as the features of idiopathic pulmonary fibrosis (see p. 872).
Investigations

- Chest X-ray shows fluffy nodular shadowing with the subsequent development of streaky shadows, particularly in the upper zones. In very advanced cases, honeycomb lung occurs.
- High-resolution CT shows reticular and nodular changes with ground glass opacity, which can be further categorized with multislice CT.
- Lung function tests show a restrictive ventilatory defect with a decrease in carbon monoxide gas transfer.
- Polymorphonuclear leucocyte count is raised in acute cases. Eosinophilia is not a feature.
- Precipitating antibodies are present in the serum. One-quarter of pigeon fanciers have precipitating IgG antibodies against pigeon protein and droppings in their serum, but only a small proportion have lung disease. Precipitating antibodies are evidence of exposure, not disease.
- Bronchoalveolar lavage shows increased T lymphocytes and granulocytes.

Differential diagnosis

Although extrinsic allergic alveolitis due to inhalation of the spores of *Microsporum faeni* is common among farmers, it is probably more common for these individuals to suffer from asthma related to inhalation of antigens from a variety of mites that infest stored grain and other vegetable material. These include *Lepidoglyphus domesticus*, *L. destructor* and *Acarus siro*. Symptoms of asthma resulting from inhalation of these allergens are often mistaken for farmer’s lung. Lung function tests will effectively discriminate between the disorders. Pigeon fancier’s lung is quite common, but alveolitis from budgerigars, parrots and parakeets is very rare.

Management

Prevention is the aim. This can be achieved by changes in work practice, with the use of silage for animal fodder and the drier storage of hay and grain. Pigeon fancier’s lung is more difficult to control since affected individuals remain strongly attached to their hobby. Prednisolone, initially in large doses of 30–60 mg daily, may achieve regression during the early stages of the disease. Established fibrosis will not resolve and in some patients the disease may progress inexorably to respiratory failure in spite of intensive therapy. Farmer’s lung is a recognized occupational disease in the UK and sufferers are entitled to compensation, depending upon their degree of disability.

Humidifier fever (Table 14.16)

Humidifier fever, one cause of building-related illnesses (p. 961), may present with the typical features of extrinsic allergic alveolitis without any radiographic changes. This disease has occurred in outbreaks in factories in the UK, particularly in printing works. In North America it is more commonly found in office blocks with contaminated air-conditioning systems. Humidifier fever may be effectively prevented by sterilization of the re-circulating water used in large humidifying plants.

Drug and radiation-induced respiratory reactions (Table 14.17)

Drugs may produce a wide variety of disorders of the respiratory tract. The mechanisms are varied and include direct toxicity (e.g. bleomycin), immune complex formation with arteritis, hypersensitivity (involving both T cell and IgE mechanisms) and autoimmunity. Tuberculosis reactivation is seen with immunosuppressive drugs.

Pulmonary infiltrates with fibrosis may result from the use of a number of cytotoxic drugs used in the treatment of cancer. The most common cause of these reactions is bleomycin. The pulmonary damage is dose-related, occurring when the total dosage is greater than 450 mg, but will regress in some cases if the drug is stopped. The most sensitive test is a decrease in carbon monoxide gas transfer, and therefore gas transfer should be measured repeatedly during treatment with the drug. The use of corticosteroids may help resolution. Drugs affecting the respiratory system are shown in Table 14.17, together with the types of reaction they produce. Anaphylaxis with bronchospasm can occur with many drugs. The list is not exhaustive; for example, over 20 different drugs are known to produce a systemic lupus erythematosus-like
syndrome, sometimes complicated by pulmonary infiltrates and fibrosis. Paraquat ingestion causes severe pulmonary oedema and death, and pulmonary fibrosis develops in many of the few who survive.

Irradiation of the lung during radiotherapy can cause a radiation pneumonitis. Patients complain of breathlessness and a dry cough. Radiation pneumonitis results in a restrictive lung defect. Corticosteroids should be given in the acute stage.

**OCCUPATIONAL LUNG DISEASE**

Exposure to dusts, gases, vapours and fumes at work can cause several different types of lung disease:

- acute bronchitis and even pulmonary oedema from irritants such as sulphur dioxide, chlorine, ammonia or the oxides of nitrogen
- pulmonary fibrosis due to mineral dust
- occupational asthma (see Table 14.12) – this is now the commonest industrial lung disease in the developed world
- extrinsic allergic alveolitis (see Table 14.16)
- bronchial carcinoma due to industrial agents (e.g. asbestos, polycyclic hydrocarbons, radon in mines).

The degree of fibrosis that follows inhalation of mineral dust varies. While iron (siderosis), barium (baritosis) and tin (stannosis) lead to dramatic dense nodular shadowing on the chest X-ray, their effect on lung function and symptoms is minimal. Exposure to silica or asbestos, on the other hand, leads to extensive fibrosis and disability. Coal dust has an intermediate fibrogenic effect and used to account for 90% of all compensated industrial lung diseases in the UK. The term ‘pneumoconiosis’ means the accumulation of dust in the lungs and the reaction of the tissue to its presence. The term is not wide enough to encompass all occupational lung disease and is now generally used only in relation to coal dust and its effects on the lung.

**Coal-worker’s pneumoconiosis**

The disease is caused by dust particles approximately 2–5 μm in diameter that are retained in the small airways and alveoli of the lung. The incidence of the disease is related to total dust exposure, which is highest at the coal face, particularly if ventilation and dust suppression are poor. Improved ventilation and working conditions have reduced the risk of this disease.

Two very different syndromes result from the inhalation of coal.

**Simple pneumoconiosis**

This simply reflects the deposition of coal dust in the lung. It produces fine micronodular shadowing on the chest X-ray and is by far the most common type of pneumoconiosis. It is graded on the chest X-ray appearance according to standard categories set by the International Labour Office (see below). Considerable dispute remains about the effects of simple pneumoconiosis on respiratory function and symptoms. In many cases the symptoms are due to COPD related to cigarette smoking, but this is not always the case. Changes to UK workers’ compensation legislation means that coal miners who develop COPD may be compensated for their disability regardless of their chest X-ray appearance.

Categories of simple pneumoconiosis are as follows:

1. small round opacities definitely present but few in number
2. small round opacities numerous but normal lung markings still visible
3. small round opacities very numerous and normal lung markings partly or totally obscured

Simple pneumoconiosis may lead to the development of progressive massive fibrosis (PMF) (see below). PMF virtually never occurs on a background of category 1 simple pneumoconiosis but occurs in about 7% of those with category 2 and in 30% of those with category 3. Miners with category 1 pneumoconiosis are unlikely to receive compensation unless they also have evidence of COPD. Those with more extensive radiographic changes may be compensated solely on the basis of their X-ray appearances.

**Progressive massive fibrosis**

In PMF, patients develop round fibrotic masses several centimetres in diameter, almost invariably in the upper lobes and sometimes having necrotic central cavities. The pathogenesis of PMF is still not understood, though it seems clear that some fibrogenic promoting factor is present in individuals developing the disease, leading to the formation of immune complexes, analogous to the development of large fibrotic nodules in coal miners with rheumatoid arthritis (Caplan’s syndrome). Rheumatoid factor and anti-nuclear antibodies are both often present in the serum of patients with PMF, and also in those suffering from asbestosis or silicosis. Pathologically there is apical destruction and disruption of the lung, resulting in emphysema and airway damage. Lung function tests show a mixed restrictive and obstructive ventilatory defect with loss of lung volume, irreversible airflow limitation and reduced gas transfer.

The patient with PMF suffers considerable effort dyspnoea, usually with a cough. The sputum may be black. The disease can progress (or even develop) after exposure to coal dust has ceased and may lead to respiratory failure.

**Silicosis**

This disease is uncommon though it may still be encountered in stonemasons, sand-blasters, pottery and ceramic workers and foundry workers involved in fettling (removing sand from metal castings made in sand-filled moulds). Silicosis is caused by the inhalation of silica (silicon dioxide). This dust is highly fibrogenic. For example, a coal miner can remain healthy with 30 g of coal dust in his lungs but 3 g of silica is sufficient to kill. Silica seems particularly toxic to alveolar macrophages and readily initiates fibrogenesis (see Fig. 14.41). The chest X-ray appearances and clinical features of silicosis are similar to those of PMF, but distinctive thin streaks of calcification may be seen around the hilar lymph nodes (‘eggshell’ calcification).

**Asbestosis**

Asbestos is a mixture of silicates of iron, magnesium, nickel, cadmium and aluminium, and has the unique property of occurring naturally as a fibre. It is remarkably resistant to
heat, acid and alkali, and has been widely used for roofing, insulation and fireproofing. Asbestos has been mined in southern Africa, Canada, Australia and eastern Europe. Several different types of asbestos are recognized: about 90% of asbestos is chrysotile, 6% crocidolite and 4% amosite. Chrysotile or white asbestos is the softest asbestos fibre. Each fibre is often as long as 2 cm but only a few microns thick. It is less fibrogenic than crocidolite.

_Crocidolite (blue asbestos)_ is particularly resistant to chemical destruction and exists in straight fibres up to 50 mm in length and 1–2 μm in width. Crocidolite is the type of asbestos most likely to produce asbestosis and mesothelioma. This may be due to the fact that it is readily trapped in the lung. Its long, thin shape means that it can be inhaled, but subsequent rotation against the long axis of the smaller airways, particularly in turbulent airflow during expiration, causes the fibres to impact. Crocidolite is also particularly resistant to macrophage and neutrophil enzymatic destruction.

Exposure to asbestos occurred particularly in shipbuilding yards and in power stations, but it was used so widely that low levels of exposure were very common. Up to 50% of city dwellers have asbestos bodies (asbestos fibres covered in protein secretions) in their lungs at post mortem. Regulations in the UK prohibit the use of crocidolite and severely restrict the use of chrysotile. Careful dust control measures are enforced, which should eventually abolish the problem. Workers continue to be exposed to blue asbestos in the course of demolition or in the replacement of insulation, and it should be remembered that there is a considerable time lag between exposure and development of disease, particularly mesothelioma (20–40 years).

The risk of primary lung cancer (usually adenocarcinoma) is increased in people exposed to asbestos, even in non-smokers. This risk is about 5–7-fold greater in those who have parenchymal asbestosis and about 1.5-fold in those with pleural plaques without parenchymal fibrosis. A synergistic relationship exists between asbestosis and cigarette smoking with the risk of bronchial carcinoma multiplied 5-fold above the risk attributable to smoking alone.

_Diseases caused by asbestos_ are summarized in Table 14.18. Bilateral diffuse pleural thickening, asbestosis, mesothelioma and asbestos-related carcinoma of the bronchus are all eligible for industrial injuries benefit in the UK.

**Asbestosis**

Asbestosis is defined as fibrosis of the lungs caused by asbestos dust, which may or may not be associated with fibrosis of the parietal or visceral layers of the pleura. It is a progressive disease characterized by breathlessness and accompanied by finger clubbing and bilateral basal end-inspiratory crackles. Fibrosis, not detectable on chest X-ray, is often revealed on high-resolution CT scan. No treatment is known to alter the progress of the disease, though corticosteroids are often prescribed.

**Mesothelioma**

The number of cases of mesothelioma has increased progressively since the mid-1980s and in 2001 there were 1848 deaths in the UK. Rates of mesothelioma are continuing to increase in the UK, and are expected to peak at about 2300 per year, between 2010 and 2020. Pleural effusions are the most common presentation of mesothelioma, typically with persistent chest wall pain, which should raise the index of

**FURTHER READING**

suspicion even if the initial pleural fluid or biopsy samples are non-diagnostic. Often a video-assisted thoracoscopic lung biopsy is needed to obtain sufficient tissue for diagnosis. In the event of a positive pleural biopsy diagnosis, local radiotherapy should be given to prevent the seeding of mesothelioma cells down the needle track. Pemetrexed and vinorelbine are being tested in trials but no treatment influences the universally fatal outcome.

**Byssinosis**

This disease occurs world-wide but is declining rapidly in areas where the numbers of people employed in cotton mills are falling. The symptoms start on the first day back at work after a break (Monday sickness) with improvement as the week progresses. Tightness in the chest, cough and breathlessness occur within the first hour in dusty areas of the mill, particularly in the blowing and carding rooms where raw cotton is cleaned and the fibres are straightened.

The exact nature of the disease and its aetiology remain disputed. Two features are that pure cotton does not cause the disease, and that cotton dust has some effect on airflow limitation in all those exposed. Individuals with asthma are particularly badly affected by exposure to cotton dust. The most likely aetiology is endotoxins from bacteria present in the raw cotton causing constriction of the airways of the lung. There are no changes on the chest X-ray and there is considerable dispute as to whether the progressive airflow limitation seen in some patients with the disease is due to the cotton dust or to other factors such as cigarette smoking or coexistent asthma.

**Berylliosis**

Beryllium–copper alloy has a high tensile strength and is resistant to metal fatigue, high temperature and corrosion. It is used in the aerospace industry, in atomic reactors and in many electrical devices.

When beryllium is inhaled, it can cause a systemic illness with a clinical picture similar to sarcoidosis. The major chronic problem is that of progressive dyspnoea with pulmonary fibrosis. However, strict control of levels in the working atmosphere has made the disease a rarity.

**LUNG CYSTS**

These may be congenital, bronchogenic cysts or may result from a sequestrated pulmonary segment. Hydatid disease causes fluid-filled cysts. Thin-walled cysts are due to lung abscesses, which are particularly found in staphylococcal pneumonia, tuberculous cavities, septic pulmonary infarction, primary bronchogenic carcinoma, cavitating metastatic neoplasm, or paragonimiasis caused by the lung fluke *Paragonimus westermani*.

**TUMOURS OF THE RESPIRATORY TRACT**

Bronchial carcinoma accounts for 95% of all primary tumours of the lung. Alveolar cell carcinoma accounts for 2% of lung tumours, and other less malignant or benign tumours account for the remaining 3%.

### MALIGNANT TUMOURS

**Bronchial carcinoma**

This is the most common malignant tumour world-wide with 1.3 million deaths annually. It is the third most common cause of death in the UK after heart disease and pneumonia. Mortality rates world-wide are highest in Scotland, closely followed by England and Wales. In the UK, 32 000 people die each year from bronchial carcinoma, with a male-to-female ratio of 3:1. Although the mortality rate from this disease has levelled off in men, it continues to rise in women and now causes more deaths from malignant disease in women than any other tumour, including breast cancer.

The strength of the association between cigarette smoking and bronchial carcinoma overshadows any other aetiological factors (Table 14.19), but there is a higher incidence of bronchial carcinoma in urban compared with rural areas, even when allowance is made for cigarette smoking. Passive smoking (the frequent inhalation of other people’s smoke by non-smokers) increases the risk of bronchial carcinoma by a factor of 1.5. Occupational factors include exposure to asbestos, and an association is also claimed for workers in contact with arsenic, chromium, iron oxide, petroleum products and oils, coal tar, products of coal combustion, and radiation. Tumours associated with occupational factors are mostly adenocarcinomas and appear to be less related to cigarette smoking.

**Cell types**

Based on the characteristics of the disease and its response to treatment bronchial carcinoma is divided into small-cell carcinoma and non-small-cell carcinoma (NSCC). Studies of mean doubling times of carcinomas indicate that development from the initial malignant change to presentation takes about 15 years for adenocarcinoma, 8 years for squamous carcinoma and 3 years for small-cell carcinoma.

**Non-small-cell carcinoma**

*Squamous or epidermoid carcinoma* is the commonest type, accounting for approximately 40% of all carcinomas. Most present as obstructive lesions of the bronchus leading to infection. It occasionally cavitates (10%) at presentation. The cells are usually well differentiated but occasionally anaplastic. Local spread is common but widespread metastases occur relatively late.

*Adenocarcinoma* arises from mucous cells in the bronchial epithelium. Invasion of the pleura and the mediastinal lymph nodes is common, as are metastases to the brain, adrenal glands and bones. Adenocarcinoma accounts for

</tbody>
</table>
approximately 10% of all bronchial carcinomas. It is the most common bronchial carcinoma associated with asbestos and is proportionally more common in non-smokers, in women, in the elderly, and in the Far East.

Large cell carcinomas are less-differentiated forms of squamous cell and adenocarcinomas. These account for about 25% of all lung cancers and metastasize early.

Bronchoalveolar cell carcinoma (also termed bronchiolar carcinoma) accounts for only 1–2% of lung tumours and occurs either as a peripheral solitary nodule or as diffuse nodular lesions of multicentric origin. Occasionally this tumour is associated with expectoration of very large volumes of mucoid sputum.

Small-cell carcinoma
This tumour accounts for 20–30% of all lung cancers. It arises from endocrine cells (Kulchitsky cells). These cells are members of the APUD system, which explains why many polypeptide hormones are secreted by these tumours. Some of these polypeptides act in an autocrine fashion: they feed back on the cells and cause cell growth. Small-cell carcinoma spreads early and is almost always inoperable at presentation. The tumour is rapidly growing and highly malignant. It responds to chemotherapy and radiotherapy but the overall prognosis remains poor.

Clinical features
The frequencies of the common symptoms of lung cancer on presentation are shown in Table 14.20. Chest pain and discomfort are often described as fullness and pressure in the chest. Sometimes the pain may be pleuritic owing to invasion of the pleura or ribs.

Often there are no abnormal physical signs. Enlarged supraclavicular lymph nodes may be present. There may be signs of a pleural effusion or of lobar collapse. Signs of an unresolved pneumonia or of associated underlying disease (eg. diffuse pulmonary fibrosis in asbestosis) may be present.

Direct spread
The tumour may directly involve the pleura and ribs. Carcinoma in the apex of the lung can erode the ribs and involve the lower part of the brachial plexus (C8, T1 and T2), causing severe pain in the shoulder and down the inner surface of the arm (Pancoast’s tumour). The sympathetic ganglion can also be involved, producing Horner’s syndrome. Hilar tumours may involve the left recurrent laryngeal nerve, causing unilateral vocal cord paresis with hoarseness and a bovine cough.

Bronchial carcinoma can also directly invade the phrenic nerve, causing paralysis of the ipsilateral hemidiaphragm. It can involve the oesophagus, producing progressive dysphagia, and the pericardium, producing pericardial effusion and malignant dysrhythmias. Superior vena caval obstruction (p. 458) causes early morning headache, facial congestion and oedema involving the upper limbs; the jugular veins are distended, as are the veins on the chest that form a collateral circulation with veins arising from the abdomen.

Metastatic complications
Bony metastases are common, giving rise to severe pain and pathological fractures. There is frequent involvement of the liver. Secondary deposits in the brain present as a change in personality, epilepsy or as a focal neurological lesion. Spinal cord compression is not uncommon and requires urgent treatment (p. 458). Secondary deposits in the adrenal gland are frequently found at post mortem but are often asymptomatic.

Non-metastatic extrapulmonary manifestations
Clinical extrapulmonary manifestations are relatively rare apart from finger clubbing (Table 14.21); approximately 10% of small-cell tumours produce ectopic hormones, giving rise

to paraneoplastic syndromes (see Box 9.1). Some antitumour markers are shown in Box 9.1 on page 455.

_Hypertrophic pulmonary osteoarthropathy_ (HPOA) (see p. 555) occurs in approximately 3% of all bronchial carcinomas, particularly squamous cell carcinomas and adenocarcinomas. Symptoms include joint stiffness and severe pain in the wrists and ankles, sometimes associated with gynaecomastia. X-rays show a characteristic proliferative periostitis at the distal ends of long bones, which have an onion-skin appearance. HPOA is invariably associated with clubbing of the fingers. It may regress after resection of the lung tumour or as a result of vagotomy at thoracotomy.

**Investigations**

**Chest X-ray**

By the time the lung cancer is causing symptoms, it will almost always be visible on chest X-ray. Asymptomatic tumours may be seen on chest X-ray if they are more than 1 cm in diameter. Lateral views are useful to assess the hilum and masses behind the heart. A minority of tumours are confined to the central airways and mediastinum without obvious change on the plain chest X-ray. These will be readily seen at bronchoscopy or on CT scanning. Although investigation of isolated haemoptysis with a normal chest X-ray is often negative, a normal chest X-ray should not deter from further investigation, especially in smokers over the age of 40. About 70% of all primary lung cancers present with a mass, including virtually all small-cell lung cancers and most squamous cell carcinomas. Adenocarcinoma occurs more often in the periphery than the other cell types.

Carcinomas causing partial obstruction of a bronchus interrupt the mucusciliary escalator, and bacteria are retained within the affected lobe. This gives rise to the so-called secondary pneumonia that is commonly seen on the chest X-ray.

Bronchial carcinoma can also appear as round shadows on a chest X-ray (see p. 822). Characteristically the edge of the tumour has a fluffy or spiked appearance, though sometimes it may be entirely smooth with cavitation.

The hilar lymph nodes on the side of the tumour are frequently involved. Bronchial carcinoma is also a common cause of large pleural effusions. Carcinoma can spread through the lymphatic channels of the lung to give rise to lymphangitis carcinomatosa; in bronchial carcinoma this is usually unilateral and associated with striking dyspnoea. The chest X-ray shows streaky shadowing throughout the lung. Bilateral lymphangitis carcinomatosa is more often due to metastatic spread, usually from tumours below the diaphragm (the stomach and colon) or from breast cancers.

**Computed tomography**

CT is useful for detection of small tumours and for identifying disease in the mediastinum, such as enlarged lymph nodes (see Fig. 14.12, p. 823) or local spread of the tumour, and for identifying secondary spread of carcinoma to the opposite lung by detecting masses too small to be seen on the chest X-ray. CT is a poor guide to whether nodes are involved by tumour but a normal CT scan prior to surgery excludes the need for mediastinoscopy and node biopsy. CT scanning should include the liver, adrenal glands and the brain since these are common sites for metastases.

**Other imaging modalities**

MRI is not useful for the diagnosis of primary lung tumours. PET or PET-CT scanning is now the investigation of choice for assessment of the mediastinum and for possible metastases (see p. 823).

**Fibreoptic bronchoscopy** (see also p. 828, Fig. 14.44) This technique is used to define the bronchial anatomy and to obtain biopsy and cytological specimens. If the carcinoma involves the first 2 cm of either main bronchus, the tumour is inoperable as there would be insufficient resection margins for pneumonectomy. Widening and loss of the sharp angle of the carina indicates the presence of enlarged mediastinal lymph nodes, either malignant or reactive. These can be biopsied by passage of a needle through the bronchial wall. Vocal cord paresis on the left indicates involvement of the recurrent laryngeal nerve and inoperability.

**Percutaneous aspiration and biopsy**

Peripheral lung lesions cannot be seen by fibreoptic bronchoscopy. Samples may be obtained by aspiration or biopsy through the chest wall under CT guidance. The commonest complication is pneumothorax (up to 25% patients), especially if the mass is deep in the lung, as opposed to lesions next to the parietal pleura. Intercostal drainage is occasionally required. Mild haemoptysis occurs in 5%. Implantation metastases do not occur.

**Other investigations**

These include full blood count for the detection of anaemia, and biochemistry for liver involvement, hypercalcaemia and hyponatraemia.

**Treatment** (see also p. 486)

Treatment of lung cancer involves several different modalities and is best planned by a multidisciplinary team. Treatment decisions need to reflect the poor overall survival rates: only 20% of patients are alive 1 year after diagnosis and only 6–8% after 5 years (cf. 50% for breast or cervix). Patients are staged according to the TNM classification (p. 456) for non-small-cell cancer but small-cell cancer is treated according to whether it is limited or extensive (p. 486).

---

**Fig. 14.44** Bronchoscopic view of a bronchial carcinoma obstructing a large bronchus.
**Surgery**

Surgery can be curative in non-small-cell lung cancer (T1, N0, M0) but only 5–10% of all cases are suitable for resection; about 70% of these survive for 5 years. Surgery is rarely appropriate in patients over 65 years as the operative mortality rate exceeds the 5-year survival rate. Trial data suggest that neo-adjuvant chemotherapy may downstage tumours to render them operable and may also improve 5-year survival in patients whose tumours are operable at presentation. Adjuvant chemotherapy following resection of adenocarcinomas may also improve survival.

Preoperative assessment includes exclusion of metastatic disease by blood tests and imaging as described above. Lung function tests, including walking oximetry, are used to predict postoperative potential. An active life after pneumonectomy is unlikely if the gas transfer is reduced below 50%.

**Radiation therapy for cure**

In patients who are fit and who have a slowly growing squamous carcinoma, high-dose radiotherapy (65 Gy or 6500 rads) can produce good results. It is the treatment of choice if surgery is declined. Poor lung function is a relative contraindication for radiotherapy. Radiation pneumonitis (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10–15% of cases. Radiation fibrosis, a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases. These complications usually cause no problems.

**Radiation treatment for symptoms**

Bone pain, haemoptysis and superior vena cava obstruction respond favourably to irradiation in the short term.

**Chemotherapy**

This is discussed on page 486. Adjuvant chemotherapy with radiotherapy improves response rate and extends median survival in non-small-cell cancer.

**Laser therapy, endobronchial irradiation and tracheobronchial stents**

These techniques are used in the palliation of inoperable lung cancer in selected patients with tracheobronchial narrowing from intraluminal tumour or extrinsic compression causing disabling breathlessness, intractable cough and complications, including infection, haemoptysis and respiratory failure.

A neodymium-Yag (Nd-Yag) laser passed through a fiberoptic bronchoscope can be used to vaporize inoperable functioning intraluminal carcinoma involving short segments of trachea or main bronchi. Benign tumours, strictures and vascular lesions can also be treated effectively with immediate relief of symptoms.

**Endobronchial irradiation (brachytherapy)** is useful for the treatment of both intraluminal tumour and malignant extrinsic compression. A radioactive source is afterloaded into a catheter placed adjacent to the carcinoma under fiberoptic bronchoscope control. Radiation dose falls rapidly with distance from the source, minimizing damage to adjacent normal tissue. Reduction in endoscopically assessed tumour size occurs in 70–95% of cases.

**Tracheobronchial stents** made of silicone or as expandable metal springs are available for insertion into strictures caused by tumour or from external compression or when there is weakening and collapse of the tracheobronchial wall.

**Palliative care** (see p. 494)

Patients dying of cancer of the lung need attention to their overall well-being. Palliative care must not be ignored simply because the patient cannot be cured. Much can be done to make the patient’s remaining life symptom-free and as active as possible. As compared to patients with fatal cancers at other sites, patients with lung cancer tend to remain relatively independent and pain-free, but die more rapidly once they reach the terminal phase.

Daily treatment with prednisolone (up to 15 mg daily) may improve appetite. Morphine or diamorphine is given regularly for pain, either in the form of sustained-release morphine sulphate tablets twice daily or as regular elixirs or injections. Many patients benefit from a continuous subcutaneous injection of opiates given by a pump. Candidiasis and other infections in the mouth are common and must be looked for and treated. Patients taking opiates are frequently constipated, so regular laxatives should be prescribed. Short courses of palliative radiotherapy are helpful for bone pain, severe cough or haemoptysis.

Both the patient and the relatives may require counselling, a task that should be shared between the respiratory teams, the primary care team and the nurses, social workers, hospital chaplains and doctors, who make up the palliative care team.

**Tracheal carcinoma**

Primary tumours of the trachea are rare – their incidence relative to laryngeal and bronchial tumours is 1:75 and 1:180 respectively. The majority are malignant and cause severe and rapidly progressive dyspnoea and stridor. Flow–volume curves show typical and dramatic reductions in inspiratory flow (extrathoracic tracheal tumours) (see p. 816). Diagnosis is confirmed by bronchoscopy. Rapid and effective destruction of tumour by laser provides temporary relief of symptoms. Radiotherapy is often given and occasionally surgery may be possible but the prognosis is very poor.

**Secondary tumours**

Metastases in the lung are very common and usually present as round shadows (1.5–3.0 cm diameter). They are usually detected on chest X-ray in patients already diagnosed as having carcinoma, but may be the first presentation. Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.

Metastases nearly always develop in the parenchyma and are often relatively asymptomatic even when the chest X-ray shows extensive pulmonary metastases. Rarely metastases may develop within the bronchi, when they may present with haemoptysis.

Carcinoma, particularly of the stomach, pancreas and breast, can involve mediastinal glands and spread along the lymphatics of both lungs (lymphangitis carcinomatosa), leading to progressive and severe breathlessness. On the chest X-ray, bilateral lymphadenopathy is seen together with streaky basal shadowing fanning out over both lung fields. Occasionally a pulmonary metastasis may be detected as a solitary round shadow on chest X-ray in an asymptomatic
patient. The most common primary tumour to do this is a renal cell carcinoma.

The differential diagnosis includes:

- primary bronchial carcinoma
- tuberculosis
- benign tumour of the lung
- hydatid cyst

Single pulmonary metastases can be removed surgically but, as CT scans usually show the presence of small metastases undetected on chest X-ray, detailed imaging including PET scanning and assessment is essential before undertaking surgery.

**SCREENING FOR LUNG CANCER**

Screening programmes (yearly chest X-ray, 4-monthly sputum cytology and CT scanning) have been tried in high-risk groups but the success rate is limited, underlining the need for prevention.

**BENIGN TUMOURS**

**Pulmonary hamartoma**

This is the most common benign tumour of the lung and is usually seen on the X-ray as a very well-defined round lesion 1–2 cm in diameter in the periphery of the lung. Growth is extremely slow, but the tumour may reach several centimetres in diameter. Rarely it arises from a major bronchus and causes obstruction.

**Bronchial carcinoma**

This rare tumour resembles an intestinal carcinoma tumour and is locally invasive, eventually spreading to mediastinal lymph nodes and finally to distant organs. It is a highly vascular tumour that projects into the lumen of a major bronchus causing recurrent haemoptysis. It grows slowly and eventually blocks the bronchus, leading to lobar collapse. As foregut derivatives, bronchial carcinoids may produce ACTH but do not usually produce the 5-hydroxytryptamine that is seen in midgut or hindgut carcinoid tumours.

**Cylindroma, chondroma and lipoma**

These are extremely rare tumours that may grow in the bronchus or trachea, causing obstruction.

**Tracheal tumours**

Benign tumours include squamous papilloma, leiomyoma, haemangiomas and tumours of neurogenic origin.

**DISORDERS OF THE CHEST WALL AND PLEURA**

**Trauma**

Trauma to the thoracic wall can cause penetrating wounds and lead to pneumothorax or haemothorax.

**Rib fractures**

Rib fractures are caused by trauma or coughing (particularly in the elderly), and can occur in patients with osteoporosis. Pathological rib fractures are due to metastatic spread from carcinoma of the bronchus, breast, kidney, prostate or thyroid. Ribs can also become involved by a mesothelioma. Fractures may not be readily visible on a PA chest X-ray, so lateral X-rays and oblique views may be necessary.

Pain prevents adequate chest expansion and coughing, and this can lead to pneumonia.

**Treatment** is with adequate oral analgesia, by local infiltration or an intercostal nerve block.

Two fractures in one rib can lead to a flail segment with paradoxical movement, i.e. part of the chest wall moves inwards during inspiration. This can produce inefficient ventilation and may require intermittent positive-pressure ventilation, especially if several ribs are similarly affected.

**Rupture of the trachea or a major bronchus**

Rupture of the trachea or even a major bronchus can occur during deceleration injuries, leading to pneumothorax, surgical emphysema, pneumomediastinum and haemoptysis. Surgical emphysema is caused by air leaking into the subcutaneous connective tissue; this can also occur after the insertion of an intercostal drainage tube. A pneumomediastinum occurs when air leaks from the lung inside the parietal pleura and extends along the bronchial walls.

**Rupture of the oesophagus** (p. 256)

Rupture of the oesophagus leads to mediastinitis usually with mixed bacterial infections. This is a serious complication of external injury, endoscopic procedures, bougienage or necrotic carcinoma, and requires vigorous antibacterial chemotherapy.

**Lung contusion**

This causes widespread fluffy shadows on the chest X-ray owing to intrapulmonary haemorrhage. This may give rise to acute respiratory distress syndrome (see p. 917).

**Kyphoscoliosis**

Kyphoscoliosis may be congenital, owing to disease of the vertebrae such as tuberculosis or osteomalacia, or due to neuromuscular disease such as Friedreich’s ataxia or poliomyelitis. The respiratory effects of severe kyphoscoliosis are often more pronounced than might be expected and respiratory failure and death often occur in the fourth or fifth decade. The abnormality should be corrected at an early stage if possible. Positive airway pressure ventilation delivered through a tightly fitting nasal mask is the treatment of choice for respiratory failure (see p. 916).

**Ankylosing spondylitis** (see also p. 532)

Limitation of chest wall movement is often well compensated by diaphragmatic movement, and so the respiratory effects of this disease are relatively mild. It is occasionally associated with upper lobe fibrosis.

**Pectus excavatum and carinatum**

Pectus excavatum causes few problems other than embarrassment about the deep vertical furrow in the chest, which can be corrected surgically. The heart is seen to lie well to the left on the chest X-ray. Pectus carinatum (pigeon chest)
is often the result of rickets but is rarely seen in the West. No treatment is required.

Pleurisy

This is the term used to describe pain arising from any disease of the pleura. The localized inflammation produces sharp localized pain, made worse on deep inspiration, coughing and occasionally on twisting and bending movements. Pleurisy occurs with pneumonia, pulmonary infarct and carcinoma. Rarer causes include rheumatoid arthritis and systemic lupus erythematosus.

*Epidemic myalgia (Bornholm disease)* is due to infection by Coxsackie B virus. This illness is common in young adults in the late summer and autumn and is characterized by an upper respiratory tract illness followed by pleuritic pain in the chest and upper abdomen with tender muscles. The chest X-ray remains normal and the illness clears within a week.

Mesothelioma (see p. 879)

This is usually associated with asbestos exposure. It is described with other pleural diseases caused by asbestosis in Table 14.18.

Pleural effusion

A pleural effusion is an excessive accumulation of fluid in the pleural space. It can be detected on X-ray when 300 mL or more of fluid is present and clinically when 500 mL or more is present. The chest X-ray appearances (Fig. 14.45) range from the obliteration of the costophrenic angle to dense homogeneous shadows occupying part or all of the hemithorax. Fluid below the lung (a subpulmonary effusion) can simulate a raised hemidiaphragm. Fluid in the fissures may resemble an intrapulmonary mass. The physical signs are shown in Table 14.1 (p. 821).

**Diagnosis**

This is by pleural aspiration (see p. 827) with ultrasound guidance if the effusion is small. The fluid that accumulates may be a transudate or an exudate.

**Transudates**

Effusions that are transudates can be bilateral, but are often larger on the right side. The protein content is less than 30 g/L and the lactic dehydrogenase is less than 200 IU/L and/or the fluid to serum ratio is <0.6. Causes include:

- heart failure
- hypoproteinaemia (e.g. nephrotic syndrome)
- constrictive pericarditis
- hypothyroidism
- ovarian tumours producing right-sided pleural effusion – Meigs’ syndrome.

**Exudates**

The protein content of exudates is >30 g/L and the lactic dehydrogenase is >200 IU/L. Causes include:

- bacterial pneumonia (common)
- carcinoma of the bronchus and pulmonary infarction – fluid may be blood-stained (common)
- tuberculosis
- connective tissue disease
- post-myocardial infarction syndrome (rare)
- acute pancreatitis (high amylase content) (rare)
- mesothelioma (rare)
- sarcoidosis (very rare)
- yellow-nail syndrome (effusion due to lymphoedema) (very rare)
- familial Mediterranean fever (rare).

Pleural biopsy (see p. 827) may be necessary if the diagnosis has not been established by simple aspiration.

![Radiographs showing (a) small and (b) large pleural effusions.](image-url)
Management of malignant pleural effusions

Malignant pleural effusions that re-accumulate and are symptomatic can be aspirated to dryness followed by the instillation of a sclerosing agent such as tetracycline or bleomycin. Effusions should be drained slowly since rapid shift of the mediastinum causes severe pain and occasionally shock. This treatment produces only temporary relief.

Chylothorax

This is due to the accumulation of lymph in the pleural space, usually resulting from leakage from the thoracic duct following trauma or infiltration by carcinoma.

Empyema

This is the presence of pus in the pleural space and can be a complication of pneumonia (see p. 863).

Pneumothorax

‘Pneumothorax’ means air in the pleural space. It may be spontaneous or occur as a result of trauma to the chest. Spontaneous pneumothorax is commonest in young males, the male-to-female ratio being 6:1. It is caused by the rupture of a pleural bleb, usually apical, and is thought to be due to congenital defects in the connective tissue of the alveolar walls. Both lungs are affected with equal frequency. Often these patients are tall and thin. In patients over 40 years of age, the usual cause is underlying COPD. Rarer causes include bronchial asthma, carcinoma, a lung abscess breaking down and leading to bronchopleural fistula, and severe pulmonary fibrosis with cyst formation.

Pneumothorax may be localized if the visceral pleura has previously become adherent to the parietal pleura, or generalized if there are no pleural adhesions. Normally the pressure in the pleural space is negative but this is lost once a communication is made with atmospheric pressure; the elastic recoil pressure of the lung then causes it to partially deflate. If the communication between the airways and the pleural space remains open, a bronchopleural fistula is created. Once the communication between the lung and the pleural space is obliterated, air will be reabsorbed at a rate of 1.25% of the total radiographic volume of the hemithorax per day. Thus, a 50% collapse of the lung will take about 40 days to reabsorb completely once the air leak is closed.

It has been postulated that a valvular mechanism may develop through which air can be sucked into the pleural space during inspiration but not expelled during expiration. The intrapleural pressure remains positive throughout breathing, the lung deflates further, the mediastinum shifts, and venous return to the heart decreases, with increasing respiratory and cardiac embarrassment. This is called tension pneumothorax and is very rare unless the patient is on positive ventilation.

The usual presenting features are sudden onset of unilateral pleuritic pain or progressively increasing breathlessness. If the pneumothorax enlarges, the patient becomes more breathless and may develop pallor and tachycardia. There may be few physical signs if the pneumothorax is small.

Practical Box 14.6 Simple aspiration of pneumothorax

1. Explain the nature of the procedure and obtain consent.
2. Infiltrate 2% lidocaine down to the pleura in the second intercostal space in the mid-clavicular line.
3. Push a 3–4 cm 16 French gauge cannula through the pleura.
4. Connect the cannula to a three-way tap and 50 mL syringe.
5. Aspirate up to 2.5 L of air. Stop if resistance to suction is felt or the patient coughs excessively.
6. Repeat chest X-ray (in expiration) in the X-ray department.

The characteristic features and management are shown in Figure 14.46. The main aim is to get the patient back to active life as soon as possible. The procedure for simple aspiration is shown in Practical box 14.6.

Recurrence. A third of patients will have a recurrence. Chemical pleurodesis with talc is used for patients with contraindication for surgery. Bleb resection and pleurodesis are achieved using a video-assisted thoracoscopic (VATS) approach or by open thoracotomy which has no recurrence.

DISORDERS OF THE DIAPHRAGM

Diaphragmatic fatigue

The diaphragm can become fatigued if the force of contraction during inspiration exceeds 40% of the force it can develop in a maximal static effort. When this occurs acutely in patients with exacerbations of COPD or cystic fibrosis or in quadriplegics, positive-pressure ventilation is required. Further rehabilitation requires exercises to increase the strength and endurance of the diaphragm by breathing against a resistance for 30 minutes a day.

Unilateral diaphragmatic paralysis

This is common and symptomless. The affected diaphragm is usually elevated and moves paradoxically on inspiration. It can be diagnosed when a sniff causes the paralysed diaphragm to rise, the unaffected diaphragm to descend. Causes include:

- surgery
- carcinoma of the bronchus with involvement of the phrenic nerve
- neurological, including polyomyelitis, herpes zoster
- trauma to cervical spine, birth injury, subclavian vein puncture
- infection: tuberculosis, syphilis, pneumonia.

Bilateral diaphragmatic weakness or paralysis

This causes breathlessness in the supine position and is a cause of sleep apnoea leading to daytime headaches and somnolence. Tidal volume is decreased and respiratory rate increased. Vital capacity is substantially reduced when lying down, and sniffing causes a paradoxical inward movement of the abdominal wall best seen in the supine position. Causes include viral infections, multiple sclerosis, motor neurone disease, polyomyelitis, Guillain–Barré syndrome, quadriplegia after trauma, and rare muscle diseases. Treat-
**Mediastinal lesions**

**Disorders of the diaphragm**

**Mediastinal lesions**

**Complete eventration of the diaphragm**
This is a congenital condition (invariably left-sided) in which muscle is replaced by fibrous tissue. It presents as marked elevation of the left hemidiaphragm, sometimes associated with gastrointestinal symptoms. Partial eventration, usually on the right, causes a hump (often anteriorly) on the diaphragmatic shadow on X-ray.

**Diaphragmatic hernias**
These are most commonly through the oesophageal hiatus, but occasionally occur anteriorly, through the foramen of Morgagni, posterolaterally through the foramen of Bochdalek, or at any site following traumatic tears.

**Hiccups**
Hiccups are due to involuntary diaphragmatic contractions with closure of the glottis and are extremely common. Occasionally patients present with persistent hiccups. This can be as a result of diaphragmatic irritation (e.g. subphrenic abscess) or a metabolic cause (e.g. uraemia). Treatment for persistent hiccups is with gabapentin 300 mg or pregabalin 50 mg three times daily. The underlying cause should be treated, if known.

**MEDIASTINAL LESIONS**

The mediastinum is defined as the region between the pleural sacs. It is additionally divided as shown in Figure 14.47. Tumours affecting the mediastinum are rare. Masses are detected very accurately on CT, as well as MR scan (Fig. 14.48).

**Retrosternal or intrathoracic thyroid**
The most common mediastinal tumour is a retrosternal or intrathoracic thyroid, which is nearly always an extension of
the thyroid present in the neck. Enlargement of the thyroid by a colloid goitre, malignant disease or rarely, in thyrotoxicosis, can cause displacement of the trachea and oesophagus to the opposite side. Symptoms of compression develop insidiously before producing the cardinal feature of dyspnoea. Very occasionally an intrathoracic thyroid may be the cause of dysphagia and, rarely, of hoarseness of the voice and vocal cord paralysis from stretching of the recurrent laryngeal nerve. The treatment is surgical removal.

**Thymic tumours (thymomas)**
The thymus is large in childhood and occupies the superior and anterior mediastinum. It involutes with age but may be enlarged by cysts, which are rarely symptomatic, or by tumours, which may cause myasthenia gravis or lead to compression of the trachea or, rarely, the oesophagus. Surgery is the treatment of choice. Approximately half of the patients presenting with a thymic tumour have myasthenia gravis. Good’s syndrome, a combined defect in humoral and cellular immunity, is seen in 10% of thymomas.

**Pleuropericardial cysts**
These cysts, which may be up to 10 cm in diameter, are filled with clear fluid and are usually situated anteriorly in the cardiophrenic angle on the right in 70% of cases. Infection only rarely occurs; malignant change does not occur. The diagnosis is usually made by needle aspiration. No treatment is required, but these patients should be followed up as an increase in cyst size suggests an alternative pathology; surgical excision is then advisable.

Intensive care medicine (or ‘critical care medicine’) is concerned predominantly with the management of patients with acute life-threatening conditions (‘the critically ill’) in specialized units. As well as emergency cases, such units admit high-risk patients electively after major surgery (Table 15.1). Intensive care medicine also encompasses the resuscitation and transport of those who become acutely ill, or are injured in the community. Management of seriously ill patients throughout the hospital (e.g. in coronary care units, acute admissions wards, postoperative recovery areas, or emergency units), including critically ill patients who have been discharged to the ward (‘outreach care’) is also undertaken. Teamwork and a multidisciplinary approach are central to the provision of intensive care and are most effective when directed and coordinated by committed specialists. An example of guidelines for involving the critical care team in the management of an acutely ill patient is shown in Box 15.1.

Intensive care units (ICUs) are usually reserved for patients with established or potential organ failure and provide facilities for the diagnosis, prevention and treatment of multiple organ dysfunction. They are fully equipped with monitoring and technical facilities, including an adjacent laboratory (or ‘near patient testing’ devices) for the rapid determination of blood gases and simple biochemical data such as serum potassium, blood glucose and blood lactate levels. Patients receive continuous expert nursing care and the constant attention of appropriately trained medical staff. High dependency units (HDUs) offer a level of care intermediate between that available on the general ward and that provided in an ICU. They provide monitoring and support for patients with acute (or acute-on-chronic) single organ failure and for those who are at risk of developing multiple organ failure. These units are a comfortable environment for less severely ill patients who are often conscious and alert. They can also

provide a ‘step-down’ facility for patients being discharged from intensive care.

The provision of staff and the level of technical support must match the needs of the individual patient and resources are used more efficiently when they are combined in a single critical care facility rather than being divided between physically and managerially separate units.

In the UK only around 2.6% of hospital beds are designated for intensive care, but elsewhere in the developed world the proportion is often much higher.

### GENERAL ASPECTS OF INTENSIVE CARE MANAGEMENT

Critically ill patients require multidisciplinary care with:

- Intensive skilled nursing care (usually 1:1 or 1:2 nurse/patient ratio in the UK).
- Regular physiotherapy.
- Careful management of pain and distress with analgesics and sedation as necessary.
- Constant reassurance and support (critically ill patients easily become disorientated and psychologically disturbed).
- Nutritional support (enteral nutrition should always be used if possible). Studies have shown pharmacological doses of various nutrients to have positive immunomodulatory effects (immunonutrition) including glutamine, polysaturated fatty acids and nucleotides. The efficacy and safety of this approach in critically ill patients remains in doubt.
- The use of insulin infusions (if necessary in high doses) to maintain blood glucose levels < 8.3 mmol/L is recommended. Hypoglycaemia must be avoided.
- H₂-receptor antagonists or proton pump inhibitors in selected cases to prevent stress-induced ulceration.
- Compression stockings (full-length and graduated) and subcutaneous low-molecular-weight heparin to prevent venous thrombosis.

- Care of the mouth, prevention of constipation and of pressure sores.

In many critically ill patients the precise underlying diagnosis is initially unclear, but in all cases the immediate objective is to preserve life and prevent, reverse or minimize damage to vital organs such as the lungs, brain, kidneys and liver. This involves a rapid assessment of the physiological derangement followed by prompt institution of measures to support cardiovascular and respiratory function in order to restore perfusion of vital organs, improve delivery of oxygen to the tissues and encourage the removal of carbon dioxide and other waste products of metabolism. The patient’s condition and response to treatment should be closely monitored throughout. The underlying diagnosis can then be established as the results of investigations become available, a more detailed history is obtained and a more thorough physical examination is performed.

Discharge of patients from intensive care should normally be planned in advance and should ideally take place during normal working hours. Planned discharge may involve a period in a ‘step-down’ intermediate care area. Premature or unplanned discharge, especially during the night, has been associated with higher hospital mortality rates. A summary including ‘points to review’ should be included in the clinical notes and there should be a detailed handover to the receiving team (medical and nursing). The intensive care team should continue to review the patient, who may deteriorate following discharge, on the ward and should be available at all times for advice on further management (e.g. tracheostomy care, nutritional support). In this way deterioration and readmission to intensive care (which is associated with a particularly poor outcome) or even cardiorespiratory arrest may be avoided.

This chapter concentrates on cardiovascular and respiratory problems. Many patients also have failure of other organs such as the kidney and liver; treatment of these is dealt with in more detail in the appropriate chapters.

### APPLIED CARDIORESPIRATORY PHYSIOLOGY

#### OXYGEN DELIVERY AND CONSUMPTION (Fig. 15.1)

Oxygen delivery (DO₂, oxygen dispatch) is defined as the total amount of oxygen delivered to the tissues per unit time. It is dependent on the volume of blood flowing through the microcirculation per minute (i.e. the total cardiac output, Q̇) and the amount of oxygen contained in that blood (i.e. the arterial oxygen content, CₐO₂). Oxygen is transported both in combination with haemoglobin and dissolved in plasma. The amount combined with haemoglobin is determined by the oxygen capacity of the haemoglobin (usually taken as 1.34 mL of oxygen per gram of haemoglobin) and its percentage saturation with oxygen (S,O₂), while the volume dissolved in plasma depends on the partial pressure of oxygen (P,O₂). Except when hyperbaric oxygen is administered, the amount of dissolved oxygen in plasma is insignificant.
Clinically, however, the utility of this global concept of oxygen dispatch is limited because it fails to account for changes in the relative flow to individual organs and its distribution through the microcirculation (i.e. the efficiency with which oxygen delivery is matched to the metabolic requirements of individual tissues or cells). Furthermore, some organs (such as the heart) have high oxygen requirements relative to their blood flow and may receive insufficient oxygen, even if the overall oxygen delivery is apparently adequate. Lastly microcirculatory flow is influenced by blood viscosity.

**Cardiac output**

Cardiac output is the product of heart rate and stroke volume, and is affected by changes in either (Fig. 15.2).

**Heart rate**

When heart rate increases, the duration of systole remains essentially unchanged, whereas diastole, and thus the time available for ventricular filling, becomes progressively shorter, and the stroke volume eventually falls. In the normal heart this occurs at rates greater than about 160 beats per minute, but in those with cardiac pathology, especially when this restricts ventricular filling (e.g. mitral stenosis), stroke volume may fall at much lower heart rates. Furthermore, tachycarrias cause a marked increase in myocardial oxygen consumption (VO₂) and this may precipitate ischaemia in areas of the myocardium with restricted coronary perfusion. When the heart rate falls, a point is reached at which the increase in stroke volume is insufficient to compensate for bradycardia and again cardiac output falls.

**Stroke volume**

The volume of blood ejected by the ventricle in a single contraction is the difference between the ventricular end-diastolic volume (VEDV) and end-systolic volume (VESV) (i.e. stroke volume = VEDV − VESV). The ejection fraction describes the stroke volume as a percentage of VEDV (i.e. ejection fraction = (VEDV − VESV)/VEDV × 100%) and is an indicator of myocardial performance.

Three interdependent factors determine the stroke volume (see p. 683).

**Myocardial contractility**

This refers to the ability of the heart to perform work, independent of changes in preload and afterload. The state of myocardial contractility determines the response of the ventricles to changes in preload and afterload. Contractility is often reduced in intensive care patients, as a result of either pre-existing myocardial damage (e.g. ischaemic heart disease), or the acute disease process itself (e.g. sepsis). Changes in myocardial contractility alter the slope and position of the Starling curve; worsening ventricular performance is manifested as a depressed, flattened curve for stroke volume (Fig. 15.3 and 13.5).

**Fig. 15.1 Tissue oxygen delivery and consumption in a normal 70 kg person breathing air.** Oxygen delivery (DO₂) = cardiac output × (haemoglobin concentration × oxygen saturation) (S₂O₂) × 1.34. In normal adults oxygen delivery is roughly 1000 mL/min, of which 250 mL is taken up by tissues. Mixed venous blood is thus 75% saturated with oxygen. C₂O₂, mixed venous oxygen content; S₂O₂, mixed venous oxygen saturation; CaO₂, arterial oxygen content. From Singer M, Grant I (eds). ABC of Intensive Care. London: BMJ books, 1999, with permission.

**Fig. 15.2 The determinants of cardiac output.**

Alterations in heart rate are often caused by disturbances of rhythm (e.g. atrial fibrillation, complete heart block) in which ventricular filling is not augmented by atrial contraction and stroke volume therefore falls.

**Fig. 15.3 The Frank–Starling relationship:** as preload is increased, stroke volume rises. If the ventricle is over stretched, stroke volume will fall (x). In myocardial failure, the curve is depressed and flattened. Increasing contractility, e.g. due to sympathetic stimulation, shifts the curve upwards and to the left (z).
Afterload
This is defined as the myocardial wall tension developed during systolic ejection. In the case of the left ventricle, the resistance imposed by the aortic valve, the peripheral vascular resistance and the elasticity of the major blood vessels are the major determinants of afterload. Ventricular wall tension will also be increased by ventricular dilatation, an increase in intraventricular pressure or a reduction in ventricular wall thickness.

Decreasing the afterload can increase the stroke volume achieved at a given preload (Fig. 15.4), whilst reducing $V_{\text{o}_2}$. The reduction in wall tension may also lead to an increase in coronary blood flow, thereby improving the myocardial oxygen supply/demand ratio. Excessive reductions in afterload will cause hypotension.

Increasing the afterload, on the other hand, can cause a fall in stroke volume and is a potent cause of increased $V_{\text{o}_2}$. Right ventricular afterload is normally negligible because the resistance of the pulmonary circulation is very low.

Oxygenation of the blood
Oxyhaemoglobin dissociation curve
The saturation of haemoglobin with oxygen is determined by the partial pressure of oxygen ($P_{O_2}$) in the blood, the relationship between the two being described by the oxyhaemoglobin dissociation curve (Fig. 15.5). The sigmoid shape of this curve is significant for a number of reasons:

- Modest falls in the partial pressure of oxygen in the arterial blood ($P_{A,\text{O}_2}$) may be tolerated (since oxygen content is relatively unaffected) provided that the percentage saturation remains above 90%.
- Increasing the $P_{A,\text{O}_2}$ to above normal has only a minimal effect on oxygen content unless hyperbaric oxygen is administered (when the amount of oxygen in solution in plasma becomes significant).
- Once on the steep ‘slippery slope’ of the curve (percentage saturation below about 90%), a small decrease in $P_{A,\text{O}_2}$ can cause large falls in oxygen content, while increasing $P_{A,\text{O}_2}$ only slightly, e.g. by administering 28% oxygen to a patient with chronic obstructive pulmonary disease (COPD), can lead to a useful increase in oxygen saturation and content.

The $P_{A,\text{O}_2}$ is in turn influenced by the alveolar oxygen tension ($P_{A,\text{O}_2}$), the efficiency of pulmonary gas exchange, and the partial pressure of oxygen in mixed venous blood ($P_{V,\text{O}_2}$).

Alveolar oxygen tension ($P_{A,\text{O}_2}$)
The partial pressures of inspired gases are shown in Figure 15.6. By the time the inspired gases reach the alveoli they are fully saturated with water vapour at body temperature (37°C), which has a partial pressure of 6.3 kPa (47 mmHg) which contains CO$_2$ at a partial pressure of approximately 5.3 kPa (40 mmHg); the $P_{A,\text{O}_2}$ is thereby reduced to approximately 13.4 kPa (100 mmHg).

The clinician can influence $P_{A,\text{O}_2}$ by administering oxygen or by increasing the barometric pressure. Because of the reciprocal relationship between the partial pressures of oxygen and carbon dioxide in the alveoli, a small increase in $P_{A,\text{O}_2}$ can be produced by lowering the $P_{A,\text{CO}_2}$ (e.g. by using mechanical ventilation).

---

**Fig. 15.4** The effect of changes in afterload on the ventricular function curve. At any given preload, decreasing afterload increases the stroke volume.

**Fig. 15.5** The oxyhaemoglobin dissociation curve. a, arterial point; v, venous point; x, arteriovenous oxygen content difference. $HbO_2$ (%) is the percentage saturation of haemoglobin with oxygen. The curve will move to the right in the presence of acidosis (metabolic or respiratory), pyrexia or an increased red cell 2,3-DPG concentration. For a given arteriovenous oxygen content difference, the mixed venous $P_{O_2}$ will then be higher. Furthermore, if the mixed venous $P_{O_2}$ is unchanged, the arteriovenous oxygen content difference increases and more oxygen is offloaded to the tissues (see p. 391).

$P_{O_2}$ (the $P_{O_2}$ at which haemoglobin is half saturated with $O_2$) is a useful index of these shifts – the higher the $P_{O_2}$ (i.e. shift to the right), the lower the affinity of haemoglobin for $O_2$.

**Fig. 15.6** The composition of inspired and alveolar gas (partial pressures in kPa).
**Pulmonary gas exchange**

In normal subjects there is a small alveolar–arterial oxygen difference ($P_{A-a}$O$_2$). This is due to:

- a small (0.133 kPa, 1 mmHg) pressure gradient across the alveolar membrane
- a small amount of blood (2% of total cardiac output) bypassing the lungs via the bronchial and thebesian veins
- a small degree of ventilation/perfusion mismatch.

Pathologically there are three possible causes of an increased $P_{A-a}$O$_2$ difference, as follows:

- **Diffusion defect.** This is not a major cause of hypoxaemia even in conditions such as lung fibrosis, in which the alveolar–capillary membrane is considerably thickened. Carbon dioxide is also not affected, as it is more soluble than oxygen.

- **Right-to-left shunts.** In certain congenital cardiac lesions, such as Fallot’s tetralogy and when a segment of lung is completely unventilated, a significant amount of blood bypasses the lungs and causes arterial hypoxaemia. This hypoxaemia cannot be corrected by administering oxygen to increase the $P_{A-a}$O$_2$, because blood leaving normal alveoli is already fully saturated and further increases in $P_{A-a}$O$_2$ will not significantly affect its oxygen content. On the other hand, because of the shape of the carbon dioxide dissociation curve (Fig. 15.7), the high $P_{A-a}$O$_2$ of the shunted blood can be compensated for by overventilating patent alveoli, thus lowering the CO$_2$ content of the effluent blood. Indeed, many patients with acute right-to-left shunts hyperventilate in response to the hypoxia and/or to stimulation of mechanoreceptors in the lung, so that the $P_{A-a}$CO$_2$ is normal or low.

- **Ventilation/perfusion mismatch** (see p. 817). Diseases of the lung parenchyma result in $V/Q$ mismatch, producing an increase in alveolar deadspace and hypoxaemia. The increased deadspace can be compensated by increasing overall ventilation. In contrast to the hypoxia resulting from a true right-to-left shunt, that due to areas of low $V/Q$ can be partially corrected by administering oxygen and thereby increasing the $P_{A-a}$O$_2$, even in poorly ventilated areas of lung.

**Mixed venous oxygen tension ($P_{v}$O$_2$) and saturation ($S_{v}$O$_2$)**

The $P_{v}$O$_2$ is the partial pressure of oxygen in pulmonary arterial blood that has been thoroughly mixed during its passage through the right heart. Assuming $P_{v}$O$_2$ remains constant, $P_{A-a}$O$_2$ and $S_{v}$O$_2$ will fall if more oxygen has to be extracted from each unit volume of blood arriving at the tissues. A low $P_{v}$O$_2$ therefore indicates either that oxygen delivery has fallen or that tissue oxygen requirements have increased without a compensatory rise in cardiac output. If $P_{v}$O$_2$ falls, the effect of a given degree of pulmonary shunting on arterial oxygenation will be exacerbated. Thus, worsening arterial hypoxaemia does not necessarily indicate a deterioration in pulmonary function but may instead reflect a fall in cardiac output and/or a rise in oxygen consumption.

Conversely, a rise in $P_{v}$O$_2$ and $S_{v}$O$_2$ may reflect impaired tissue oxygen extraction (due to microcirculatory dysfunction) and/or a reduced oxygen utilization (due, for example, to mitochondrial dysfunction) as may be seen in severe sepsis (see below).

Monitoring the oxygen saturation in central venous ($S_{v}$O$_2$), rather than pulmonary artery blood is less invasive and has been shown to be a valuable guide to the resuscitation of critically ill patients (see p. 899).

**DISTURBANCES OF ACID–BASE BALANCE**

The physiology of acid–base control is discussed on page 672. Acid–base disturbances can be described in relation to the diagram illustrated in Figure 12.14 (p. 675) (which shows $P_{A-a}$CO$_2$ plotted against arterial [H$^+$]).

Both acidosis and alkalosis can occur, each of which may be either metabolic (primarily affecting the bicarbonate component of the system) or respiratory (primarily affecting $P_{A-a}$CO$_2$). Compensatory changes may also be apparent. In clinical practice, arterial [H$^+$] values outside the range 18–126 mmol/L (pH 6.9–7.7) are rarely encountered.

**Respiratory acidosis.** This is caused by retention of carbon dioxide. The $P_{A-a}$CO$_2$ and [H$^+$] rise. A chronically raised $P_{A-a}$CO$_2$ is compensated by renal retention of bicarbonate, and the [H$^+$] returns towards normal. A constant arterial bicarbonate concentration is then usually established within 2–5 days. This represents a primary respiratory acidosis with a compensatory metabolic alkalosis (see p. 678). Common causes of respiratory acidosis include ventilatory failure and COPD (type II respiratory failure where there is a high $P_{A-a}$CO$_2$ and a low $P_{A-a}$O$_2$ – see p. 837).

**Respiratory alkalosis.** In this case the reverse occurs and there is a fall in $P_{A-a}$CO$_2$ and [H$^+$], often with a small reduction.

![Fig. 15.7 The carbon dioxide dissociation curve. Note that in the physiological range the curve is essentially linear.](image-url)

in bicarbonate concentration. If hypocarbia persists, some degree of renal compensation may occur, producing a metabolic acidosis, although in practice this is unusual. A respiratory alkalosis is often produced, intentionally or unintentionally, when patients are mechanically ventilated; it may also be seen with hypoxaemic (type I) respiratory failure (see Ch. 14), spontaneous hyperventilation and in those living at high altitudes.

**Metabolic acidosis** (p. 675). This may be due to excessive acid production, most commonly lactate and H+ (lactic acidosis) as a consequence of anaerobic metabolism during an episode of shock or following cardiac arrest. A metabolic acidosis may also develop in chronic renal failure or in diabetic ketoacidosis. It can also follow the loss of bicarbonate from the gut, for example, or from the kidney in renal tubular acidosis. Respiratory compensation for a metabolic acidosis is usually slightly delayed because the blood-brain barrier initially prevents the respiratory centre from sensing the increased blood [H+]. Following this short delay, however, the patient hyperventilates and “blows off” carbon dioxide to produce a compensatory respiratory alkalosis. There is a limit to this respiratory compensation, since in practice values for \( P_{\text{CO}_2} \) less than about 1.4 kPa (11 mmHg) are rarely achieved. Spontaneous respiratory compensation cannot occur if the patient’s ventilation is controlled or if the respiratory centre is depressed, for example by drugs or head injury.

**Metabolic alkalosis.** This can be caused by loss of acid, for example from the stomach with nasogastric suction, or in high intestinal obstruction, or excessive administration of absorbable alkali. Overzealous treatment with intravenous sodium bicarbonate is sometimes implicated. Respiratory compensation for a metabolic alkalosis is often slight, and it is rare to encounter a \( P_{\text{CO}_2} \) above 6.5 kPa (50 mmHg), even with severe alkalosis.

**SHOCK AND ACUTE DISTURBANCES OF HAEMODYNAMIC FUNCTION**

Shock is the term used to describe acute circulatory failure with inadequate or inappropriately distributed tissue perfusion resulting in generalized cellular hypoxia and/or an inability of the cells to utilize oxygen.

**Causes of shock**
Abnormalities of tissue perfusion may result from:
- failure of the heart to act as an effective pump
- mechanical impediments to forward flow
- loss of circulatory volume
- abnormalities of the peripheral circulation.

The causes of shock are shown in Table 15.3. Often shock can result from a combination of these factors (e.g. in sepsis, distributive shock is frequently complicated by hypovolaemia and myocardial depression).

**Fig. 15.8** The sympatho-adrenal response to shock showing the effect of increased catecholamines on the left of the diagram and the release of angiotensin and aldosterone on the right. Both mechanisms result in maintaining the cardiac output in shock.

**PATHOPHYSIOLOGY**

**The sympatho-adrenal response to shock** (Fig. 15.8)

Hypotension stimulates the baroreceptors, and to a lesser extent the chemoreceptors, causing increased sympathetic nervous activity with ‘spill-over’ of norepinephrine (noradrenaline) into the circulation. Later this is augmented by the release of catecholamines (predominantly epinephrine (adrenaline)) from the adrenal medulla. The resulting vasoconstriction, together with increased myocardial contractility and heart rate, help to restore blood pressure and cardiac output.
Reduction in perfusion of the renal cortex stimulates the juxtaglomerular apparatus to release renin. This converts angiotensinogen to angiotensin I, which in turn is converted in the lungs and by the vascular endothelium to the potent vasoconstrictor angiotensin II. Angiotensin II also stimulates secretion of aldosterone by the adrenal cortex, causing sodium and water retention (p. 1023). This helps to restore the circulating volume (see p. 652).

**Neuroendocrine response**

- There is release of pituitary hormones such as adrenocorticotropic hormone (ACTH), vasopressin (antidiuretic hormone, ADH) and endogenous opioid peptides. (In septic shock there may be a relative deficiency of vasopressin.)
- There is release of cortisol, which causes fluid retention and antagonizes insulin.
- There is release of glucagon, which raises the blood sugar level.

Although absolute adrenocortical insufficiency (due, for example, to bilateral adrenal haemorrhage or necrosis) is rare, there is evidence that patients with septic shock have a blunted response to exogenous ACTH (so-called ‘relative’ or ‘occult’ adrenocortical insufficiency) and that this may be associated with an impaired pressor response to norepinephrine (noradrenaline) and a worse prognosis. The diagnosis, causes and clinical significance of this phenomenon remain unclear.

**Release of pro- and anti-inflammatory mediators** (see also Ch. 3)

Severe infection (often with bacteraemia or endotoxaemia), the presence of large areas of damaged tissue (e.g. following trauma or extensive surgery) or prolonged/repeated episodes of hypoperfusion can trigger an exaggerated inflammatory response with systemic activation of leucocytes and release of a variety of potentially damaging ‘mediators’. Although beneficial when targeted against local areas of infection or necrotic tissue, dissemination of this ‘innate immune’ response can produce shock and widespread tissue damage. Characteristically the initial episode of overwhelming inflammation is followed by a period of immune suppression, which in some cases may be profound and during which the patient is at increased risk of developing secondary infections. It also seems that pro- and anti-inflammatory elements of the host response may coexist.

**Microorganisms and their toxic products** (Fig. 15.9)

In sepsis/septic shock the innate immune response and inflammatory cascade are triggered by the recognition of pathogen-associated molecular patterns (PAMPs) including cell wall components (e.g. endotoxin) and/or exotoxins (antigenic proteins produced by bacteria such as staphylococci, streptococci and *Pseudomonas*). Endotoxin is a lipopolysaccharide (LPS) derived from the cell wall of Gram-negative bacteria and is a potent trigger of the inflammatory response. The lipid A portion of LPS can be bound by a protein normally present in human serum known as lipopolysaccharide binding protein (LBP). The LBP/LPS complex attaches to the cell surface marker CD14 and, combined with a secreted protein (MD2), this complex then binds to a member of the toll-like receptor family (TLR4), which transduces the activation signal into the cell. These receptors act through a critical adaptor molecule, myeloid differentiation factor 88 (MyD 88) to regulate the activity of NFκB pathways. Another mechanism in this complex area involves TREM-1 (triggering receptor expressed in myeloid cells, see p. 59) which triggers secretion of pro-inflammatory cytokines.

Specific kinases then phosphorylate inhibitory kappa B (IκB), releasing the nuclear transcription factor NFκB, which passes into the nucleus where it binds to DNA and promotes the synthesis of a wide variety of inflammatory mediators. Cell wall components from Gram-positive bacteria, some of which are similar in structure to LPS (e.g. lipoteichoic acid), can also trigger a systemic inflammatory response, probably through similar (TLR2), but not identical pathways (see Fig. 15.9).

**Activation of complement cascade** (see p. 55)

One of the many functions of the complement system is to attract and activate leucocytes, which then marginate onto endothelium and release inflammatory mediators such as proteases and toxic free radicals of oxygen and other reactive oxygen and nitrogen species (see below).

**Cytokines** (see also p. 54)

Pro-inflammatory cytokines such as the interleukins (ILs) and tumour necrosis factor (TNF) are also mediators of the systemic inflammatory response. TNF release initiates many of the responses to endotoxin, for example, and acts synergistically with IL-1, in part through induction of cyclo-oxygenase, platelet-activating factor (PAF) and nitric oxide synthase (see below). The cytokine network is extremely complex, with many endogenous self-regulating mechanisms. For example, naturally occurring soluble TNF receptors are shed from cell surfaces during the inflammatory response, binding to TNF and thereby reducing its biological activity. An endogenous inhibitory protein that binds competitively to the IL-1 receptor has also been identified.

In addition to pro-inflammatory mediators such as TNF, anti-inflammatory cytokines, e.g. IL-10, are released. The ratio of IL-10 to TNF, and of TNF to TNF receptors, has been shown to be related to mortality in severe sepsis/septic shock. When excessive, this compensatory anti-inflammatory response syndrome (CARS) may be associated with an inappropriate immune hyporesponsiveness.

**Platelet-activating factor (PAF)**

This vasoactive lipid is released from various cell populations, such as leucocytes and macrophages, in shock. Its effects, which are caused both directly and through the secondary release of other mediators, include hypotension, increased vascular permeability and platelet aggregation.

**Products of arachidonic acid metabolism**

(see Fig. 14.32)

Arachidonic acid, derived from the breakdown of membrane phospholipid, is metabolized to form prostanoids and leukotrienes, which are key inflammatory mediators (see p. 849).

**Lysosomal enzymes**

These can cause myocardial depression and coronary vasoconstriction. Furthermore, lysosomal enzymes can convert
inactive kininogens to vasoactive kinins such as bradykinins. These substances cause vasodilatation and increased capillary permeability, as well as myocardial depression. They can also activate clotting mechanisms.

**Adhesion molecules** (see also p. 25)
Adhesion of activated leucocytes to the vessel wall and their subsequent extravascular migration is a key component of the sequence of events leading to endothelial injury, tissue damage and organ dysfunction. This process is mediated by inducible intercellular adhesion molecules (ICAMs) found on the surface of leucocytes and endothelial cells. Expression of these molecules can be induced by endotoxin and pro-inflammatory cytokines such as IL-1 and TNF. Several families of molecules are involved in promoting leucocyte–endothelial interaction. The selectins are ‘capture’ molecules and initiate the process of leucocyte rolling on vascular endothelium, whilst members of the immunoglobulin superfamily (ICAM-1 and vascular cell adhesion molecule-1) are involved in the formation of a more secure bond which leads to leucocyte migration into the tissues (see Fig. 3.13).

**Endothelium-derived vasoactive mediators**
Endothelial cells synthesize a number of mediators which contribute to the regulation of blood vessel tone and the fluidity of the blood; these include nitric oxide, prostacyclin and endothelin-1 (a potent vasoconstritor). Nitric oxide (NO) is synthesized from the terminal guanidino-nitrogen atoms of the amino acid L-arginine under the influence of nitric oxide synthase (NOS). NO inhibits platelet aggregation and adhesion and produces vasodilatation by activating guanylate cyclase in the underlying vascular smooth muscle to form cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP) (Fig. 15.10). There are several distinct NOS enzymes.

- **Constitutive or endothelial NOS** (cNOS or eNOS) present in endothelial cells is responsible for the basal release of NO and is involved in the physiological regulation of vascular tone, blood pressure and tissue perfusion.
- **Neuronal NOS** (nNOS). The role of nerves containing nNOS is uncertain but they probably provide neurogenic vasodilator tone. In the central nervous system nNOS
may be a regulator of local cerebral blood flow as well as fulfilling a number of other physiological functions, such as the acute modulation of neuronal firing behaviour.

**Inducible NOS (iNOS)** is induced in vascular endothelial smooth muscle cells and monocytes within 4–18 hours of stimulation with certain cytokines, such as TNF, and endotoxin. The resulting prolonged increase in NO formation is believed to be a cause of the sustained vasodilatation, hypotension and reduced reactivity to adrenergic agonists (‘vasoplegia’) that characterizes septic shock. This mechanism may also be involved in severe prolonged haemorrhage-traumatic shock. The NO generated by macrophages contributes to their role as highly effective killers of intracellular and extracellular pathogens, in part as a consequence of its ability to bind to cytochrome oxidase and inhibit electron transport, but also via the production of the highly reactive radical peroxynitrite.

**Redox imbalance**

In health the balance between reducing and oxidizing conditions (redox) is controlled by antioxidants which may either prevent radical formation (e.g. transferrin and lactoferrin which bind iron, a catalyst for radical formation) or remove/inactivate reactive oxygen and nitrogen species (e.g. enzymes such as superoxide dismutases, vitamins C and E, and sulphhydryl group donors such as glutathione). There are also mechanisms to remove and repair oxidatively damaged molecules and in particular to preserve DNA integrity. In severe systemic inflammation the uncontrolled production of oxygen-derived free radicals and reactive nitrogen species, e.g. superoxide (O_2^-•), hydroxyl radicals (OH••), hydrogen peroxide (H_2O_2) and peroxynitrite (ONOO•), particularly by activated polymorphonuclear leucocytes, can overwhelm these defensive mechanisms and cause:

- lipid and protein peroxidation
- damage to cell membranes
- increased capillary permeability
- impaired mitochondrial respiration
- DNA strand breakage
- apoptosis, which may contribute to the organ damage and immune hypo-responsiveness associated with sepsis.

**Influence of genetic variation**

Individuals vary considerably in their susceptibility to infection, as well as their ability to recover from apparently similar infections, illnesses or traumatic insults. Evidence now indicates that interindividual variations in susceptibility to, and outcome from, sepsis can be partly explained by polymorphisms of the genes encoding proteins involved in mediating and controlling innate immunity and the inflammatory response.

**Haemodynamic and microcirculatory changes**

The dominant haemodynamic feature of septic shock is peripheral vascular failure with:

- vasodilatation
- maldistribution of regional blood flow
- abnormalities in the microcirculation:
  - ‘stop-flow’ capillaries (flow is intermittent)
  - ‘no-flow’ capillaries (capillaries are obstructed)
  - failure of capillary recruitment
  - increased capillary permeability with interstitial oedema.

Although these vascular and microvascular abnormalities may partly account for the reduced oxygen extraction often seen in septic shock, there is also a primary defect of cellular oxygen utilization owing to mitochondrial dysfunction (see above). Initially, before hypovolaemia supervenes, or when therapeutic replacement of circulating volume has been inadequate, cardiac output is usually high and peripheral resistance is low. These changes may be associated with impaired oxygen consumption, a reduced arteriovenous oxygen content difference, an increased S_O2 and a lactic acidosis (so-called ‘tissue dysoxia’). Vasodilatation and increased permeability also occur in anaphylactic shock.

In the initial stages of other forms of shock, and sometimes when hypovolaemia and myocardial depression supervene in sepsis and anaphylaxis, cardiac output is low and increased sympathetic activity causes constriction of both precapillary arterioles and, to a lesser extent, the postcapillary venules. This helps to maintain the systemic blood pressure. In addition, the hydrostatic pressure within the capillaries falls and fluid is mobilized from the extravascular space into the intravascular compartment.

**Activation of the coagulation system**

The inflammatory response to shock, tissue injury and infection is frequently associated with systemic activation of the clotting cascade, leading to platelet aggregation, widespread microvascular thrombosis and inadequate tissue perfusion.

Initially the production of PG12 by the capillary endothelium is impaired. Cell damage (for example to the vascular endothelium) leads to exposure to tissue factor (p. 431), which triggers coagulation. In severe cases these changes are compounded by elevated levels of plasminogen activation inhibitor type 1 which impairs fibrinolysis, as well as by deficiencies in physiological inhibitors of coagulation (including antithrombin, proteins C and S and tissue factor-pathway inhibitor). Antithrombin and protein C have a number of anti-inflammatory properties, whereas thrombin is pro-inflammatory.
Plasminogen is converted to plasmin, which breaks down thrombus, liberating fibrin/fibrinogen degradation products (FDPs). Circulating levels of FDPs are therefore increased, the thrombin time, PTT and PT are prolonged and platelet and fibrinogen levels fall. Activation of the coagulation cascade can be confirmed by demonstrating increased plasma levels of D-dimers. The development of disseminated intravascular coagulation (DIC) often heralds the onset of multiple organ failure. Because clotting factors and platelets are consumed in DIC, they are unavailable for haemostasis elsewhere and a coagulation defect results – hence the alternative name for DIC is ‘consumption coagulopathy’. In some cases a microangiopathic haemolytic anaemia develops. DIC is particularly associated with septic shock, especially when due to meningococcal infection (see below) (Fig. 15.11). The gut mucosa seems to be especially vulnerable to this ‘ischaemia-reperfusion injury’.

**Reperfusion injury**

Restoration of flow to previously hypoxic tissues can exacerbate cell damage through the generation of large quantities of reactive oxygen species and activation of polymorphonuclear leucocytes (see above) (Fig. 15.11). The gut mucosa seems to be especially vulnerable to this ‘ischaemia-reperfusion injury’.

---

**Metabolic response to trauma, major surgery and severe infection** (see also p. 213)

This is initiated and controlled by the neuroendocrine system and various cytokines (e.g. IL-6) acting in concert, and is characterized initially by an increase in energy expenditure (‘hypermetabolism’). Gluconeogenesis is stimulated by increased glucagon and catecholamine levels, whilst hepatic mobilization of glucose from glycogen is increased. Catecholamines inhibit insulin release and reduce peripheral glucose uptake. Combined with elevated circulating levels of other insulin antagonists such as cortisol, and downregulation of insulin receptors, these changes ensure that the majority of patients are hyperglycaemic (‘insulin resistance’). Later hypoglycaemia may be precipitated by depletion of hepatic glycogen stores and inhibition of gluconeogenesis. Free fatty acid synthesis is also increased, leading to hypertriglyceridaemia.

Protein breakdown is initiated to provide energy from amino acids, and hepatic protein synthesis is preferentially augmented to produce the ‘acute phase reactants’. The amino acid glutamine (which is indispensable in this situation) is mobilized from muscle for use as a metabolic fuel in rapidly dividing cells such as leucocytes and enterocytes. Glutamine is also required for hepatic production of the free radical scavenger glutathione. When severe and prolonged, this catabolic response can lead to considerable weight loss. Protein breakdown is associated with wasting and weakness of skeletal and respiratory muscle, prolonging the need for mechanical ventilation and delaying mobilization. Tissue repair, wound healing and immune function may also be compromised.

---

**CLINICAL FEATURES OF SHOCK**

Although many clinical features are common to all types of shock, there are certain aspects in which they differ (Box 15.2).

**Hypovolaemic shock**

- Inadequate tissue perfusion:
  - (a) Skin – cold, pale, slate-grey, slow capillary refill, ‘clammy’
  - (b) Kidneys – oliguria, anuria
  - (c) Brain – drowsiness, confusion and irritability.

- Increased sympathetic tone:
  - (a) Tachycardia, narrowed pulse pressure, ‘weak’ or ‘thready’ pulse
  - (b) Sweating
  - (c) Blood pressure – may be maintained initially (despite up to a 25% reduction in circulating volume if the patient is young and fit), but later hypotension supervenes.

- Metabolic acidosis – compensatory tachypnoea.

Extreme hypovolaemia may be associated with bradycardia. Additional clinical features may occur in the following types of shock.

**Cardiogenic shock** (see p. 742)

Signs of myocardial failure, e.g. raised jugular venous pressure (JVP), pulsus alternans, ‘gallop’ rhythm, basal crackles, pulmonary oedema.
Box 15.2 Haemodynamic changes in shock

**Hypovolaemic shock**
- Low central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP)
- Low cardiac output
- Increased systemic vascular resistance

**Cardiogenic shock**
- Signs of myocardial failure
- Increased systemic vascular resistance
- CVP and PAOP high (except when hypovolaemic)

**Cardiac tamponade**
- Parallel increases in CVP and PAOP
- Low cardiac output
- Increased systemic vascular resistance

**Pulmonary embolism**
- Low cardiac output
- High CVP, high pulmonary artery pressure but low PAOP
- Increased systemic vascular resistance

**Anaphylaxis**
- Low systemic vascular resistance
- Low CVP and PAOP
- High cardiac output

**Septic shock**
- Low systemic vascular resistance
- Low CVP and PAOP
- Cardiac output usually high
- Myocardial depression – low ejection fraction
- Stroke volume maintained by ventricular dilatation
- Cardiac output maintained or increased by tachycardia

**Obstructive shock**
- Elevated JVP.
- Pulsus paradoxus and muffled heart sounds in cardiac tamponade.
- Signs of pulmonary embolism (see p. 784).

**Anaphylactic shock** (see p. 73)
- Signs of profound vasodilatation:
  - (a) Warm peripheries
  - (b) Low blood pressure
  - (c) Tachycardia.
- Erythema, urticaria, angio-oedema, pallor, cyanosis.
- Bronchospasm, rhinitis.
- Oedema of the face, pharynx and larynx.
- Pulmonary oedema.
- Hypovolaemia due to capillary leak.
- Nausea, vomiting, abdominal cramps, diarrhoea.

**Sepsis, severe sepsis and septic shock**
- Pyrexia and rigors, or hypothermia (unusual).
- Nausea, vomiting.
- Vasodilatation, warm peripheries.
- Bounding pulse.
- Rapid capillary refill.
- Hypotension (septic shock).
- Occasionally signs of cutaneous vasoconstriction.
- Other signs:
  - (a) Jaundice
  - (b) Coma, stupor
  - (c) Bleeding due to coagulopathy (e.g. from vascular puncture sites, GI tract and surgical wounds)
  - (d) Rash and meningism
  - (c) Hyper-, and in more severe cases hypoglycaemia.

The diagnosis of sepsis is easily missed, particularly in the elderly when the classical signs may not be present. Mild confusion, tachycardia and tachypnoea may be the only clues, sometimes associated with unexplained hypotension, a reduction in urine output, a rising plasma creatinine and glucose intolerance.

The clinical signs of sepsis are not always associated with bacteraemia and can occur with non-infectious processes such as pancreatitis or severe trauma. The term ‘systemic inflammatory response syndrome’ (SIRS) describes the disseminated inflammation that can complicate this diverse range of disorders (Box 15.3). Patterns of systemic inflammatory response are shown in Figure 15.12, which illustrates the proinflammatory response (SIRS) and the counter-regulatory anti-inflammatory response (CARS).

### MONITORING CRITICALLY ILL PATIENTS

As well as allowing immediate recognition of changes in the patient’s condition, monitoring can also be used to establish or confirm a diagnosis, to gauge the severity of the condition,

Box 15.3 Terminology used in systemic inflammation and sepsis

**Infection**
- Invasion of normally sterile host tissue by microorganisms

**Bacteraemia**
- Viable bacteria in blood

**Systemic inflammatory response syndrome (SIRS)**
- The systemic inflammatory response to a variety of severe clinical insults. The response is manifested by two or more of the following:
  - Temperature >38°C or <36°C
  - Heart rate > 90 beats/min
  - Respiratory rate > 20 breaths/min or \( P_{CO_2} < 4.3 \text{kPa} \)
  - White cell count >12 x 10^3/L, <4 x 10^3/L or >10% immature forms

**Sepsis**
- SIRS resulting from documented infection

**Severe sepsis**
- Sepsis associated with organ dysfunction, hypoperfusion or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria or an acute alteration in mental state

**Septic shock**
- Severe sepsis with hypotension (systolic BP <90 mmHg or a reduction of >40 mmHg from baseline) in the absence of other causes for hypotension and despite adequate fluid resuscitation
  - (Patients receiving inotropic or vasopressor agents may not be hypotensive when perfusion abnormalities are documented)

**Refractory shock**
- Shock unresponsive to conventional therapy (intravenous fluids and inotropic/vasoactive agents) within 1 hour

**Compensatory anti-inflammatory response syndrome (CARS)**
- Release of anti-inflammatory mediators which downregulate the inflammatory response. If excessive, may lead to inappropriate immune hyporesponsiveness

**Mixed antagonistic response syndrome (MARS)**
- Alternating pro- and anti-inflammatory responses
to follow the evolution of the illness, to guide interventions and to assess the response to treatment. Invasive monitoring is generally indicated in the more seriously ill patients and in those who fail to respond to initial treatment. These techniques are, however, associated with a significant risk of complications, as well as additional costs and patient discomfort and should therefore only be used when the potential benefits outweigh the dangers. Likewise, invasive devices should be removed as soon as possible.

Assessment of tissue perfusion

- **Pale, cold skin**, delayed capillary refill and the absence of visible veins in the hands and feet indicate poor perfusion. Although peripheral skin temperature measurements can help clinical evaluation, the earliest compensatory response to hypovolaemia or a low cardiac output, and the last to resolve after resuscitation, is vasoconstriction in the splanchnic region.

- **Metabolic acidosis with raised lactate concentration** may suggest that tissue perfusion is sufficiently compromised to cause cellular hypoxia and anaerobic glycolysis. Persistent, severe lactic acidosis is associated with a very poor prognosis. In many critically ill patients, especially those with sepsis, however, lactic acidosis can also be caused by metabolic disorders unrelated to tissue hypoxia and may be exacerbated by reduced clearance owing to hepatic or renal dysfunction.

- **Urinary flow** is a sensitive indicator of renal perfusion and haemodynamic performance.

**Blood pressure**

Alterations in blood pressure are often interpreted as reflecting changes in cardiac output. However, if there is vasoconstriction with a high peripheral resistance, the blood pressure may be normal, even when the cardiac output is reduced. Conversely, the vasodilated patient may be hypotensive despite a very high cardiac output.

**Hypotension** may jeopardize perfusion of vital organs. The adequacy of blood pressure in an individual patient must always be assessed in relation to the premorbid value. Blood pressure is traditionally measured using a sphygmomanometer but if rapid alterations are anticipated, continuous monitoring using an intra-arterial cannula is indicated (Practical box 15.1, Fig. 15.13).
Central venous pressure (CVP)

This provides a fairly simple, but approximate method of gauging the adequacy of a patient’s circulating volume and the contractile state of the myocardium. The absolute value of the CVP is not as useful as its response to a fluid challenge (the infusion of 100–200 mL of fluid over a few minutes) (Fig. 15.14). The hypovolaemic patient will initially respond to transfusion with little or no change in CVP, together with some improvement in cardiovascular function (falling heart rate, rising blood pressure, increased peripheral temperature and urine output). As the normovolaemic state is approached, the CVP usually rises slightly and stabilizes, while other cardiovascular values begin to normalize. At this stage, volume replacement should be slowed, or even stopped, in order to avoid overtransfusion (indicated by abrupt and sustained rise in CVP, often accompanied by some deterioration in the patient’s condition). In cardiac failure the venous pressure is usually high; the patient will not improve in response to volume replacement, which will cause a further, sometimes dramatic, rise in CVP.

The central venous catheter is usually inserted via a percutaneous puncture of a subclavian or internal jugular vein (Practical box 15.2, Fig. 15.15). Techniques using a guidewire are generally safer and more reliable than the catheter over needle devices (Fig. 15.16). They can also be used in conjunction with a vein dilator for inserting multilumen catheters, double lumen cannulae for haemofiltration or pulmonary artery catheter introducers.

The CVP may be read intermittently using a manometer system or continuously using a transducer and bedside monitor. It is essential that the pressure recorded always be related to the level of the right atrium. Various landmarks are advocated (e.g. sternal notch with the patient supine, sternal angle or mid-axilla when the patient is at 45 degrees), but which is chosen is largely immaterial provided it is used consistently in an individual patient. Pressure measurements should be obtained at end-expiration.

The following are common pitfalls in interpreting central venous pressure readings:

![Fig. 15.14](image) The effects on the central venous pressure of a rapid administration of a ‘fluid challenge’ to patients with a CVP within the normal range. From Sykes MK. Venous pressure as a clinical indication of adequacy of transfusion. Annals of Royal College of Surgeons of England 1963; 33: 185–197.

![Fig. 15.15](image) Cannulation of the right internal jugular vein.

Practical Box 15.2 Internal jugular vein cannulation

**Technique**

1. The procedure is explained to the patient and, if possible, consent obtained.
2. The patient is placed head-down to distend the central veins (this facilitates cannulation and minimizes the risk of air embolism but may exacerbate respiratory distress and is dangerous in those with raised intracranial pressure).
3. The skin is cleaned with an antiseptic solution such as chlorhexidine. Sterile precautions are taken throughout the procedure.
4. Local anaesthetic (1% plain lidocaine) is injected intradermally to raise a weal at the apex of a triangle formed by the two heads of sternomastoid with the clavicle at its base.
5. A small incision is made through the weal.
6. The cannula or needle is inserted through the incision and directed laterally downwards and backwards in the direction of the nipple until the vein is punctured just beneath the skin and deep to the lateral head of sternomastoid. Ultrasound-guided puncture has been recommended, at least for difficult cases, to reduce the incidence of complications.
7. Check that venous blood is easily aspirated.
8. The cannula is threaded off the needle into the vein or the guidewire is passed through the needle (Fig. 15.16).
9. The CVP manometer line is connected to a manometer/transducer.
10. A chest X-ray should be taken to verify that the tip of the catheter is in the superior vena cava and to exclude pneumothorax.

**Possible complications**

- Haemorrhage
- Accidental arterial puncture (carotid or subclavian)
- Pneumothorax
- Damage to thoracic duct on left
- Air embolism
- Thrombosis
- Catheter-related sepsis
Seldinger technique – insertion of a catheter over guidewire. (1) Puncture vessel; (2) advance guidewire; (3) remove needle; (4) dilate vessel; (5) advance catheter over guidewire; (6) remove guidewire; (7) catheter in situ.

Blocked catheter. This results in a sustained high reading, with a damped or absent waveform which often does not correlate with clinical assessment.

Transducer wrongly positioned. Failure to level the system is a common cause of erroneous readings.

Catheter tip in right ventricle. If the catheter is advanced too far, an unexpectedly high pressure with pronounced oscillations is recorded. This is easily recognized when the waveform is displayed.

Arterial pressure variation as a guide to hypovolaemia

Systolic arterial pressure decreases during the inspiratory phase of intermittent positive pressure ventilation (p. 912). The magnitude of this cyclical variability has been shown to correlate more closely with hypovolaemia than other monitored variables, including CVP. Systolic pressure variation during mechanical ventilation can therefore be used as a simple and reliable guide to the adequacy of the circulatory volume.

Left atrial pressure

In uncomplicated cases, careful interpretation of the CVP provides a reasonable guide to the filling pressures of both sides of the heart. In many critically ill patients, however, this is not the case and there is a disparity in function between the two ventricles. Most commonly, left ventricular performance is worst, so that the left ventricular function curve is displaced downward and to the right (Fig. 15.17). High right ventricular filling pressures, with normal or low left atrial pressures, are less common but may occur with right ventricular dysfunction and in situations where the pulmonary vascular resistance (i.e. right ventricular afterload) is raised, such as in acute respiratory failure and pulmonary embolism.

Pulmonary artery pressure

A ‘balloon flotation catheter’ enables reliable catheterization of the pulmonary artery. These ‘Swan–Ganz’ catheters can be inserted centrally (see Fig. 15.15) or through the femoral vein, or via a vein in the antecubital fossa. Passage of the catheter from the major veins, through the chambers of the heart, into the pulmonary artery and into the wedged position is monitored and guided by the pressure waveforms recorded from the distal lumen (Fig. 15.18 and Practical box 15.3). A

Consent should be obtained from the patient after explanation of the procedure

1 A balloon flotation catheter is inserted through a large vein (see text)
2 Once in the thorax, internal jugular, subclavian or respiratory oscillations are seen. The catheter should be advanced further towards the lower superior vena cava/right atrium (a), where pressure oscillations become more pronounced. The balloon should then be inflated and the catheter advanced
3 When the catheter is in the right ventricle (b), there is no dicrotic notch and the diastolic pressure is close to zero. The patient should be returned to the horizontal, or slightly head-up, position before advancing the catheter further
4 When the catheter reaches the pulmonary artery (c) a dicrotic notch appears and there is elevation of the diastolic pressure. The catheter should be advanced further with the balloon inflated
5 Reappearance of a venous waveform indicates that the catheter is ‘wedge’. The balloon is deflated to obtain the pulmonary artery pressure. The balloon is inflated intermittently to obtain the pulmonary artery occlusion (also known as pulmonary artery, or capillary, ‘wedge’) pressure (d)

a, b, c, d refer to Fig. 15.18.
chest X-ray should always be obtained to check the final position of the catheter. In difficult cases screening with an image intensifier may be required.

Once in place, the balloon is deflated and the pulmonary artery mean, systolic and end-diastolic pressures (PAEDP) can be recorded. The pulmonary artery occlusion pressure (PAOP, previously referred to as the pulmonary artery or capillary ‘wedge’ pressure) is measured by reinflating the balloon, thereby propelling the catheter distally until it impacts in a medium-sized pulmonary artery. In this position there is a continuous column of fluid between the distal lumen of the catheter and the left atrium, so that PAOP is usually a reflection of left atrial pressure.

The technique is generally safe – the majority of complications are related to user inexperience. Pulmonary artery catheters should preferably be removed within 72 hours, since the incidence of complications, especially infection, then increases progressively (Table 15.4).

**Cardiac output**

Until recently cardiac output was most commonly determined by the thermodilution method, using a modified pulmonary artery catheter with a lumen opening in the right atrium and a thermistor located a few centimetres from its tip. In this method, a known volume (usually 10 mL) of cold 5% dextrose is injected as a bolus into the right atrium. This mixes with, and cools, the blood passing through the heart, and the transient fall in temperature is continuously recorded by the thermistor in the pulmonary artery. The cardiac output is computed from the total amount of indicator (i.e. cold) injected, divided by the average concentration, i.e. the amount of cooling, and the time taken to pass the thermistor. It is also possible to measure cardiac output continuously using a modified pulmonary artery catheter which transmits low heat energy into the surrounding blood and constructs a ‘thermodilution curve’. These catheters also optically measure and continuously display $S_pO_2$.

![Fig. 15.18 Passage of pulmonary artery balloon flotation catheter through the chambers of the heart into the 'wedge' position to measure the pulmonary artery occlusion pressure. See Practical box 15.3.](image)

In general, pulmonary artery catheters enable the clinician to optimize cardiac output and oxygen delivery, whilst minimizing the risk of pulmonary oedema. They can also be used to guide the rational use of inotropes and vasoactive agents. There is increasing evidence, however, to suggest that the use of this monitoring device may not lead to improved outcomes and less invasive techniques are increasingly preferred.
Less invasive techniques for assessing cardiac function

**Oesophageal Doppler**
Cardiac output and myocardial function can be determined non-invasively using Doppler ultrasonography. A probe is passed into the oesophagus to continuously monitor velocity waveforms from the descending aorta (Fig. 15.19). Although reasonable estimates of stroke volume and cardiac output can be obtained, the technique is best used for trend analysis rather than for making absolute measurements. It is particularly valuable for perioperative optimization of the circulating volume and cardiac performance.

**Lithium dilution**
Lithium dilution methods do not require pulmonary artery catheterization and are suitable for use in conscious patients. A bolus of lithium chloride is administered via a central venous catheter and the change in arterial plasma lithium concentration is detected by a lithium-sensitive electrode. This sensor can be connected to an existing arterial cannula via a three-way tap. A small battery-powered peristaltic pump is used to create a constant blood flow through the sensor and over the electrode tip. The cardiac output determined in this way can be used to calibrate an arterial pressure waveform (‘pulse contour’) analysis programme that will continuously monitor changes in cardiac output. Repeated calibration of this system is required.

**Echocardiography**
Echocardiography is being used increasingly often to provide immediate diagnostic information about cardiac structure and function in the critically ill patient. Transoesophageal echocardiography is preferred because of its superior image clarity.

If there is disagreement between clinical signs and a monitored variable, it should be assumed that the monitor is incorrect until all sources of potential error have been checked and eliminated. Changes and trends in monitored variables are more informative than a single reading.

---

**MANAGEMENT OF SHOCK** (see Fig. 15.20)

Delays in making the diagnosis and in initiating treatment, as well as inadequate resuscitation, contribute to the development of multiple organ failure (MOF) and should be avoided (see p. 909).

A patent airway must be maintained and oxygen must be given. If necessary, an oropharyngeal airway or an endotracheal tube is inserted. The latter has the advantage of preventing aspiration of gastric contents. Very rarely, emergency tracheostomy is indicated (see below). Some patients may require mechanical ventilation.

The underlying cause of shock should be corrected – for example, haemorrhage should be controlled or infection eradicated. In patients with septic shock, every effort must be made to identify the source of infection and isolate the causative organism. As well as a thorough history and clinical examination, X-rays, ultrasonography or CT scanning may be required to locate the origin of the infection. Appropriate samples (urine, sputum, cerebrospinal fluid, pus drained from abscesses) should be sent to the laboratory for microscopy, culture and sensitivities. Several blood cultures should be performed and empirical, broad-spectrum antibiotic therapy (p. 89) should be commenced within the first hour of recognition of sepsis. If an organism is isolated later, therapy can be adjusted appropriately. The choice of antibiotic depends on the likely source of infection, previous antibiotic therapy and known local resistance patterns, as well as on whether infection was acquired in hospital or in the community. Abscesses must be drained and infected indwelling catheters removed.

Whatever the aetiology of the haemodynamic abnormality, tissue blood flow must be restored by achieving and maintaining an adequate cardiac output, as well as ensuring that arterial blood pressure is sufficient to maintain perfusion of vital organs. Recently published guidelines for adult patients suffering severe sepsis or septic shock advocate targeting an MAP > 65 mmHg, CVP 8–12 mmHg (~12 mmHg if mechanically ventilated), urine output >0.5 mL/kg/h and an $\text{S}_2\text{O}_2 \geq 70\%$ (or $\text{S}_2\text{O}_2 \geq 65\%$) as the initial goals of resuscitation.

---

**Preload and volume replacement**

Optimizing preload is the most efficient way of increasing cardiac output. Volume replacement is obviously essential in hypovolaemic shock but is also required in anaphylactic and septic shock because of vasodilatation, sequestration of blood and loss of circulating volume because of capillary leak.

In obstructive shock, high filling pressures may be required to maintain an adequate stroke volume. Even in cardiogenic shock, careful volume expansion may, on occasions, lead to a useful increase in cardiac output. On the other hand, patients with severe cardiac failure, in whom ventricular filling pressures may be markedly elevated, often benefit from measures to reduce preload (and afterload) – such as the administration of diuretics and vasodilators (see below). Adequate perioperative volume replacement also reduces morbidity and mortality in high-risk surgical patients.

---

**Fig. 15.19** Doppler ultrasonography. Stylized velocity waveform traces obtained using oesophageal Doppler ultrasonography. Reproduced from Singer et al. (1991), with permission © 1991 The Williams and Wilkins Co., Baltimore.
The circulating volume must be replaced quickly (in minutes not hours) to reduce tissue damage and prevent acute kidney injury. Fluid is administered via wide-bore intravenous cannulae to allow large volumes to be given quickly, and the effect is continuously monitored.

Care must be taken to prevent volume overload, which leads to cardiac dilatation, a reduction in stroke volume, and a rise in left atrial pressure with a risk of pulmonary oedema. Pulmonary oedema is more likely in very ill patients because of a low colloid osmotic pressure (usually due to a low serum albumin) and disruption of the alveolar–capillary membrane (e.g. in acute lung injury).

**Choice of fluid for volume replacement**

**Blood**

This is conventionally given for haemorrhagic shock as soon as it is available. In extreme emergencies, group-specific crossmatch can be performed in minutes (see p. 425).

Although red cell transfusion will augment oxygen-carrying capacity, and hence global oxygen delivery, tissue oxygenation is also dependent on microcirculatory flow. This is influenced by the viscosity of the blood and hence the packed cell volume (PCV). Conventionally a PCV of 30–35% has been considered to provide the optimal balance between oxygen-carrying capacity and tissue flow, although it is well recognized that previously fit patients with haemorrhagic shock can tolerate extremely low Hb concentrations provided their circulating volume and cardiac output are maintained. Transfusion of old stored red cells, which are poorly deformable, may be associated with microvascular occlusion and worsening tissue hypoxia.

**Complications** of blood transfusion are discussed on page 425. Special problems arise when large volumes of stored blood are transfused rapidly. These include:

- **Temperature changes**. Bank blood is stored at 4°C and transfusion may result in hypothermia, peripheral
venoconstriction (which slows the rate of the infusion) and arrhythmias. If possible, blood should therefore be warmed during massive transfusion and in those at risk of hypothermia (e.g. during prolonged major surgery with open body cavity).

- **Coagulopathy.** Stored blood has virtually no effective platelets and is deficient in clotting factors. Large transfusions can therefore produce a coagulation defect. This may need to be treated by replacing clotting factors with fresh frozen plasma and administering platelet concentrates. Occasionally cryoprecipitate may be required.

- **Metabolic acidosis/alkalosis.** Stored blood is preserved in citrate/phosphate/dextrose (CPD) solution, and metabolic acidosis attributable solely to blood transfusion is rare and in any case seldom requires correction. A metabolic alkalosis often develops 24–48 hours after a large blood transfusion, probably mainly owing to metabolism of the citrate. This will be exacerbated if any preceding acidosis has been corrected with intravenous sodium bicarbonate.

- **Hypocalcaemia.** Citrate in stored blood binds calcium ions. During rapid transfusion, citrate may reduce total body ionized calcium levels, causing myocardial depression. This is uncommon in practice, but can be corrected by administering 10 mL of 10% calcium chloride intravenously. Routine treatment with calcium is not recommended.

- **Increased oxygen affinity.** In stored blood, the red cell 2,3-diphosphoglycerate (2,3-DPG) content is reduced, so that the oxyhaemoglobin dissociation curve is shifted to the left. The oxygen affinity of haemoglobin is therefore increased and oxygen unloading is impaired. This effect is less marked with CPD blood. Red cell levels of 2,3-DPG are substantially restored within 12 hours of transfusion.

- **Hyperkalaemia.** Plasma potassium levels rise progressively as blood is stored. However, hyperkalaemia is rarely a problem as rewarming of the blood increases red cell metabolism – the sodium pump becomes active and potassium levels fall.

- **Microembolism.** Microaggregates in stored blood may be filtered out by the pulmonary capillaries. This process is thought by some to contribute to acute lung injury (ALI) (see p. 917).

### Red cell concentrates

Standard red cell concentrates are being replaced by supplemental red cell concentrates, in which most of the plasma is removed and the red cells are suspended in 100 mL of nutrient additive solution. The most commonly used additive is SAG (saline, adenine, glucose) to which mannitol (M) is added to reduce spontaneous lysis (SAGM blood).

Concern about the supply, cost and safety of blood, including the risk of disease transmission and immune suppression, has encouraged a more conservative approach to transfusion. There is some evidence to suggest that in normovolaemic critically ill patients a restrictive strategy of red cell transfusion (Hb maintained at >7.0 g/dL) is at least as effective, and may be safer than a liberal transfusion strategy (Hb maintained at 10–12 g/dL). However, in some groups of patients (e.g. the elderly and those with significant cardiac or respiratory disease and patients who are actively bleeding) it may be preferable to maintain Hb closer to the higher level.

### Blood substitutes

Attempts to develop an effective and safe oxygen-carrying blood substitute have so far been unsuccessful.

### Crystalloids and colloids

The choice of intravenous fluid for resuscitation and the relative merits of crystalloids or colloids has long been controversial. Crystalloid solutions such as saline are cheap, convenient to use and free of side-effects, although they are rapidly lost from the circulation into the extravascular spaces. It has been generally accepted that volumes of crystalloid several times that of colloid are required to achieve an equivalent haemodynamic response and that colloidal solutions produce a greater and more sustained increase in circulating volume, with associated improvements in cardiovascular function and oxygen transport.

Nevertheless, a large, prospective, randomized, controlled trial has demonstrated that in a heterogeneous group of critically ill patients the use of either physiological saline or 4% albumin for fluid resuscitation resulted in similar outcomes.

**Polygelatin solutions** (Haemaccel, Gelofusin) have an average molecular weight of 35000, which is iso-osmotic with plasma. They are cheap and do not interfere with cross-matching. Large volumes can be administered, as clinically significant coagulation defects are unusual and renal function is not impaired. However, because they readily cross the glomerular basement membrane, their half-life in the circulation is only approximately 4 hours and they can promote an osmotic diuresis. These solutions are particularly useful during the acute phase of resuscitation, especially when volume losses are continuing. Allergic reactions can, however, occur.

**Hydroxyethyl starches** (HES). Numerous preparations are now available, characterized by their concentrations (3%, 6%, 10%) and low, medium or high molecular weight. The half-life of high and medium molecular weight solutions is between 12 and 24 hours, whilst that of the low molecular weight solutions is 4–6 hours. Elimination of HES occurs primarily via the kidneys following hydrolysis by amylase. HES are stored in the reticuloendothelial system, apparently without causing functional impairment, but skin deposits have been associated with persistent pruritus. HES, especially the higher molecular weight fractions, have anticoagulant properties and many therefore recommend limiting the volume administered. Recent evidence has implicated HES in the development of acute kidney injury.

**Dextran** are polymolecular polysaccharides that have a powerful osmotic effect. They interfere with crossmatching and have a small rate of allergic reactions (0.1–1%) which may be life-threatening. Normally a dose of 1.5 g dextran per kilogram of bodyweight (as Dextran 70) should not be exceeded because of the risk of renal damage. In practice, dextrans are rarely used in the UK because of the availability of other agents.

**Human albumin solution** (HAS) is a natural colloid which has been used for volume replacement in shock and burns, and for the treatment of hypoproteinaemia. HAS is not generally recommended for routine volume replacement, because supplies are limited and other cheaper solutions are equally effective.
Myocardial contractility and inotropic agents

Myocardial contractility can be impaired by many factors such as hypoxaemia and hypocalcaemia, as well as by some drugs (e.g. beta-blockers, antiarrhythmics, angiotensin-converting enzyme inhibitors and sedatives).

Severe lactic acidosis conventionally is said to depress myocardial contractility and limit the response to vasopressor agents. Attempted correction of acidosis with intravenous sodium bicarbonate, however, generates additional carbon dioxide which diffuses across cell membranes, producing or exacerbating intracellular acidosis. Other disadvantages of bicarbonate therapy include sodium overload and a left shift of the oxyhaemoglobin dissociation curve. Ionized calcium levels may be reduced and, combined with the fall in intracellular pH, this may impair myocardial performance. Treatment of lactic acidosis should therefore concentrate on correcting the cause. Bicarbonate should only be administered to correct extreme persistent metabolic acidosis (see p. 675).

If the signs of shock persist despite adequate volume replacement, and perfusion of vital organs is jeopardized, pressor agents should be administered to improve cardiac output and blood pressure. Vasopressor therapy may also be required to maintain perfusion in those with life-threatening hypotension, even when volume replacement is incomplete. All inotropes increase myocardial oxygen consumption, particularly if a tachycardia develops, and this can lead to an imbalance between myocardial oxygen supply and demand, with the development or extension of ischaemic areas. Inotropes should therefore be used with caution, particularly in cardiogenic shock following myocardial infarction and in those known to have ischaemic heart disease.

Many of the most seriously ill patients become increasingly resistant to the effects of pressor agents, an observation attributed to ‘downregulation’ of adrenergic receptors and NO-induced ‘vasoplegia’ (p. 895).

All inotropic agents should be administered via a large central vein, and their effects monitored (see also p. 908 and Table 15.5).

Adrenaline (epinephrine)
Epinephrine stimulates both α- and β-adrenergic receptors, but at low doses β effects seem to predominate. This increases heart rate and cardiac index whilst reducing peripheral resistance. If this is associated with an increase in perfusion pressure, urine output may improve. Epinephrine at higher doses can cause excessive (α-mediated) vasoconstriction, with reductions in splanchnic flow, and cardiac output may fall. Prolonged high-dose administration can cause peripheral gangrene and lactic acidosis. The minimum effective dose of adrenaline should therefore be used for as short a time as possible.

Noradrenaline (norepinephrine)
This is predominantly an α-adrenergic agonist. It is particularly useful in those with hypotension associated with a low systemic vascular resistance, for example in septic shock. There is a risk of producing excessive vasoconstriction with impaired organ perfusion and increased afterload. Noradrenaline administration should normally therefore be guided by comprehensive haemodynamic monitoring, including invasive or non-invasive determination of cardiac output (see p. 903) and calculation of systemic vascular resistance.

Dopamine
Dopamine is a natural precursor of adrenaline (epinephrine) which acts on β receptors and α receptors, as well as dopaminergic DA1 and DA2 receptors.

In low doses (e.g. 1–3 µg/kg/min), dopaminergic vasodilatory receptors in the renal, mesenteric, cerebral and coronary circulations are activated. DA1 receptors are located on post-synaptic membranes and mediate vasodilatation, whilst DA2 receptors are presynaptic and potentiate these vasodilatory effects by preventing the release of adrenaline (epinephrine).

Renal and hepatic flow increase and urine output is improved. The significance of the renal vasodilator effect of dopamine has, however, been questioned and it has been suggested that the increased urine output is largely attributable to the rise in cardiac output and blood pressure, combined with a decrease in aldosterone and inhibition of tubular sodium reabsorption mediated via DA1 stimulation.

In moderate doses (e.g. 3–10 µg/kg/min), dopamine increases heart rate, myocardial contractility and cardiac output. In some patients the dose of dopamine is limited by β-receptor effects such as tachycardia and arrhythmias.

In higher doses (e.g. >10 µg/kg/min) the increased noradrenaline (norepinephrine) produced is associated with vasoconstriction. This increases afterload and raises ventricular filling pressures.

Dopexamine
Dopexamine is an analogue of dopamine which activates β2 receptors as well as DA1 and DA2 receptors. Dopexamine is a weak positive inotrope, but is a powerful splanchnic vasodilator, reducing afterload and improving blood flow to vital organs, including the kidneys. In septic shock, dopexamine can increase cardiac index and heart rate, but causes further reductions in peripheral resistance. It is most useful in those with low cardiac output and peripheral vasoconstriction and has been used as an adjunct to the perioperative management of high-risk patients (see below).

Dobutamine
Dobutamine is closely related to dopamine and has predominantly β1 activity. Dobutamine has no specific effect on the renal vasculature but urine output often increases as cardiac output and blood pressure improve. It reduces systemic vascular resistance, as well as improving cardiac performance, thereby decreasing afterload and ventricular filling pressures. Dobutamine is therefore useful in patients with cardiogenic shock and cardiac failure. In septic shock, dobutamine can be used to increase cardiac output and oxygen delivery.

Phosphodiesterase inhibitors
(e.g. milrinone, enoximone)
These agents have both inotropic and vasodilator properties. Because the phosphodiesterase type III inhibitors bypass the β-adrenergic receptor they do not cause tachycardia and are less arrhythmogenic than β agonists. They may be useful in patients with receptor ‘downregulation’, those receiving beta-blockers, for weaning patients from cardiopulmonary bypass and for patients with cardiac failure. In vasodilated septic patients, however, they may precipitate or worsen hypotension.

\[ \text{Vasopressin} \]

Patients with septic shock have inappropriately low circulating levels of vasopressin. Low-dose vasopressin can increase blood pressure and systemic vascular resistance in patients with vasodilatory septic shock unresponsive to other vasopressors. A recent randomized controlled trial suggests that low-dose vasopressin added to conventional vasopressors may also have some value in less severe septic shock.

\[ \text{Guidelines for use of inotrope and vasopressor agents} \]

Some still consider dopamine in low to moderate doses to be the first-line agent for restoring blood pressure. Dobutamine is particularly indicated in patients in whom the vasocostriction caused by dopamine could be dangerous (i.e. patients with cardiac disease and septic patients with fluid overload or myocardial failure). Others favour dopexamine as a means of increasing cardiac output and organ blood flow. The combination of dobutamine and (norepinephrine) noradrenaline is popular for the management of patients who are shocked with a low systemic vascular resistance (e.g. septic shock). Dobutamine is given to achieve an optimal cardiac output, while noradrenaline (norepinephrine) is used to restore an adequate blood pressure by reducing vasodilatation. In vasodilated septic patients with a high cardiac output, noradrenaline (norepinephrine) is used alone. Adrenaline (epinephrine), because of its potency, also remains a useful agent in patients with refractory hypotension. Recent evidence, however, indicates that in septic shock, the specific inotrope/vasopressor selected has little influence on outcome.

\[ \text{Targeting ‘supranormal’ values for oxygen delivery (DO$_2$) and oxygen consumption (VO$_2$)} \]

Although resuscitation has conventionally aimed at achieving normal haemodynamics, survival of many critically ill patients is associated with raised values for cardiac output, DO$_2$ and VO$_2$. However, elevation of DO$_2$ and VO$_2$ to these ‘supranormal’ levels following admission to intensive care produces no benefit and may be harmful. By contrast, early goal-directed therapy in the emergency room, aimed at maintaining a central venous oxygen saturation of more than 70%, significantly improves outcome in patients with severe sepsis or septic shock.

\[ \text{High-risk surgical patients (Box 15.4)} \]

These patients benefit from intensive perioperative monitoring and circulatory support, in particular maintenance of an adequate circulating volume, and postoperative admission to ICU/HDU. Volume replacement and administration of inotropes or vasopressors should be guided by monitoring of stroke volume/cardiac output, usually using an oesophageal Doppler or lithium dilution. The value of the routine use of inotodilators such as dopexamine remains unclear.

\[ \text{Vasodilator therapy} \] (see p. 739)

In selected cases, afterload reduction is used to increase stroke volume and decrease myocardial oxygen requirements by reducing the systolic ventricular wall tension. Vasodilatation also decreases heart size and the diastolic ventricular wall tension so that coronary blood flow is improved. The relative magnitude of the falls in preload and
afterload depends on the pre-existing haemodynamic disturbance, concurrent volume replacement and the agent selected (see below). Specific vasodilators may also improve microcirculatory flow.

Vasodilator therapy can be particularly helpful in patients with cardiac failure in whom the ventricular function curve is flat (see Fig. 15.3) so that falls in preload have only a limited effect on stroke volume. This form of treatment, combined in selected cases with inotropic support, is therefore useful in cardiogenic shock and in the management of patients with cardiogenic pulmonary oedema, mitral regurgitation or an acute ventricular septal defect.

Nitrate vasodilators are usually used. Nitrates, because of their ability to improve the myocardial oxygen supply/demand ratio, also help to control angina and limit ischaemic myocardial injury. The agents used most commonly to achieve vasodilatation in the critically ill are those which act directly on the vessel wall.

Sodium nitroprusside (SNP) dilates arterioles and venous capacitance vessels, as well as the pulmonary vasculature by donating nitric oxide. SNP therefore reduces the afterload and preload of both ventricles and can improve cardiac output and the myocardial oxygen supply/demand ratio. SNP, however, can exacerbate myocardial ischaemia by producing a 'steal' phenomenon in the coronary circulation. The effects of SNP are rapid in onset and spontaneously reversible within a few minutes of discontinuing the infusion. A large overdose of SNP can cause cyanide poisoning, with intracranial hypoxia caused by inhibition of cytochrome oxidase, the terminal enzyme of the respiratory chain. This is manifested as a metabolic acidosis and a fall in the arteriovenous oxygen content difference.

Nitroglycerine (NTG) and isosorbide dinitrate (ISDN). At low doses, these agents are both predominantly venodilators, but as the dose is increased, they also cause arterial dilatation, thereby decreasing both preload and afterload. Nitrates are particularly useful in the treatment of cardiac failure with pulmonary oedema and are usually used in combination with intravenous furosemide. Both NTG and ISDN reduce pulmonary vascular resistance, an effect that can occasionally be exploited in patients with a low cardiac output secondary to pulmonary hypertension.

Hydralazine predominantly affects arterial resistance vessels. It therefore reduces afterload and blood pressure, while cardiac output and heart rate increase. Hydralazine is usually given as an intravenous bolus to control acute increases in blood pressure.

### Mechanical support of the myocardium

Intra-aortic balloon counterpulsation (IABCP) is the technique used most widely for mechanical support of the failing myocardium. It is discussed on page 714.

### Sepsis and multiple organ failure (MOF) (also known as multiple organ dysfunction syndrome – MODS)

Sepsis is being diagnosed with increasing frequency and is now the commonest cause of death in non-coronary adult intensive care units. The estimated incidence of severe sepsis has varied from 77 to 300 cases per 100,000 of the population. Mortality rates are high (between 20% and 60%) and are closely related to the severity of illness and the number of organs which fail. Those who die are overwhelmed by persistent or recurrent sepsis, with fever, intractable hypotension and failure of several organs.

Sequential failure of vital organs occurs progressively over weeks, although the pattern of organ dysfunction is variable. In most cases the lungs are the first to be affected (acute lung injury – ALI; acute respiratory distress syndrome – ARDS; see p. 917) in association with cardiovascular instability and deteriorating renal function. Damage to the mucosal lining of the gastrointestinal tract, as a result of reduced splanchnic flow followed by reperfusion, allows bacteria within the gut lumen, or their cell wall components, to gain access to the circulation. The liver defences, which are often compromised by poor perfusion, are overwhelmed and the lungs and other organs are exposed to bacterial toxins and inflammatory mediators released by liver macrophages. Some have therefore called the gut the ‘motor of multiple organ failure’. Secondary pulmonary infection, complicating ALI/ARDS, also frequently acts as a further stimulus to the inflammatory response. Later, renal failure and liver dysfunction develop (see p. 910). Gastrointestinal failure, with an inability to tolerate enteral feeding and paralytic ileus, is common. Ischaemic colitis, acalculous cholecystitis, pancreatitis and gastrointestinal haemorrhage may also occur. Features of central nervous system dysfunction include impaired consciousness and disorientation, progressing to coma. Characteristically, these patients initially have a hyperdynamic circulation with vasodilatation and a high cardiac output, associated with an increased metabolic rate. Eventually, however, cardiovascular collapse supervenes and is the usual terminal event.

### Adjunctive treatment

Initial attempts to combat the high mortality associated with sepsis concentrated on cardiovascular and respiratory support in the hope that survival could be prolonged until surgery, antibiotics and the patient’s own defences had eradicated the infection and injured tissues were repaired. Despite some success, mortality rates remained unacceptably high. So far, attempts to improve outcome by modulating the inflammatory response (including high-dose steroids) or neutralizing endotoxin (Table 15.6) or inhibiting nitric oxide synthesis (e.g. with N-monomethyl-L-arginine) have proved disappointing and in some cases may even have been harmful.

Administration of recombinant human activated protein C (rhAPC), an endogenous anticoagulant with anti-inflammatory properties, may improve outcome in some adult patients with severe sepsis and multiple organ dysfunction. Also, it
seems that the administration of relatively low, ‘stress’ doses of hydrocortisone to patients with refractory vasopressor dependent septic shock may assist shock reversal. Careful control of the blood sugar level to below 8.3 mmol/L (‘tight glycaemic control’) is also recommended.

The aim of current sepsis guidelines is to combine these, and other evidence-based interventions, with early effective resuscitation (aimed especially at achieving an adequate circulating volume, combined with the rational use of inotropes and/or vasoactive agents to maintain blood pressure, cardiac output and oxygen transport) in order to create ‘bundles of care’ delivered within specific time limits (see http://www.survivingsepsis.org).

**RESPIRATORY FAILURE (SEE CH. 14)**

Types and causes

The respiratory system consists of a gas-exchanging organ (the lungs) and a ventilatory pump (respiratory muscles/thorax), either or both of which can fail and precipitate respiratory failure. Respiratory failure occurs when pulmonary gas exchange is sufficiently impaired to cause hypoxaemia with or without hypercarbia. In practical terms, respiratory failure is present when the $P_{O_2}$ is <8 kPa (60 mmHg) or the $P_{CO_2}$ is >7 kPa (55 mmHg). It can be divided into:

- **Type I** respiratory failure, in which the $P_{O_2}$ is low and the $P_{CO_2}$ is normal or low
- **Type II** respiratory failure, in which the $P_{O_2}$ is low and the $P_{CO_2}$ is high.

**FURTHER READING**

disease (COPD). Other causes include chest-wall deformities, respiratory muscle weakness (e.g. Guillain–Barré syndrome) and depression of the respiratory centre (e.g. overdose).

Deterioration in the mechanical properties of the lungs and/or chest wall increases the work of breathing and the oxygen consumption/carbon dioxide production of the respiratory muscles. The concept that respiratory muscle fatigue (either acute or chronic) is a major factor in the pathogenesis of respiratory failure is controversial.

### MONITORING OF RESPIRATORY FAILURE

A clinical assessment of respiratory distress should be made on the following criteria (those marked with an asterisk* may be indicative of respiratory muscle fatigue):

- the use of accessory muscles of respiration
- intercostal recession
- tachypnoea*
- tachycardia
- sweating
- pulsus paradoxus (rarely present)
- inability to speak, unwillingness to lie flat
- agitation, restlessness, diminished conscious level
- asynchronous respiration (a discrepancy in the timing of movement of the abdominal and thoracic compartments)*
- paradoxical respiration (abdominal and thoracic compartments move in opposite directions)*
- respiratory alternans (breath-to-breath alteration in the relative contribution of intercostal/accessory muscles and the diaphragm).*

Blood gas analysis should be performed to guide oxygen therapy and to provide an objective assessment of the severity of the respiratory failure. The most sensitive clinical indicator of increasing respiratory difficulty is a rising respiratory rate. Measurement of tidal volume is a less sensitive indicator.

Vital capacity is often a better guide to deterioration and is particularly useful in patients with respiratory inadequacy that is due to neuromuscular problems such as the Guillain–Barré syndrome or myasthenia gravis, in which the vital capacity decreases as weakness increases.

### Pulse oximetry

Lightweight oximeters can be applied to an ear lobe or finger. They measure the changing amount of light transmitted through the pulsating arterial blood and provide a continuous, non-invasive assessment of arterial oxygen saturation ($S_O_2$). These devices are reliable, easy to use and do not require calibration, although remember that pulse oximetry is not a sensitive guide to changes in oxygenation. An $S_pO_2$ within normal limits in a patient receiving supplemental oxygen does not exclude the possibility of hypoventilation. Readings may be inaccurate in those with poor peripheral perfusion.

### Blood gas analysis

Normal values of blood gas analysis are shown in Table 15.2, p. 893.

Errors can result from malfunctioning of the analyser or incorrect sampling of arterial blood. Disposable pre-heparinized syringes are available for blood gas analysis.

- The sample should be analysed immediately. Alternatively, the syringe should be immersed in iced water (the end having first been sealed with a cap) to prevent the continuing metabolism of white cells causing a reduction in $P_O_2$ and a rise in $P_CO_2$.
- The sample must be adequately anticoagulated to prevent clot formation within the analyser. However, excessive dilution of the blood with heparin, which is acidic, will significantly reduce its pH. Heparin (1000 i.u./ml) should just fill the deadspace of the syringe, i.e. approximately 0.1 mL. This will adequately anticoagulate a 2 mL sample.
- Air almost inevitably enters the sample. The gas tensions within these air bubbles will equilibrate with those in the blood, thereby lowering the $P_CO_2$ and usually raising the $P_O_2$ of the sample. However, provided the bubbles are ejected immediately by inverting the syringe and expelling the air that rises to the top of the sample, their effect is insignificant.

Interpretation of the results of blood gas analysis can be considered in two separate parts:

- Disturbances of acid-base balance (see pp. 672 and 893).
- Alterations in oxygenation.

Correct interpretation requires a knowledge of the clinical history, the age of the patient, the inspired oxygen concentration and any other relevant treatment (e.g. the ventilator settings for those on mechanical ventilation and the administration of sodium bicarbonate). The oxygen content of the arterial blood is determined by the percentage saturation of haemoglobin with oxygen. The relationship between the latter and the $P_O_2$ is determined by the oxyhaemoglobin dissociation curve (Fig. 15.5).

### Capnography

Continuous breath-by-breath analysis of expired carbon dioxide concentration can be used to:

- confirm tracheal intubation
- continuously monitor end-tidal $P_CO_2$, which approximates to $P_CO_2$ in normal subjects (may be useful when transporting critically ill patients, for example)
- detect apparatus malfunction
- detect acute alterations in cardiorespiratory function.

### MANAGEMENT OF RESPIRATORY FAILURE

Standard management of patients with respiratory failure includes:

- administration of supplemental oxygen
- treatment for airways obstruction
- measures to limit pulmonary oedema
- control of secretions
- treatment of pulmonary infection.

The load on the respiratory muscles should be reduced by improving lung mechanics. Correction of abnormalities which may lead to respiratory muscle weakness, such as hypophosphataemia and malnutrition, is also necessary.
Oxygen therapy

Methods of oxygen administration

Oxygen is initially given via a face mask. In the majority of patients (except patients with COPD and chronically elevated P_{\text{a}}CO_2) the concentration of oxygen given is not vital and oxygen can therefore be given by a ‘variable performance’ device such as a simple face mask or nasal cannulae (Fig. 15.21).

With these devices the inspired oxygen concentration varies from about 35% to 55%, with oxygen flow rates of between 6 and 10 L/min. Nasal cannulae are often preferred because they are less claustrophobic and do not interfere with feeding or speaking, but they can cause ulceration of the nasal or pharyngeal mucosa. Higher concentrations of oxygen can be administered by using a mask with a reservoir bag attached (Fig. 15.21c). Figure 15.21 should be compared with the fixed-performance mask shown in Figure 14.27, p. 841, with which the oxygen concentration can be controlled. This latter type of mask is used in patients with COPD and chronic type II failure; the dangers of reducing hypoxic drive can be overemphasized – remember, hypoxaemia is more dangerous than hypercapnia.

Oxygen toxicity

Experimentally, mammalian lungs have been shown to be damaged by continuous exposure to high concentrations of oxygen, but oxygen toxicity in humans is less well proven. Nevertheless, it is reasonable to assume that high concentrations of oxygen might damage the lungs, and so the lowest inspired oxygen concentration compatible with adequate arterial oxygenation should be used. Dangerous hypoxia should never be tolerated through a fear of pulmonary oxygen toxicity.

Respiratory support

If, despite the above measures, the patient continues to deteriorate or fails to improve, the institution of some form of respiratory support is necessary (see Table 15.9). Non-invasive ventilation (see p. 916) can be used, particularly in respiratory failure due to COPD, but in the intensive care unit, intermittent positive-pressure ventilation (IPPV) is usually used.

IPPV is achieved by intermittently inflating the lungs with a positive pressure delivered by a ventilator via an endotracheal tube or a tracheostomy. More recently there have been a number of refinements and modifications to the manner in which positive pressure is applied to the airway and in the interplay between the patient’s respiratory efforts and mechanical assistance (p. 914).

Controlled mechanical ventilation (CMV), with the abolition of spontaneous breathing, rapidly leads to atrophy of respiratory muscles so that assisted modes that are triggered by the patient’s inspiratory efforts (see below) are preferred.

The rational use of mechanical ventilation depends on a clear understanding of its potential beneficial effects, as well as its dangers.

Beneficial effects of mechanical ventilation

- Improved carbon dioxide elimination. By increasing the volume of ventilation, the P_{\text{a}}CO_2 can be controlled.
- Relief from exhaustion. Mechanical ventilation reduces the work of breathing, ‘rests’ the respiratory muscles and relieves the extreme exhaustion that may be present in patients with respiratory failure. In some cases, if ventilation is not instituted, this exhaustion may culminate in respiratory arrest.
- Effects on oxygenation. Application of positive pressure can prevent or reverse atelectasis. In those with severe pulmonary parenchymal disease, the lungs may be very stiff and the work of breathing is therefore greatly increased. Under these circumstances the institution of respiratory support may significantly reduce total body oxygen consumption; consequently P_{\text{a}}O_2 and thus P_{\text{a}}O_2 may improve. Because ventilated patients are connected to a leak-free circuit, it is possible to administer high concentrations of oxygen (up to 100%) accurately and to apply a positive end-expiratory pressure (PEEP). In selected cases the latter may reduce shunting and increase P_{\text{a}}O_2 (see below).

Indications for mechanical ventilation

- Acute respiratory failure, with signs of severe respiratory distress (e.g. respiratory rate >40/min, inability to speak, patient exhausted) persisting despite maximal therapy. Confusion, restlessness, agitation, a decreased conscious level, a rising P_{\text{a}}CO_2 (>8 kPa) and extreme hypoxaemia (<8 kPa), despite oxygen therapy, are further indications.
- Acute ventilatory failure due, for example, to myasthenia gravis or Guillain–Barré syndrome. Mechanical ventilation should usually be instituted when the vital

*Fig. 15.21 Methods of administering supplemental oxygen to the unintubated patient. (a) Simple face mask. (b) Nasal cannulae. (c) Mask with reservoir bag.*
capacity has fallen to 10 mL/kg or less. This will avoid complications such as atelectasis and infection as well as preventing respiratory arrest. The tidal volume and respiratory rate are relatively insensitive indicators of respiratory failure in the above conditions and change late in the course of the disease. A high $P_{CO_2}$ (particularly if rising) is an indication for urgent mechanical ventilation.

By no means all patients with respiratory failure and/or a reduced vital capacity require ventilation; however, clinical assessment of each individual case is essential. The patient’s general condition, degree of exhaustion and level of consciousness are as useful as blood gas values.

Other indications include:

- prophylactic postoperative ventilation in high-risk patients
- head injury – to avoid hypoxia and hypercarbia which increase cerebral blood flow and intracranial pressure
- trauma – chest injury and lung contusion
- severe left ventricular failure with pulmonary oedema
- coma with breathing difficulties, e.g. following drug overdose.

**Institution of invasive respiratory support**

This requires tracheal intubation. If the patient is conscious, the procedure must be fully explained before anaesthesia is induced and consent obtained. The complications of tracheal intubation are given in Table 15.7.

Intubating patients in severe respiratory failure is an extremely hazardous undertaking and should only be performed by experienced staff. In extreme emergencies it may be preferable to ventilate the patient by hand using an oro- or nasopharyngeal airway, a face mask and a self-inflating bag with added oxygen until experienced help arrives. An alternative is insertion of a laryngeal mask airway.

The patient is usually hypoxic and hypercarbic, with increased sympathetic activity; the stimulus of laryngoscopy and intubation can precipitate dangerous arrhythmias and even cardiac arrest. Except in an extreme emergency, therefore, the ECG and oxygen saturation should be monitored, and the patient preoxygenated with 100% oxygen before intubation. Resuscitation drugs should be immediately available. If time allows, the circulating volume should be optimized and, if necessary, inotropes commenced before attempting intubation. In some cases it may be appropriate to establish intra-arterial and central venous pressure monitoring before instituting mechanical ventilation, although many patients will not tolerate the supine or head-down position. In some deeply comatose patients, no sedation may be required, but in the majority of patients a short-acting intravenous anaesthetic agent followed by muscle relaxation will be necessary. When available, capnography can confirm tracheal intubation.

**Tracheostomy**

Tracheostomy may be required for the long-term control of excessive bronchial secretions, particularly in those with a reduced conscious level, and/or to maintain an airway and protect the lungs in those with impaired pharyngeal and laryngeal reflexes. Tracheostomy is also performed when intubation is likely to be prolonged, for patient comfort and to facilitate weaning from mechanical ventilation.

Tracheostomy can be performed at the bedside in an ICU or in theatre. A percutaneous dilatational technique, which is quick and economical, is a suitable technique in critically ill patients (and can be used in an emergency). Alternatively, the trachea can be opened through the second, third and fourth tracheal rings via a transverse skin incision in theatre.

A life-threatening obstruction of the upper respiratory tract that cannot be bypassed with an endotracheal tube can

</table>
be relieved by a cricothyroidotomy, which is safer, quicker and easier to perform than a formal tracheostomy.

Tracheostomy has a small but significant mortality rate. Complications of tracheostomy are shown in Table 15.8. With any tracheostomy, care should be taken to ensure that the tube is not blocked by secretions.

**Complications associated with mechanical ventilation**

**Airway complications.** There may be complications with tracheal intubation with additional local complications of a tracheostomy (see above) (Tables 15.7 and 15.8).

**Disconnection, failure of gas or power supply, mechanical faults.** These are unusual but dangerous. A method of manual ventilation, such as a self-inflating bag, and oxygen must always be available by the bedside.

**Cardiovascular complications.** The application of positive pressure to the lungs and thoracic wall impedes venous return and distends alveoli, thereby ‘stretching’ the pulmonary capillaries and causing a rise in pulmonary vascular resistance. Both these mechanisms can produce a fall in cardiac output.

**Respiratory complications.** Mechanical ventilation can be complicated by a deterioration in gas exchange because of $V/Q$ mismatch and collapse of peripheral alveoli. Traditionally the latter was prevented by using high tidal volumes (10–12 mL/kg) but high inflation pressures, with overdistension of compliant alveoli, perhaps exacerbated by the repeated opening and closure of distal airways, can disrupt the alveolar-capillary membrane. There is an increase in microvascular permeability and release of inflammatory mediators leading to ‘ventilator-associated lung injury’. Extreme overdistension of the lungs during mechanical ventilation with high tidal volumes and PEEP can rupture alveoli and cause air to dissect centrally along the perivascular sheaths. This ‘barotrauma’ may be complicated by pneumomediastinum, subcutaneous emphysema, pneumoperitoneum, pneumothorax, and intra-abdominal air. The risk of pneumothorax is increased in those with destructive lung disease (e.g. necrotising pneumonia, emphysema), asthma or fractured ribs.

A tension pneumothorax can be rapidly fatal in ventilated patients. Suggestive signs include the development or worsening of hypoxia, hypercarbia, respiratory distress, an unexplained increase in airway pressure, as well as hypotension and tachycardia, sometimes accompanied by a rising CVP. Examination may reveal unequal chest expansion, mediastinal shift away from the side of the pneumothorax (deviated trachea, displaced apex beat) and a hyperresonant hemithorax. Although, traditionally, breath sounds are diminished over the pneumothorax, this sign can be extremely misleading in ventilated patients. If there is time, the diagnosis can be confirmed by chest X-ray prior to definitive treatment with chest tube drainage.

**Ventilator-associated pneumonia.** Nosocomial pneumonia occurs in as many as one-third of patients receiving mechanical ventilation and may be associated with a significant increase in mortality. It can be difficult to diagnose. Multiple organisms have been isolated such as aerobic Gram-negative bacilli, e.g. *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *E. coli*, *Acinetobacter* spp. and *Staphylococcus aureus*, including MRSA. Leakage of infected oropharyngeal secretions past the tracheal cuff is thought to be largely responsible. Bacterial colonization of the oropharynx may be promoted by regurgitation of colonized gastric fluid and the risk of nosocomial pneumonia can be reduced by nursing patients in the semi-recumbent, rather than the supine, position and by oropharyngeal decontamination. Treatment is complicated by multiple drug resistance to many antibiotics and mortality is high.

**Gastrointestinal complications.** Initially, many ventilated patients will develop abdominal distension associated with an ileus. The cause is unknown, although the use of opiates may in part be responsible.

**Salt and water retention.** Mechanical ventilation, particularly with PEEP, causes increased ADH secretion and possibly a reduction in circulating levels of atrial natriuretic peptide. Combined with a fall in cardiac output and a reduction in renal blood flow, these can cause salt and water retention.

**Techniques for respiratory support** (Table 15.9)

**Controlled mechanical ventilation (CMV)**

This technique is used in patients in whom respiratory efforts are absent, with preset values on the ventilator for tidal volume and respiratory rate.
Ventilation may be volume limited or pressure limited:

- **Volume controlled ventilation.** The tidal volume, respiratory rate and the positive end-expiratory pressure (PEEP) are preset on the ventilator. The airway pressure varies according to both the ventilatory settings and the patient’s lung mechanics (airways resistance and compliance).
- **Pressure controlled ventilation.** Both the inspiratory pressure and the respiratory rate are preset but the tidal volume varies according to the patient’s lung compliance and airways resistance.

**Positive end-expiratory pressure (PEEP)**
A positive airway pressure can be maintained at a chosen level throughout expiration by attaching a threshold resistor valve to the expiratory limb of the circuit. PEEP re-expands underventilated lung units, and redistributes lung water from the alveoli to the perivascular interstitial space, thereby reducing shunt and increasing the $P_{aO_2}$. Unfortunately, however, the inevitable rise in mean intrathoracic pressure that follows the application of PEEP may further impede venous return, increase pulmonary vascular resistance and thus reduce cardiac output. This effect is probably least when the lungs are stiff. The fall in cardiac output can be ameliorated by expanding the circulating volume, although in some cases isotropic support or a vasopressor may be required. Thus, although arterial oxygenation is often improved by the application of PEEP, a simultaneous fall in cardiac output can lead to a reduction in total oxygen delivery.

PEEP should be considered if it proves difficult to achieve adequate oxygenation of arterial blood (more than 90% saturation) despite raising the inspired oxygen concentration above 50%. Many use low levels of PEEP (5–7 cmH$_2$O) in the majority of mechanically ventilated patients in order to maintain lung volume.

**Continuous positive airway pressure (CPAP)**
The application of CPAP achieves for the spontaneously breathing patient what PEEP does for the ventilated patient. Oxygen and air are delivered under pressure via an endotracheal tube, a tracheostomy, a tightly fitting face mask or a hood. Not only can this improve oxygenation, but the lungs become less stiff, and the work of breathing is reduced.

**Pressure support ventilation (PSV)**
Spontaneous breaths are augmented by a pre-set level of positive pressure (usually between 5 and 20 cmH$_2$O) triggered by the patient’s spontaneous respiratory effort and applied for a given fraction of inspiratory time or until inspiratory flow falls below a certain level. Tidal volume is determined by the set pressure, the patient’s effort and pulmonary mechanics. The level of pressure support can be reduced progressively as the patient improves.

**Intermittent mandatory ventilation (IMV)**
This technique allows the patient to breathe spontaneously between the ‘mandatory’ tidal volumes delivered by the ventilator. These mandatory breaths are timed to coincide with the patient’s own inspiratory effort (synchronized IMV, or SIMV). SIMV can be used with or without CPAP, and spontaneous breaths may be assisted with pressure support.

**‘Lung-protective’ ventilatory strategies**
These are designed to avoid exacerbating or perpetuating lung injury by avoiding overdistension of alveoli, minimizing airway pressures and preventing the repeated opening and closure of distal airways. Alveolar volume is maintained with PEEP, and sometimes by prolonging the inspiratory phase, while tidal volumes are limited to 6 mL/kg predicted body weight. Peak airway pressures should not exceed 35–40 cmH$_2$O. An alternative is to deliver a constant pre-set

inspiratory pressure for a prescribed time in order to generate a low tidal volume at reduced airway pressures (‘pressure-limited’ mechanical ventilation). Respiratory rate can be increased to improve CO₂ removal and avoid severe acidosis (pH < 7.2), but hypercapnia is frequent and should be accepted (‘permissive hypercapnia’). Both techniques can be used with SIMV. Ventilation with low tidal volumes has been shown to improve outcome in patients with acute lung injury (ALI) or the acute respiratory distress syndrome (ARDS) (see p. 917).

**Extracorporeal gas exchange (ECGE)**

In patients with severe refractory respiratory failure venovenous bypass through a membrane lung (extracorporeal membrane oxygenation – ECMO, or extracorporeal carbon dioxide removal – ECCO₂-R) has been used to reduce ventilation requirements, thereby minimizing ventilation-induced lung damage and encouraging resolution of the lung injury. Although randomized controlled trials have indicated that this technique does not improve outcome in adults, some authorities remain convinced that, when used by experienced teams in specialist centres, extracorporeal gas exchange can significantly reduce the high mortality associated with severe ARDS.

**Non-invasive ventilation (NIV)**

NIV can be used as a therapeutic trial with a view to tracheal intubation if it fails. It is also used as the ceiling of treatment in patients who are not candidates for intubation. NIV is suitable for patients who are conscious, cooperative and able to protect their airway; they must also be able to expectorate effectively. Positive pressure is applied to the airways using tight-fitting full-face or nasal masks or a hood so that tracheal intubation is avoided. Techniques include CPAP, and/or bilevel positive airway pressure (BiPAP). With the latter technique, inspiratory and expiratory pressure levels and times are set independently and unrestricted spontaneous respiration is possible throughout the respiratory cycle. BiPAP can also be patient triggered. There is a reduced risk of ventilator-associated pneumonia and improved patient comfort, with preservation of airway defence mechanisms, speech and swallowing which allows better nutrition. Spontaneous coughing and expectoration are not hampered, allowing effective physiotherapy, and sedation is unnecessary. Institution of non-invasive respiratory support can rest the respiratory muscles, reduce respiratory acidosis and breathlessness, improve clearance of secretions and re-expand collapsed lung segments. The intubation rate, length of ICU and hospital stay and, in some categories of patient, mortality, may all be reduced. NIV is particularly useful in acute hypercapnic respiratory failure associated with COPD, provided the patient is not profoundly hypoxic. NIV may also be useful as a means of avoiding tracheal intubation in immunocompromised patients with acute respiratory failure. Box 15.5 shows some indications for the use of NIV when standard medical treatment has failed. Remember, NIV should not be used as a substitute for invasive ventilation when the latter is clearly more appropriate.

**Weaning**

Weakness and wasting of respiratory muscles is an inevitable consequence of the catabolic response to critical illness and may be exacerbated by the reduction in respiratory work during mechanical ventilation. Often abnormalities of gas exchange and lung mechanics persist. Not surprisingly, therefore, many patients experience difficulty in resuming spontaneous ventilation. In a significant proportion of patients who have undergone a prolonged period of respiratory support the situation is further complicated by the development of a neuropathy, a myopathy or both.

**Critical illness polyneuropathy and myopathy**

Polyneuropathies have most often been described in association with persistent sepsis and multiple organ failure (see below). Polyneuropathy is characterized by a primary axonal neuropathy involving both motor and, to a lesser extent, sensory nerves. Clinically the initial manifestation is often difficulty in weaning the patient from respiratory support. There is muscle wasting, the limbs are weak and flaccid, and deep tendon reflexes are reduced or absent. Cranial nerves are relatively spared. Nerve conduction studies confirm axonal damage. The cerebrospinal fluid (CSF) protein concentration is normal or minimally elevated. These findings differentiate critical illness neuropathy from Guillain–Barré syndrome, in which nerve conduction studies show evidence of demyelination and CSF protein is usually high.

The cause of critical illness polyneuropathy is not known and there is no specific treatment. Weaning from respiratory support and rehabilitation are likely to be prolonged. With resolution of the underlying critical illness, recovery can be expected after 1–6 months but muscle weakness and fatigue frequently persist.

Myopathies can also occur. A severe quadriplegic myopathy has been particularly associated with the administration of steroids and muscle relaxants to mechanically ventilated patients with acute, severe asthma.

Often the most severely ill patients will have a combined neuropathy and myopathy.

**Criteria for weaning patients from mechanical ventilation**

Clinical assessment is the best way of deciding whether a patient can be weaned from the ventilator. The patient’s

---

**Box 15.5 Some indications for the use of non-invasive ventilation (NIV)**

- Acute exacerbation of COPD (pH < 7.35)
- Cardiogenic pulmonary oedema
- Chest wall deformity/neuromuscular disease (hypercapnic respiratory failure)
- Obstructive sleep apnoea
- Severe pneumonia (see Box 14.5)
- Asthma (occasionally)
- Weaning patients from invasive ventilation (p. 917)

**Contraindications** include facial or upper airway surgery, upper gastrointestinal surgery, inability to protect the airway.

conscious level, psychological state, metabolic function, the effects of drugs and cardiovascular performance must all be taken into account. A subjective evaluation by an experienced clinician of the patient’s response to a short period of spontaneous breathing (spontaneous breathing trial) is the most reliable predictor of weaning success or failure. Objective criteria are based on an assessment of pulmonary gas exchange (blood gas analysis), lung mechanics and muscular strength.

**Techniques for weaning**

Patients who have received mechanical ventilation for less than 24 hours – for example, after elective major surgery – can usually resume spontaneous respiration immediately and no weaning process is required. This procedure can also be adopted for those who have been ventilated for longer periods but who tolerate a spontaneous breathing trial and clearly fulfill objective criteria for weaning. Techniques of weaning include:

- SIMV as a gradual, controlled method of weaning from mechanical ventilation.
- Gradual reduction of the level of pressure support, with no mandatory breaths, is currently considered by many to be the preferred technique.
- CPAP can prevent the alveolar collapse, hypoxaemia and fall in compliance that might otherwise occur when patients start to breathe spontaneously. It is therefore often used during weaning with SIMV/pressure support and in spontaneously breathing patients prior to extubation.
- Non-invasive ventilation via tightly fitting facial or nasal masks (BiPAP, CPAP).
- Tracheostomy is used frequently in critically ill patients to facilitate weaning from mechanical ventilation.
- The traditional method is to allow the patient to breathe entirely spontaneously for a short time, following which respiratory support is reinstalled. The periods of spontaneous breathing are gradually increased and the periods of respiratory support are reduced. Initially it is usually advisable to ventilate the patient throughout the night. This method can be stressful and tiring for both patients and staff, although this approach is sometimes successful when other methods have failed.

**Extubation and tracheostomy decannulation**

This should not be performed until patients can cough, swallow, protect their own airway and are sufficiently alert to be cooperative. Patients who fulfil these criteria can be extubated provided their respiratory function has improved sufficiently to sustain spontaneous ventilation indefinitely. Similar considerations guide the elective removal of tracheostomy tubes.

**Acute lung injury/acute respiratory distress syndrome**

**Definition and causes** (see Table 15.10)

Acute lung injury (ALI) and the more severe acute respiratory distress syndrome (ARDS) are diagnosed in an appropriate clinical setting with one or more recognized risk factors. ALI/ARDS can be defined as follows:

- **Respiratory distress.**
- **Stiff lungs** (reduced pulmonary compliance resulting in high inflation pressures).
- **Chest radiograph:** new bilateral, diffuse, patchy or homogeneous pulmonary infiltrates.
- **Cardiac:** no apparent cardiogenic cause of pulmonary oedema (pulmonary artery occlusion pressure <18 mmHg if measured or no clinical evidence of left atrial hypertension).
- **Gas exchange abnormalities:** at – arterial oxygen tension/ fractional inspired oxygen (P_a/O_2) ratio <40 kPa (<300 mmHg); ARDS – P_a/O_2 <26.6 kPa (<200 mmHg) (in both cases despite normal arterial carbon dioxide tension and regardless of positive end-expiratory pressure). The criterion for arterial oxygen tension/fractional inspired oxygen is arbitrary and the value of differentiating ALI from ARDS has been questioned.

ALI/ARDS can occur as a non-specific reaction of the lungs to a wide variety of direct pulmonary and indirect non-pulmonary insults. By far the commonest predisposing factor is sepsis, and 20–40% of patients with severe sepsis will develop ALI/ARDS (Table 15.10).

**Pathogenesis and pathophysiology of ALI/ARDS**

Acute lung injury can be considered as an early manifestation of a generalized inflammatory response with endothelial dysfunction and is therefore frequently associated with the development of multiple organ dysfunction syndrome (MODS).

**Non-cardiogenic pulmonary oedema**

This is the cardinal feature of ALI and is the first and clinically most evident sign of a generalized increase in vascular permeability caused by the microcirculatory changes and release of inflammatory mediators described previously (see p. 895).

**FURTHER READING**

with activated neutrophils playing a particularly key role. The pulmonary epithelium is also damaged in the early stages, reducing surfactant production and lowering the threshold for alveolar flooding.

**Pulmonary hypertension**
This is a common feature. Initially, mechanical obstruction of the pulmonary circulation may occur as a result of vascular compression by interstitial oedema, whilst local activation of the coagulation cascade leads to thrombosis and obstruction in the pulmonary microvasculature. Later, pulmonary vasoconstriction may develop in response to increased autonomic nervous activity and circulating substances such as catecholamines, serotonin, thromboxane and complement. Those vessels supplying alveoli with low oxygen tensions constrict (the 'hypoxic vasoconstrictor response'), diverting pulmonary blood flow to better oxygenated areas of lung, thus limiting the degree of shunt.

**Haemorrhagic intra-alveolar exudate**
This exudate is rich in platelets, fibrin, fibrinogen and clotting factors and may inactivate surfactant and stimulate inflammation, as well as promoting hyaline membrane formation and the migration of fibroblasts into the air spaces.

**Resolution, fibrosis and repair**
Within days of the onset of lung injury, formation of a new epithelial lining is underway and activated fibroblasts accumulate in the interstitial spaces. Subsequently, interstitial fibrosis progresses, with loss of elastic tissue and obliteration of the lung vasculature, together with lung destruction and emphysema. In those who recover, the lungs are substantially remodelled.

**Physiological changes**
Shunt and deadspace increase, compliance falls, and there is evidence of airflow limitation. Although the lungs in ALI and ARDS are diffusely injured, the pulmonary lesions, when identified as densities on a CT scan, are predominantly located in dependent regions (Fig. 15.22 a and b). This is partly explained by the effects of gravity on the distribution of extravascular lung water and areas of lung collapse. Pleural effusions are common.

### CLINICAL PRESENTATION OF ALI/ARDS

The first sign of the development of ALI/ARDS is often an unexplained tachypnoea, followed by increasing hypoxaemia, with central cyanosis, and breathlessness. Fine crackles are heard throughout both lung fields. Later, the chest X-ray shows bilateral diffuse shadowing, interstitial at first, but subsequently with an alveolar pattern and air bronchograms that may then progress to the picture of complete ‘white-out’ (Fig. 15.23). The differential diagnosis includes cardiac failure and lung fibrosis.

### MANAGEMENT OF ALI/ARDS

This is based on treatment of the underlying condition (e.g. eradication of sepsis), avoidance of complications such as ventilator-associated pneumonia, and supportive measures.

**Mechanical ventilation**
Strategies designed to minimize ventilator-induced lung injury and encourage lung healing should be used (see p. 915).

**Pulmonary oedema limitation.** Pulmonary oedema formation should be limited by minimizing left ventricular filling pressure with fluid restriction, the use of diuretics and, if these measures fail, preventing fluid overload by haemofiltration. The aim should be to achieve a consistently negative fluid balance. Some recommend that plasma oncotic pressure should be maintained by using colloidal solutions to expand

---

Aerosolized prosta cyclin. This appears to have similar effects to inhaled NO and is easier to monitor and deliver. As with inhaled NO, the response to aerosolized prosta cyclin is, however, variable and although it has been shown to improve oxygenation its effect on outcomes has yet to be established.

Aerosolized surfactant. Surfactant replacement therapy reduces morbidity and mortality in neonatal respiratory distress syndrome and is beneficial in animal models of ALI/ARDS. In adults with ARDS, however, the value of surfactant administration remains uncertain.

Steroids. Administration of steroids to patients with established ALI/ARDS does not appear to improve outcome.

Prognosis
Mortality from ALI/ARDS has fallen over the last decade, from around 60% to between 30% and 40%, perhaps as a consequence of improved general care, the increasing use of management protocols, and attention to infection control and nutrition, as well as the introduction of novel treatments and lung-protective strategies for respiratory support. Prognosis is, however, still very dependent on aetiology. When ARDS occurs in association with intra-abdominal sepsis, mortality rates remain very high, whereas much lower mortality rates are to be expected in those with ‘primary’ ARDS (pneumonia, aspiration, lung contusion). Mortality rises with increasing age and failure of other organs. Most of those dying with ARDS do so as a result of MODS and haemodynamic instability rather than impaired gas exchange.

PATIENT SELECTION – WITHholding AND WITHDRAWING TREATMENT
For many critically ill patients, intensive care is undoubtedly life-saving and resumption of a normal lifestyle is to be expected. In the most seriously ill patients, however, immediate mortality rates are high, a significant number die soon after discharge from the intensive care unit, and the quality of life for some of those who do survive may be poor. Moreover, intensive care is expensive, particularly for those with the worst prognosis, and resources are limited.

Inappropriate use of intensive care facilities has other implications. The patient may experience unnecessary suffering and loss of dignity, while relatives may also have to endure considerable emotional pressures. In some cases treatment may simply prolong the process of dying, or sustain life of dubious quality, and in others the risk of interventions may outweigh the potential benefits.

Both for a humane approach to the management of critically ill patients and to ensure that limited resources are used appropriately, it is necessary to avoid admitting patients who cannot benefit from intensive care and to limit further aggressive therapy when the prognosis is clearly hopeless. Such decisions can be extremely difficult and every case must be assessed individually, taking into account the patient’s previous health and quality of life, the primary diagnosis, the medium- and long-term prognosis of the underlying condition (both in terms of survival and quality of life) and the
survivability of the acute illness. Age alone should not be a consideration. When in doubt, active measures should continue but should be reviewed regularly in the light of response to treatment and any further information which may become available. Decisions to limit therapy, not to resuscitate in the event of cardiorespiratory arrest, or to withdraw treatment should be made jointly by the medical staff of the unit, the primary physician or surgeon, the nurses and if possible the patient, normally in consultation with the patient’s family.

Withdrawal or limitation of active treatment should not be viewed negatively as the cessation of all medical or nursing care. Rather, a caring approach should be adopted to ensure that the patient dies with dignity, free of pain and distress, and that family and friends receive support and comfort.

Scoring systems
A variety of scoring systems have been developed that can be used to evaluate the severity of a patient’s illness. Some have included an assessment of the patient’s previous state of health and the severity of the acute disturbance of physiological function (acute physiology, age, chronic health evaluation – APACHE, and simplified acute physiology score – SAPS). Other systems have been designed for particular categories of patient (e.g. the injury severity score for trauma victims).

The APACHE and SAPS scores are widely applicable and have been extensively validated. They can quantify accurately the severity of illness and predict the overall mortality for large groups of critically ill patients, and are therefore useful for defining the ‘casemix’ of patients when auditing a unit’s clinical activity, for comparing results nationally or internationally, and as a means of characterizing groups of patients in clinical studies. Although the APACHE and SAPS methodologies can also be used to estimate risks of mortality, no scoring system has yet been devised that can predict with certainty the outcome in an individual patient. They must not, therefore, be used in isolation as a basis for limiting or discontinuing treatment.

FURTHER READING

BRAIN DEATH
Brain death means ‘the irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity to breathe’. Both of these are essentially functions of the brainstem. Death, if thought of in this way, can arise either from causes outside the brain (i.e. respiratory and cardiac arrest) or from causes within the cranial cavity. With the advent of mechanical ventilation it became possible to support such a dead patient temporarily, although in all cases cardiovascular failure eventually supervenes and progresses to asystole.

Before considering a diagnosis of brainstem death it is essential that certain preconditions and exclusions be fulfilled.

Preconditions
■ The patient must be in apnoeic coma (i.e. unresponsive and on a ventilator, with no spontaneous respiratory efforts).
■ Irretrievable structural brain damage due to a disorder that can cause brainstem death must have been diagnosed with certainty (e.g. head injury, intracranial haemorrhage).

Exclusions
■ The possibility that unresponsive apnoea is the result of poisoning, sedative drugs or neuromuscular blocking agents must be excluded.
■ Hypothermia must be excluded as a cause of coma. The central body temperature should be more than 35°C.
■ There must be no significant metabolic or endocrine disturbance that could produce or contribute to coma or cause it to persist.
■ There should be no profound abnormality of the plasma electrolytes, acid–base balance, or blood glucose levels.

Diagnostic tests for the confirmation of brainstem death
All brainstem reflexes are absent in brainstem death.

Tests
The following tests should not be performed in the presence of seizures or abnormal postures.
■ Oculocephalic reflexes should be absent: In a comatose patient whose brainstem is intact, the eyes will rotate relative to the orbit (i.e. doll’s eye movements will be present). In a brainstem dead patient, when the head is rotated from side to side, the eyes move with the head and therefore remain stationary relative to the orbit.
■ The pupils are fixed and unresponsive to bright light. Both direct and consensual light reflexes are absent. The size of the pupils is irrelevant, although most often they will be dilated.
■ Convergent reflexes are absent.
■ There are no vestibulo-ocular reflexes on caloric testing (see p. 1109).
■ There is no motor response within the cranial nerve territory to painful stimuli applied centrally or peripherally. Spinal reflex movements may be present.
■ There is no gag or cough reflex in response to pharyngeal, laryngeal or tracheal stimulation.
■ Spontaneous respiration is absent. The patient should be ventilated with 100% O₂ (or 5% CO₂ in 95% O₂) for 10 minutes and then temporarily disconnected from the ventilator for up to 10 minutes. Oxygenation is maintained by insufflation with 100% oxygen via a catheter placed in the endotracheal tube. The patient is observed for any signs of spontaneous respiratory
efforts. A blood gas sample should be obtained during this period to ensure that the $P_{a}{CO}_2$ is sufficiently high to stimulate spontaneous respiration (> 6.7 kPa (50 mmHg)). The examination should be performed and repeated by two senior doctors.

In the UK it is not considered necessary to perform confirmatory tests such as EEG and carotid angiography.

The primary purpose of establishing a diagnosis of brainstem death is to demonstrate beyond doubt that it is futile to continue mechanical ventilation and other life-supporting measures.

In suitable cases, and provided the assent of relatives has been obtained (easier if the patient was carrying an organ donor card or is on the organ donor register), the organs of those in whom brainstem death has been established may be used for transplantation. In the UK each region has a transplant coordinator who can help with the process, as well as providing information, training and advice about organ donation. They should be informed of all potential donors. In all cases in the UK the coroner’s consent must be obtained.

DRUG THERAPY

Introduction
This chapter provides an introduction to the principles of rational therapeutics whose cardinal features are encompassed within the 1984 ‘Nairobi Declaration’. This emphasizes the importance of prescribing:

- to the right patient
- the right drug
- at the right dose
- and at an affordable cost.

THE PATIENT

The prerequisite of any form of therapeutic intervention is a reliable diagnosis or, at least, an assessment of clinical need. An accurate diagnosis ensures that a patient is not exposed, unnecessarily, to the hazards or costs of a particular intervention. Nevertheless there are some circumstances when treatment is used in the absence of a clear diagnosis. Examples include:

- the symptomatic treatment of severe pain
- the initiation of ‘blind’ antimicrobial therapy where delay would expose a patient to hazard, or discomfort (e.g. antimicrobial therapy to a patient in the community with suspected meningococcal meningitis or a suspected lower urinary tract infection).

In some instances a particular medicine is only effective in subgroups of patients with a particular disorder. Trastuzumab, for example, is only effective in women with breast cancer whose malignant cells express the HER2 epidermal growth factor receptor. It is likely, in the future, that there will be fragmentation of many diseases we currently consider as single entities, with a more precise definition of sites against which drugs can be targeted.

Medicines are also given to otherwise healthy individuals. In such circumstances there must be a very clear imperative to ensure that the benefits to the individual outweigh the harm. Examples include:

- immunization against serious microbial infections (e.g. influenza vaccination)
- the reduction of individual risk factors for overt disease (e.g. the use of antihypertensive, or lipid-lowering, agents)
- the use of oral contraceptives in sexually active women who wish to avoid pregnancy.

Co-morbidity may also significantly alter the way in which conditions are managed, particularly in the elderly. Some examples are shown in Table 16.1.

Prescribing in neonates, infants and children

The use of drugs in the newborn, infants and children poses special problems. Extrapolating from adult dosage regimens, merely adjusting for weight, leads to excessive (and potentially toxic) doses because:

- The rates of hepatic metabolism and renal excretion of drugs are reduced in neonates and infants.
- Premature babies have approximately 1% of their body weight as fat (compared to 20% in adults), leading to a marked increase in plasma drug levels of fat-soluble drugs.

Other difficulties in paediatric prescribing:

- Many treatments have never been subject to formal trials in children and their benefits and risks have not, therefore, been adequately assessed in this age group. Efforts are being made, internationally, to redress this.
- For many drugs, there are no paediatric preparations or formulations. Instead, adult products are used.
- Precise oral dosing is often impossible in babies who spit out unpleasant-tasting products!

Prescribing for the elderly

The use of drugs in the elderly is often a problem because:

- Rates of hepatic drug metabolism and renal excretion decline with age. Extrapolation of drug dosages, from those appropriate in younger adults, may therefore lead to toxic plasma levels.
- Changes in drug distribution, associated with a reduction in body mass, changes in body composition, and the preferential distribution of the cardiac output to the brain, may also predispose to toxicity.
- Co-morbidity, often associated with polypharmacy, leads to increased opportunities for drug interactions.
- Concordance with treatment regimens diminishes as the number of prescribed drugs increases, and is especially poor in the face of cognitive impairment.
- Exaggerated pharmacodynamic effects of drugs acting on the central nervous, cardiovascular and gastrointestinal systems are common.

Examples of common problems encountered in the use of drugs amongst older people are shown in Table 16.2.

Drug use in pregnancy

Clinicians should be extremely cautious about prescribing drugs to pregnant women, and only essential treatments should be given. When a known teratogen is needed during pregnancy (e.g. an anti-convulsant drug or lithium) the potential adverse effects should be discussed with the parents preferably before conception. If they decide to go ahead with the pregnancy, they should be offered an appropriate ultrasound scan to assess whether there is any fetal damage. Some known human teratogens are shown in Table 16.3.

Breast-feeding

Although most drugs can be detected in breast milk, the quantity is generally small. This is because, for most drugs, the concentration in milk is in equilibrium with plasma water (i.e. the non-protein-bound fraction). A few drugs (e.g. aspirin, carbimazole) may, however, cause harm to the infant if ingested in breast milk. Relevant drug literature should be consulted when prescribing to a nursing mother.

**THE DRUG**

Selecting the right drug involves three elements:

- the drug’s clinical efficacy for the proposed use
- the balance between the drug’s efficacy and safety
- patient preference.

The ‘gold standard’ (see p. 929) to demonstrating the clinical efficacy of a drug is the randomized controlled trial (RCT), although other approaches (see p. 931) can be informative. The demonstration of absolute efficacy (against placebo) may, itself, be insufficient. Where there is more than one
treatment for the same indication these should be compared with one another, taking account of the magnitude of their benefits, their individual adverse reaction profiles and their costs. Comparative RCTs are particularly useful in this respect.

Patient’s preferences should be discussed to enable them to be equal partners in decision-making about whether and how they wish to undergo treatment. A full understanding of the reasons for considering treatment, the likely benefits and the possible adverse reactions, has repeatedly been shown to improve ‘concordance’ with treatment regimens.

THE DOSE

Appropriate drug dosages will have usually been determined from the results of so-called ‘dose-ranging’ studies during the original development programme. Such studies are generally conducted as RCTs covering a range of potential doses. Drug doses and dosage regimens may be fixed or adjusted.

Fixed dosage regimens

Drugs suitable (in adults) for prescribing at fixed doses for all patients share common features. Efficacy is optimal in virtually all patients; and the risks of dose-related (type A) adverse reactions (see p. 927) are normally low. These drugs have a high ‘therapeutic ratio’ (i.e. the ratio between toxic and therapeutic doses). Examples of drugs prescribed at a fixed dose are shown in Table 16.4.

Titrated dosage regimens

For many drugs there are wide interindividual variations in response. As a consequence, whilst a particular dose may in one person lack any therapeutic effect, the same dose in another may cause serious toxicity. The reasons for such variability are partly due to pharmacokinetic factors (differences in the rates of drug absorption, distribution or metabolism) and partly due to pharmacodynamic factors (differences in the sensitivity of target organs).

Pharmacokinetics

The intensity of a drug’s action, immediately after parenteral administration, is largely a function of its volume of distribution. This, in turn, is predominantly governed by body composition and regional blood flow. Dosage adjustments, for bodyweight or surface area, are therefore common, for example in cancer chemotherapy in order to optimize treatment.

The main determinants of a drug’s plasma concentrations are its bioavailability (the proportion of the unchanged drug that reaches the systemic circulation) and its rate of systemic clearance (by hepatic metabolism or renal excretion). After oral administration, a drug’s bioavailability depends on the extent to which it is:

- Destroyed in the gastrointestinal tract.
- Crosses the gastrointestinal epithelium.
- Metabolized by the liver before reaching the systemic circulation (so called presystemic or first pass metabolism). First pass metabolism can be avoided by the intravascular (i.v.), intramuscular (i.m.) or sublingual route.

Liver drug metabolism occurs in two stages:

- **Phase I** is the modification of a drug, by oxidation, reduction or hydrolysis. Of these, oxidation is the most frequent route and is largely undertaken by a family of isoenzymes known as the cytochrome P450 system (see p. 926). Inhibition or induction of cytochrome P450 isoenzymes are major causes of drug interaction (Table 16.5).
- **Phase II** involves conjugation with glucuronic acid, sulphate, acetate or other substances to render it more soluble and therefore able to be excreted in the urine.

**Genetic causes of altered pharmacokinetics**

Both presystemic hepatic metabolism, and the rate of systemic hepatic clearance, may vary markedly between healthy individuals.

Variability in the genes encoding drug metabolizing (Table 16.6) enzymes are major determinants of the inter-individual differences in the therapeutic and adverse responses to drug treatment. The most common involve polymorphisms of the cytochrome P450 family of enzymes. The first to be discovered was the polymorphism in the hydroxylation of the anti-hypertensive agent debrisoquin (CYP2D6). Defective

*Hyperforin is one of the ingredients of the herbal product known as St John’s Wort used by herbalists to treat depression. Although it is marketed as a licensed medicine, it is a reminder that drug interactions can occur with alternative, as well as conventional, medicines.
catabolism was shown to be a monogenetically inherited trait, involving 5–10% of Caucasian populations and leading to an exaggerated hypotensive response. Figure 16.1 shows the distribution of debrisoquin metabolic ratios in a UK population. Those with a ratio of more than 10 are homozygous slow metabolizers; those with a ratio of less than 0.5 are homozygous rapid metabolizers. Those with intermediate metabolic ratios are predominantly heterozygotes.

*Selective serotonin reuptake inhibitors.

A very large number of drugs – estimated at 15–25% of all medicines in use – are substrates for CYP2D6. The frequency of the variant alleles show racial variation and a small proportion of individuals have two or more copies of the active gene. The phenotypic consequences of the defective CYP2D6 include the increased risk of toxicity with those antidepressants or antipsychotics undergoing metabolism by this pathway. Conversely, in those with multiple copies of the active gene, there is extremely rapid rates of metabolism and therapeutic failure at conventional doses.

Warfarin is predominantly metabolized by CYP2C9. In most populations, between 2% and 10% are homozygous for an allele that results in low enzyme activity. Such individuals will therefore metabolize warfarin more slowly leading to higher plasma levels, a greater risk of bleeding, and a requirement for lower doses if the international normalized ratio (INR) is to be maintained within the therapeutic range.

Individual differences in the activity of thiopurine methyltransferase (TPMT) determine the dose of mercaptopurine and azathioprine that are used. TPMT activity is therefore undertaken routinely in children undergoing treatment for acute lymphatic leukaemia and patients with Crohn’s disease (see p. 290).

Many drugs undergo metabolism by more than one member of the cytochrome P450 family. Individuals deficient in one enzyme may have normal, or even overexpressed, activities of others. Current knowledge (and cost) does not therefore permit predictions of an individual’s dosage requirements, to a wide range of drugs, based on scans of all the genes concerned with drug metabolism. This may, though, become possible in the future, leading – in part – to the prospect of so-called ‘personalized prescribing’.

### Other causes of altered pharmacokinetics

Rates of hepatic drug clearance can also be influenced by environmental factors including diet, alcohol consumption and concomitant therapy with drugs capable of inducing or inhibiting (Table 16.5) drug metabolism. Hepatic drug clearance also decreases with age. By contrast, renal drug clearance does not show substantial variation between healthy individuals although it declines with age and in patients with intrinsic renal disease.

### Pharmacodynamics

Pharmacodynamic sources of variability in the intensity of drug action are at least partly due to drug receptor and
receptor polymorphisms (Table 16.7). At present, the only pharmacodynamic tests used routinely in clinical practice are the expressions of the oestrogen and HER2 receptors in women with breast cancer.

The prospect for ‘personalized prescribing’ will be enhanced further, when pharmacodynamic polymorphisms can be elicited by gene scanning. The interplay between pharmacokinetics and pharmacodynamics will influence drug selection and dosing.

### Monitoring the effects of treatment

The combination of pharmacokinetic and pharmacodynamic causes of variability makes monitoring of the effects of treatment essential. Three approaches are used.

#### Pre-treatment dose selection

In patients with known, or suspected, impaired renal function it is usually possible to predict their dose requirements from the serum creatinine concentration. If treatment needs to be started before the serum creatinine concentration is available, or in patients with very advanced renal impairment, or if renal function is fluctuating, then start with conventional doses but be prepared to make adjustments within 24 hours. Frequent assessments of renal function, coupled with measurements of plasma drug concentrations, may be necessary.

#### Measuring plasma drug concentrations

For a few drugs, dosages can be effectively monitored by reference to their plasma concentrations (Table 16.8). This technique is only useful, however, if both the following criteria are fulfilled:

- There is a reliable and available drug assay.
- Plasma concentrations correlate well with therapeutic efficacy and toxicity.

### Measuring drug effects

For many drugs, dosage adjustments are made in line with patients’ responses. Monitoring can involve dose titration against a therapeutic end-point or a toxic effect. Objective measures (such as monitoring antihypertensive therapy by measuring blood pressure, or cytotoxic therapy with serial white blood cell counts) are most helpful, but subjective ones are necessary in many instances (as with antipsychotic therapy in patients with schizophrenia).

### AFFORDABILITY

The money available for healthcare varies widely across the world and there are marked differences (Fig. 16.2). All healthcare systems try to provide their populations with the highest standards of care within the resources they have at their disposal. The expenditure of large sums on a few people may deprive many of cost-effective remedies – a phenomenon known as the ‘opportunity cost’.

In many countries cost-containment measures are encouraged (or mandated). For example, to reduce costs all drugs should be prescribed by their generic (approved) names rather than their ‘brand’ ones because, once their patents have expired, they are cheaper. Despite occasional claims to the contrary, generic products are required to go through the same stringent regulatory processes as their branded counterparts.

Some countries, including Australia, Canada and Britain, assess the cost effectiveness of new drugs (value for money) before they are available under their publicly funded healthcare systems.

### ADVERSE DRUG REACTIONS

Adverse drug reactions (ADRs), defined as ‘the unwanted effects of drugs occurring under normal conditions of use’, are a significant cause of morbidity and mortality.Around 5% of acute medical emergencies are admitted with ADRs, and around 10–20% of hospital inpatients suffer an ADR during their stay. Unwanted effects of drugs are five to six times more likely in the elderly, compared to young adults; and the risk of an ADR rises sharply with the number of drugs administered.

</table>

Whilst some such reactions as hypotension with ACE inhibitors may occur after a single dose, others may develop only after months (pulmonary fibrosis with amiodarone) or years (second cancers with cytotoxic drugs).

Type B (idiosyncratic) reactions (Table 16.9) have no resemblance to the recognized pharmacological or toxicological effects of the drug. They are:

- qualitatively abnormal responses to the drug
- unpredictable from a compound’s known pharmacological or toxicological actions
- generally dose-independent
- usually rare
- often serious.

**Diagnosis**

All ADRs mimic some naturally occurring disease, and the distinction between an iatrogenic aetiology and an event unrelated to the drug is often difficult. Although some effects are obviously iatrogenic (e.g. acute anaphylaxis occurring a few minutes after intravenous penicillin), many are less so. There are six characteristics that can help distinguish an adverse reaction from an event due to some other cause:

- **Appropriate time interval.** The time interval between the administration of a drug and the suspected adverse reaction should be appropriate. Acute anaphylaxis usually occurs within a few minutes of administration, whilst aplastic anaemia will only become apparent after a few weeks (because of the life-span of erythrocytes). Drug-induced malignancy, however, will take years to develop.

- **Nature of the reaction.** Some conditions (maculopapular rashes, angio-oedema, fixed drug eruptions, toxic epidermal necrolysis) are so typically iatrogenic that an adverse drug reaction is very likely.

- **Plausibility.** Where an event is a manifestation of the known pharmacological property of the drug, its recognition as a type A adverse drug reaction can be made (e.g. hypotension with an antihypertensive agent, or hypoglycaemia with an antidiabetic drug). Unless there have been previous reports in the literature, the recognition of type B reactions may be very difficult. The first cases of depression with isotretinoin, for example, were difficult to recognize as an ADR even though a causal association is now acknowledged.

**Classification**

Two types of ADR are recognized.

Type A (augmented) reactions (Table 16.9) are:

- qualitatively normal, but quantitatively abnormal, manifestations of a compound’s pharmacological or toxicological properties
- predictable from a compound’s known pharmacological or toxicological actions
- generally dose-dependent
- usually common
- only occasionally serious.
■ **Exclusion of other causes.** In some instances, particularly suspected hepatotoxicity, an iatrogenic diagnosis can only be made after the exclusion of other causes of disease.

■ **Results of laboratory tests.** In a few instances, the diagnosis of an adverse reaction can be inferred from the plasma concentration (Table 16.8). Occasionally, an ADR produces diagnostic histopathological features. Examples include putative reactions involving the skin and liver.

■ **Results of dechallenge and rechallenge.** Failure of remission when the drug is withdrawn (i.e. ‘dechallenge’) is unlikely to be an ADR. The diagnostic reliability of dechallenge, however, is not absolute: if the ADR has caused irreversible organ damage (e.g. malignancy) then dechallenge will result in a false-negative response. Rechallenge, involving re-institution of the suspected drug to see if the event recurs, is often regarded as an absolute diagnostic test. This is, in many instances, correct but there are two caveats. First, it is rarely ethically justified to subject a patient to further hazard. Second, some adverse drug reactions develop because of particular circumstances which may not necessarily be replicated on rechallenge (e.g. hypoglycaemia with an antidiabetic agent).

**Management**

As a general rule, type A reactions can usually be managed by a reduction in dosage whilst type B reactions almost invariably require the drug to be withdrawn (and never re-instituted).

Specific therapy is sometimes required for ADRs such as bleeding with warfarin (vitamin K), acute dystonias (benzatropine) or acute anaphylaxis (see Emergency Box 3.1, p. 73).

**Randomized controlled trials**

**Parallel group design.** In this type of study, patients with a particular condition are given, prospectively, one of two (or more) treatments. Treatments are usually allocated randomly (a ‘randomized’ controlled trial). In order to reduce patient bias, the patients themselves are generally unaware of their treatment allocations (a ‘single-blind’ trial); and in order to reduce doctor bias the treatment allocation is also withheld from the investigators (a ‘double-blind’ trial). To recruit sufficient numbers of patients, and to examine the effects of treatment in different settings, it is often necessary to conduct the trial at several locations (a ‘multicentre’ trial). The ‘gold standard’ for demonstrating the efficacy of a treatment is, thus, the prospective, randomized, double-blind, multicentre, controlled trial.

Prospective randomized controlled trials are designed either to show that one treatment is better than another (a ‘superiority’ trial); or that one treatment is similar to another (an ‘equivalence’ trial). In a superiority trial the study treatment is usually compared to placebo, no treatment or to current standard practice. With drugs, the comparators may include different doses of the study (‘active’) drug in order to define the optimum treatment regimen. In an equivalence trial the treatment under study is usually compared to another treatment for the same condition.

Although RCTs were originally introduced to investigate the efficacy of drugs, the methodology is used for surgical procedures and medical devices.

**Cross-over design.** In some circumstances patients can receive both the active and the comparator, in random sequence, thus acting as their own control. Cross-over trials have the advantage that, since each patient is his/her own control, fewer numbers are required to demonstrate efficacy. Such designs, however, are usually only appropriate in circumstances where the drug is intended to produce improvement in a chronic condition. Examples include hypnotics, bronchodilators and antihypertensive agents.

**Assessing randomized controlled trials**

In assessing the relevance and reliability of an RCT a number of features need to be taken into account.

■ **Was ethical approval obtained?** All clinical trials should have received approval, before the start of the study, from a properly constituted research ethics committee. In particular, patients taking part should have given their full and informed consent to participate.

■ **Randomization.** In any RCT the method of randomization should be robust. In particular, the investigator should be unaware of which treatment a patient entering a trial will receive. This avoids selection bias.

■ **Maintaining blindness.** Although, ideally, in RCTs neither the investigator nor the patient is aware of the treatment allocation until the end of the study, this is not always possible. Adverse drug reactions, for example, may make it obvious which treatment a patient has been given. Nevertheless maintaining ‘blindness’ is necessary where the outcome is subjective (e.g. relief of pain, alleviation of depression) if bias is to be avoided.

■ **Were the treated and control groups comparable?** Were the treated and control groups similar in their ‘baseline’

---

**FURTHER READING**

**EVIDENCE-BASED MEDICINE**

There is general acceptance that clinical practice should, as far as possible, be based on scientific evidence of benefit rather than theoretical speculation, anecdote or pronouncement.

One of the main applications of ‘evidence-based medicine’ is in therapeutics. Treatments should be introduced into, and used in, routine clinical care only if they have been demonstrated to be effective in formal clinical trials. Three approaches have been used:

- randomized controlled trials
- controlled observational trials
- uncontrolled observational studies.
characteristics? Were they, for example, of similar age, severity and duration of illness? If not, are the differences likely to bias the results? Or has the statistical analysis (using analysis of covariance, or Cox’s proportional hazards model) (see below) tried to adjust for them? Table 16.10 shows some of the baseline characteristics of a trial comparing prednisolone with placebo in the treatment of Bell’s palsy (idiopathic facial paralysis).

- **Outcomes.** There are two ways to look at the outcomes of an RCT. One is to include only those who completed the study (‘per protocol analysis’) and the other is to include all patients from the time of randomization (‘intention-to-treat analysis’). Ideally there should be no difference but in reality the results of a per protocol analysis are usually more advantageous to a treatment than an intention-to-treat analysis. The reason is that the intention-to-treat analysis will take account of patients who have withdrawn from the trial because of intolerance of the treatment or adverse drug reactions. It is therefore a much more robust approach. The results of the intention-to-treat analysis, in the trial of prednisolone in Bell’s palsy, are shown in Table 16.10. The trial results indicate a high probability that treatment of Bell’s palsy with prednisolone will increase the chances of a full recovery of facial nerve function.

- **Are the results generalizable?** Were the patients enrolled into the study a reasonable reflection of those likely to be treated in routine clinical practice (a so-called pragmatic trial)? Or were they a selected population that excluded significant patient groups (such as the elderly)? If the latter, view the results with caution.

- **Analysis of a superiority trial.** The aim of a superiority trial is to determine whether one treatment (or dose) is better (or more effective) than another. It is usual to estimate the probability that there is ‘no difference’ between the treatments; if this is less than 1 in 20 ($p < 0.05$) it is regarded as ‘statistically significant’. There are two caveats. First, any difference may still be due to chance and it is better to await the results of two independent studies before adopting a new treatment. Second, a trial may show no ‘statistically significant’ difference, when one in fact exists, because too few patients have been included. The ‘power’ of a study (the number of patients needed in each treatment group to detect a predefined difference) should have been defined at the outset. If not, the results of the study should be interpreted with extreme care.

- **Effect size.** Considerable care needs to be taken in interpreting the magnitude of the reported differences in a superiority trial. The results of the well-designed trial in Table 16.10 show, very convincingly, that the treatment of Bell’s palsy with prednisolone increases the likelihood of a complete recovery of facial nerve function, at 12 months, from 81.6% to 94.4%. One expression of the benefit of prednisolone, in this indication, can be derived from the number needed to treat (NNT). In the study shown in Table 16.10 the NNT to enable one patient to regain normal facial nerve function is 8.

- **Analysis of an equivalence trial.** The aim in this trial is to determine whether two (or possibly more) treatments produce similar benefits. During the design of such trials, it is necessary to decide what difference is unimportant and then to calculate the number of patients needed in order to have an 80% or 90%
chance of showing this. In equivalence trials such power calculations show that the number of patients required is invariably greater than those needed for superiority trials. The results of equivalence trials are usually reported as a ‘hazard ratio’ (the ratio of the response rate to the study treatment to that of the comparator) with its 95% confidence intervals. A hazard ratio of around unity (and with a confidence interval of – say – 0.9–1.1) would indicate that the two treatments were indeed likely to be equivalent. A hazard ratio of 0.5 (confidence interval 0.3–0.7) would suggest inequivalence, and superiority of the study treatment. By contrast, a hazard ratio of 2.0 (confidence interval 1.7–2.3) would suggest that the new treatment was inferior. In equivalence trials, it should be obvious that the comparator itself must have been shown to be effective.

Meta-analysis. An analysis of all controlled trials that have been performed in a particular area can minimize random errors in the assessment of treatment effects because more patients and treatments are included than in any individual trial. Meta-analysis should be performed (and interpreted) carefully because of the heterogeneity of studies.

Controlled observational trials

Three types of observational study have been used to test the clinical effectiveness of therapeutic interventions – historical controlled trials, case-control studies and before-and-after studies.

Historical controlled trials. Despite the pre-eminence of the prospective randomized controlled trial there are many treatments that have never been subjected to this technique, yet their efficacy is unquestioned. Examples include insulin in the treatment of diabetic ketoadiabetes, thyroxine for hypothyroidism, vitamin B₂ in pernicious anaemia and defibrillation for ventricular fibrillation.

In a historical controlled trial the outcome in patients treated with the study drug is compared to that of previously untreated patients with the same disease. The circumstances when it is legitimate for a treatment to be accepted into routine use on the basis of favourable comparisons with historical controls are generally limited to the following:

- There should be a biologically plausible reason why the treatment might be effective. From a knowledge of the underlying nature of the condition, and the properties of the treatment, it should be reasonable to infer likely benefit.
- There should be no other effective form of treatment. If there is, then the study treatment should be compared with the alternative in a prospective, randomized controlled trial.
- The disease, if untreated, should result in death or permanent disability.
- The condition should have a known, and predictable, natural history.

New treatments that fulfil these stringent criteria are uncommon. Historical controlled trials are most frequently (though inappropriately) used in the assessment of, for example, new anticancer treatments; in most instances prospective, comparative, randomized, and controlled trials would be more informative.

Case-control studies. This type of study design compares patients with a particular condition (the ‘cases’) with those without (the ‘controls’). The approach has predominately been used to identify ‘risk factors’ for specific conditions such as lung cancer (smoking), sudden infant death syndrome (lying prone) or deep venous thrombosis (oral contraceptives). Such a study allows an estimation of the odds ratio (OR), e.g. the ratio of the probability of an event occurring to the probability of the event not occurring:

\[
\text{Risk factor present} = a/b \quad \text{Risk factor absent} = c/d
\]

The odds ratio (OR) = \( a/b ÷ c/d \)

An OR that is significantly greater than unity indicates a statistical association that may be causal. The OR for deep venous thrombosis and current use of oral contraceptives equals 2–4 (depending on the preparation): this indicates that the risk of developing a deep venous thrombosis on oral contraceptives is between 2 and 4 times greater than the background rate.

In some studies, the OR for a particular observation has been found to be significantly less than unity, suggesting ‘protection’ from the condition under study. Some studies of women with myocardial infarction indicated protection in those using hormone-replacement therapies but it has been subsequently shown that the result was due to bias. On the other hand, case-control studies have consistently shown that aspirin and other non-steroidal anti-inflammatory drugs are associated with a reduced risk of colon cancer. This seems to be a causal effect.

Case-control studies claiming to demonstrate the efficacy of a drug need to be interpreted with great care: the possibility of bias and confounding is substantial as was seen in the studies of hormone-replacement therapy and myocardial infarction. Confirmation from one or more RCTs is usually essential.

Before-and-after studies. It has sometimes been inferred that observed improvements seen in patients before, and after, the application of a particular treatment is evidence of efficacy. Such an approach is fraught with difficulties: the combination of a placebo effect, as well as regression to the mean, is likely to negate most studies using this type of design. Nevertheless there are some circumstances where genuine efficacy can be confidently observed with such designs: the consequences of hip replacement, and cataract surgery, are good examples. Such instances can be regarded as special examples of the use of implicit historical controls.

Uncontrolled observational studies

Uncontrolled case series cannot be considered as providing primary evidence of efficacy unless they are undertaken in circumstances that are virtually those of historical controlled trials. When used in this way to demonstrate clinical effectiveness their validity relies on the use of implicit historical trials. Case series can, however, sometimes be of value in demonstrating the generalizability of the results of RCTs.
**Dangers**

Drug trials are carried out in specific groups of selected patients under strict supervision. The results, particularly when dramatic, are often used outside these strict criteria. The dramatic effect of spironolactone in heart failure (30% reduction in all-cause mortality) has not always been replicated in clinical practice because the wrong patients have been treated, often with higher doses, leading to hyperkalaemia and death.

**Evaluation of new drugs**

New drugs are subjected to a vigorous programme of preclinical and clinical testing before they are licensed for general use (Table 16.11) and are also monitored for safety following licensing. Doctors are recommended to fill in yellow cards when they suspect an adverse reaction has taken place.

**FURTHER READING**

**STATISTICAL ANALYSES**

The relevance of statistics is not confined to those who undertake research but also to anyone who wants to understand the relevance of research studies to their clinical practice.

**The average**

Clinical studies may describe, quantitatively, the value of a particular variable (e.g. height, weight, blood pressure, haemoglobin) in a sample of a defined population. The ‘average’ value (or ‘central tendency’ in statistical language) can be expressed as the mean, median or mode depending on the circumstances:

- The *mean* is the average of a distribution of values that are grouped symmetrically around the central tendency.
- The *median* is the middle value of a sample. It is used, particularly, where the values in a sample are asymmetrically distributed around the central tendency.
- The *mode* is the interval, in a frequency distribution of values, that contains more values than any other.

In a symmetrically distributed population the mean, median and mode are the same.

The average value of a sample, on its own, is of only modest interest. Of equal (and often greater) relevance is the confidence we can place on the sample average as truly reflecting the average value of the population from which it has been drawn. This is most often expressed as a *confidence interval*, which describes the probability of a sample mean being a certain distance from the population mean. If, for example, the mean systolic blood pressure of 100 undergraduates is 124 mmHg, with a 95% confidence interval of ± 15 mmHg, we can be confident that if we replicated the study 100 times the value of the mean would be within the range 109–139 mmHg on 95 occasions. It is intuitively obvious that the larger the sample the smaller will be the size of the confidence interval.

**Correlation**

In clinical studies two, or more, independent variables may be measured in the same individuals in a sample population (e.g. weight and blood pressure). The degree of correlation between the two can be investigated by calculating the *correlation coefficient* (often abbreviated to ‘r’). The correlation coefficient measures the degree of association between the two variables and may range from 1 to −1. If r = 1, there is complete and direct concordance between the two variables: if r = −1, there is complete but inverse concordance; and where r = 0 there is no concordance.

Statistical tables are available to inform investigators as to the probability that r is due to chance. As in other areas of statistics, if the probability is less than 1 in 20 (p < 0.05) then by custom and practice it is regarded as ‘statistically significant’. There are, however, two caveats. First, the 1 in 20 rule is a convention and does not exclude the possibility that a presumed association is due to chance. Second, the

</table>
fact that there is an association between two variables does not necessarily mean that it is causal. A correlation between blood pressure and weight, with $r = 0.75$ and $p < 0.05$, does not mean that weight has a direct effect on blood pressure (or vice versa).

Correlation analyses can become complicated. The simplest (least squares regression analysis) presumes a straight-line relationship between the two variables. More complicated techniques can be used to estimate $r$ where a non-linear relationship is presumed (or assumed); where the distributions deviate from normal; where the scales of one or both variables are intervals or ranks; or where a correlation between three or more variables is sought.

### Hypothesis testing

Much of statistics is concerned with testing hypotheses. The basic assumption – known as the ‘null hypothesis’ – is that there is no difference between the groups. The reason for this confusing terminology is that statistical techniques are designed to assess the extent to which a zero difference might be due to the play of chance (such as a sampling ‘error’). In the analysis of the RCT in Table 16.10, the null hypothesis asserts that there is no difference between the results in patients treated with placebo and those on active treatment. Statistical tests are used to determine the probability that the observed difference is due to chance. Where this is less than 1 in 20 ($p < 0.05$) it is described as ‘statistically significant’. Again, the 1 in 20 rule is arbitrary but is a convention that is widely adopted.

The choice of statistical test to examine the null hypothesis is a complicated one. It is dependent on the type of data collected (whether it is ordinal, cardinal or categorical); and whether it conforms to a normal (parametric) or other (non-parametric) distribution. Those most commonly used include Student’s t test (parametric) and chi-squared ($\chi^2$) test, analysis of variance and various tests for non-parametric data. In some circumstances it is possible to use the confidence intervals of the means of two (or more) groups to test the null hypothesis.

When the results of a statistical test indicate that it is reasonable to reject the null hypothesis, and that the probability of the results being due to chance is less than 1 in 20 ($p < 0.05$), it means that 95 times out of 100 we will be right, but that 5 times out of 100 we will be wrong. Statisticians call erroneous rejection of the null hypothesis a type 1 error. In this situation the null hypothesis is actually true, although we believe it to be false. Erroneous acceptance of the null hypothesis when there is indeed a difference is known as a type 2 error. Type 1 errors can be reduced by requiring a higher level of significance (e.g. $p < 0.01$ or $p < 0.005$) but can never be absolutely excluded. Type 2 errors are usually the result of too few participants in the study and can be avoided by estimating the numbers needed to examine specific levels of difference before the trial is started. Such estimates are known as ‘power calculations’.

### Other statistical techniques

Statisticians have developed a range of sophisticated methods to handle a wide variety of biomedical problems. Unless an investigator is supremely (and usually unwisely) confident it is wise to seek professional advice in analysing numerical data that look complicated. In doing so, it is invariably wiser to do so at the time the study is being designed rather than after the results have been generated!

### FURTHER READING

### INFORMATION

Pharmacotherapy moves at a very rapid pace and it is impossible for anyone to keep up with contemporary advances. Details of current prescribing advice can be found in:

- the Summary of Product Characteristics (SmPCs) produced by manufacturers but vetted by the UK drug regulatory authority (the Medicines and Healthcare Products Regulatory Agency)
- the British National Formulary (BNF) produced, jointly, by the British Medical Association and the Royal Pharmaceutical Society. Many countries have their own formularies
- the Technology Appraisals Guidance series from the National Institute for Health and Clinical Excellence (NICE).

Advice on the management of individual conditions, in the form of clinical guidelines (systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances), can be accessed from:

- the National Institute for Clinical Excellence (NICE): [http://www.nice.org.uk](http://www.nice.org.uk)
- the Scottish Intercollegiate Guidelines Network (SIGN): [http://www.sign.ac.uk](http://www.sign.ac.uk/)

Patient information leaflets are supplied with all prescribed medication.

### POISONING

#### The nature of the problem

Exposure to a substance is often equated with poisoning. However, absorption is necessary for there to be a toxic effect and, even if this occurs, poisoning does not necessarily result, because the amount absorbed may be too small. In developed countries, poisoning causes approximately 10% of acute hospital medical presentations. In such cases poisoning is usually by self-administration of prescribed and over-the-counter medicines, or illicit drugs. Poisoning in children aged less than 6 months is most commonly iatrogenic and involves overtreatment with, for example, paracetamol.
Children between 8 months and 5 years of age also ingest poisons accidentally, or they may be administered deliberately to cause harm, or for financial or sexual gain. Occupational poisoning as a result of dermal or inhalational exposure to chemicals is a common occurrence in the developing world and still occurs in the developed world. Sometimes inappropriate treatment of a patient by a doctor is responsible for the development of poisoning, for example, in the case of digoxin toxicity.

In adults, self-poisoning is commonly a "cry for help". Those involved are most often females under the age of 35 who are in good physical health. They take an overdose in circumstances where they are likely to be found, or in the presence of others. In those older than 55 years of age, men predominate and the overdose is usually taken in the course of a depressive illness or because of poor physical health.

The type of agent taken in overdose is also heavily influenced by availability and culture. In the UK, paracetamol poisoning is responsible for approximately one-third of all admissions, whereas in Sri Lanka, for example, the agents ingested are more often pesticides or plants, such as olean- der, and in South India, copper sulphate is a problem. In addition, ingestion of heating fuels (e.g. petroleum distillates), antimalarials, anti-tuberculous drugs and traditional medicine is reported frequently in the developing world.

A third of patients admitted with an overdose in the UK state that they are unaware of the toxic effects of the substance involved; the majority take whatever drug is easily available at home (Box 16.1). Studies of the agents involved reveal that:

- Acute overdoses usually involve more than one agent.
- Alcohol is the most commonly implicated second agent in mixed self-poisonings – 60% of men and 45% of women consume some alcohol at the same time as the drug.
- There is often a poor correlation between the drug history and the toxicological analytical findings. Therefore, a patient’s statement about the type and amount of drug ingested cannot always be relied upon.

The majority of cases of self-poisoning do not require intensive medical management, but all patients require a sympathetic and caring approach, a psychiatric and social assessment and, sometimes, psychiatric treatment. However, as the majority of patients ingest relatively non-toxic agents, receive good supportive care and, when appropriate, the administration of specific antidotes, the in-hospital mortality in most developed countries is now less than 1%. Fatalities in the UK are due predominantly to carbon monoxide, anti-depressants, paracetamol, analgesic combinations containing paracetamol and an opioid, heroin, methadone or cocaine. Deaths from poisoning in children are usually accidental and due to inappropriate storage of drugs such as digoxin and quinine and from drugs of abuse purchased or prescribed for a parent/carer.

### THE APPROACH TO THE PATIENT (Table 16.12)

#### History

More than 80% of adults are conscious on arrival at hospital in the UK and the diagnosis of self-poisoning can usually be made from the history (Table 16.12). In the unconscious patient a history from friends or relatives is helpful, and the diagnosis can often be inferred from the medicine containers or a ‘suicide note’ brought by the paramedics. It should be emphasized that in any patient with an altered level of consciousness, drug overdose must always be considered in the differential diagnosis.

#### Examination

On arrival at hospital the patient must be assessed urgently (Airways, Breathing and Circulation). The following should be evaluated:

- **Level of consciousness** – The Glasgow Coma Scale should be used (see p. 1123).
- **Ventilation** – Pulse oximetry can be used to measure oxygen saturation. The displayed reading may be inaccurate when the saturation is below 70%, there is poor peripheral perfusion and in the presence of carboxyhaemoglobin and methaemoglobin. Only measurement of arterial blood gases will indicate the presence both of hypercapnia and hypoxia.
- **Blood pressure and pulse rate**.
- **Pupil size and reaction to light**.
- **Evidence of intravenous drug abuse**.
- **A head injury complicating poisoning**.

If the patient is unconscious the following should also be checked:

- **Cough and gag reflex** – present or absent.
- **Temperature** – measured with a low-reading rectal thermometer.

Some of the physical signs that may aid identification of the agents responsible for poisoning are shown in Table 16.13. The cluster of features on presentation may be distinctive and diagnostic. For example, sinus tachycardia, fixed

### Prevention of self-poisoning

Patients usually take what is readily available at home.

- Small amounts only of drugs should be bought
- Foil-wrapped drugs are less likely to be taken
- Keep drugs in a safe place
- Keep drugs and liquids in their original containers
- Child-resistant drug containers should be used
- Doctors should be careful in prescribing all drugs
- Prescriptions for any susceptible patient (e.g. the depressed) must be monitored carefully
- Household products should be labelled and kept safely, away from children

**Self-poisoning can kill**

All people must be aware of the dangers of drugs and chemicals. Education on safe storage and careful handling of household and workplace chemicals is necessary on a continual basis.

### Table 16.12

**Diagnostic process in acute poisoning**

- Obtain history, if possible, from the patient, relative, friend or paramedics
- Is there circumstantial evidence of an overdose?
- Are the circumstances in which the patient has been found suggestive?
- Was a suicide note left?
- Are the symptoms suggestive of an overdose?
- Do the physical signs suggest an overdose (Tables 16.13 and 16.14)
Table 16.13  Some physical signs of poisoning

**Table 16.15  Management strategy in acute poisoning**

Provide supportive treatment
Is the use of an antidote appropriate? (Table 16.16)
Is it appropriate to attempt to reduce poison absorption?
Is it appropriate to perform toxicological investigations?
Will non-toxicological investigations assist? (Table 16.17)
Should urine alkalization, multiple-dose activated charcoal, haemodialysis or haemoperfusion be employed to increase poison elimination?

Most patients with self-poisoning require only general care and support of the vital systems. However, for a few drugs additional therapy is required.

**PRINCIPLES OF MANAGEMENT** (Table 16.15)

In all cases the patient should be nursed in the lateral position with the lower leg straight and the upper leg flexed; in this position the risk of aspiration is reduced. A clear passage for air should be ensured by the removal of any obstructing object, vomit or dentures, and by backward pressure on the mandible. Nursing care of the mouth and pressure areas should be instituted. Immediate catheterization of the bladder in unconscious patients is usually unnecessary as it can be emptied by gentle suprapubic pressure. Insertion of a venous cannula is usual, but administration of intravenous fluids is unnecessary unless the patient has been unconscious for more than 12 hours or is hypotensive.

**Ventilatory support**

If respiratory depression is present, as determined by pulse oximetry or preferably by arterial blood gas analysis, an oropharyngeal airway should be inserted, and supplemented oxygen should be administered. Pulse oximetry alone will not detect hypercapnia. Loss of the cough or gag reflex is the prime indication for intubation. The gag reflex can be assessed by positioning the patient on one side and making him or her gag using a suction tube. In many severely poisoned patients the reflexes are depressed sufficiently to allow intubation without the use of sedatives or relaxants. The complications of endotracheal tubes are discussed on page 914. If ventilation remains inadequate after intubation, as shown by hypoxaemia and hypercapnia, intermittent positive-pressure ventilation (IPPV) should be instituted.

**Cardiovascular support**

Although hypotension (systolic blood pressure below 80 mmHg) is a recognized feature of acute poisoning, the classic features of shock – tachycardia and pale cold skin – are observed only rarely.

Hypotension and shock may be caused by:
- a direct cardio-depressant action of the poison (e.g. beta-blockers, calcium channel-blockers, tricyclic antidepressants)
vasodilation and venous pooling in the lower limbs (e.g. ACE inhibitors, phenothiazines)

- decrease in circulating blood volume because of gastrointestinal losses (e.g. profuse vomiting in theophylline poisoning), increased insensible losses (e.g. salicylate poisoning), increased renal losses (e.g. poisoning due to diuretics) and increased capillary permeability.

Hypotension may be exacerbated by coexisting hypoxia, acidosis and dysrhythmias. In patients with marked hypotension, volume expansion with crystalloids should be used, guided by monitoring of central venous pressure (CVP). Urine output (aiming for 35–50 mL/h) is also a useful guide to the adequacy of the circulation. If a patient fails to respond to the above measures, more intensive therapy is required. In such patients, it is helpful to undertake invasive haemodynamic monitoring to confirm that adequate volume replacement has been administered. Volume replacement and the use of inotropes are discussed on page 905.

Systemic hypertension can be caused by a few drugs when taken in overdose. If this is mild and associated with agitation, a benzodiazepine may suffice. In more severe cases, for example those due to a monoamine oxidase inhibitor, there may be a risk of arterial rupture, particularly intracranially. To prevent this, an α-adrenergic blocking agent (e.g. phentolamine, 5 mg i.v. every 10–15 minutes), or intravenous isosorbide dinitrate 2–10 mg/hour up to 20 mg/hour if necessary, or sodium nitroprusside 0.5–1.5 μg/kg/min by intravenous infusion, should be administered until the blood pressure is controlled.

Arrhythmias occur, e.g. tachyarrhythmias following ingestion of a tricyclic antidepressant or theophylline; bradyarrhythmias with digoxin poisoning. Known arrhythmogenic factors such as hypoxia, acidosis and hypokalaemia should be corrected. All patients with shock should have ECG monitoring.

Other problems

Hypothermia and hyperthermia

A rectal temperature below 35°C is a recognized complication of poisoning, especially in older patients or those who are comatose. The patient should be covered with a ‘space blanket’ and, if necessary, given intravenous and intragastric fluids at normal body temperature. The administration of heated (37°C) humidified oxygen delivered by face mask is also useful.

Rarely, body temperature may increase to potentially fatal levels after poisoning with central nervous system stimulants such as cocaine, amphetamines including ecstasy (MDMA), monoamine oxidase inhibitors or theophylline. Muscle tone is often increased and convulsions and rhabdomyolysis are common. Cooling measures, sedation with diazepam and, in severe cases, i.v. dantrolene 1 mg/kg body weight should be given.

Skin blisters

Skin blisters may be found in poisoned patients who are, or have been, unconscious. Such lesions are not diagnostic of specific poisons, but are sufficiently common in poisoned patients (and sufficiently uncommon in patients unconscious from other causes) to be of diagnostic value.

Rhabdomyolysis

Rhabdomyolysis can occur from pressure necrosis in drug-induced coma, or it may complicate, for example, ecstasy (MDMA) abuse in the absence of coma. Patients with rhabdomyolysis are at risk of developing, firstly, acute kidney injury from myoglobinemia, particularly if they are hypovolaemic and have an acidosis and, secondly, wrist or ankle drop from the development of a compartment syndrome (see p. 516).

Convulsions

These may occur, for example, in poisoning due to tricyclic antidepressants, mefenamic acid or opioids. Usually the seizures are short-lived but, if they are prolonged, diazepam 10–20 mg i.v. or lorazepam 4 mg i.v. should be administered. Persistent fits must be controlled rapidly to prevent severe hypoxia, brain damage and laryngeal trauma. If diazepam or lorazepam in repeated dose is ineffective, the patient should also receive a loading dose of phenytoin (18 mg/kg) administered intravenously at not more than 50 mg/min, with ECG monitoring.

Stress ulceration and bleeding

Measures to prevent stress ulceration of the stomach should be started on admission in all patients who are unconscious and require intensive care. A proton pump inhibitor should be administered intravenously.

‘Body packers’ and ‘body stuffers’

‘Body packers’ (also known as ‘mules’) are individuals who attempt to smuggle drugs across national borders or into prisons by ingesting multiple small packets that are swallowed for later retrieval from vomit or faeces, or are inserted into the vagina or rectum. Body packers often swallow large numbers of packages, with each package containing a potentially fatal dose of drug. Acute intestinal obstruction may result, and poisoning is a hazard if a packet bursts. The commonest drugs carried are cocaine, heroin, amphetamines and cannabis, though most deaths are opiate-induced.

Drugs are packaged in 2–4 layers of wrapping (condoms, latex gloves, balloons) and seen on plain X-ray as circular white densities. Alternatively, drugs may be covered by 6–7 layers of tied tubular latex (less susceptible to breakage) and seen on X-ray as soft tissue densities with surrounding gas haloes. Hardened drug paste may be wrapped in aluminium foil and overwrapped with 3–5 layers of tubular latex; these packages are least likely to break and may be difficult to detect on X-ray.

‘Body stuffers’, by contrast, are individuals who ingest drugs to avoid detection or arrest by the police. These drugs are usually either unpackaged or poorly packaged, and bodystuffers are at risk of developing features of toxicity soon after the drug has been ingested.

Management

All suspected cases should have an abdominal X-ray on presentation. CT of the abdomen should be arranged as soon as possible. A urine screen for drugs of abuse should be performed on admission. A screen that is positive for one or more drugs of abuse suggests ingestion of the abused drug in the previous few days, or a leaking packet. A negative screen strongly suggests that no packet is leaking. Packets in the stomach should not be removed by endoscopy or by inducing emesis, as these are potentially dangerous. Packets
in the vagina can usually be removed manually. With packets in the small bowel (if there is no clinical, analytical or radiological evidence to support leakage), sorbitol or lactulose to encourage transit through the gut is appropriate. Alternatively, for faster results, whole-bowel irrigation using polyethylene glycol electrolyte solutions can be used. Liquid paraffin should not be used because it can weaken the rubber, leading to bursting of the packets. Activated charcoal is contraindicated as it induces constipation when used in substantial doses. Packets in the colon or rectum are probably best managed by giving sorbitol or lactulose and allowing them to pass spontaneously, with least risk of rupture. Immediate surgery is indicated if acute intestinal obstruction develops, or when packets can be seen radiologically and there is radiological, clinical or analytical evidence to suggest leakage, particularly if the drug involved is a CNS stimulant (e.g. cocaine).

**SPECIFIC MANAGEMENT**

**Antidotes**

Specific antidotes are available for only a small number of poisons (Table 16.16).

† Dimercaptosuccinic acid.

Antidotes may exert a beneficial effect by:

- **Forming an inert complex** with the poison (e.g. desferrioxamine (defereroxamine), d-penicillamine, dicobalt edetate, digoxin-specific antibody fragments, dimercaprol, Hi-6, hydroxocobalamin, obidoxime, pralidoxime, protamine, Prussian (Berlin) blue, sodium calcium edetate, succimer [DMSA], unithiol [DMPS]).
- **Accelerating detoxification** of the poison (e.g. N-acetylcysteine, sodium thiosulphate).
- **Reducing the rate of conversion** of the poison to a more toxic compound (e.g. ethanol, fomepizole).
- **Competing with the poison** for essential receptor sites (e.g. oxygen, naloxone, phytomenadione).
- **Blocking essential receptors** through which the toxic effects are mediated (e.g. atropine).
- **Bypassing the effect** of the poison (e.g. oxygen, glucagon).

**Reducing poison absorption**

To reduce poison absorption through the lungs, remove the casualty from the toxic atmosphere, making sure that rescuers themselves are not put at risk. Contaminated clothing should be removed to reduce dermal absorption and contaminated skin washed thoroughly with soap and water.

**Gut decontamination.** While it appears logical to assume that removal of unabsorbed drug from the gastrointestinal tract will be beneficial (gut decontamination), the efficacy of current methods remains unproven and efforts to remove small amounts of non-toxic drugs are clinically not worthwhile or appropriate.

**Gastric lavage.** Gastric lavage should not be employed as the amount of marker removed by gastric lavage is highly variable and diminishes with time; it may cause significant morbidity. It should only be performed if a patient has ingested a potentially life-threatening amount of a poison, e.g. iron, and the procedure can be undertaken within 60 minutes of ingestion. Intubation is required if airway protective reflexes are lost. Lavage is also contraindicated if a hydrocarbon with high aspiration potential or a corrosive substance has been ingested.

In some countries gastric lavage is still widely practised.

**Syrup of ipecacuanha** contains two alkaloids, emetine and cephaeline, which induce vomiting by a central, as well as a local (emetine) action. It should not be used as the amount removed is highly variable, diminishes with time and there is no evidence that it improves the outcome of poisoned patients.

**Single-dose activated charcoal.** Activated charcoal has a highly developed internal pore structure which is able to adsorb a wide variety of compounds. Exceptions are strong acids and alkalis, ethanol, ethylene glycol, iron, lithium, mercury and methanol.

In studies in volunteers given 50 g activated charcoal, the mean reduction in absorption was 40%, 16% and 21% at 60 minutes, 120 minutes and 180 minutes respectively after ingestion. Based on these studies, activated charcoal should
be given in those who have ingested a potentially toxic amount of a poison (known to be adsorbed by charcoal) up to 1 hour previously. There are insufficient data to support or exclude its use after 1 hour. There is no evidence that administration of activated charcoal improves the clinical outcome.

**Cathartics** alone have no role in the management of the poisoned patient and are not recommended as a method of gut decontamination. Their use in combination with activated charcoal has produced conflicting data and there are no data on the reduction of the bioavailability of drugs or improvement in outcome of poisoned patients.

**Whole bowel irrigation (WBI)** requires the insertion of a nasogastric tube into the stomach and the introduction of polyethylene glycol electrolyte solution 1500–2000 mL/h in an adult. WBI is continued until the rectal effluent is clear.

WBI should not be used routinely in the management of the poisoned patient as there are no controlled clinical trials and no conclusive evidence that it improves the outcome. Based on volunteer studies, WBI may be used for potentially toxic ingestions of sustained-release or enteric-coated drugs. There is insufficient data to support or exclude the use of WBI for potentially toxic ingestions of iron, lead, zinc, or packets of illicit drugs. WBI is contraindicated in patients with bowel obstruction, perforation, ileus, and in patients with haemodynamic instability or compromised unprotected airways.

**Urine alkalization.** Increasing the urine pH enhances elimination of salicylate, phenobarbital, chloropropamide and chlorophenoxy herbicides (e.g. 2,4-dichlorophenoxyacetic acid) by mechanisms which are not clearly understood. However, with the exception of moderate and severe salicylate poisoning, urine alkalization is not recommended as first-line therapy for poisoning with these agents as MDAC is superior for phenobarbital, and supportive care is invariably adequate for chlorpropamide. A substantial diuresis is required in addition to urine alkalization to achieve clinically relevant elimination of chlorophenoxy herbicides.

**Increasing poison elimination**

**Multiple-dose activated charcoal (MDAC)** involves the repeated administration of oral activated charcoal to increase the elimination of a drug that has already been absorbed into the body. Drugs are secreted in the bile and re-enter the gut by passive diffusion if the concentration in the gut is lower than that in the blood. The rate of passive diffusion depends on the concentration gradient and the intestinal surface area, permeability and blood flow. Occasionally, drugs such as digoxin may be secreted actively by the intestinal mucosa, though this effect is small. Activated charcoal will bind any drug that is in the gut lumen.

Elimination of drugs with a small volume of distribution (<1 litre/kg), low pK\textsubscript{a} (which maximizes transport across membranes), low binding affinity and prolonged elimination half-life following overdose is particularly likely to be enhanced by MDAC. MDAC also improves total body clearance of the drug when endogenous processes are compromised by liver and/or renal failure.

Although MDAC has been shown to significantly increase drug elimination, it has not reduced morbidity and mortality in controlled studies. At present, MDAC should only be used in patients who have ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine and theophylline.

**Dosage.** In adults, charcoal should be administered in an initial dose of 50–100 g and then at a rate of not less than 12.5 g/h, preferably via a nasogastric tube. Smaller initial doses (10–25 g) can be used in children because, generally, smaller overdoses have been ingested and the capacity of the gut lumen is smaller. If the patient has ingested a drug that induces protracted vomiting (e.g. theophylline), intravenous ondansetron is effective as an antiemetic and thus enables administration of MDAC.

**FURTHER READING**

**Haemodialysis, haemofiltration and haemoperfusion.** Haemodialysis, haemofiltration (haemodialysis and haemofiltration done in parallel) and haemoperfusion are of little value in patients poisoned with drugs with large volumes of distribution (e.g. tricyclic antidepressants), because the plasma contains only a small proportion of the total amount of drug in the body. These methods to increase poison elimination are indicated in patients with both severe clinical features and high plasma toxin concentrations.

**Haemodialysis** significantly increases elimination of ethanol, ethylene glycol, isopropanol, lithium, methanol and salicylate, and is the treatment of choice in all cases of severe poisoning with these agents. *Haemofiltration* is more widely and readily available and increases elimination of poisons such as ethylene glycol and methanol, though it is
less efficient than haemodialysis. Charcoal haemoperfusion can significantly reduce the body burden of phenobarbital, carbamazepine and theophylline, but MDAC is as effective and simpler to use.

**Toxicological investigations**

On admission, or at an appropriate time post overdose, a timed blood sample should be taken if it is suspected that aspirin, digoxin, ethylene glycol, iron, lithium, methanol, paracetamol, paraquat, quinine or theophylline has been ingested. The determination of the concentrations of these drugs will be valuable in management. Drug screens on blood and urine are occasionally indicated in severely poisoned patients in whom the cause of coma is unknown. A poison information service will advise.

**Non-toxicological investigations (Table 16.17)**

Some routine investigations are of value in the differential diagnosis of coma or the detection of poison-induced hypokalaemia, hyperkalaemia, hypoglycaemia, hyperglycaemia, hepatic or renal failure or acid–base disturbances (Table 16.18). Measurement of carboxyhaemoglobin, methaemo-

globin and cholinesterase activities are of assistance in the diagnosis and management of cases of poisoning due to carbon monoxide, methaemoglobin-inducing agents such as nitrates, and organophosphorus insecticides respectively.

**ECG**

Routine ECG is of limited diagnostic value, but continuous ECG monitoring should be undertaken in those ingesting potentially cardiotoxic drugs; for example, sinus tachycardia with prolongation of the PR and QRS intervals in an unconscious patient suggests tricyclic antidepressant overdose. Q–T interval prolongation is an adverse effect of several drugs (e.g. quetiapine and quinine).

**Radiology**

Routine radiology is of little diagnostic value. It can confirm ingestion of metallic objects (e.g. coins, button batteries) or injection of globules of metallic mercury. Rarely, hydrocarbon solvents (e.g. carbon tetrachloride) may be seen as a slightly opaque layer floating on the top of the gastric contents with the patient upright, or outlining the small bowel. Some enteric-coated or sustained-release drug formulations may be seen on plain abdominal radiographs, but, with the exception of iron salts, ordinary formulations are seldom seen. Ingested packets of illicit substances can sometimes been seen on CT (see p. 936). Radiology can confirm complications of poisoning, for example, aspiration pneumonia, non-cardiogenic pulmonary oedema (salicylates), bronchiolitis obliterans (nitrogen oxides), ARDS, fibrosis (parquat).

### SPECIFIC POISONS: DRUGS AND OTHER CHEMICALS

In this section only specific treatment regimens will be discussed. The general principles of management of self-poisoning will always be required.

**Amfetamines including ecstasy (MDMA)**

The medicinal product is usually the dextro-isomer, dexamfetamine. The N-methylated derivative, metamfetamine, is now abused widely, and the crystalline form of this salt is known as ‘crystal meth’ or ‘ice’. Since the 1980s, the so-called designer amfetamine, 3,4-methylenedioxyamphetamine (MDMA), commonly known as ecstasy, has been abused world-wide.

Amfetamines are CNS and cardiovascular stimulants. These effects are mediated by increasing synaptic concentrations of epinephrine and dopamine. Poisoning is usually the result of their use for pleasurable purposes.

**Clinical features**

Amfetamines cause euphoria, extrovert behaviour, a lack of desire to eat or sleep, tremor, dilated pupils, tachycardia and hypertension. More severe intoxication is associated with agitation, paranoid delusions, hallucinations and violent behaviour. Convulsions, rhabdomyolysis, hyperthermia and cardiac arrhythmias may develop in severe poisoning. Rarely, intracerebral and subarachnoid haemorrhage occur and can be fatal.

Mild MDMA poisoning is characterized by agitation, tachycardia, hypertension, widely dilated pupils, trismus and
sweating. In more severe cases, hyperthermia, disseminated intravascular coagulation, rhabdomyolysis, acute kidney injury and hyponatraemia (secondary to inappropriate antidiuretic hormone secretion), predominate.

**Treatment**

Agitation is controlled by diazepam 10–20 mg i.v. or chlorpromazine 50–100 mg i.m. The peripheral sympathomimetic actions of amphetamines are antagonized by β-adrenoceptor blocking drugs. If hyperthermia is present dantrolene 1 mg/kg body weight i.v. is used.

**Anticonvulsants**

**Clinical features**

**Carbamazepine.** In overdose, carbamazepine causes dry mouth, coma, convulsions, nystagmus, ataxia and incoordination. The pupils are often dilated, divergent strabismus may be present and complete external ophthalmoplegia has been reported. Hallucinations occur, particularly in the recovery phase.

**Phenytoin.** Acute overdose of phenytoin results in nausea, vomiting, headache, tremor, cerebellar ataxia, nystagmus, and, rarely, loss of consciousness.

**Sodium valproate.** Sodium valproate most frequently causes drowsiness, impairment of consciousness and respiratory depression. In very severe poisoning myoclonic jerks and seizures occur and cerebral oedema has been reported. Liver damage, hyperammonaemia and metabolic acidosis are uncommon complications.

**Gabapentin and pregabalin.** Lethargy, ataxia, slurred speech and gastrointestinal symptoms may develop.

**Lamotrigine.** Lethargy, coma, ataxia, nystagmus, seizures and cardiac conduction abnormalities have been reported.

**Levetiracetam.** Lethargy, coma and respiratory depression have been observed.

**Tiagabine.** Lethargy, facial grimacing, nystagmus, posturing, agitation, coma, hallucinations and seizures have been reported.

**Topiramate.** Lethargy, ataxia, nystagmus, myoclonus, coma, seizures and a non-anion gap metabolic acidosis have been observed. Metabolic acidosis can appear within hours of ingestion and persist for days.

**Management**

A single dose of charcoal 50–100 g administered within 1 hour of ingestion will reduce absorption substantially. Multiple-dose activated charcoal has been shown to significantly increase elimination of carbamazepine. Although haemodialysis is effective in removing sodium valproate the indications for its use remain uncertain.

**Antidiabetic agents**

In all cases of poisoning with insulin and sulfonylureas, prompt diagnosis and treatment are essential if death or cerebral damage from neuroglycopenia is to be prevented. Metformin overdose rarely causes hypoglycaemia, since its mode of action is to increase glucose utilization, but lactic acidosis is a potentially serious complication. Thiazolidinediones cause mild hypoglycaemia but the risk of hepatic injury (recognized in regular treatment) is low after acute single ingestion. Moderate to severe poisoning occurs in overdose with insulin (= 15%), biguanides (= 12%) and also sulfonylureas (= 5%). Overdose with the newer antidiabetic drugs (see p. 1039) has not been a problem so far.

**Clinical features**

Features include drowsiness, coma, twitching, convulsions, depressed limb reflexes, extensor plantar responses, hyperpyrexia, pulmonary oedema, tachycardia and circulatory failure. Hypoglycaemia is to be expected, and hypokalaemia, cerebral oedema and metabolic acidosis may occur. Neurogenic diabetes insipidus and persistent vegetative states are possible long-term complications. Cholestatic jaundice has been described as a late complication of chlorpropamide poisoning.

**Treatment**

The blood or plasma glucose concentration should be measured urgently and intravenous glucose given, if necessary. Glucagon may be ineffective, although can reduce the amount of glucose required (see p. 1043). Recurring hypoglycaemia is highly likely. A continuous infusion of glucose (with K+ 10–20 mmol/L) together with carbohydrate-rich meals are required in cases of severe insulin poisoning, though there may be difficulty in maintaining normoglycaemia.

Even if the blood sugar is normal, gastric lavage should only be used if the patient has presented within 1 hour of a very large ingestion of a sulphonylurea. In the case of sulphonylurea poisoning, the administration of glucose only serves to increase already high circulating insulin concentrations. Instead, octreotide 50 μg in adults (1 μg/kg in children) i.v. should be given as it has been shown to be effective in patients developing sulphonylurea-induced hypoglycaemia.

**Antimalariais**

**Chloroquine.** Hypotension is often the first clinical manifestation of chloroquine poisoning. It may progress to acute heart failure, pulmonary oedema and cardiac arrest. Agitation and acute psychosis, convulsions and coma may ensue. Hypokalaemia is common and is due to chloroquine-induced potassium channel blockade. Bradyarrhythmias and tachyarrhythmias are common and ECG conduction abnormalities are similar to those seen in quinine poisoning.

**Quinine.** Cinchonism (tinnitus, deafness, vertigo, nausea, headache and diarrhoea) is common. In more severe poisoning, convulsions, hypotension, pulmonary oedema and cardiorespiratory arrest is seen (due to ventricular arrhythmias which are often preceded by ECG conduction abnormalities, particularly QT prolongation). Quinine cardiotoxicity is due to sodium channel blockade. Patients may also develop ocular features, including blindness, which can be permanent.

**Primaquine.** The main concern regarding primaquine is its propensity to cause methaemoglobinaemia and haemolytic anaemia following overdose.
Management
Gastric lavage or activated charcoal 50–100 g is sometimes used if the patient presents within 1 hour of taking a large dose of drugs. Multiple-dose oral activated charcoal increases quinine and probably chloroquine clearance. Hypokalaemia should be corrected. Sodium bicarbonate 50–100 mmol i.v. is given if the ECG shows intraventricular block but will exacerbate hypokalaemia which should be corrected first. Mechanical ventilation, the administration of an inotrope and high doses of diazepam (1 mg/kg as a loading dose and 0.25–0.4 mg/kg/h maintenance) may reduce the mortality in severe chloroquine poisoning. Overdrive pacing may be required if torsade de pointes (p. 728) occurs in quinine poisoning and does not respond to magnesium sulphate infusion. If clinically significant methaemoglobinemia (generally above 30%) develops in primaquine poisoning, methylthioninium (methylene blue) 1–2 mg/kg body weight should be administered.

β-Adrenoceptor blocking drugs
Clinical features
In mild poisoning sinus bradycardia is the only feature, but if a substantial amount has been ingested, coma, convulsions and hypotension develop. Less commonly delirium, hallucinations and cardiac arrest supervene.

Treatment
Glucagon 50–150 µg/kg (typically 5–10 mg in an adult) followed by an infusion of 1–5 mg/h is the most effective agent. It acts by bypassing the blocked beta-receptor thus activating adenylyl cyclase and promoting formation of cyclic AMP from ATP; cyclic AMP in turn exerts a direct beta-stimulant effect on the heart. Atropine 0.6–1.2 mg i.v. can be used but is usually less effective.

Batteries
Children occasionally ingest disc button batteries, less commonly larger batteries. In the past there was concern that disc batteries might leak and release mercuric oxide but this metal is not used now in Europe. Most disc batteries will pass through the gut in 2 or 3 days. If they lodge in the oesophagus, removal is by endoscopy.

Benzodiazepines
Benzodiazepines are commonly taken in overdose but rarely produce severe poisoning except in the elderly or those with chronic respiratory disease.

Clinical features
Benzodiazepines produce drowsiness, ataxia, dysarthria and nystagmus. Coma and respiratory depression develop in severe intoxication.

Treatment
If respiratory depression is present in patients with severe benzodiazepine poisoning, flumazenil 0.5–1.0 mg i.v. is given in an adult and this dose often needs repeating. Flumazenil is used to avoid ventilation. It is contraindicated in mixed tricyclic antidepressant (TCA)/benzodiazepine poisoning and in those with a history of epilepsy because it may cause convulsions.

Calcium channel blockers
Calcium channel blockers (phenylalkylamines, e.g. verapamil; benzothiazepines, e.g. diltiazem; dihydropyridines, see p. 806) all act by blocking voltage-gated calcium channels. Dihydropyridines (e.g. amlodipine, felodipine, nifedipine) are predominantly peripheral vasodilators while verapamil and, to a lesser extent, diltiazem also have significant cardiac effects. Overdose of these drugs, particularly with verapamil and diltiazem, are serious with heart block and hypotension causing a significant fatality rate.

Clinical features
Hypotension occurs due to peripheral vasodilatation, myocardial depression and conduction block. The electrocardiogram may progress from sinus bradycardia through first, then higher, degrees of block, to asystole. Cardiac and non-cardiac pulmonary oedema may ensue in severely poisoned patients. Other features include nausea, vomiting, seizures and a lactic acidosis. When a sustained-release preparation has been ingested the onset of severe features are delayed, sometimes for more than 12 hours. Overdose with even small amounts can have profound effects.

Treatment
Activated charcoal 50–100 g should be given in an adult to reduce absorption. Treat hypotension initially with intravenous crystalloid. If significant hypotension persists despite volume replacement, administer glucagon (see p. 1043) as it activates myosin kinase independent of calcium. Give i.v. glucagon 10 mg (150 µg/kg) as a slow bolus and repeat every 3–5 minutes. If there is a favourable response in blood pressure, an infusion 5–10 mg/h is commenced; if there is no response after repeated initial boluses, discontinue. Monitor blood glucose.

If hypotension persists despite the above measures, high dose dopamine (10–30 µg/kg/min) is a reasonable choice if hypotension is thought to be mainly due to reduced systemic vascular resistance. Alternatively, adrenaline (epinephrine) 0.1–1.0 µg/kg/min, which has both alpha and beta adrenergic effects, should be administered. Insulin–dextrose euglycaemia has been shown to improve myocardial contractility and systemic perfusion and may be used in addition to sympathomimetic amine therapy. Insulin is given as a bolus dose of 1 U/kg, followed by an infusion of 0.5 U/kg/h with 10% glucose and frequent monitoring of blood glucose and potassium.

Acidosis impairs L-type channel function (see p. 684) and is corrected by the administration of sodium bicarbonate, which has been shown experimentally to improve myocardial contractility and cardiac output.

Intravenous atropine 0.6–1.2 mg in an adult, repeated as required, should be given for bradycardia and heart block. The response to atropine may be improved following parenteral 10% calcium chloride, 5–10 mL (at 1–2 mL/min). The initial dose can be repeated every 3–5 minutes but if there is no response in pulse rate or blood pressure after three such doses it is unlikely that further boluses will be helpful. If there is an initial response to calcium, a continuous infusion may be warranted; this may be given as 10% calcium chloride, 1–10 mL/h. Cardiac pacing may have a role if there is evidence of AV conduction delay but there may be failure to capture.
Cannabis (marijuana)
Cannabis is usually smoked but may be ingested as a ‘cake’, made into a tea or injected intravenously. Apart from alcohol, it is the drug most widely abused in developed countries. The major psychoactive constituent is delta-11-tetrahydrocannabinol (THC). THC possesses activity at the benzodiazepine, opioid and cannabinoid receptors. Street names include pot, grass, ganja, reefs and spiff. It is prepared as marijuana (ganga) from the female flowers; hashish or charas – a concentrated resin of glandular trichomes; kief – chopped female plants; and bhang – a drink prepared from cannabis leaves boiled in milk with spices.

Clinical features
Initially there is euphoria, followed by distorted and height-en ed images, colours and sounds, altered tactile sensations and sinus tachycardia. Visual and auditory hallucinations and acute psychosis are particularly likely to occur after substantial ingestion in naïve cannabis users. Intravenous injection leads to watery diarrhoea, tachycardia, hypotension and arthralgia.

Heavy users suffer impairment of memory and attention and poor academic performance. There is an increased risk of anxiety and depression. Regular users are at risk of dependence. Cannabis use results in an overall increase in the relative risk for later schizophrenia and psychotic episodes (see p. 1216). Cannabis smoke is probably carcinogenic.

Treatment
Reassurance is usually the only treatment required, though sedation with intravenous diazepam 10–20 mg i.v. in an adult or chlorpromazine 50–100 mg i.m. in an adult is sometimes required. Hypotension requires i.v. fluids.

Carbamate insecticides
Carbamate insecticides inhibit acetylcholinesterase but the duration of this effect is comparatively short-lived since the carbamate–enzyme complex tends to dissociate spontaneously. The clinical features are similar to those of organophosphorus insecticide poisoning (see p. 947). Atropine 0.6–2 mg i.v. is required for bradycardia and recovery invariably occurs within 24 hours.

Carbon monoxide
The commonest source of carbon monoxide is an improperly maintained and poor, ventilated heating system. In addition, inhalation of methylene chloride (found in paint strippers) may also lead to carbon monoxide poisoning as methylene chloride is metabolized in vivo to carbon monoxide. The affinity of haemoglobin for carbon monoxide is some 240 times greater than that for oxygen. Carbon monoxide combines with haemoglobin to form carboxyhaemoglobin, thereby reducing the total oxygen carrying capacity of the blood and increasing the affinity of the remaining haem groups for oxygen. This results in tissue hypoxia. In addition, carbon monoxide also inhibits cytochrome oxidase a3.

Clinical features
Symptoms of mild to moderate exposure to carbon monoxide may be mistaken for a viral illness. A peak carboxyhaemoglobin (COHb) concentration of less than 10% is not normally associated with symptoms and peak COHb concentrations of 10–30% result only in headache and mild exertional dyspnoea. Higher concentrations of COHb are associated with coma, convulsions and cardiorespiratory arrest. Neuropsychiatric features occur after apparent recovery from carbon monoxide intoxication.

Treatment
In addition to removing the patient from carbon monoxide exposure, high flow oxygen should be administered using a tightly fitting face mask. Endotracheal intubation and mechanical ventilation is required in those who are unconscious. Several controlled studies of hyperbaric oxygen have now been published but none have shown long-term clinical benefit.

Cocaine
Cocaine hydrochloride (‘street’ cocaine, ‘coke’) is a water-soluble powder or granule that can be taken orally, intrave-nously or intranasally. ‘Freebase’ or ‘crack’ cocaine comprises crystals of relatively pure cocaine without the hydrochloride moiety and is obtained in rocks (150 mg of cocaine). It is more suitable for smoking in a pipe or mixed with tobacco and can also be heated on foil and the vapour inhaled (approximately 35 mg of drug per ‘line’ or a ‘rail’). The ‘effects’ of cocaine are experienced almost immediately with i.v. or smoking routes, about 10 minutes in the intranasal route and 45–90 minutes when taken orally. The effects start resolving in about 20 minutes and may last up to 90 minutes. In severe poisoning, death may occur in minutes but survival beyond 3 hours is not usually fatal. Cocaine blocks the reuptake of biogenic amines. Inhibition of dopamine reuptake is responsible for the psychomotor agitation which commonly accompa-nies cocaine use. Blockade of norepinephrine reuptake produces tachycardia, and inhibition of serotonin reuptake may induce hallucinations. Cocaine also enhances CNS arousal by potentiating the effects of excitatory amino acids. Cocaine is also a powerful local anaesthetic and vasoconstrictor.

Clinical features
After initial euphoria, cocaine produces agitation, tachycar-dia, hypertension, sweating, hallucinations, convulsions, metabolic acidosis, hyperthermia, rhabdomyolysis and ventricular arrhythmias. Dissection of the aorta, myocarditis, myocardial infarction, dilated cardiomyopathy, subarachnoid haemorrhage, and cerebral haemorrhage and infarction also occur. If a young person presents with a stroke or myocardial infarction, cocaine overdosage is a possibility because of its vasoconstrictor effect.

Treatment
Diazepam 10 mg i.v. is used to control agitation and convulsions. Active external cooling should be used for hyperthermia. β-adrenoceptor blockers are contraindicated for the treatment of hypertension as they may cause paradoxical hypertension; phenolamine 2–5 mg i.v. can be used. Early use of a benzodiazepine, aspirin and nitrates is effective in relieving cocaine-associated chest pain. β-adrenoceptor blocking drugs are contraindicated because they may exacerbate cocaine-induced coronary artery vasoconstriction.

Cyanide

Cyanide and its derivatives are used widely in industry. Hydrogen cyanide is also released during the thermal decomposition of polyurethane foams. Cyanide reversibly inhibits cytochrome oxidase, so that cellular respiration ceases.

Clinical features

Inhalation of hydrogen cyanide gas produces symptoms within seconds and death within minutes. By contrast, the ingestion of a cyanide salt may not produce features for 1 hour. After exposure initial symptoms are non-specific and include a feeling of constriction in the chest and dyspnoea. Coma, convulsions and metabolic acidosis may then supervene.

Treatment

Dicobalt edetate (and the free cobalt contained in the preparation) complexes free cyanide. Sodium thiosulphate and hydroxocobalamin enhance endogenous cyanide detoxification mechanisms. Sodium nitrite produces methaemoglobinemia; methaemoglobin combines with cyanide to form cyanmethaemoglobin.

Oxygen should be administered and, if available, dicobalt edetate 300 mg should be administered i.v.; the dose is repeated in severe cases. An alternative but very expensive antidote is hydroxocobalamin 5 g i.v.; a second dose may be required in severe cases. If these two antidotes are not available, sodium nitrite 300 mg i.v. and sodium thiosulphate 12.5 g i.v. should be administered.

Digoxin

Toxicity occurring during chronic administration is common, though acute poisoning is infrequent.

Clinical features

These include nausea, vomiting, dizziness, anorexia and drowsiness. Rarely, confusion, visual disturbances and hallucinations occur. Sinus bradycardia is often marked and may be followed by supraventricular arrhythmias with or without heart block, ventricular premature beats and ventricular tachycardia. Hyperkalaemia occurs due to the inhibition of the sodium-potassium activated ATPase pump.

Treatment

Sinus bradycardia, atrioventricular block and sinoatrial standstill are often reduced or even abolished by atropine 1.2–2.4 mg i.v. If cardiac output is compromised, however, digoxin-specific antibody fragments (digoxin-Fab) should be administered. In both acute and chronic poisoning, only half the estimated dose (calculated from amount of drug taken or serum digoxin concentration) required for full neutralization need be given initially; a further dose may be given if clinically indicated.

Ethanol

Ethanol is commonly ingested in beverages and deliberately with other substances in overdose. It is also present in many cosmetic and antiseptic preparations. Following absorption, ethanol is oxidized to acetaldehyde and then to acetate. Ethanol is a CNS depressant and the features of ethanol intoxication are generally related to blood concentrations (Table 16.19).

Clinical features

In children in particular severe hypoglycaemia may accompany alcohol intoxication due to inhibition of gluconeogenesis. Hypoglycaemia is also observed in those who are malnourished or who have fasted in the previous 24 hours. In severe cases of intoxication, coma and hypothermia are often present and lactic acidosis, ketoadiposis and acute renal failure have been reported.

Treatment

As ethanol-induced hypoglycaemia is not responsive to glu- cocan, i.v. glucose 25 g (50 mL of 50% dextrose) should be given. Haemodialysis is used if the blood ethanol concentration exceeds 7500 mg/L and if a severe metabolic acidosis is present.

Ethylene glycol

Ethylene glycol is a common constituent of antifreeze fluid used in car radiators. Ethylene glycol itself is non-toxic but is metabolized to toxic products (Fig. 16.3).

Clinical features

Initially the features of ethylene glycol poisoning are similar to ethanol intoxication (though there is no ethanol on the breath). Coma and convulsions follow and a variety of neurological abnormalities including nystagmus and oph- thalmoplegias can be seen. Severe metabolic acidosis, hypocalcaemia and the presence of calcium oxalate crystaluria are well recognized complications.

Treatment

If the patient presents early after ingestion, the first priority is to inhibit metabolism using either intravenous ethanol or fomepizole. Secondly, following a substantial ingestion, haemodialysis or haemodialfiltration should be employed to
remove ethylene glycol, its aldehyde metabolites and glycolate. A loading dose of ethanol 50 g should be administered followed by an i.v. infusion of ethanol 10–12 g/h to produce blood ethanol concentrations of 500–1000 mg/L (11–22 mmol/L). The infusion is continued until ethylene glycol is no longer detectable in the blood. If haemodialysis is employed, the rate of ethanol administration will need to be increased to 17–22 g/h as ethanol is dialyzable. Alternatively, fomepizole 15 mg/kg body weight can be administered followed by four 12-hourly doses of 10 mg/kg, then 15 mg/kg every 12 hours until ethylene glycol concentrations are less than 200 mg/L. If dialysis is employed the frequency of fomepizole dosing should be increased to 4-hourly because fomepizole is dialyzable. Supportive measure to combat shock, hypocalcaemia and metabolic acidosis should be instituted.

Gamma-hydroxybutyric acid (GHB)

Gamma-hydroxybutyric acid occurs naturally in mammalian brain where it is derived metabolically from gamma-aminobutyric acid (GABA). GHB has emerged as a major recreational drug for body building, weight loss and for producing a ‘high’. Street names include cherry meth and liquid X. It is taken as a colourless liquid dissolved in water.

Clinical features

Poisoning with GHB is characterized by aggressive behaviour, ataxia, amnesia, vomiting, drowsiness, bradycardia, respiratory depression and apnoea, seizures and coma, which is often short lived.

Management

In a patient who is breathing spontaneously, the management of GHB poisoning is primarily supportive with oxygen supplementation and the administration of atropine for persistent bradycardia, as necessary. Those who are severely poisoned will require mechanical ventilation, though recovery is usually complete within 6–8 hours.

Household products

The agents most commonly involved are bleach, cosmetics, toiletries, detergents, disinfectants and petroleum distillates such as paraffin and white spirit. Ingestion of household products is usually accidental and is most common among children less than 5 years of age. If the ingestion is accidental, features very rarely occur except in the case of petroleum distillates where aspiration is a recognized complication because of their low surface tension. Powder detergents, sterilizing tablets, denture cleaning tablets and industrial bleaches (which contain high concentrations of sodium hypochlorite) are corrosive to the mouth and pharynx if ingested. Nail polish and nail polish remover contain acetone that may produce coma if ingested in substantial quantities. Inhalation by small children of substantial quantities of talcum powder has occasionally given rise to severe pulmonary oedema and death.

Iron

Unless more than 60 mg of elemental iron per kg of body weight is ingested (a ferrous sulphate tablet contains 60 mg of iron), features are unlikely to develop. As a result poisoning is seldom severe but deaths still occur. Iron salts have a direct corrosive effect on the upper gastrointestinal tract.

Clinical features

The initial features are characterized by nausea, vomiting (the vomit may be grey or black in colour), abdominal pain and diarrhoea. Severely poisoned patients develop haematemesis, hypotension, coma and shock at an early stage. Usually, however, most patients only suffer mild gastrointestinal symptoms. A small minority deteriorate 12–48 hours after ingestion and develop shock, metabolic acidosis, acute renal tubular necrosis and hepatocellular necrosis. Rarely, up to 6 weeks after ingestion, strictures due to corrosive damage occur. The serum iron concentration should be measured some 4 hours after ingestion and if the concentration exceeds the predicted normal iron binding capacity (usually more than 5 mg/L [90 μmol/L]), free iron is circulating and treatment with desferrioxamine may be required.

Treatment

The majority of patients ingesting iron do not require desferrioxamine therapy. If a patient develops coma or shock, desferrioxamine should be given without delay in a dose of 15 mg/kg/h i.v. (total amount of infusion not to exceed 80 mg/kg in 24 hours). If the recommended rate of administration is exceeded, or the therapy is continued for several days, adverse effects including pulmonary oedema and ARDS have been reported.

Lead

Exposure to lead occurs occupationally, children may eat lead-painted items in their homes (pica) and the use of lead-containing cosmetics or ‘drugs’ has also resulted in lead poisoning.

Clinical features

Mild intoxication may result in no more than lethargy and occasional abdominal discomfort, though abdominal pain, vomiting, constipation and encephalopathy (seizures, delirium, coma) may develop in more severe cases. Encephalopathy is more common in children than in adults but is now rare in the developed world. Typically, though very rarely,
lead poisoning results in foot drop attributable to peripheral motor neuropathy. A bluish discolouration of the gum margins due to the deposition of lead sulphide is observed occasionally.

The characteristic haematological features include:

- **sideroblastic anaemia**, due to inhibition by lead of several enzymes involved in haem synthesis, including ALA synthetase
- **haemolysis**, which is usually mild, resulting from damage to the red cell membrane
- **punctate basophilia** (or basophilic stippling: the blood film shows red cells with small, round, blue particles), due to aggregates of RNA in immature red cells owing to inhibition by lead of pyrimidine-5-nucleotidase, which normally disperses residual RNA to produce a diffuse blue staining seen in reticulocytes on blood films (polychromasia).

**Treatment**

The social and occupational dimensions of lead poisoning must be recognized. Simply giving children chelation therapy and then returning them to a contaminated home environment is of no value. Similarly, returning a worker to an environment where he was exposed previously and excessively to lead is inappropriate.

The decision to use chelation therapy is based not only on the blood lead concentration but on the presence of symptoms. Parenteral sodium calcium edetate 75 mg/kg/day has been the chelating agent of choice for over 50 years. However, there is accumulating evidence to suggest that oral DMSA 30 mg/kg/day is of similar efficacy.

**Lithium**

Lithium toxicity is usually the result of therapeutic overdosage (chronic toxicity) rather than deliberate self-poisoning (acute toxicity). However, single large doses are occasionally ingested by individuals on long-term treatment with the drug (acute on therapeutic toxicity).

**Clinical features**

Features of intoxication include thirst, polyuria, diarrhoea and vomiting and in more serious cases impairment of consciousness, hypotonia and convulsions; irreversible neurological damage may occur. Measurement of the serum lithium concentration confirms the diagnosis. Therapeutic toxicity is usually associated with concentrations above 1.5 mmol/L (10.4 mg/L). Acute massive overdose may produce concentrations of 5 mmol/L (34.7 mg/L) without causing toxic features.

**Treatment**

Forced diuresis with sodium chloride 0.9% is effective in increasing elimination of lithium, though haemodialysis is far superior and should be undertaken particularly if neurological features are present, if renal function is impaired and if chronic toxicity or acute on chronic toxicity are the modes of presentation.

**Mercury**

Mercury is the only metal that is liquid at room temperature. It exists in three oxidation states, (elemental/metallic Hg°, mercurous Hg²⁻ and mercuric Hg³⁺) and can form inorganic (e.g. mercuric chloride) and organic (e.g. methylmercury) compounds. Metallic mercury is very volatile and when spilled has a large surface area so that high atmospheric concentrations may be produced in enclosed spaces, particularly when environmental temperatures are high. Thus, great care should be taken in clearing up a spillage of mercury if a thermometer or sphygmomanometer is broken. If ingested, metallic mercury will usually be eliminated per rectum, though small amounts may be found in the appendix. Mercury salts are well absorbed following ingestion as are organometallic compounds where mercury is covalently bound to carbon.

**Clinical features**

Inhalation of acute mercury vapour causes headache, nausea, cough, chest pain, bronchitis and occasionally pneumonia. Proteinuria and nephrotic syndrome are observed rarely. In addition a fine tremor and neurobehavioural impairment occurs and peripheral nerve involvement has also been observed. Ingestion of inorganic and organic mercury compounds causes an irritant gastroenteritis with corrosive ulceration, bloody diarrhoea and abdominal cramps and may lead to circulatory collapse and shock. Mercurous compounds are less corrosive and toxic than mercuric salts.

**Treatment**

Dimercaptopropanesulphonate (DMPS) is the antidote of choice and is given orally in a dose of 30 mg/kg per day. At least 5 days’ treatment is usually required.

**Methanol**

Methanol is used widely as a solvent and is found in anti-freeze solutions. Methanol is metabolized to formaldehyde and formate (Fig. 16.4). The concentration of formate increases greatly and is accompanied by accumulation of hydrogen ions causing metabolic acidosis.

**Clinical features**

Methanol causes inebriation and drowsiness. After a latent period coma supervenes. Blurred vision and diminished visual acuity occur. The presence of dilated pupils that are unreactive to light suggests that permanent blindness is likely to ensue. A severe metabolic acidosis may develop and be accompanied by hyperglycaemia and a raised serum amylase activity. A blood methanol concentration of 500 mg/L (15.63 mmol/L) confirms serious poisoning. The mortality correlates well with the severity and duration of metabolic acidosis. Survivors may show permanent neuro-
logical sequelae including parkinsonian-like signs as well as blindness.

**Treatment**

Treatment is similar to that of ethylene glycol poisoning (see p. 943). Metabolic acidosis should be corrected, methanol metabolism should be inhibited by the administration of ethanol or fomepizole, and haemodialysis is used to remove high circulating methanol concentrations. Folic acid 30 mg i.v. 6-hourly may protect against ocular toxicity by accelerating formate metabolism.

**Monoamine oxidase inhibitors**

These are now used less frequently in the treatment of depression because of the dangers of dietary and drug interactions. Hence, poisoning with them is correspondingly uncommon. Clinical features after overdose may be delayed for 12–24 hours. They include excitement, restlessness, hyperpyrexia, hyper-reflexia, convulsions, opisthotonos, rhabdomyolysis and coma. Sinus tachycardia and either hypo- or hypertension have also been observed.

Treatment is supportive with control of convulsions and marked excitement; diazepam 10–20 mg i.v. in an adult should be given as necessary and repeated. Dantrolene 1 mg/kg i.v. should be administered if hyperpyrexia develops. Hypotension should be treated with plasma expansion and hypertension by the administration of an α-adrenoceptor blocker such as chlorpromazine.

**Nerve agents**

Nerve agents are related chemically to organophosphorus insecticides and have a similar mechanism of toxicity, but a much higher mammalian acute toxicity, particularly via the dermal route. Two classes of nerve agent are recognized: G agents (named for Gerhardt Schrader who synthesized the first agents) and V agents (V allegedly stands for venomous). G agents include tabun, sarin, soman and cyclosarin. The V agents were introduced later, e.g. VX. The G agents are both dermal and respiratory hazards, whereas the V agents, unless aerosolized, are contact poisons.

Agents used in bioterrorism are described on page 959.

**Clinical features**

Systemic features include increased salivation and rhinorhoea, miosis and eye pain, abdominal pain, nausea, vomiting and diarrhoea; involuntary micturition and defecation; muscle weakness and fasciculation, tremor, restlessness, ataxia and convulsions. Bradycardia, tachycardia and hypotension occur, dependent on whether muscarinic or nicotinic effects predominate. Death occurs from respiratory failure within minutes but mild or moderately exposed individuals usually recover completely.

**Treatment**

The parenteral administration of atropine 2 mg i.v. to patients presenting with rhinorhoea and bronchorrhoea may be lifesaving. In addition, an oxime (pralidoxime, obidoxime or HI-6) should be given by slow i.v. injection; for example pralidoxime mesilate 30 mg/kg; the dose may be repeated 4- to 6-hourly. Outside hospital, atropine and oxime can be administered most conveniently by the use of an autoinjeter. After admission, bolus doses of atropine and an infusion of an oxime (e.g. pralidoxime mesilate 8–10 mg/kg/h) should be given. Intravenous diazepam (adult 10–20 mg; child 1–5 mg) is useful in controlling apprehension, agitation, fasciculation and convulsions; the dose is repeated as required.

**Neuroleptics and atypical neuroleptics**

Neuroleptic (antipsychotic) drugs are thought to act predominantly by effects on dopamine D₂ receptors. Older neuroleptics include the phenothiazines, the butyrophenones and the substituted benzamides. More recently more selective ‘atypical’ antipsychotic drugs have been developed, including amisulpride, aripiprazole, clozapine, olanzapine, quetiapine and risperidone.

**Clinical features**

These include impaired consciousness, hypotension, respiratory depression, hyperthermia or hyperthermia, antimuscarinic effects such as tachycardia, dry mouth and blurred vision, occasionally seizures, rhabdomyolysis, cardiac arrhythmias (both atrial and ventricular) and acute respiratory distress syndrome. Extrapyramidal effects, including acute dystonic reactions, occur but are not dose related. Most ‘atypical’ antipsychotics have less profound sedative actions than the older neuroleptics. Q–T interval prolongation and subsequent ventricular arrhythmias (including torsades de pointes) have occurred following overdose with the atypical neuroleptics. Unpredictable fluctuations in conscious level, with variations between agitation and marked somnolence, have been particularly associated with olanzapine overdose.

**Treatment**

Gastric lavage or the administration of oral activated charcoal 50–100 g is used in an adult who presents within 1 hour of a substantial overdose. Benztropine 2 mg i.v. in an adult is occasionally required for the treatment of dyskinesia and oculogyric crisis. If hypotension is severe and does not respond to intravenous fluids, a sympathomimetic amine such as noradrenaline (norepinephrine) may be required. After correcting acidosis with sodium bicarbonate, the preferred treatment for arrhythmias caused by antipsychotic drugs (usually torsade de pointes) is intravenous magnesium or cardiac pacing. Lidocaine or phenytoin may be effective if multifocal ventricular arrhythmias occur.

**Non-steroidal anti-inflammatory agents (NSAIDs)**

Self-poisoning with NSAIDs has increased, particularly now that ibuprofen is available without prescription in many countries.

**Clinical features**

In most cases minor gastrointestinal disturbance is the only feature but, in more severe cases, coma, convulsions and renal failure have occurred. Poisoning with mefenamic acid commonly results in convulsions though these are usually short-lived.

*Treatment* is symptomatic and supportive.
Opiates and opioids
Cardinal signs of opiate poisoning are pinpoint pupils, reduced respiratory rate and coma. Hypothermia, hypoglycaemia and convulsions are occasionally observed in severe cases. In severe heroin overdose, non-cardiogenic pulmonary oedema has been reported.

Treatment. Naloxone 1.2 mg i.v. in an adult (5–10 µg body weight in a child) will reverse severe respiratory depression and coma at least partially. In severe poisoning larger initial doses or repeat doses will be required. The duration of action of naloxone is often less than the drug taken in overdose, e.g. methadone, which has a very long half-life. For this reason an infusion of naloxone is often required. Non-cardiogenic pulmonary oedema should be treated with mechanical ventilation.

Organophosphorus insecticides
Organophosphorus insecticides are used widely throughout the world and are a common cause of poisoning, causing thousands of deaths, in the developing world. Intoxication may follow ingestion, inhalation or dermal absorption. Organophosphorus insecticides inhibit acetylcholinesterase causing accumulation of acetylcholine at central and peripheral cholinergic nerve endings, including neuromuscular junctions. Many OP insecticides require biotransformation before becoming active and so the features of intoxication may be delayed.

Clinical features
Poisoning is characterized by anxiety, restlessness, tiredness, headache, and muscarinic features such as nausea, vomiting, abdominal colic, diarrhoea, tenesmus, sweating, hypersalivation and chest tightness. Miosis may be present. Nicotinic effects include muscle fasciculation and flaccid paresis of limb muscles, respiratory muscles, and, occasionally of extraocular muscles. Respiratory failure will ensue in severe cases and is exacerbated by the development of bronchospasm and pulmonary oedema. Coma and convulsions occur in severe poisoning. Diagnosis is confirmed by measuring the erythrocyte cholinesterase activity; plasma cholinesterase activity is less specific but may also be depressed.

The intermediate syndrome usually becomes established 2–4 days after exposure when the symptoms and signs of the acute cholinergic syndrome are no longer obvious. The characteristic features of the syndrome are weakness of the muscles of respiration (diaphragm, intercostal muscles and accessory muscles including neck muscles) and of proximal limb muscles. Accompanying features often include weakness of muscles innervated by some cranial nerves.

Treatment
Mild cases require no specific treatment other then the removal of soiled clothing; contaminated skin should be washed with soap and water to prevent further absorption. Atropine 2 mg i.v. should be given to reduce bronchospasm. In addition, an oxime (e.g. pralidoxime mesilate 30 mg/kg by slow i.v. injection 4-hourly or an infusion of pralidoxime mesilate 8–10 mg/kg/h), which reactivates phosphorylated acetylcholinesterase, should be given in symptomatic patients where the diagnosis has been confirmed.

Paracetamol (acetaminophen)
Paracetamol is the most common form of poisoning encountered in the UK. In therapeutic dose, paracetamol is conjugated with glucuronide and sulphate. A small amount of paracetamol is metabolized by mixed function oxidase enzymes to form a highly reactive compound (N-acetyl-p-benzoquinoneimine, NAPQI), which is then immediately conjugated with glutathione and subsequently excreted as cysteine and mercapturic conjugates. In overdose, large amounts of paracetamol are metabolized by oxidation because of saturation of the sulphate conjugation pathway. Liver glutathione stores become depleted so that the liver is unable to deactivate the toxic metabolite. Paracetamol-induced renal damage probably results from a mechanism similar to that which is responsible for hepatotoxicity.

The severity of paracetamol poisoning is dose related. There is, however, some variation in individual susceptibility to paracetamol-induced hepatotoxicity. Patients with pre-existing liver disease, those with a high alcohol intake and poor nutrition, those receiving enzyme-inducing drugs, those suffering from anorexia nervosa and other eating disorders and HIV infection should be considered to be at greater risk and given treatment at plasma paracetamol concentrations lower than those normally used for interpretation (Fig. 16.5).

Clinical features
Following the ingestion of an overdose of paracetamol, patients usually remain asymptomatic for the first 24 hours or at the most develop anorexia, nausea and vomiting. Liver damage is not usually detectable by routine liver function tests until at least 18 hours after ingestion of the drug. Liver damage usually reaches a peak, as assessed by measurement of alanine transferase (ALT) activity and prothrombin time (INR), at 72–96 hours after ingestion. Without treatment, a small percentage of patients will develop fulminant hepatic

---

**Fig. 16.5** Nomogram of paracetamol. For definition of 'high-risk patients', see text.
failure. Renal failure due to acute tubular necrosis occurs in 25% of patients with severe hepatic damage and in a few without evidence of serious disturbance of liver function.

**Treatment**

The treatment protocol is dependent on the time of presentation and is summarized in Table 16.20. N-acetylcysteine (NAC) has emerged as an effective protective agent provided that it is administered within 8–10 hours of ingestion of the overdose. NAC acts by replenishing cellular glutathione stores, though it may also repair oxidation damage caused by NAPQI. The treatment regimen is shown in Table 16.21.

Up to 10% of patients treated with intravenous NAC (20.25 h regimen) develop rash, angio-oedema, hypotension and bronchospasm. These reactions, which are related to the initial bolus, are seldom serious and discontinuing the infusion is usually all that is required. In more severe cases, chlorphenamine 10–20 mg i.v. in an adult should be given.

If liver or renal failure ensues, this should be treated conventionally though there is evidence that a continuing infusion of NAC (continue 16-h infusion until recovery) will improve the morbidity and mortality. Liver transplantation has been performed successfully in patients with paracetamol-induced fulminant hepatic failure (see p. 342).

**Phosphides**

Aluminium and zinc phosphides are used as rodenticides and insecticides. They react with moisture in the air (and the gastrointestinal tract) to produce phosgene, the active pesticide. Acute poisoning with these compounds may be direct, due to ingestion of the salts, or indirect from accidental inhalation of phosgene generated during their approved use. Both forms of poisoning are mediated by phosgene which inhibits cytochrome c oxidase.

**Clinical features**

Ingestion causes vomiting, epigastric pain, peripheral circulatory failure, severe metabolic acidosis, renal failure and disseminated intravascular coagulation, in addition to the features induced by phosgene. Exposure to phosgene causes lacrimation, rhinorrhea, productive cough, breathlessness, chest tightness, dizziness, headache, nausea and drowsiness. Acute pulmonary oedema, hypertension, cardiac arrhythmias, convulsions and jaundice have been described in severe cases. Ataxia, intention tremor and diplopia are found on examination.

**Treatment**

Treatment is symptomatic and supportive. Gastric lavage should be avoided as it might increase the rate of disintegration of the product ingested and increase toxicity. Activated charcoal may bind metal phosphides. The mortality is very high despite supportive care.

**Salicylates**

Aspirin is metabolized to salicylic acid (salicylate) by esterases present in many tissues, especially the liver, and subsequently to salicylic acid and salicylic phenolic glucuronide (Fig. 16.6); these two pathways become saturated with the consequence that the renal excretion of salicylic acid increases after overdose; this excretion pathway is extremely sensitive to changes in urinary pH.

### Table 16.20 Management of patients with paracetamol poisoning

<table>
<thead>
<tr>
<th>Time after ingestion</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>≤8 hours after ingestion</td>
<td>Take blood for urgent estimation of the plasma paracetamol concentration as soon as 4 hours or more have elapsed since ingestion. Check INR, plasma creatinine and alanine transferase (ALT) activity. Assess whether the patient is at increased risk of liver damage. Give treatment if needed (Fig. 16.5) If the plasma paracetamol concentration is not available within 8 hours of the overdose and, if &gt;150 mg/kg paracetamol has been ingested, treatment should be started at once and stopped if the plasma paracetamol concentration subsequently indicates that treatment is not required. Check INR, plasma creatinine and ALT activity on the completion of treatment and before discharge.</td>
</tr>
<tr>
<td>8–15 hours after ingestion</td>
<td>Urgent action is required because the efficacy of treatment declines progressively from 8 hours after overdose. If &gt;150 mg/kg paracetamol has been ingested, start treatment immediately. Take blood for urgent estimation of the plasma paracetamol concentration, INR, plasma creatinine and ALT activity. Assess whether the patient is at increased risk of liver damage. The need for treatment should be determined by using Fig. 16.5. In patients already receiving treatment, only discontinue if the plasma paracetamol concentration is below the relevant treatment line (Fig. 16.5) and there is no abnormality of the INR, plasma creatinine or ALT activity and the patient is asymptomatic. Do not discontinue the infusion if there is any doubt as to the timing of the overdose. At the end of treatment, measure INR, plasma creatinine and ALT activity. If any test is abnormal or the patient is symptomatic, further monitoring is required and expert advice should be sought. Patients with normal INR, plasma creatinine and ALT activity and who are asymptomatic may be discharged.</td>
</tr>
<tr>
<td>15–24 hours after ingestion</td>
<td>Urgent action is required because the efficacy of treatment is limited more than 15 hours after overdose. Start treatment immediately if &gt;150 mg/kg paracetamol has been ingested. In all patients, take blood for urgent estimation of the plasma paracetamol concentration, INR, plasma creatinine and ALT activity. Assess whether the patient is at increased risk of liver damage. Give treatment if needed (Fig. 16.5). The prognostic accuracy of the ‘200 mg/L line’ after 15 hours is uncertain but a plasma paracetamol concentration above the extended treatment line should be regarded as carrying serious risk of severe liver damage. At the end of treatment, check INR, plasma creatinine and ALT activity. If any test is abnormal or the patient is symptomatic, further monitoring is required and expert advice should be sought.</td>
</tr>

**Further Reading**

Clinical features
Salicylates stimulate the respiratory centre, increase the depth and rate of ventilation, and induce a respiratory alkalosis. Compensatory mechanisms, including renal excretion of bicarbonate and potassium, result in a metabolic acidosis. Salicylates also interfere with carbohydrate, fat, and protein metabolism, disrupt oxidative phosphorylation, producing increased concentrations of lactate, pyruvate and ketone bodies, all of which contribute to the acidosis.

Thus, tachypnoea, sweating, vomiting, epigastric pain, tinnitus and deafness develop. Respiratory alkalosis and metabolic acidosis supervene and a mixed acid–base disturbance is observed commonly. Rarely, in severe poisoning, non-cardiogenic pulmonary oedema, coma and convulsions ensue.

Treatment
Fluid and electrolyte replacement is required and special attention should be paid to potassium supplementation. Severe metabolic acidosis requires at least partial correction with the administration of sodium bicarbonate intravenously. Mild cases of salicylate poisoning are managed with parenteral fluid and electrolyte replacement only. Patients whose plasma salicylate concentrations are in excess of 500 mg/L (3.62 mmol/L) should receive urine alkalinization (see p. 938). Haemodialysis is the treatment of choice for severely poisoned patients (plasma salicylate concentration >700 mg/L (>5.07 mmol/L)), particularly those with coma and metabolic acidosis.

Selective serotonin reuptake inhibitors (SSRIs)
Citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline are antidepressants that inhibit serotonin reuptake. They lack the antimuscarinic actions of tricyclic antidepressants.

Clinical features
Even large overdoses appear to be relatively safe unless potentiated by ethanol. Most patients will show no signs of toxicity but drowsiness, nausea, diarrhea and sinus tachycardia have been reported. Rarely, junctional bradycardia, seizures and hypertension have been encountered and influenza-like symptoms may develop.

Treatment
Supportive measures are all that are required.

Theophylline
Poisoning may complicate therapeutic use as well as being the result of deliberate self-poisoning. If a slow-release preparation is involved, peak plasma concentrations are not attained until 6–12 hours after overdosage and the onset of toxic features is correspondingly delayed.

Clinical features
Nausea, vomiting, hyperventilation, haematemesis, abdominal pain, diarrhoea, sinus tachycardia, supraventricular and ventricular arrhythmias, hypotension, restlessness, irritability, headache, hyperreflexia, tremors and convulsions have been observed. Hypokalaemia probably results from activation of Na’K’ ATPase. A mixed acid–base disturbance is common. Most symptomatic patients have plasma theophylline concentrations in excess of 25 mg/L (430 µmol/L). Convulsions are seen more commonly when concentrations are >50 mg/L (>860 µmol/L). Plasma potassium concentrations of <2.6 mmol/L, metabolic acidosis, hypotension, seizures and arrhythmias are indications of severe poisoning.

Treatment
There is good evidence that multiple-dose (12.5 g/h) activated charcoal enhances the elimination of theophylline. However, protracted theophylline-induced vomiting may mitigate the benefit of this therapy, unless vomiting is suppressed by a 5HT3 antagonist such as ondansetron 8 mg i.v. in an adult. Correction of hypokalaemia to prevent or treat tachyarrhythmias is of great importance. A non-selective β-adrenoceptor blocking drug, such as propranolol, is also useful in the treatment of tachyarrhythmias secondary to hypokalaemia, but should not be given if the patient has severe airways disease. Convulsions should be treated with diazepam 10–20 mg i.v. in an adult.

Tricyclic antidepressants
Tricyclic antidepressants block the reuptake of norepinephrine into peripheral and intracerebral neurones thereby increasing the concentration of monoamines in these areas. These drugs also have antimuscarinic actions and class 1 antiarrhythmic (quinidine-like) activity.

Clinical features
Features of poisoning usually appear within 60 minutes after ingestion. Drowsiness, sinus tachycardia, dry mouth, dilated pupils, urinary retention, increased reflexes and extensor plantar responses are the most common features of mild poisoning. Severe intoxication leads to coma, often with divergent strabismus and convulsions. Plantar, oculocephalic and oculovestibular reflexes may be abolished temporarily. An ECG will often show a wide QRS interval and there is a reasonable correlation between the width of the QRS complex and the severity of poisoning. Metabolic acidosis and cardiorespiratory depression are observed in severe cases.

Treatment
The majority of patients recover with supportive therapy alone (adequate oxygenation, control of convulsions and cor-
rejection of acidosis), though a small percentage of patients will require mechanical ventilation for 24–48 hours. The onset of supraventricular tachycardia and ventricular tachycardia should be treated with sodium bicarbonate (8.4%) 50 mmol intravenously over 20 minutes, even if there is no acidosis present. If ventricular tachycardia is compromising cardiac output, lidocaine 50–100 mg i.v. should be administered in an adult.

SPECIFIC POISONS: MARINE ANIMALS

Ciguatera fish poisoning

Over 400 fish species have been reported as ciguatoxic (Cigu is Spanish for poisonous snail), though barracuda, red snapper, amberjack and grouper are most commonly implicated. Ciguatera fish contain ciguatoxin, maitotoxin and scaritoxin, which are lipid-soluble, heat-stable compounds that are derived from dinoflagellates such as Gambierdiscus toxicus. Ciguatoxin opens voltage-sensitive sodium channels at the neuromuscular junction and maitotoxin opens calcium channels of the cell plasma membrane.

Clinical features

The onset of symptoms occurs from a few minutes to 30 hours after ingestion of toxic fish. Typically features appear between 1 and 6 hours and include abdominal cramps, nausea, vomiting and watery diarrhea. In some cases, numbness and paraesthesia of the lips, tongue and throat occur. Other features described include malaise, dry mouth, metallic taste, myalgia, arthralgia, blurred vision, photophobia and transient blindness. In more severe cases, hypotension, cranial nerve palsies and respiratory paralysis have been reported. The mortality in severe cases may be as high as 12%. Recovery takes from 48 hours to one week in the mild form and from one to several weeks in the severe form.

Treatment

Treatment is symptomatic, although in a few patients atropine has lessened some of the cardiovascular and gastrointestinal manifestations.

Paralytic shell fish poisoning

This is uncommon and is caused by bivalve molluscs being contaminated with neurotoxins, including saxitoxin, produced by the toxic dinoflagellates Gonyaulax catenella and Gonyaulax tamarensis. Saxitoxin blocks voltage-gated sodium channels in nerve and muscle cell membranes, blocking nerve signal transmission.

Clinical features

Symptoms develop within 30 minutes of ingestion. The illness is characterized by paraesthesia of the mouth, lips, face and extremities and is often accompanied by nausea, vomiting and diarrhea. In more severe cases, dysphonia, dysphagia, muscle weakness, paralysis, ataxia and respiratory depression occur.

Treatment

Treatment is symptomatic and supportive.

Scombroid fish poisoning

This is due to the action of bacteria such as Proteus morganii and Klebsiella pneumoniae in decomposing the flesh of fish such as tuna, mackerel, mahi-mahi, bonito and skipjack if the fish are stored at insufficiently low temperatures. The spoiled fish can contain excessively high concentrations of histamine (muscle histidine is broken down by the bacteria to histamine), though the precise role of histamine in the pathogenesis of the clinical syndrome is uncertain.

Clinically the mean incubation period is 30 minutes. The illness is characterized by flushing, headache, sweating, dizziness, burning of the mouth and throat, abdominal cramps, nausea, vomiting and diarrhea and is usually short lived; the mean duration is 4 hours.

Treatment is symptomatic and supportive. Antihistamines may alleviate the symptoms.

Stings from marine animals

Several species of fish have venomous spines in their fins. These include the weaver fish, short-spine cottus, spiny dogfish and the stingray. Bathers and fishermen may be stung if they tread on or handle these species.

The immediate result of a sting is intense local pain, swelling, bruising, blistering, necrosis and, if the poisoned spine is not removed, chronic sepsis (though this is uncommon). Occasionally systemic symptoms including, vomiting, diarrhea, hypotension and tachycardia occur.

Treatment by immersing the affected part in hot water may relieve local symptoms as this denatures the thermolabile toxin.

Jellyfish

Most of the jellyfish found in North European coastal waters are non-toxic as their stings cannot penetrate human skin. A notable exception is the ‘Portuguese man-o’-war’ (Physalia physalis) whose sting contains a toxic peptide, phospholipase A, and a histamine-liberating factor. Toxic jellyfish are found more frequently in Australia and some cause the Irukandji syndrome.

Clinical features

Local pain occurs followed by malaise, and may be accompanied by nausea, vomiting and diarrhea, muscle cramps in all four limbs, the abdomen and chest, sweating, anxiety, restlessness, nausea, vomiting, headache, palpitations, tachycardia, and toxic global heart dilatation.

Treatment

Adhesive tape may be used to remove any tentacles still adherent to the bather. Local application of 5% acetic acid is said to prevent stinging cells adherent to the skin discharging. Local analgesia and antihistamine creams provide symptomatic relief. Other features should be treated symptomatically and supportively.
SPECIFIC POISONS: VENOMOUS ANIMALS

Insect stings and bites

Insect stings from wasps and bees, and bites from ants, produce pain and swelling at the puncture site. Following the sting or bite, patients should be observed for 2 hours for any signs of evolving urticaria, pruritus, bronchospasm or oropharyngeal oedema. The onset of anaphylaxis requires urgent treatment (see p. 73).

Scorpions

Scorpion stings are a serious problem in North Africa, the Middle East and the Americas. Scorpion venoms stimulate the release of acetylcholine and catecholamines causing both cholinergic and adrenergic symptoms.

Severe pain occurs immediately at the site of puncture, followed by swelling. Signs of systemic involvement, which may be delayed for 24 hours, include vomiting, sweating, piloerection, abdominal colic, diarrhoea. In some cases, depending on the species, shock, respiratory depression and pulmonary oedema may develop.

*Treatment* by local infiltration with anaesthetic or a ring block will usually alleviate local pain, though systemic analgesia may be required. Specific antivenom, if available, should be administered as soon possible.

Spiders

The black widow spider (*Latrodectus mactans*) is found in North America and the tropics and occasionally in Mediterranean countries.

The bite quickly becomes painful and generalized muscle pain, sweating, headache and shock may occur.

No systemic treatment is required except in cases of severe systemic toxicity, when specific antivenom should be given, if this is available.

Venomous snakes

Approximately 15% of the 3000 species of snake found world-wide are considered to be dangerous to humans. Snake bite is common in some tropical countries. For example, in Sri Lanka there are some 6 bites per 100000 population and 900 deaths per year. In Nigeria there are some 500 bites per 100000 population with a 12% mortality. In Myanmar there are 15 deaths per 100000 population from snake bites. In the USA (population 301 million) there are some 45000 bites per year, 8000 of which are by venomous species, with some six deaths annually. In the UK (population 60 million) approximately 100 people are admitted to hospital annually but no deaths have occurred since 1970. In Australia (population 20 million) there are two or three deaths annually.

There are three main groups of venomous snakes, representing some 200 species, which have in their upper jaws a pair of enlarged teeth (fangs) that inject venom into the tissues of their victim. These are Viperidae (with two subgroups: Viperinae – European adders and Russell’s vipers; and Crotalinae – American rattlesnakes, moccasins, lance-headed vipers and Asian pit vipers), Elapidae (cobras, kraits, mambas, coral snakes, Australian venomous snakes) and Hydrophiidae (sea snakes). In addition, some members of the family Colubridae are mildly venomous (mongoose snake).

Clinical features

**Viperidae (Viperinae and Crotalinae)**

Russell’s viper causes most of the snake-bite mortality in India, Pakistan and Burma. There is local swelling at the site of the bite (Fig. 16.7) which may become massive. Local tissue necrosis may occur, particularly with cobra bites. Evidence of systemic involvement occurs within 30 minutes, including vomiting, evidence of shock and hypotension. Haemorrhage due to incoagulable blood can be fatal.

**Elapidae**

There is not usually any swelling at the site of the bite, except with Asian cobras and African spitting cobras – here the bite is painful and is followed by local tissue necrosis. Vomiting occurs first followed by shock and then neurological symptoms and muscle weakness, with paralysis of the respiratory muscles in severe cases. Cardiac muscle can be involved.

**Hydrophiidae**

Systemic features are muscle involvement, myalgia and myoglobinuria, which can lead to acute renal failure. Cardiac and respiratory paralysis may occur.

Management

As a first aid measure, a firm pressure bandage should be placed over the bite and the limb immobilized. This may delay the spread of the venom. Arterial tourniquets should not be used, and incision or excision of the bite area should not be performed. Local wounds often require little treatment. If necrosis is present, antibiotics should be given. Skin grafting may be required later. Antitetanus prophylaxis must be given. The type of snake should be identified if possible.

In about 50% of cases no venom has been injected by the bite. Nevertheless, careful observation for 12–24 hours is necessary in case systemic features (envenomation) develop. General supportive measures should be given, as necessary. These include intravenous fluids with volume expanders for hypotension and diazepam for anxiety. Treatment of acute respiratory, cardiac and renal failure is instituted as necessary.

Antivenoms are not generally indicated unless envenomation is present, as they can cause severe allergic reactions. Antivenoms can rapidly neutralize venom, but only if an amount in excess of the amount of venom is given. Large quantities of antivenom may be required. As antivenoms cannot reverse the effects of the venom, they must be given early to minimize some of the local effects and may prevent necrosis at the site of the bite. Antivenoms should be administered intravenously by slow infusion, the same dose being given to children and adults.
Allergic reactions are frequent, and adrenaline (epinephrine) 1 in 1000 solution should be available. In severe cases, the antivenom infusion should be continued even if an allergic reaction occurs, with subcutaneous injections of adrenaline being given as necessary. Some forms of neurotoxicity, such as those induced by the death adder, respond to anticholinesterase therapy with neostigmine and atropine.

**SPECIFIC POISONS: PLANTS**

Many plants are known to be poisonous, but it is unusual for severe poisoning to occur. In some regions of the world, however, plant poisonings cause substantial morbidity and mortality. While deaths do occur after unintentional poisoning with plants such as *Atractylis gummifera* (bird-lime or blue thistle) and *Blighia sapida* (ackee tree), the majority of deaths globally occur following intentional self-poisoning with plants such as *Thevetia peruviana* (yellow oleander).

**Atropa belladonna**

*Atropa belladonna* (deadly nightshade) contains hyoscyamine and atropine and causes antimuscarinic effects – a dry mouth, nausea and vomiting – leading to blurred vision, hallucinations, confusion and hyperpyrexia.

**Cicuta species**

*Cicuta* spp. (water hemlock) and the related genus *Oenanthe* contain cicutoxin, a potent central nervous system (CNS) stimulant that produces violent seizure activity. The CNS effects of cicutoxin are similar to those of picrotoxin, a known inhibitor of GABA. Severe gastrointestinal symptoms, diaphoresis, salivation and skeletal muscle stimulation may precede the seizure activity.

**Conium maculatum**

*Conium maculatum* (poison hemlock) contains a variety of volatile pyridine alkaloids, including conine, N-methylconine and gamma-coniceine. Coniceine is significantly more toxic than conine and is thought to be the precursor to conine. The toxic activity of the alkaloids is similar to that of nicotine. Large doses produce non-polarizing neuromuscular blockade which may result in respiratory depression and death.

**Datura stramonium**

*Datura stramonium* (jimsonweed) and other *Datura* species contain l-hyoscyamine and atropine. These alkaloids are potent antagonists of acetylcholine at muscarinic receptors and produce the anticholinergic syndrome. While morbidity is significant, fatalities are rare and are the consequence of hyperthermia, seizures and/or arrhythmias.

**Digitalis purpurea, Nerium oleander, Thevetia peruviana**

Ingestion of *Digitalis purpurea*, or the common (*Nerium oleander*) or yellow (*Thevetia peruviana*) oleander can produce a syndrome similar to digoxin poisoning. A randomized controlled trial has shown that digoxin-specific antibody fragments rapidly and safely reverse yellow oleander-induced arrhythmias, restore sinus rhythm, and rapidly reverse bradycardia and hypokalaemia. The administration of multiple doses of activated charcoal is used, but the effect on survival is debated.

**SPECIFIC POISONS: MUSHROOMS**

Most mushrooms and edible fungi are not poisonous, but transient nausea, vomiting and diarrhea can occur after ingestion of some varieties. There are a few species which are toxic.

**Amanita muscaria, Amanita pantherina**

*Amanita muscaria* (fly agaric) and *Amanita pantherina* (false blusher) contain isoxazoles (γ-aminobutyric acid agonists) which cause inebriation, visual disturbances, hallucinations, myoclonic jerks, muscle fasciculation, convulsions and coma. Treatment is supportive.

**Amanita phalloides**

*Amanita phalloides* (death cap mushroom) contains amatoxins which inhibit transcription from DNA to mRNA by blockade of nuclear RNA polymerase II, resulting in impaired protein synthesis and cell death. Amatoxins are not inactivated by cooking. Hepatocellular necrosis follows 72 hours after ingestion and some varieties cause renal failure. Haemodialysis or liver/renal transplantation may be necessary. The value of silibinin and N-acetylcysteine is unproven.

**Coprinus atramentarius**

*Coprinus atramentarius* (ink cap) contains coprin, an acetaldehyde dehydrogenase inhibitor with a disulfiram-like effect, causing flushing and rash. Treatment is supportive.

**Cortinarius orellanus, Cortinarius speciosissimus**

*Cortinarius orellanus* and *Cortinarius speciosissimus* contain orellanin, a potent nephrotoxin. Renal function may recover only partially.

**‘Magic’ mushrooms**

‘Magic’ mushrooms, such as *Psilocybe*, *Panaeolus*, *Conocybe*, *Gymnopilus*, *Stropharia*, *Pluteus* and *Panaeolina* spp., contain the hallucinogen, psilocybin. Treatment is supportive.

Environmental medicine

DISEASE AND THE ENVIRONMENT

The incidence and prevalence of disease and causes of death within a community are a reflection of interrelated factors:

- Genetic predisposition.
- Nutrition, wealth and poverty.
- Purity of water sources, sanitation and atmospheric pollution.
- Environmental disasters and accidents.
- Background ionizing radiation and man-made radiation exposure, deliberate or accidental.
- Environmental temperature.
- Patterns of infective disease.
- Political forces determining levels of healthcare, preventative strategies and effects of war on civilian populations.

Some of these environmental effects have been clearly documented within the last decade, for example the civilian mortality during the current Iraq War, and loss of life and disease prevalence following the 2006 tsunami, the 2008 earthquake in Sechuan and cyclone Nargis in the Irawaddy delta. Flooding caused by El Niño in East Africa not only resulted in an increase in breeding sites for mosquito vectors but a major outbreak of rift valley fever due to the enforced close proximity of cattle with humans.

Environmental temperature

The effect of environmental temperature ($T_{\text{Env}}$) is paramount in infective diseases; changes as small as 1°C cause major changes in disease vectors. Climate change is an unquestionable phenomenon. Patterns of infective disease are likely to change radically within the next 20 years. There are suggestions that these effects are already becoming apparent, for example:

- Patterns of malaria in South East Asia.
- The occurrence of dengue fever in southern Italy.

- Outbreaks of cholera, and seasonal variation in diarrhoea and vomiting.

Research into the effect of climate change on the changing patterns of infective diseases will point to potential ways in which national and international efforts can be targeted.

HEAT

Body core temperature ($T_{\text{Core}}$) is maintained at 37°C by the thermoregulator centre in the hypothalamus.

Heat is produced by cellular metabolism and is dissipated through the skin by both vasodilatation and sweating and in expired air via the alveoli. When the environmental temperature ($T_{\text{Env}}$) is $>32.5°C$, profuse sweating occurs. Sweat evaporation is the principal mechanism for controlling $T_{\text{Core}}$, following exercise or in response to an increase in $T_{\text{Env}}$.

**Heat acclimatization.** Acclimatization to heat takes place over several weeks. The sweat volume increases and the sweat salt content falls. Increased evaporation of sweat reduces $T_{\text{Core}}$.

**Heat cramps.** Painful muscle cramps, usually in the legs, often occur in fit people when they exercise excessively, especially in hot weather. Cramps are probably due to low extracellular sodium caused by excess intake of water over salt. Cramps can be prevented by increasing dietary salt. They respond to combined salt and water replacement, and in the acute stage to stretching and muscle massage. $T_{\text{Core}}$ remains normal.

**Heat illness.** At any environmental temperature (especially with $T_{\text{Env}}$ of $>25°C$), and with a high humidity, exercise in clothes that inhibit sweating can cause an elevation in $T_{\text{Core}}$ in less than 15 minutes. Weakness/exhaustion, cramps, dizziness and syncope, with $T_{\text{Core}} > 37°C$, define heat illness (heat exhaustion). Elevation of $T_{\text{Core}}$ is more critical than water
and sodium loss. Heat illness may progress to heat injury, a serious emergency.

**Management**
Reduce $T_{\text{env}}$ if possible. Cool with sponging and fans. Give $O_2$ by mask. Other causes of high $T_{\text{core}}$, e.g. malaria, should be ruled out if necessary.

Oral rehydration with both salt and water (25 g of salt per 5 L of water/day) is given in the first instance, with adequate replacement thereafter. In severe heat illness, i.v. fluids are needed. 0.9% saline is given; monitor serum sodium and correct secondary potassium loss.

**Heat injury**
Heat injury (heat stroke) is an acute life-threatening situation when $T_{\text{core}}$ rises above 41°C. There is headache, nausea, vomiting and weakness, progressing to confusion, coma and death. The skin feels intensely hot to the touch. Sweating is often absent, but not invariably.

Heat injury can develop in unacclimatized people in hot, humid windless climates, even without exercise. Sweating may be limited by prickly heat. Excessive exercise in inappropriate clothing, e.g. exercising on land in a wetsuit, can lead to heat injury in temperate climates. Diabetes and drugs, e.g. alcohol, antimuscarinics, diuretics and phenothiazines, can contribute. Heat injury can lead to a fall in cardiac output, lactic acidosis and intravascular coagulation.

**Prevention**
Acclimatization, fluids, avoiding inappropriate clothing and common sense.

**Management**
- Reduce $T_{\text{env}}$ if possible.
- Cool: sponging, icepacks, fanning. Give $O_2$ by mask.
- Manage in intensive care: monitor cardiac output, respiration, biochemistry, clotting and muscle enzymes.
- Give fluids intravenously with caution: intravascular volume can remain normal.

Prompt treatment is essential and can be curative even with $T_{\text{core}}$ of more than 41°C. Delay can be fatal. Complications are hypovolaemia, intravascular coagulation, cerebral oedema, rhabdomyolysis, and renal and hepatic failure.

**Malignant hyperpyrexia**
See p. 1182.

---

**COLD**

Hypothermia is defined as a core temperature of less than 32°C. It is frequently lethal when $T_{\text{core}}$ falls below 30°C. Survival, with full recovery has however been recorded with $T_{\text{core}}$ of less than 16°C.

Cold injury includes:
- **Frostbite**: the local cold injury that follows freezing of tissue.
- **Non-freezing cold injury**: the damage – usually to feet – following prolonged exposure to $T_{\text{env}}$ between 0 and 5°C, usually in damp conditions.

**Hypothermia**
Hypothermia occurs in many settings.

At home. Hypothermia can occur when $T_{\text{env}}$ is below 8°C, when there is poor heating, inadequate clothing and poor nutrition. Depressant drugs, e.g. hypnotics, alcohol, hypothyroidism or intercurrent illness also contribute. Hypothermia is commonly seen in the poor, frail and elderly. The elderly have diminished ability to sense cold and also have little insulating fat. Neonates and infants become hypothermic rapidly because of a relatively large surface area in proportion to subcutaneous fat.

Outdoors on land. Hypothermia is a prominent cause of death in climbers, skiers, polar travellers and in wartime. Wet, cold conditions with wind chill, physical exhaustion, injuries and inadequate clothing are contributory. Children are especially susceptible.

Cold water immersion. Dangerous hypothermia can develop following immersion for more than one hour in water temperatures of 15–20°C. In $T_{\text{water}}$ below 12°C limbs rapidly become numb and weak. Recovery takes place gradually, several hours following rescue.

**Clinical features**
Mild hypothermia ($T_{\text{core}} < 32°C$) causes shivering and initially intense discomfort. However, the hypothermic subject, though aware, may not act appropriately to warm, e.g. by huddling, wearing extra clothing or exercising. As the $T_{\text{core}}$ falls below 32°C, severe hypothermia causes impaired judgement – including lack of awareness of cold – drowsiness and coma. Death follows, usually from ventricular fibrillation.

**Diagnosis**
Diagnosis is straightforward, if a low-reading thermometer is available. If not, rapid clinical assessment is reliable. Someone who feels icy to touch – abdomen, groin, axillae – is probably hypothermic. If they are clammy, uncooperative or sleepy, $T_{\text{core}}$ is almost certainly <32°C.

**Sequelae**
Pulse rate and systemic BP fall. Cardiac output and cerebral blood flow are greatly affected by change in posture in hypothermia, and can fall further if the upright position is maintained, or the thorax restrained by a harness. This is why air-sea helicopter winch rescues are often carried out using a stretcher, rather than a chest harness. Respiration becomes shallow and slow. Muscle stiffness develops; tendon reflexes become sluggish and/or lost.

As coma ensues, pupillary and other brainstem reflexes are lost; pupils are fixed and may be dilated in severe hypothermia.

Metabolic changes are variable, with either metabolic acido-osis or alkalosis. Arterial $P_{O_2}$ may appear normal, i.e. falsely high.

Reduction in the temperature of haemoglobin shifts the oxygen dissociation curve to the left. Thus, if an arterial blood sample from a hypothermic patient is analysed at 37°C, the $P_{O_2}$ will be falsely high. Within the range 37–33°C this factor is around 7% per °C. Many blood gas machines also calculate the arterial saturation; this too will be falsely high. When a patient is monitored using a pulse oximeter, the level of arterial oxygen saturation ($S_{O_2}$) will however be correct – but if $S_{O_2}$ is then converted by calculation to $P_{O_2}$, a downwards correction must be applied – simply due to hypothermia.
Bradydarya with 'J' waves (rounded waves above the isoelectric line at the junction of the QRS complex and ST segment (Fig. 17.1)) are pathognomonic of hypothermia. Prolongation of PR and QT intervals and QRS complex also occur. Ventricular dysrhythmias (tachycardia/fibrillation) or asystole are the usual causes of death.

**Principles of management**

- Maintain the patient horizontal, or slightly head down.
- Rewarm gradually.
- Correct metabolic abnormalities.
- Anticipate and treat dysrhythmias.
- Check for hypothyroidism (see p. 985).

If the patient is awake, with a core temperature of more than 32°C, place them in a warm room, use a foil wrap and give warm fluids orally. Outdoors, add extra dry clothing, huddle together and use a warmed sleeping bag. Rewarming may take several hours. Avoid alcohol: this adds to confusion, boosts confidence factitiously, causes peripheral vasodilatation and further heat loss, and can precipitate hypoglycaemia.

**Severe hypothermia**

In severe hypothermia, people look dead. Always exclude hypothermia before diagnosing brainstem death (see p. 920). Warm gradually, aiming at a 1°C per hour increase in Tcore. Direct mild surface heat from an electric blanket can be helpful. Treat any underlying condition promptly, e.g. sepsis. Monitor all vital functions. Correct dysrhythmias. Drug screening is essential.

Give warm i.v. fluids slowly. Correct metabolic abnormalities. Hypothyroidism, if present, should be treated with liothyronine. Various methods of artificial rewarming exist—inhaled warm humidified air, gastric or peritoneal lavage, and haemodialysis. These are rarely used.

**Prevention**

Hypothermia in the field can often be prevented by forethought and action. For the elderly, improved home heating and insulation, central heating in bedrooms and electric blankets are helpful in cold spells. Finance is often needed for this.

**Cold injury**

**Frostbite**

Ice crystals form within skin and superficial tissues when the temperature of the tissue (Ttissue) falls to −3°C; Tenv generally must be below −6°C. Wind chill is frequently a factor. Typically, fingers, toes, nose and ears become frostbitten.

Frostbitten tissue is pale, greyish and initially doughy to touch. Later, tissue freezes hard, looking like meat from a freezer. Frostbite can easily occur when working or exercising in low temperatures and typically develops without the patient’s knowledge. Below Tenv −5°C, hands or feet that have lost their feeling are at risk of cold injury.

**Management**

Transport the patient — or if this is impossible, make them walk, even on frostbitten feet — to a place of safety before commencing warming. Warm the frozen part by immersion in hand hot water at 39–42°C, if feasible. Assess hypothermia. Continue warming until obvious thawing occurs; this can be painful. Vasodilator drugs have no part in management. Blisters form within several days and, depending on the depth of frostbite, a blackened shell – the carapace – develops as blisters regress or burst. Dry, non-adherent dressings and aseptic precautions are essential, though hard to achieve. Frostbitten tissues are anaesthetic and at risk from further trauma and infection. Recovery takes place over many weeks, and may be incomplete. Surgery may be needed, but should be avoided in the early stages.

**Chillblains**

These are small, purplish itchy inflammatory lesions, occurring on toes and fingers. They occur in cold, wet conditions. They are more common in women and heal in 7–14 days. Prevention is by keeping warm and wearing gloves and warm footwear.

**Non-freezing cold injury (NFCI)**

NFCI (trench foot) describes tissue damage following prolonged exposure, usually for several hours or more, at Tenv around or slightly above freezing, but without frostbite. Wet socks and boots are the usual cause. There is severe vasoconstriction, blanching of the lower limbs, with pain and oedema on rewarming. Recovery usually follows over several weeks. There may be prolonged late susceptibility to cold. NFCI is a prominent cause of morbidity in troops operating in low temperatures.

**Prevention** of frostbite and NFCI is largely by education and common sense: avoid damp feet and wet boots. Always carry spare dry socks, gloves and headgear.

![Fig. 17.2 The decrease in oxygen and barometric pressure with increasing altitude.](image_url)
On land, below 3000 m there are few clinical effects. The resulting hypoxaemia causes breathlessness only in those with severe cardiorespiratory disease. Above 3000–3500 m hypoxia causes a spectrum of related syndromes that affect high-altitude visitors, principally climbers, trekkers, skiers, and troops (Table 17.1). These conditions occur largely during acclimatization. Acclimatization takes several weeks and once completed can enable man to live – permanently if necessary – up to about 5600 m. At greater heights, although people can survive for days or weeks, deterioration due to chronic hypoxia is inevitable. The world’s highest railway to Lhasa travels over 5000 m. Oxygen is provided in the carriages. Roads to similar altitudes are used extensively for transport in central Asia. Ascent of the world’s highest 8000 m summits is just possible without supplementary oxygen. At the summit of Everest (8848 m) the barometric pressure is 34 kPa (253 mmHg). An acclimatized mountaineer has an alveolar $P_O_2$ of 4.0–4.7 kPa (30–35 mmHg) – near man’s absolute physiological limit.

**Acute mountain sickness (AMS)**

AMS describes malaise, nausea, headache and lassitude and affects the majority of people for a few days above 3500 m. Following arrival at this altitude there is usually a latent interval of 6–36 hours before symptoms begin. Treatment is rest, with analgesics if necessary. Recovery is usually spontaneous over several days.

Prophylactic treatment with acetazolamide, a carbonic anhydrase inhibitor and a respiratory stimulant, is of some value in preventing AMS. Acclimatizing, i.e. ascending gradually, provides better, and more natural prophylaxis.

In the minority, more serious sequelae – high-altitude pulmonary oedema and high-altitude cerebral oedema develop.

**High-altitude pulmonary oedema**

Predisposing factors include youth, rapidity of ascent, heavy exertion and severe AMS. Breathlessness, occasionally with frothy blood-stained sputum, indicates established oedema. Unless treated rapidly this leads to cardiorespiratory failure and death. Milder forms are common. Breathlessness at rest should raise the suspicion of pulmonary oedema.

**High-altitude cerebral oedema**

Cerebral oedema is the result of abrupt increase in cerebral blood flow that occurs even at modest altitudes of 3500–4000 m. It is unusual below 4500 m, and usually occurs in the first two weeks, during acclimatization. Cerebral oedema can also develop suddenly in well-acclimatized climbers above 7000 m. Headache is typical, and is accompanied by drowsiness, ataxia and papilloedema. Coma and death follow if brain oedema progresses.

**Treatment**

Any but the milder forms of AMS require urgent treatment. Oxygen should be given by mask if available, and descent to a lower altitude should take place as quickly as possible. Nifedipine reduces pulmonary hypertension and is used in the treatment of pulmonary oedema. Dexamethasone is effective in reducing brain oedema. Portable pressure bags inflated by a foot pump are widely used; the patient is enclosed in the pressure bag.

**Retinal haemorrhages**

Small ‘flame’ haemorrhages within the retinal nerve fibre layer are common above 5000 m and usually symptomless. Rarely a haemorrhage will cover the macula, causing painless loss of central vision. Recovery is usual.

**Deterioration**

Prolonged residence between 6000 and 7000 m leads to weight loss, anorexia and listlessness after several weeks. Above 7500 m, the effects of deterioration become apparent more rapidly over several days, although it is possible to survive for a week or more at altitudes near 8000 m without supplementary oxygen.

**Chronic mountain sickness**

Chronic mountain sickness occurs in long-term residents at high altitudes, usually after several decades and is seen in the Andes and in central Asia.

Headache, polycythaemia, lassitude, cyanosis, finger clubbing, congested cheeks and ear lobes, and right ventricular enlargement develop. Chronic mountain sickness is gradually progressive.

By contrast, coronary artery disease and hypertension are rare in high-altitude native populations.

---

**DIVING**

Free diving by breath-holding is possible to around 5 m, or to greater depths with practice. Various methods are used to supply air to a diver. With the simplest, e.g. a snorkel, providing air at around 0.5 m, the limiting factor is inspiratory
effort. At depths $>0.5$ m, i.e. with a longer snorkel tube, forced negative-pressure ventilation can cause pulmonary capillary damage and haemorrhagic alveolar oedema. Scuba divers – the usual recreational sports diving down to 30 m – carry bottled compressed air, or a nitrogen–oxygen mixture. Divers who work at great depths commercially or in underwater exploration breathe helium–oxygen or nitrogen–oxygen mixtures, delivered by hose from the surface. Ambient pressures at various depths are shown in Table 17.2.

### Problems during descent

**Middle ear barotrauma (squeeze)** is common and caused by inability to equalize pressure in the middle ear – usually the result of Eustachian tube blockage. Hearing loss occurs, sometimes with tympanic membrane rupture and acute vertigo. **Sinus squeeze** is due to blockage of the nasal and paranasal sinus ostia – there is intense local pain. **Treatment** is by holding the nostrils closed and swallowing, or similar manoeuvres – and decongestants. Avoid diving with a respiratory or sinus infection.

**Oxygen narcosis**

Pure oxygen is not used for diving because of oxygen toxicity. Lung damage – atelectasis, endothelial cell damage and pulmonary oedema – occurs when the alveolar oxygen pressure exceeds 1.5 atmospheres, a depth around 5 m. At around 10 m the CNS begins to be affected: apprehension, nausea and sweating are followed by muscle twitching and generalized convulsions.

**Nitrogen narcosis**

When compressed air is breathed below 30 m, narcotic effects of nitrogen begin to impair brain function. This problem sometimes also occurs with nitrogen–oxygen mixtures used for recreational diving. Changes of mood and performance may be hazardous. These resolve on ascent to the surface. Nitrogen narcosis is avoided by replacing air with helium–oxygen mixtures, enabling descent to 700 m. At these extreme depths direct effect of pressure on neurones can cause tremor, hemiparesis and cognitive impairment.

### Problems during and following ascent

Free divers who breath-hold often hyperventilate deliberately prior to plunging in. This drives off $CO_2$ – reducing the stimulus to inspire. During the subsequent breath-hold $P_{CO_2}$ rises; $P_{O_2}$ falls. On surfacing, decompression lowers $P_{O_2}$ further. This can lead to syncope, known as a shallow water blackout. Since loss of consciousness can take place in the water, this can lead to fatalities.

#### Decompression sickness

**Decompression sickness** (the bends) can follow returning too rapidly to the surface. Problems are caused by the release of bubbles of nitrogen or helium. Decompression tables indicate the duration required for safe return to the surface from a given depth.

The bends can be mild (Type 1, non-neurological bends), with skin irritation and mottling and/or joint pain. Type 2, neurological bends, are more serious – cortical blindness, hemiparesis, sensory disturbances or cord lesions develop.

If bubbles form in pulmonary vessels, divers experience retrosternal discomfort, dyspnoea and cough, known as the chokes. These develop within minutes or hours of a dive. Decompression problems do not only occur immediately on reaching the surface, they may take some hours to become apparent. Over the subsequent 24 hours, further ascent, e.g. air travel, can occasionally provoke the bends.

Other problems during ascent include severe paranasal sinus pain, nosebleeds and dental pain – gas bubbles within rotten fillings. Whilst medically minor, these can be dramatic, e.g. causing excruciating pain and a mask filled with blood-stained fluid.

**Management** all but the mildest forms of decompression sickness, e.g. skin mottling alone, require recompression in a pressure chamber, following strict international guidelines. Recovery is usual. A long-term problem is aseptic necrosis of the hip due to nitrogen bubbles causing infarction of nutrient arteries. Distinct focal neurological damage may persist, but complaints of fatigue, poor concentration and difficulties with employment are issues compounded by the litigation that commonly follows diving accidents. Objective, evidence-based assessments are essential.

**Lung rupture, pneumothorax and surgical emphysema**

These emergencies occur particularly when divers breathhold during emergency ascents after exhausting or losing their bottled gas supply. There is severe dyspnoea, cough and haemoptysis. Pneumothorax and emphysema usually resolve gradually with 100% oxygen. Air embolism can also occur and is treated with recompression/hyperbaric oxygen.

### DROWNING AND NEAR-DROWNING

Drowning is the third commonest reason for accidental death in the UK and caused over 500,000 deaths worldwide in 2007. In the UK, some 40% of drownings occur in children under five. People can also drown following an epileptic seizure or a myocardial infarct whilst in water. Exhaustion, alcohol, drugs and hypothermia all contribute to deaths following immersion.

**Dry drowning**

Between 10% and 15% of drownings occur without water aspiration into the lungs. Laryngeal spasm develops acutely, followed by apnoea and cardiac arrest.

**Wet drowning**

Fresh or seawater aspiration destroys pulmonary surfactant, leading to alveolar collapse, ventilation/perfusion mismatch.
and hypoxaemia. Aspiration of hypertonic seawater (5% NaCl) pulls additional fluid into the alveoli with further ventilation/perfusion mismatch. In practice, there is little difference between saltwater and freshwater aspiration. In both, severe hypoxaemia develops rapidly. Severe metabolic acidosis develops in the majority of survivors.

**Emergency treatment**

CPR should be started immediately (see p. 710). Patients have survived for up to 30 minutes under water without suffering brain damage – and sometimes for longer periods if the temperature of the water (T\textsubscript{water}) is near 10°C. Survival is probably related to the protective role of the **diving reflex** – submersion causes reflex bradycardia and vasoconstriction. In addition, hypothermia decreases oxygen consumption.

Resuscitation should always be attempted, even with an absent pulse and fixed dilated pupils. Patients frequently make a dramatic recovery. All survivors should be admitted to hospital for intensive monitoring – they are liable to develop effects of acute lung injury during the subsequent 48 hours.

**Prognosis**

Recovery is frequently complete if the patient regains consciousness within several minutes following initiation of resuscitation but poor if they remain stuporose or in coma at 30 minutes.

---

**IONIZING RADIATION**

Ionizing radiation is either penetrating (X-rays, γ-rays or neutrons) or non-penetrating (α- or β-particles). Penetrating radiation affects the skin and deeper tissues, while non-penetrating radiation affects the skin alone. All radiation effects depend on the type of radiation, the distribution of dose and the dose rate.

**Dosage** is measured in **joules per kilogram**, J/kg; 1 J/kg = 1 gray (1 Gy) = 100 rads.

**Radioactivity** is measured in **becquerels**, Bq. 1 Bq is defined as the activity of a quantity of radioactive material in which one nucleus decays per second. 3.7 × 10\textsuperscript{10} Bq = one curie (Ci), the older, non SI unit.

Radiation differs in the density of ionization it causes. Therefore a dose-equivalent called a **sievert** (Sv) is used. This is the absorbed dose weighted for the damaging effect of the radiation. The annual background radiation is approximately 2.5 mSv. A chest X-ray delivers 0.02 mSv, and CT of the abdomen/pelvis about 10 mSv.

Excessive exposure to ionizing radiation follows accidents in industry, nuclear power plants and hospitals and deliberate nuclear explosions designed to eliminate populations – and exceptionally, by poisoning, e.g. with polonium.

**Mild acute radiation sickness**

Nausea, vomiting and malaise follow doses of approximately 1 Gy. Lymphopenia occurs within several days, followed 2–3 weeks later by a fall in all white cells and platelets.

**Acute radiation sickness**

Many systems are affected; the extent depends on the dose of radiation (Table 17.3).

---

**Haemopoietic syndrome**

Absorption of 2–10 Gy is followed by transient vomiting in some individuals, followed by a period of improvement. Lymphocytes are particularly sensitive to radiation damage; severe lymphopenia develops over several days. A decrease in granulocytes and platelets follows 2–3 weeks later, since no new cells are formed in the marrow. Thrombocytopenia with bleeding develops and frequent overwhelming infections, with a high mortality.

**Gastrointestinal syndrome**

Doses >6 Gy cause vomiting several hours after exposure. This then stops, only to recur some 4 days later accompanied by diarrhea. The villous lining of the intestine becomes denuded. Intractable bloody diarrhea follows, with dehydration, secondary infection and sometimes death.

**CNS syndrome**

Exposures of >30 Gy are followed rapidly by nausea, vomiting, disorientation and coma. Death due to cerebral oedema can follow, usually within 36 hours.

**Radiation dermatitis**

Skin erythema, purpura, blistering and secondary infection occur. Total loss of body hair is a bad prognostic sign and usually follows an exposure >5 Gy.

**Late effects of radiation exposure**

Survivors of the US nuclear bombing of Hiroshima and Nagasaki provided data on long-term radiation effects. Risks of acute myeloid leukaemia and cancer, particularly of skin, thyroid and salivary glands, increase. Infertility, teratogenesis and cataract are also late sequelae, developing years after exposure.

The sequelae of **therapeutic** radiation – early, early-delayed and late-delayed radiation effects are discussed on page 466. Focussing techniques are used to target radiation towards the field being treated; radiosensitive structures such as the ovaries are protected by shielding.

**Treatment**

Acute radiation sickness is an emergency. Absorption of the initial radiation dose can be reduced by removing contaminated clothing.

Treatment is largely supportive – prevention and treatment of infection, haemorrhage and fluid loss. Harvesting of blood products is sometimes carried out.

Accidental ingestion of, or exposure to, bone-seeking radioisotopes (e.g. strontium-90 and caesium-137) are treated with chelating agents, e.g. EDTA and massive doses of oral calcium. Radio-iodine contamination should be treated
immediately with potassium iodide to block radiiodine absorption by the thyroid.

**ELECTRIC SHOCK**

Electric shock can produce:

- **Pain and psychological sequelae.** The common domestic electric shock is typically painful, rarely fatal or followed by serious sequelae. Nevertheless, it is an unpleasant and intensely frightening experience. A brief immediate jerking episode can occur, but not an epileptic seizure. There is typically no lasting neurological, cardiac or skin damage. More serious effects are distinctly rare following accidents in the home or in industry, but claims by survivors following industrial accidents are frequently made.

- **Cardiac, neurological and muscle damage.** Ventricular fibrillation, muscular contraction and spinal cord damage can follow a major shock. These are seen typically following lightning strikes with exceedingly high-voltage and amperage.

- **Electrical burns.** These are commonly restricted to the skin – non-fatal lightning strikes can cause fern-shaped burns. Deeper injuries can also occur, with muscle and spinal cord damage.

- **Electrocution.** This means death following ventricular fibrillation, either accidentally, or deliberately as a method of execution. In the US an initial voltage of >2000 volts was applied for some 15 seconds in the electric chair, causing loss of consciousness and ventricular fibrillation before the voltage was lowered. The T core during the execution process would sometimes increase to levels >50°C, leading to severe damage to internal organs.

**SMOKE**

Smoke consists of carbon particles in hot air and gases. The particles are coated with organic acids, aldehydes and synthetic materials. On combustion, other toxins such as carbon monoxide, sulphur dioxide, sulphuric and hydrochloric acids are released into smoke. The highly toxic polyvinyl chloride is no longer used in household goods. Air pollution is discussed on page 830.

Respiratory symptoms are typically immediate. Patients are dyspnoeic and tachypnoeic. Laryngeal stidor may require intubation. Hypoxia and pulmonary oedema can be fatal.

Patients should breathe through an aspirator or wet towel and be removed as rapidly as possible from the smoke. Give oxygen and arrange ITU support to monitor pulmonary damage.

**Prevention:** smoke alarms should be in every household.

**NOISE**

Sound intensity is expressed as the square of sound pressure. The bel is the ratio equivalent to a 10-fold increase in sound intensity; a decibel (dB) is one-tenth of a bel. Sound is made up of a number of frequencies ranging from 30 Hz to 20 kHz, with most being between 1 and 4 kHz. In practice a scale known as A-weighted sound is used; sound levels are reported as dBA. A hazardous sound source is defined as one with an overall sound pressure of >90 dBA.

Repeated prolonged exposure to loud noise, particularly between 2 and 6 kHz, causes first temporary and later permanent hearing loss, by physically destroying hair cells in the organ of Corti and, eventually, auditory neurones. This is a common occupational problem, not only in industry and the armed forces, but also in the home (drills and Sanders), in sport (motor racing) and in entertainment (musicians, DJs and their audiences).

Serious noise-induced hearing loss is almost wholly preventable by personal protection (ear muffs, ear plugs). Little can be offered once hearing loss has become established.

**Other effects of noise**

Noise is intensely irritating, increasing or producing anxiety and anger. Excessive, repetitive noise is used in torture. Excess noise possibly affects child development and reading skills.

**BIOTERRORISM/BIOWARFARE**

Particular interest in biological warfare and bioterrorism intensified during the 1991 Iraq war and later following the destruction of the Twin Towers in New York in 2001. The potential of bacteria as weapons is illustrated by a suggestion that several kilograms of anthrax spores might kill as many people as a Hiroshima-sized nuclear weapon.

**Potential pathogens**

The US Center for Disease Control in Atlanta, Georgia, has developed a classification of potential biological agents (Table 17.4).

**Smallpox**

Smallpox is a highly infectious disease with a mortality >30%. There is no proven therapy, but there is an effective

vaccine. Universal vaccination was stopped in the early 1970s: the vast majority of the world’s population is now unprotected against the variola virus (see p. 109). The potential exists for a world-wide epidemic of smallpox, possibly initiated by a bioterrorist act.

Smallpox has an incubation period of around 12 days, allowing any initial source of infection to go undetected until the rash (Fig. 17.3), similar to chicken pox, develops on the second or third day of the illness. Infection is transmitted by the airborne route; the patient becomes infectious to others 12–24 hours before the rash appears, thus allowing a potential infected volunteer to pass infection to others before being recognized as suffering from smallpox. If vaccines were to be administered widely to those potentially infected within 3 days of contact, an epidemic might well be prevented. Smallpox virus is stored in two secure laboratories – in Russia and in the USA. Supplies of vaccine are potentially available world-wide.

**Anthrax** (see p. 142)

In late 2001, anthrax organisms were sent through the US mail and infected 22 individuals. Eleven developed pulmonary anthrax, five of whom died; 11 suffered from cutaneous anthrax.

A simulated anthrax attack postulated release of anthrax powder from a truck passing a sports stadium with 74000 spectators. 16000 were estimated to become infected, with a death rate of 25%. In Russia, following accidental release of anthrax from a biowarfare factory, the death rate was substantial in those nearby and especially downwind of the factory.

**Botulism**

The toxin produced by *Clostridium botulinum* is one of the most potent poisons known to man (see p. 134).

As a bioweapon, botulinum toxin could be transmitted in food or by air, e.g. from a crop-spraying light aircraft. The toxin is inactivated by chlorine in domestic water supplies. There is no vaccine available.

**Plague** (see p. 146)

Plague could be transmitted as a bioweapon either by airborne dissemination or by infected rats. Immunization is of limited value.

Other potential infective agents are listed in Table 17.4.

**Emergency planning**

Many countries have plans to deal with bioterrorist attacks. These include training of healthcare staff and police. Such plans indicate the awareness of governments of the possibility of these threats. Stock piling of vaccines, antibiotics and protective clothing is essential.

**TRAVEL**

**Motion sickness**

This common problem is caused by repetitive stimulation of the labyrinth. It occurs frequently at sea and in cars (especially in children), but also occurs with less usual forms of transport such as camels or elephants. Nowadays, motion sickness is rare during commercial flights, but it is a problem during space travel, and one reason why the airship industry has not flourished.

Nausea, sweating, dizziness, vertigo and profuse vomiting occur, accompanied by an irresistible desire either to stop moving or return to land. Prostration and intense incapacitating malaise can occur, for example in seasickness.

Prophylactic antihistamines, vestibular sedatives (hyoscine or cinnarizine) and stern ginger are of some value.

**Jet-lag**

Jet-lag (circadian dyschronism) is the well-known phenomenon that follows travelling through time-zones, particularly from West to East. Intense insomnia, fatigue, poor concentration, irritability, and loss of appetite are common. Headaches may occur. Symptoms last several days.

Mechanisms relate to the hypothalamic body clock within the suprachiasmatic nuclei. The clock is regulated by various zeitgebers (time-givers), e.g. light and melatonin.

Management of jet-lag includes its acceptance as a phenomenon causing poor performance – and thus waiting for 3–5 days to recover. Drink plenty of fluid, avoiding alcohol. Various hypnotics can help insomnia, but their value is disputed. Oral melatonin is widely used to reduce jet-lag. This probably hastens resetting of the body clock. Melatonin is not available on prescription in the UK.

**BUILDING-RELATED ILLNESSES**

**Non-specific building-related illness**

Multi-storey buildings typically have a controlled environment, often with automated heating and air-conditioning, and without ready access to external ventilation. More than half the adult workforce in developed countries work in such offices.

Headache, fatigue and difficulty in concentrating, sometimes in apparent epidemics, are the main complaints – and have become less frequent during the last decade. Psychological factors are very likely to have a substantial role. Temperature, humidity, dust, volatile organic compounds, e.g. paints and solvents, and even low level carbon monoxide toxicity have all been blamed, none with any scientific foundation. Maintenance of ready access to outdoor air is usually recommended, but changes in ventilation sometimes fail to improve matters.
Specific building-related illnesses

Legionnaires' disease (see p. 860) can certainly be caused by contamination of air-conditioning systems. Humidifier fever (see p. 877) is also due to contaminated systems, probably by fungi, bacteria and protozoa. Many common viruses are potentially transmissible in an enclosed environment, e.g. the common cold, influenza and rarely pulmonary TB. Allergic disorders, e.g. rhinitis, asthma and dermatitis, also occur following exposure to indoor allergens such as dust mites and plants. Office equipment, e.g. fumes from photocopiers, has also been implicated. Passive smoking (see p. 829) is no longer an issue in Europe and North America, following legislation against smoking.

### INTRODUCTION

Endocrine disease can involve all of the endocrine (or hormone) glands of the body as illustrated in Figure 18.1.

The most common endocrine disorders, excluding diabetes mellitus (Ch. 19) are:

- thyroid disorders, affecting 4–8 new patients per primary care physician each year (the most common problems are primary hypothyroidism, thyrotoxicosis and goitre)
- menstrual disorders and excessive hair growth in young women, most commonly polycystic ovary syndrome (PCOS)
- osteoporosis, especially in postmenopausal women largely owing to gonadal steroid deficiency
- primary hyperparathyroidism, affecting about 0.1% of the population
- subfertility, affecting 5–10% of all couples, often with an endocrine component
- disorders of growth or puberty.

While most other endocrine conditions are uncommon, they often affect young people and are usually curable or completely controllable with appropriate therapy.

### Symptoms

Hormones produce widespread effects upon the body, and states of deficiency or excess typically present with symptoms that are generalized rather than focused on the anatomical location of the gland. Many endocrine symptoms are diffuse and vague, and the differential diagnosis is often wide. Symptoms of tiredness, weakness or lack of energy or drive and changes in appetite or thirst are common presentations of endocrine disease. Other typical ‘hormonal’ symptoms include changes in body size and shape, problems with libido and potency, periods or sexual development, and changes in the skin (dry, greasy, acne, bruising, thinning or thickening) and hair (loss or excess). Endocrine disorders should be always considered when assessing any patient with these common complaints.

### History and examination

The past, family and social history is essential for making the diagnosis, planning appropriate management and interpreting results of borderline hormonal blood tests. The past history should include previous surgery or radiation involving endocrine glands, menstrual history, pregnancy and growth in childhood. A full drug history will exclude iatrogenic endocrine problems (Table 18.1). Family history of autoimmune disease, endocrine disease including tumours, diabetes and cardiovascular disease is frequently relevant, and knowledge of family members’ height, weight, body habitus, hair growth and age of sexual development may aid interpretation of the patient’s own symptoms.

**Physical signs** are listed under the relevant systems.

### Aetiology of endocrine disease

Aetiological mechanisms common to many endocrine disorders include:
**Fig. 18.1** The major endocrine organs and common endocrine problems.

**Autoimmune disease**

Organ-specific autoimmune diseases can affect every major endocrine organ (Table 18.2). They are characterized by the presence of specific antibodies in the serum, often present years before clinical symptoms are evident. The conditions are usually more common in women and have a strong genetic component, often with an identical-twin concordance rate of 50% and with HLA associations (see individual diseases). Several of the autoantigens have been identified.

**Endocrine tumours**

Hormone-secreting tumours occur in all endocrine organs, most commonly pituitary, thyroid and parathyroid. Fortunately, they are more commonly benign than malignant. While often considered to be ‘autonomous’ — that is, independent of the physiological control mechanisms — many do show evidence of feedback occurring at a higher ‘set-point’ than normal (e.g., ACTH secretion from a pituitary basophil adenoma). Non-functioning benign tumours of endocrine organs are even more common and often present as ‘incidentalomas’ found incidentally during imaging for another condition.

The molecular basis of some of these tumours is sometimes a very specific mutation of a single gene, such as the mutations of the RET proto-oncogene in MEN 2 (see p. 1026), but more commonly a wide variety of different mutations in tumour suppressor genes, growth factor receptors and other intracellular mediators have been identified.

**Enzymatic defects**

The biosynthesis of most hormones involves many stages. Deficient or abnormal enzymes can lead to absent or reduced production of the secreted hormone. In general, severe deficiencies present early in life with obvious signs; partial deficiencies usually present later with mild signs or are only evident under stress. An example of an enzyme deficiency is congenital adrenal hyperplasia (CAH) where the molecular basis has also been identified as mutations or deletions of the gene encoding the relevant enzymes.

**Receptor abnormalities** (see p. 971)

Hormones work by activating cellular receptors. There are rare conditions in which hormone secretion and control are normal but the receptors are defective; thus, if androgen receptors are defective, normal levels of androgen will not produce masculinization (e.g. testicular feminization). There are also a number of rare syndromes of diabetes and insulin resistance from receptor abnormalities (p. 1035); other examples include nephrogenic diabetes insipidus, thyroid hormone resistance and pseudohypoparathyroidism.

**Hormones as therapy**

Hormones are also widely used therapeutically:

- The oral contraceptive pill is the choice of perhaps 20–30% of women aged 18–35 years using contraception.
- Corticosteroid therapy is widely used in non-endocrine disease such as asthma (see p. 855).
- Hormone replacement therapy (HRT; oestrogens ± progestogens) is used for control of menopausal symptoms in postmenopausal women (see p. 997).

**HORMONAL ACTIVITY**

Hormones are chemical messengers produced by a variety of specialized secretory cells. They are transported in the blood to a distant site of action (‘endocrine’ activity) and sometimes act directly upon nearby cells (‘paracrine’ activity). Classic hormones are secreted by the main endocrine glands — pituitary, thyroid, adrenals, gonads, parathyroids and pancreas — and have effects elsewhere in the body. In addition, there are many other cells that secrete hormones, e.g. in the hypothalamus and elsewhere in the brain and in the gastrointestinal tract. These can have true endocrine or paracrine activity or behave more like neurotransmitters or neuromodulators. At the molecular level there is little difference in the way cellular activity is regulated between classical neurotransmitters that act across synaptic clefts,
intercellular factors acting across gap junctions, classic endocrine and paracrine activity and a variety of other chemical messengers involved in cell regulation – such as cytokines, growth factors and interleukins. Progress in basic cell biology has revealed the biochemical similarities in the messengers, receptors and intracellular post-receptor mechanisms underlying all these aspects of cell function.

Synthesis, storage and release of hormones

Hormones may be of several chemical structures: polypeptide, glycoprotein, steroid or amine. Hormone release is the end-product of a long cascade of intracellular events. In the case of polypeptide hormones, neural or endocrine stimulation of the cell leads to increased transcription from DNA to a specific mRNA, which is in turn translated to the peptide product. This is often in the form of a precursor molecule that may itself be biologically inactive. This ‘prohormone’ is then further processed before being packaged into granules, in the Golgi apparatus. These granules are then transported to the plasma membrane before release, which is itself regulated by a complex combination of intracellular regulators. Hormone release may be in a brief spurt caused by the sudden stimulation of granules, often induced by an intracellular Ca\(^{2+}\)-dependent process, or it is ‘constitutive’ (immediate and continuous secretion).

Plasma transport

Most classical hormones are secreted into the systemic circulation. In contrast, hypothalamic releasing hormones are released into the pituitary portal system so that much higher concentrations of the releasing hormones reach the pituitary than occur in the systemic circulation.

Many hormones are bound to proteins within the circulation. In most cases, only the free (unbound) hormone is available to the tissues and thus biologically active. This binding serves to buffer against very rapid changes in plasma levels of the hormone, and some binding protein interactions are also involved in the active regulation of hormone action. Many tests of endocrine function measure total rather than free hormone, which can give rise to difficulties in interpretation when binding proteins are altered in disease states or by drugs. Binding proteins comprise both specific, high-affinity proteins of limited capacity, such as thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), sex-hormone-binding globulin (SHBG) and IGF-binding proteins (e.g. IGF-BP3) and other less specific, low-affinity ones, such as prealbumin and albumin.

Hormone action and receptors

Hormones act by binding to specific receptors in the target cell. Most hormone receptors are proteins with complex tertiary structures. The structure of the hormone-binding domain of the receptor complements the tertiary structure of the hormone, while changes in other parts of the receptor in response to hormone binding are responsible for the effects of the activated receptor within the cell. Hormone receptors may be broadly divided into:

- **Cell surface or membrane receptors** – typically transmembrane receptors which contain hydrophobic sections spanning the lipid-rich plasma membrane and which trigger internal cellular messengers (see also p. 22)
- **Nuclear receptors** which typically bind hormones and translocate them to the nucleus where they bind hormone response elements of nuclear DNA via characteristic amino-acid sequences (e.g. so-called ‘zinc fingers’, see p. 32).

Common structural mechanisms of hormone–receptor action are illustrated in Figure 2.4 (p. 23) and include:

- **G-protein coupled receptors** (7-transmembrane or serpentine receptors). These bind hormones on their extracellular domain and activate the membrane G-protein complex with their intracellular domain. The activated complex may then:
  - stimulate cyclic AMP (cAMP) generation by adenylate cyclase – activating further intracellular kinases and leading to phosphorylation
  - activate phospholipase C (PLC) leading to generation of inositol 1,4,5-triphosphate (IP\(_3\)) and release of intracellular calcium – in turn leading to calmodulin-dependent kinase activity and phosphorylation.
  - lead to diacylglycerol (DAG) activation of C-kinase and subsequent protein phosphorylation.

Most peptide hormones act via G-protein coupled receptors. **Dimeric transmembrane receptors**, from several receptor superfamilies, bind hormone in their extracellular components (sometimes causing the dimerization of the receptor monomer) and directly phosphorylate intracellular messengers via their intracellular components, leading to a variety of intracellular activation cascades. Growth hormone, prolactin and insulin-like growth factor-1 (IGF-1) act via this type of receptor.

**Lipid-soluble molecules** pass through the cell membrane and typically bind with their **nuclear receptors** in the cell cytoplasm before translocation of the activated hormone–receptor complex to the nucleus where it binds to nuclear DNA, often in combination with a multi-component complex of promoters, inhibitors and transcription factors. This interaction usually leads to increased transcription of the relevant gene product. Steroid and thyroid hormones act via this type of receptor.

The structure of common hormones and their receptors is described under individual hormone axes.

The activation of intracellular kinases, phosphorylation, release of intracellular calcium and other ‘second messenger’ pathways and the direct stimulation of DNA transcription results in some or all of:

- stimulation or release of pre-formed hormone from storage granules
- stimulation or synthesis of hormone and other cellular components
- opening or closing of ion or water channels in the cell membrane (e.g. calcium channels or aquaporin water channels)
- activation or deactivation of other DNA binding proteins leading to stimulation or inhibition of DNA transcription.

In each case, binding of the hormone to its receptor is the first step in a complex cascade of interrelated intracellular events which eventually lead to the overall effects of that hormone on cellular function.

The sensitivity and/or number of receptors for a hormone are often decreased after prolonged exposure to a high hormone concentration, the receptors thus becoming less sensitive (‘downregulation’, e.g. angiotensin II receptors, β-
adrenoceptors). The reverse is true when stimulation is absent or minimal, the receptors showing increased numbers or sensitivity (‘upregulation’).

Abnormal receptors are an occasional cause of endocrine disease (see p. 971), recognized and characterized more frequently owing to advances in molecular endocrinology.

**Control and feedback**

Most hormone systems are controlled by some form of feedback; an example is the hypothalamic–pituitary–thyroid axis (Fig. 18.2).

- TRH (thyrotrophin-releasing hormone) is secreted in the hypothalamus and travels via the portal system to the pituitary where it stimulates the thyrotrophs to produce thyroid-stimulating hormone (TSH).
- TSH is secreted into the systemic circulation where it stimulates increased thyroid iodine uptake by the thyroid and the synthesis and release of thyroid hormone (T₃) and triiodothyronine (T₄).
- Serum levels of T₃ and T₄ are thus increased by TSH; in addition, the conversion of T₄ to T₃ (the more active hormone) in peripheral tissues is stimulated by TSH.
- T₃ and T₄ then enter cells where they bind to nuclear receptors and promote increased metabolic and cellular activity.
- Levels of T₃ (from the blood and from local conversion of T₄) are sensed by receptors in the pituitary and possibly the hypothalamus. If they rise above normal, TRH and TSH production is suppressed, leading to reduced T₃ and T₄ secretion.
- Peripheral T₃ and T₄ levels thus fall to normal.
- If, however, T₃ and T₄ levels are low (e.g. after thyroidectomy), increased amounts of TRH and thus TSH are secreted, stimulating the remaining thyroid to produce more T₃ and T₄; blood levels of T₃ and T₄ may be restored to normal, although at the expense of increased TSH drive, reflected by a high TSH level (‘compensated euthyroidism’). Conversely, in thyrotoxicosis when factors other than TSH itself are maintaining high T₃ and T₄ levels, the same mechanisms lead to suppression of TSH secretion.

This is known as a ‘negative feedback’ system, referring to the effect of T₃ and T₄ on the pituitary and hypothalamus, which represents the most common mechanism for regulation of circulating hormone levels. There are also ‘positive feedback’ systems, classically seen in the regulation of the normal menstrual cycle (p. 996).

**Patterns of secretion**

Hormone secretion is continuous or intermittent. The former is shown by the thyroid hormones, where T₃ has a half-life of 7–10 days and T₄ of about 6–10 hours. Levels over the day, month and year show little variation.

In contrast, secretion of the gonadotrophins, LH and FSH, is normally pulsatile, with major pulses released every 1–2 hours depending on the phase of the menstrual cycle. Continuous infusion of LH to produce a steady equivalent level does not produce the same result (e.g. ovulation in the female) as the intermittent pulsatility, and may indeed produce down-regulation. Thus a long-acting superactive gonadotrophin-releasing hormone (GnRH) analogue, such as goserelin, produces down-regulation of the GnRH receptors and subsequent very low androgen or oestrogen levels, which is clinically valuable both in carcinoma of the prostate in men and in ovulation-induction regimens in infertile women. In contrast, pulsatile GnRH administration can produce normal menstrual cyclicity, ovulation and fertility in women with hypothalamic amenorrhoea but intact pituitary LH and FSH stores.

Growth hormone is also secreted in a pulsatile fashion, with undetectable levels in between pulses. A single measurement is therefore not helpful to diagnose GH deficiency or excess.

**Biological rhythms**

_Circadian_ means changes over the 24 hours of the day–night cycle and is best shown for the pituitary–adrenal axis. Figure 18.3 shows plasma cortisol levels measured over 24 hours – levels are highest in the early morning and lowest overnight. Additionally, cortisol release is pulsatile, following the pulsatility of pituitary ACTH. Thus ‘normal’ cortisol levels vary during the day and great variations can be seen in samples taken only 30 minutes apart. The circadian (light–dark) rhythm is seen in reverse with the pineal hormone, melatonin, which shows high levels during darkness. Melatonin may be involved in entraining other hormonal rhythms and systems to the current light–dark cycle, but there is no known clinical syndrome related to abnormalities of this hormone, though a synthetic preparation has been used for ‘jet-lag’ (p. 960).

The menstrual cycle is the best example of a longer and more complex (28-day) biological rhythm (see p. 996).

**Other regulatory factors**

- **Stress.** Physiological ‘stress’ and acute illness produce rapid increases in ACTH and cortisol, growth hormone (GH), prolactin, epinephrine (adrenaline) and norepinephrine (noradrenaline). These can occur within seconds or minutes.

![Fig. 18.2 The hypothalamic–pituitary–thyroid axis. Pituitary TSH is secreted in response to hypothalamic TRH and stimulates secretion of T₃ and T₄ from the thyroid. T₃ and T₄ have actions in peripheral tissues and exert negative feedback on pituitary and hypothalamus.](image-url)
Sleep. Secretion of GH and prolactin is increased during sleep, especially the rapid eye movement (REM) phase.

Feeding and fasting. Many hormones regulate the body’s control of energy intake and expenditure and are therefore profoundly influenced by feeding and fasting. Secretion of insulin is increased and growth hormone decreased after ingestion of food, and secretion of a number of hormones is altered during prolonged food deprivation.

Measurement of hormone levels in normal individuals and in patients with disease must take these factors into account. For example, cortisol levels will often be high and fail to suppress during standard tests in a patient who is severely stressed by serious illness, and growth hormone will usually be low in postprandial individuals during the daytime.

**TESTING ENDOCRINE FUNCTION**

Endocrine function is assessed by measurement of hormone levels in blood (or more precisely in plasma or serum) and sometimes in other body fluids on samples obtained basally and in response to stimulation and suppression tests.

Basal blood levels

Assays for all clinically relevant pituitary and end-organ hormones are available. Hypothalamic hormones are not measured because of their low concentration and local action within the hypothalamo–pituitary axis.

The time, day and condition of measurement make great differences to hormone levels, and the method and timing of samples therefore depends upon the characteristics of the endocrine system involved. There are also sex, developmental and age differences.

Basal levels are especially useful for systems with long half-lives (e.g. T₄ and T₃). These vary little over the short term and random samples are therefore satisfactory.

Basal samples for other hormones may also be satisfactory if interpreted with respect to normal ranges for the time of day/month, diet or posture concerned. Examples are FSH, oestrogen and progesterone (varying with time of cycle) and renin/aldosterone (varying with sodium intake, posture and age). For these hormones, all relevant details must be recorded or the results may prove uninterpretable.

**Stress-related hormones**

Stress-related hormones (e.g. catecholamines, prolactin, GH, ACTH and cortisol) require samples to be taken via an indwelling needle some time after initial venepuncture; otherwise, high levels may be artefactual.

**Urine collections**

Collections over 24 hours have the advantage of providing an ‘integrated mean’ of a day’s secretion but in practice are often incomplete or wrongly timed. They also vary with sex and body size or age. Written instructions should be provided for the patient to ensure accurate collection.

**Saliva**

Saliva is sometimes used for steroid estimations, especially in children or for samples taken at home. Midnight salivary cortisol levels are increasingly used for the diagnosis of Cushing’s syndrome due to the practical difficulties in obtaining a midnight blood sample.

**Stimulation and suppression tests**

These tests are used when basal levels give equivocal information. In general, stimulation tests are used to confirm suspected deficiency, and suppression tests to confirm suspected excess of hormone secretion. These tests are valuable in many instances.

For example, where the secretory capacity of a gland is damaged, maximal stimulation by the trophic hormone will give a diminished output. Thus, in the short ACTH stimulation test for adrenal reserve (Box 18.1 and Figure 18.4a), the healthy subject shows a normal response while the subject with primary hypoadrenalism (Addison’s disease) demonstrates an impaired cortisol response to tetracosactide (an ACTH analogue).

A patient with a hormone-producing tumour usually fails to show normal negative feedback. A patient with Cushing’s disease (excess pituitary ACTH) will thus fail to suppress ACTH and cortisol production when given a dose of synthetic steroid, in contrast to normal subjects. Figure 18.4b shows the response of a normal subject given dexamethasone 1 mg at midnight; cortisol is suppressed the following morning. The subject with Cushing’s disease shows inadequate suppression.

The detailed protocol for each test must be followed exactly, since differences in technique will produce variations in results.

**Box 18.1 Short ACTH (tetracosactide) stimulation test**

**Indication**

Diagnosis of Addison’s disease
Screening test for ACTH deficiency

**Procedure**

Intravenous cannula for sampling
Any time of day, but best at 0900 h; non-fasting
Tetracosactide 250 μg, i.v. or i.m. at time 0
Measure serum cortisol at time 0 and time +30 min

**Normal response**

30 min cortisol >600 nmol/L*
(400–600 nmol/L, borderline and may indicate deficiency)

*Precise cortisol normal ranges are variable between laboratories and assays – appropriate local reference ranges must be used.
Disorders of pituitary and hypothalamus

Measurement of hormone concentrations
Circulating levels of most hormones are very low (10⁻⁹–10⁻¹⁵ mol/L) and cannot be measured by simple chemical techniques. Hormones are therefore usually measured by immunoassays which rely on highly specific antibodies (polyclonal or more usually monoclonal) which bind specifically to the hormone being measured during the assay incubation. This hormone–antibody interaction is measured by use of labelled hormone after separation of bound and free fractions (Fig. 18.5).

Immunoassay is sensitive but has limitations. In particular, the immunological activity of a hormone, as used in developing the antibody, may not necessarily correspond to biological activity. Other measurement techniques include high-pressure liquid chromatography (HPLC).

Disorders of pituitary and hypothalamus

Anatomy
Most peripheral hormone systems are controlled by the hypothalamus and pituitary. The hypothalamus is situated at the base of the brain around the third ventricle and above the pituitary stalk, which leads down to the pituitary itself, carrying the hypophyseal–pituitary portal blood supply.

Fig. 18.5 Principles of measurement of hormone levels in plasma by immunoassay (precise details vary with different assays and manufacturers). Immunoassays use two antibodies specific to the hormone being measured – one typically attached to a solid phase and one labelled antibody in the liquid phase. (a) High hormone levels in plasma: large amount of hormone binds to antibody on solid phase – large amount of labelled antibody linked to solid phase via molecules of the hormone. (b) Low hormone levels in plasma: less hormone, and therefore less labelled antibody, is linked to the solid phase. Label (radioactive, chemiluminescent, enzymatic or fluorescent) can be measured in either solid or liquid phase after separation of phases; levels of label will be proportional to the amount of hormone in the sample.

Fig. 18.6 MR image of a sagittal section of the brain, showing the pituitary fossa and adjacent structures. By kind permission of Dr Martin Jeffree.
may rarely reach the temporal lobe of the brain. The pituitary is itself encased in a bony box; any lateral, anterior or posterior expansion must cause bony erosion.

Embryologically, the anterior pituitary is formed from an upgrowth of Rathke’s pouch (ectodermal) which meets an outpouching of the third ventricular floor which becomes the posterior pituitary. This unique combination of primitive gut and neural tissue provides an essential link between the rapidly responsive central nervous system and the longer-acting endocrine system. Several transcription factors – LHX3, HESX1, PROP1, POUIF1 – are responsible for the differentiation and development of the pituitary cells. Mutation of these produces pituitary disease.

**Physiology**

**Hypothalamus**

This contains many vital centres for such functions as appetite, thirst, thermal regulation and sleeping/waking. It acts as an integrator of many neural and endocrine inputs to control the release of pituitary hormone-releasing factors. It plays a role in the circadian rhythm, menstrual cyclicity, and responses to stress, exercise and mood.

Hypothalamic neurones secrete pituitary hormone-releasing and -inhibiting factors and hormones (Table 18.3) into the portal system which runs down the stalk to the pituitary. As well as the classical hormones illustrated in Figure 18.7, the hypothalamus also contains large amounts of other neuropeptides and neurotransmitters such as neuropeptide Y, vasoactive intestinal peptide (VIP) and nitric oxide that can also alter pituitary hormone secretion.

Synthetic hypothalamic hormones and their antagonists are available for the testing of many aspects of endocrine function and for treatment.

**Anterior pituitary**

Hormone secretion is controlled by hypothalamic releasing or inhibitory hormones (Fig. 18.7). Many hormones are under dual control by both stimulatory and inhibitory hypothalamic factors. Examples are:

- Growth hormone release is stimulated by growth hormone-releasing hormone (GHRH) but inhibited by somatostatin (growth hormone release inhibitory hormone, GHRH).
- TSH release is stimulated by TRH but partially inhibited by somatostatin.

Some hormones have a dual stimulatory control. For example, corticotrophin-releasing hormone (CRH) and vasopressin are both endogenous stimulators of ACTH release. Uniquely, prolactin is under predominant inhibitory dopaminergic control with some stimulatory TRH control. This means that disruption of the pituitary stalk leads to an elevation in serum prolactin but reduction in all other pituitary hormones.

**Posterior pituitary**

This, in contrast, acts merely as a storage organ. Antidiuretic hormone (ADH, also called vasopressin) and oxytocin, both nonapeptides, are synthesized in the supraoptic and paraventricular nuclei in the anterior hypothalamus. They are then transported along the axon and stored in the posterior pituitary. This means that damage to the stalk or pituitary alone does not prevent synthesis and release of ADH and oxytocin. ADH is discussed on page 1016; oxytocin produces milk ejection and uterine myometrial contraction.

**PRESENTATIONS OF PITUITARY AND HYPOTHALAMIC DISEASE**

Diseases of the pituitary can cause under- or over-activity of each of the hypothalamo–pituitary–end-organ axes which are under the control of this gland. The clinical features of the syndromes associated with such altered pituitary function, e.g. Cushing’s syndrome, can be the presenting symptom of

pituitary disease or of end-organ disease and are discussed later. First, however, we consider clinical features of pituitary disease which are common to all hormonal axes.

**Pituitary space-occupying lesions and tumours**

Pituitary tumours (Table 18.4) are the most common cause of pituitary disease, and the great majority of these are benign pituitary adenomas, usually mononclonal in origin. Problems are caused by:

- excess hormone secretion
- local effects of a tumour
- the result of inadequate production of hormone by the remaining normal pituitary, i.e. hypopituitarism.

**Investigations (of a possible or proven mass)**

**Is there a tumour?**

If there is, how big is it and what local anatomical effects is it exerting? Pituitary and hypothalamic space-occupying lesions, hormonally active or not, can cause symptoms by pressure on, or infiltration of:

- the visual pathways, with field defects and visual loss (most common)
- the cavernous sinus, with III, IV and VI cranial nerve lesions
- bony structures and the meninges surrounding the fossa, causing headache
- hypothalamic centres: altered appetite, obesity, thirst, somnolence/wakefulness or precocious puberty
- the ventricles, causing interruption of cerebrospinal fluid (CSF) flow leading to hydrocephalus
- the sphenoid sinus with invasion causing CSF rhinorrhea.

**Investigations:**

- MRI of the pituitary. MRI is superior to CT scanning (Fig. 18.8) and will readily show any significant pituitary mass. Small lesions within the pituitary fossa on MRI consistent with small pituitary microadenomas are very common (10% of normal individuals in some studies). Such small lesions are sometimes detected during MRI scanning of the head for other reasons – so-called ‘pituitary incidentalomas’.

  - **Visual fields.** These should be plotted formally by automated computer perimetry or Goldmann perimetry, but clinical assessment by confrontation using a small red pin as target is also sensitive and valuable. Common defects are upper temporal quadrantanopia and bitemporal hemianopia (see p. 1101). Subtle defects may also be revealed by delay or attenuation of visual evoked potentials (VEPs).

**Is there a hormonal excess?**

There are three major conditions usually caused by secretion from pituitary adenomas which will show positive immunostaining for the relevant hormone:

- prolactin excess (prolactinoma or hyperprolactinaemia) – histologically, prolactinomas are ‘chromophobe’ adenomas (a description of their appearance on classical histological staining)
- GH excess (acromegaly or gigantism) – somatotroph adenomas, usually ‘acidophil’, and sometimes due to specific G-protein mutations (see p. 971)
- excess ACTH secretion (Cushing’s disease and Nelson’s syndrome) – corticotroph adenomas, usually ‘basophil’.

Many tumours are able to synthesize several pituitary hormones, and occasionally more than one hormone is secreted in clinically significant excess (e.g. both GH and prolactin).

The clinical features of acromegaly, Cushing’s disease or hyperprolactinaemia are usually (but not always) obvious, and are discussed on pages 979, 1012, and 980. Hyperprolactinaemia may be clinically ‘silent’. Tumours producing LH, FSH or TSH are well described but very rare.

Some common pituitary tumours, usually ‘chromophobe’ adenomas, cause no clinically apparent hormone excess and are referred to as ‘non-functioning’ tumours. Laboratory studies such as immunocytochemistry or in situ hybridization.
show that these tumours may often produce small amounts of LH and FSH or the α-subunit of LH, FSH and TSH, and occasionally ACTH.

Is there a deficiency of any hormone?
Clinical examination may give clues; thus, short stature in a child with a pituitary tumour is likely to be due to GH deficiency. A slow, lethargic adult with pale skin is likely to be deficient in TSH and/or ACTH. Milder deficiencies may not be obvious, and require specific testing (see Table 18.7).

Treatment
Treatment depends on the type and size of tumour (Table 18.5). In general, therapy has three aims:

Removal/control of tumour
- **Surgery** via the trans-sphenoidal route is usually the treatment of choice. Very large tumours are occasionally removed via the open transfrontal route.

Radiotherapy – by an external three-beam technique, stereotactic or rarely via implant of yttrium needles – is usually employed when surgery is impracticable or incomplete, as it controls but rarely abolishes tumour mass. The standard regimen involves a dose of 45 Gy, given as 20–25 fractions via three fields.

**Medical therapy** with somatostatin analogues and/or dopamine agonists sometimes cause shrinkage of specific types of tumour (see p. 980) and if successful can be used as primary therapy.

Reduction of excess hormone secretion
Reduction is usually obtained by surgical removal but sometimes by medical treatment. Useful control can be achieved with dopamine agonists for prolactinomas or somatostatin analogues for acromegaly, but ACTH secretion usually cannot be controlled by medical means. Growth hormone antagonists are also available for acromegaly (p. 980).
Replacement of hormone deficiencies

Replacement of hormone deficiencies, i.e. hypopituitarism, is discussed below (see Table 18.8).

Small tumours producing no significant symptoms, pressure or endocrine effects may be observed with appropriate clinical, visual field, imaging and endocrine assessments.

Differential diagnosis of pituitary or hypothalamic masses

Although pituitary adenomas are the most common mass lesion of the pituitary (90%), a variety of other conditions may also present as a pituitary or hypothalamic mass and form part of the differential diagnosis.

Other tumours

- Cranioopharyngioma (1-2%), a usually cystic hypothalamic tumour, often calcified, arising from Rathke’s pouch, often mimics an intrinsic pituitary lesion. It is the most common pituitary tumour in children but may present at any age.
- Uncommon tumours include meningiomas, gliomas, chondromas, germinomas and pinealomas. Secondary deposits occasionally present as apparent pituitary tumours, typically presenting with headache and diabetes insipidus.

Hypophysitis and other inflammatory masses

A variety of inflammatory masses occur in the pituitary or hypothalamus. These include rare pituitary-specific conditions (e.g. postpartum hypophysitis, lymphocytic hypophysitis, giant cell hypophysitis) or pituitary manifestations of more generalized disease processes (sarcoidosis, Langerhans’ cell histiocytosis, Wegener’s granulomatosis). These lesions may be associated with diabetes insipidus and/or an unusual pattern of hypopituitarism.

Other lesions

Carotid artery aneurysms may masquerade as pituitary tumours and must be diagnosed before surgery. Cystic lesions may also present as a pituitary mass, including arachnoid and Rathke cleft cysts.

Hypopituitarism

Pathophysiology

Deficiency of hypothalamic releasing hormones or of pituitary trophic hormones can be selective or multiple. Thus isolated deficiencies of GH, LH/FSH, ACTH, TSH and vasopressin are all seen, some cases of which are genetic and congenital and others sporadic and autoimmune or idiopathic in nature.

Multiple deficiencies usually result from tumour growth or other destructive lesions. There is generally a progressive loss of anterior pituitary function. GH and gonadotrophins are usually first affected. Hyperprolactinaemia, rather than prolactin deficiency, occurs relatively early because of loss of tonic inhibitory control by dopamine. TSH and ACTH are usually last to be affected.

Panhypopituitarism refers to deficiency of all anterior pituitary hormones; it is most commonly caused by pituitary tumours, surgery or radiotherapy. Vasopressin and oxytocin secretion will be significantly affected only if the hypothalamus is involved by a hypothalamic tumour or major supraselar extension of a pituitary lesion, or if there is an infiltrative/inflammatory process. Posterior pituitary deficiency is rare in an uncomplicated pituitary adenoma.

Genetics of hypopituitarism

Specific genes are responsible for the development of the anterior pituitary involving interaction between signalling molecules and transcription factors. For example, mutations in PROP1 and POUIF1 (previously PIT-1) prevent the differentiation of anterior pituitary cells (precursors to somatotroph, lactotroph, thyrotroph and gonadotroph cells), leading to deficiencies of GH, prolactin, TSH and GnRH. In addition, novel mutations within GH and GHRH receptor genes have been identified which may explain the pathogenesis of isolated GH deficiency in children. Despite these advances, most cases of hypopituitarism do not have specific identifiable genetic causes.

Causes

Disorders causing hypopituitarism are listed in Table 18.6. Pituitary and hypothalamic tumours, and surgical or radiotherapy treatment, are the most common.

Clinical features

Symptoms and signs depend upon the extent of hypothalamic and/or pituitary deficiencies, and mild deficiencies may not lead to any complaint by the patient. In general, symptoms of deficiency of a pituitary-stimulating hormone are the same as primary deficiency of the peripheral endocrine gland (e.g. TSH deficiency and primary hypothyroidism cause similar symptoms due to lack of thyroid hormone secretion).

- Secondary hypothyroidism and adrenal failure both lead to tiredness and general malaise.
- Hypothyroidism causes weight gain, slowness of thought and action, dry skin and cold intolerance.
- Hypoadrenalism causes mild hypertension, hyponatraemia and ultimately cardiovascular collapse during severe intercurrent stressful illness.
- Gonadotrophin and thus gonadal deficiencies lead to loss of libido, loss of secondary sexual hair, amenorrhoea and erectile dysfunction.
- Hyperprolactinaemia may cause galactorrhoea and hypogonadism.
- GH deficiency causes growth failure in children and impaired well-being in some adults.
- Weight may increase (due to hypothyroidism, see above) or decrease in severe combined deficiency (pituitary cachexia).
- Long-standing panhypopituitarism gives the classic picture of pallor with hairlessness (‘alabaster skin’). Particular syndromes related to hypopituitarism are:
  - Kallmann’s syndrome. This syndrome is isolated gonadotrophin (GnRH) deficiency (p. 1000).
  - Septo-optic dysplasia. This is a rare congenital syndrome (associated with mutations in the HESX-1 gene) presenting in childhood with a clinical triad of midline forebrain abnormalities, optic nerve hypoplasia and hypopituitarism.
  - Sheehan’s syndrome is due to pituitary infarction following postpartum haemorrhage and is rare in developed countries.

</tbody>
</table>

*Pituitary apoplexy.* A pituitary tumour occasionally enlarges rapidly owing to infarction or haemorrhage. This may produce severe headache and sudden severe visual loss sometimes followed by acute life-threatening hypopituitarism.

*The ‘empty sella’ syndrome.* An ‘empty sella’ is sometimes reported on pituitary imaging. This is sometimes due to a defect in the diaphragma and extension of the subarachnoid space (cisternal herniation) or may follow spontaneous infarction or regression of a pituitary tumour. All or most of the sella turcica is devoid of apparent pituitary tissue, but, despite this, pituitary function is usually normal, the pituitary being eccentrically placed and flattened against the floor or roof of the fossa.

### Investigations

Each axis of the hypothalamic–pituitary system requires separate investigation. However, the presence of normal gonadal function (ovulation/menstruation or normal libido/erects) suggests that multiple defects of anterior pituitary function are unlikely.

Tests range from the simple basal levels (e.g. free T₄ for the thyroid axis), to stimulatory tests for the pituitary, and tests of feedback for the hypothalamus (Table 18.7). Assessment of the hypothalamic–pituitary–adrenal axis remains controversial: basal 0900 h cortisol levels above 400 nmol/L usually indicate an adequate reserve, while levels below 100 nmol/L predict an inadequate stress response. In many cases basal levels are equivocal and a dynamic test is essential: the insulin tolerance test (Box 18.2) is widely regarded as the ‘gold standard’ but the short ACTH stimulation test (see Box 18.1), though an indirect measure, is used by many as a routine test of hypothalamic–pituitary–adrenal status. Occasionally, the difference between ACTH deficiency and normal HPA axis can be subtle, and the assessment of adrenal reserve is best left to an experienced endocrinologist.

### Treatment

- **Steroid and thyroid hormones are essential for life.** Both are given as oral replacement drugs, as in primary thyroid and adrenal deficiency, aiming to restore the patient to clinical and biochemical normality (Table 18.8) and levels are monitored by routine hormone assays. **NB** Thyroid replacement should not commence until normal glucocorticoid function has been demonstrated or replacement steroid therapy initiated, as an adrenal ‘crisis’ may otherwise be precipitated.

- **Sex hormones are replaced with androgens and oestrogens, both for symptomatic control and to prevent long-term problems related to deficiency (e.g. osteoporosis).**

- When fertility is desired, gonadotrophin function is stimulated directly by human chorionic gonadotrophin (HCG, mainly acting as LH), purified or biosynthetic gonadotrophins, or indirectly by pulsatile gonadotrophin-releasing hormone (GnRH – also known as luteinizing hormone-releasing hormone, LHRH); all are expensive and time-consuming and should be restricted to specialist units.

- **GH therapy is given in the growing child, under the care of a paediatric endocrinologist.** In adult GH deficiency, GH therapy also produces improvements in body composition, work capacity and psychological well-being, together with reversal of lipid abnormalities associated with a high cardiovascular risk, and this may result in significant symptomatic benefit in some cases. The long-term safety and efficacy of GH therapy is the subject of ongoing multinational studies. It is expensive and in the UK costs £2500–6000 per annum.

- **Glucocorticoid deficiency may mask impaired urine concentrating ability, diabetes insipidus only becoming apparent after steroid replacement.**
Table 18.7 Tests for hypothalamic–pituitary (HP) function

- All hormone levels are measured in plasma unless otherwise stated.
- Tests shown in bold are those normally measured on a single basal 0900 h sample in the initial assessment of pituitary function.

Box 18.2 Insulin tolerance test

**Indication**

Diagnosis or exclusion of ACTH and growth hormone deficiency

**Procedure**

Test explained to patient and consent obtained

Should only be performed in experienced, specialist units

Exclude cardiovascular disease (ECG), epilepsy or unexplained blackouts; exclude severe untreated hypopituitarism (basal cortisol must be >100 nmol/L; normal free T4)

Intravenous hydrocortisone and glucose available for emergency

Overnight fast, begin at 0800–0900 h

Soluble insulin, 0.15 Units/kg, i.v. at time 0

Glucose, cortisol and GH levels at 0, 30, 45, 60, 90, 120 min

**Normal response**

Cortisol rises above 550 nmol/L

GH rises above 7 ng/L (severe deficiency = <3 ng/L

(<9 mU/L))

Glucose must be <2.2 mmol/L to achieve adequate stress response

*Precise cortisol normal ranges are variable between laboratories and assays – appropriate local reference ranges must be used.

**FURTHER READING**

GROWTH AND ABNORMAL STATURE

Physiology and control of growth hormone (GH) (Fig. 18.9)

GH is the pituitary responsible for stimulation of body growth in humans. Its secretion is stimulated by GHRH, released into the portal system from the hypothalamus; it is also under inhibitory control by somatostatin. A separate GH stimulating system involves a distinct receptor (GH secretogogue receptor), which interacts with ghrelin (see p. 229). It is not known how these two systems interact but because ghrelin is synthesized in the stomach, it suggests a nutritional role for GH.

- **GH** acts by binding to a specific (single transmembrane) receptor located mainly in the liver (Table 18.3). This induces an intracellular phosphorylation cascade involving the JAK/STAT (signal transducing activators of transcription) pathway (p. 24). STAT proteins are translocated from the cytoplasm into the cell nucleus and cause GH-specific effects by binding to nuclear DNA.

- **IGF-1** (insulin-like growth factor-1) stimulates growth and its hepatic secretion is stimulated by a tissue-specific effect of GH on the liver. Plasma levels of IGF-1, however, reflect local growth activity poorly, partly as there are multiple IGF-binding proteins (IGF-BP) – mainly IGF-BP3.

The metabolic actions of the system are:

- increasing collagen and protein synthesis
- promoting retention of calcium, phosphorus and nitrogen, necessary substrates for anabolism
- opposing the action of insulin.

GH release is intermittent and mainly nocturnal, especially during REM sleep. The frequency and size of GH pulses increase during the growth spurt of adolescence and decline thereafter. Acute stress and exercise both stimulate GH release while, in the normal subject, hyperglycaemia suppresses it.

IGF-1 may, in addition, play a major role in maintaining neoplastic growth. A relationship has been shown between circulating IGF-1 concentrations and breast cancer in premenopausal women and prostate cancer in men.

NORMAL GROWTH

There are factors other than GH involved in linear growth in the human.

- **Genetic factors.** Children of two short parents will probably be short and vice versa.
- **Nutritional factors.** Adequate nutrients must be available. Impaired growth can result from inadequate dietary intake or small bowel disease (e.g. coeliac disease).
- **General health.** Any serious systemic disease in childhood is likely to reduce growth (e.g. chronic kidney disease or chronic infection).
- **Intrauterine growth retardation.** These infants often grow poorly in the long term, while infants with simple prematurity usually catch up. There is some evidence that low birthweight may predispose to hypertension, diabetes and other health problems in later adult life (p. 208).
- **Emotional deprivation and psychological factors.** These can impair growth by complex, poorly understood mechanisms, probably involving temporarily decreased GH secretion.

The relevant aspects of history and examination in the assessment of problems are shown in Box 18.3.

Assessment of growth

Charts showing ranges of height and weight for normal British children are available (Fig. 18.10), and other national data are available. Height must be measured, ideally at the same time of day on the same instrument by the same observer.

**Box 18.3** Assessment of problems of growth and development

**History**

- Pregnancy records
- Rate of growth (home/school records, e.g. heights on kitchen door)
- Comparison with peers at school and siblings
- Change in appearance (old photographs)
- Change in shoe/glove/hat size or frequency of ‘growing out’
- Age of appearance of pubic hair, breasts, menarche

**Physical signs**

- Evidence of systemic disease
- Body habitus, size, relative weight, proportions (span versus height)
- Skin thickness, interdental separation
- Facial features
- Spade hands/feet
- Grading of secondary sexual characteristics
**GROWTH FAILURE: SHORT STATURE**

When children or their parents complain of short stature, particular attention should focus on:

- intrauterine growth retardation, weight and gestation at birth
- possible systemic disorders – any system, but especially small bowel disease
- evidence of skeletal, chromosomal or other congenital abnormalities
- endocrine status – particularly thyroid
- dietary intake and use of drugs, especially steroids for asthma
- emotional, psychological, family and school problems.

School, general practitioner, clinic and home records of height and weight should be obtained if possible to allow growth-velocity calculation. If unavailable, such data must be obtained prospectively.

A child with normal growth velocity is unlikely to have significant endocrine disease and the commonest cause of short stature in this situation is pubertal ‘constitutional’ delay. However, low growth velocity without apparent systemic cause requires further investigation. Sudden cessation of growth suggests major physical disease; if no gastrointestinal, respiratory, renal or skeletal abnormality is apparent, then a cerebral tumour or hypothyroidism is likeliest.

Consistently slow-growing children require full endocrine assessment. Features of the more common causes of growth failure are given in Table 18.9.

Around the time of puberty, where constitutional delay is clearly shown and symptoms require intervention, then very-low-dose sex steroids in 3- to 6-month courses will usually induce acceleration of growth.

**Investigations**

Systemic disease having been excluded, perform:

- **Thyroid function tests** – serum TSH and free T4 to exclude hypothyroidism.
- **GH status.** Basal levels are of little value, though urinary GH measurements may prove to be of some value in screening. Dynamic tests include the GH response to insulin (the ‘gold standard’; Box 18.2), glucagon, arginine, exercise and clonidine. Tests should only be performed in centres experienced in their use and interpretation. Normal responses depend on test and GH assay used.
- **Blood levels of IGF-1 (insulin-like growth factor-1) and IGF-BP3 (binding protein 3)** may provide evidence of GH undersecretion.
- **Assessment of bone age.** Non-dominant hand and wrist X-rays allow assessment of bone age by comparison with standard charts.
- **Karyotyping in females.** Turner’s syndrome (p. 1007) is associated with short stature. It is thought that this is due to a defect in the short stature homeobox (SHOX) gene which has a role in non-GH mediated growth.

**Treatment**

Systemic illness should be treated and primary hypothyroidism treated with levothyroxine.

For GH insufficiency, recombinant GH (somatropin) is given as nightly injections in doses of 0.17–0.35 mg/kg per day.
week. Treatment is expensive and should be supervised in expert centres. Human GH (collected from pituitaries) was previously used but was withdrawn as cases of Creutzfeldt–Jakob disease were reported.

GH treatment in so-called ‘short normal’ children has not been shown to produce any worthwhile increase in final height. In Turner’s syndrome (see p. 1007) large doses of GH are effective in increasing final height, especially in combination with appropriate very-low-dose oestrogen replacement. Familial cases of resistance to GH owing to an abnormal GH receptor (Laron-type dwarfism) are well described. They are very rare but may respond to therapy with synthetic IGF-1.

## TALL STATURE

The most common causes are hereditary (two tall parents!), idiopathic (constitutional) or early development. It can occasionally be due to hyperthyroidism. Other causes include chromosomal abnormalities (e.g. Klinefelter’s syndrome, Marfan’s syndrome) or metabolic abnormalities. GH excess is a very rare cause and is usually clinically obvious).

## PITUITARY HYPERSECRETION SYNDROMES

### ACROMEGALY AND GIGANTISM

Growth hormone stimulates skeletal and soft tissue growth. GH excess therefore produces gigantism in children (if acquired before epiphyseal fusion) and acromegaly in adults.

Both are due to a pituitary tumour in almost all cases. Hyperplasia due to GHRH excess is very rare. Overall incidence is approximately 3–4/million per year and the prevalence is 50–80/million world-wide.

#### Clinical features

Symptoms and signs of acromegaly are shown in Figure 18.11. One-third of patients present with changes in appearance, one-quarter with visual field defects or headaches; in the remainder the diagnosis is made by an alert observer in another clinic, e.g. GP, diabetic, hypertension, dental, dermatology. Sleep apnoea is common and requires investigation and treatment if there are suggestive symptoms (see p. 842). Sweating, headaches and soft tissue swelling are particularly useful symptoms of persistent growth hormone secretion. Headache is very common in acromegaly and may be severe even with small tumours; it is often improved after surgical cure or with somatostatin analogues.

#### Investigations

- **GH levels** may exclude acromegaly if undetectable but a detectable value is non-diagnostic taken alone. Normal adult levels are <1 mU/L for most of the day except during stress or a ‘GH pulse’.
- **A glucose tolerance test** is diagnostic if there is no suppression of GH. Acromegals fail to suppress GH below 1 mU/L and some show a paradoxical rise: about 25% of acromegals have a diabetic glucose tolerance test.
- **IGF-1 levels** are almost always raised in acromegaly – a single plasma level of IGF-1 reflects mean 24-hour GH levels and is useful in diagnosis. A normal IGF-1 together with GH <5 mU/L (2.5 ng/L) may be taken to exclude acromegaly if the diagnosis is clinically unlikely.
- **Visual field examination** – defects are common, e.g. bitemporal hemianopia.
- **MRI scan** of pituitary if above tests abnormal. This will almost always reveal the pituitary adenoma.
- **Pituitary function** – partial or complete anterior hypopituitarism is common.
- **Prolactin** – mild to moderate hyperprolactinaemia occurs in 30% of patients (see Fig. 18.13). In some, the adenoma secretes both GH and prolactin.

#### Management and treatment

Untreated acromegaly results in markedly reduced survival. Most deaths occur from heart failure, coronary artery disease and hypertension-related causes. In addition, there is an increase in deaths due to neoplasia, particularly large bowel tumours. Treatment is therefore indicated in all except the elderly or those with minimal abnormalities. The aim of therapy is to achieve a mean growth hormone level below 5 mU/L (or 2.5 ng/L); this has been shown to reduce mortality to normal levels. A normal IGF-1 is also a goal of therapy.

Somatostatin receptor agonists

Dopamine agonists improve acromegaly – symptoms and signs.

Pituitary radiotherapy conventionally; secretion is a medical therapy for prolactin.

Prognostic value of some parameters, including GH levels, is of general interest.

Surgery. Trans-sphenoidal surgery is the appropriate first-line therapy. It will result in clinical remission in a majority of cases (60–90%) with pituitary microadenoma, but in only 50% of those with macroadenoma. Very high pre-operative GH and IGF-1 levels are also poor prognostic markers of surgical cure. Surgical success rates are variable and highly dependent upon experience, and a specialist pituitary surgeon is essential. Transfrontal surgery is rarely required except for massive macroadenomas. There is approximately a 10% recurrence rate.

Pituitary radiotherapy. External radiotherapy is normally used after pituitary surgery fails to normalize GH levels rather than as primary therapy. It is often combined with medium-term treatment with a somatostatin analogue or a dopamine agonist because of the slow biochemical response to radiotherapy, which may take 10 years or more and is often associated with hypopituitarism which makes it unattractive in patients of reproductive age. Stereotactic radiotherapy is used in some centres.

Medical therapy. There are three receptor targets for the treatment of acromegaly, viz. pituitary somatostatin receptors, dopamine (D2) receptors and growth hormone receptors in the periphery.

- Somatostatin receptor agonists. Octreotide and lanreotide are synthetic analogues of somatostatin (p. 977) that selectively act on somatostatin receptor subtypes (SST2 and SST5), which are highly expressed in growth-hormone-secreting tumours. These drugs were used as a short-term treatment whilst other modalities become effective, but now are sometimes used as primary therapy. They reduce GH and IGF levels in most patients. Both drugs are typically administered as monthly depot injections and are generally well tolerated but are associated with an increased incidence of gallstones and are expensive.

- Dopamine agonists. Dopamine agonists act on D2 receptors (p. 907) and can be given to shrink tumours prior to definitive therapy or to control symptoms and persisting GH secretion; they are probably most effective in mixed-growth-hormone-producing (somatotroph) and prolactin-producing (mammothroph) tumours. The doses are bromocriptine 10–60 mg daily or cabergoline 0.5 mg daily (higher than for prolactinomas) which should be started slowly (see p. 982). Given alone they reduce GH to ‘safe’ levels in only a minority of cases – but they are useful for mild residual disease or in combination with somatostatin analogues. Drugs with combined somatostatin and dopamine receptor activity are under development.

- Growth hormone antagonists. Pegvisomant (a genetically modified analogue of GH) is a GH receptor antagonist which has its effect by binding to and preventing dimerization of the GH receptor. It does not lower growth hormone levels or reduce tumour size but has been shown to normalize IGF-1 levels in 90% of patients. Its main role at the present time is treatment of patients in whom GH and IGF levels cannot be reduced to safe levels with somatostatin analogues alone, surgery or radiotherapy.

**HYPERPROLACTINAEMIA**

The hypothalamic–pituitary control of prolactin secretion is illustrated in Figure 18.12. Prolactin is a large peptide...
secreted in the pituitary and acts via a transmembrane receptor stimulating JAK 2 and other pathways (Table 8.3).

Prolactin is under tonic dopamine inhibition: factors known to increase prolactin secretion (e.g. TRH) are probably of less relevance. Prolactin stimulates milk secretion (but not breast tissue development) but also reduces gonadal activity. It decreases GnRH pulsatility at the hypothalamic level and, to a lesser extent, blocks the action of LH on the ovary or testis, producing hypogonadism even when the pituitary gonadal axis itself is intact.

The role of prolactin outside pregnancy and lactation is not well defined, although there is some epidemiological evidence of a link between high prolactin levels and breast cancer which has led to an interest in the development of prolactin receptor antagonists.

Physiological hyperprolactinaemia occurs in pregnancy, lactation and severe stress, as well as during sleep and coitus. The range of serum prolactin seen in common causes of hyperprolactinaemia is illustrated in Figure 18.13. Mildly increased prolactin levels (400–600 mU/L) may be physiological and asymptomatic but higher levels require a diagnosis. Levels above 5000 mU/L always imply a prolactin-secreting pituitary tumour.

**Causes**

Hyperprolactinaemia has many causes. Common pathological causes include prolactinoma, co-secretion of prolactin in tumours causing acromegaly, stalk compression due to pituitary adenomas and other pituitary masses, polycystic ovary syndrome, primary hypothyroidism and ‘idiopathic’ hyperprolactinaemia. Rarer causes are oestrogen therapy (e.g. the ‘pill’), renal failure, liver failure, post-ictal state and chest wall injury. Dopamine antagonist drugs (metoclopramide, domperidone, most antipsychotics) are a common iatrogenic cause, as well as most other antiemetics (except cyclizine) and opiates.

**Clinical features**

Hyperprolactinaemia stimulates milk production in the breast and inhibits GnRH and gonadotrophin secretion per se. It usually presents with:

- galactorrhea, spontaneous or expressible (60% of cases)
- oligomenorrhoea or amenorrhoea
- decreased libido in both sexes
- decreased potency in men
- subfertility
- symptoms or signs of oestrogen or androgen deficiency — in the long term osteoporosis may result, especially in women
- delayed or arrested puberty in the peripubertal patient
- mild gynaecomastia is often seen in men due to the associated hypogonadism rather than a direct effect of prolactin.

Additionally, headaches and/or visual field defects occur if there is a pituitary tumour (more common in men). Not all patients with galactorrhoea have hyperprolactinaemia, but the other causes are poorly understood — ‘normoprolactinaemic galactorrhoea’ and duct ectasia.

**Investigations**

Hyperprolactinaemia should be confirmed by repeat measurement. Further tests are appropriate after physiological and drug causes have been excluded:

- **Visual fields** should be checked.
- **Hypothyroidism** must be excluded since this is a cause of hyperprolactinaemia.
- **Anterior pituitary function** should be assessed if there is any clinical evidence of hypopituitarism or radiological evidence of a pituitary tumour (Table 18.7; Box 18.1 and Box 18.2).
- **MRI of the pituitary** is necessary if there are any clinical features suggestive of a pituitary tumour, and
desirable in all cases when prolactin is significantly elevated (above 1000 mU/L).

In the presence of a pituitary mass on MRI, the level of prolactin helps determine whether the mass is a prolactinoma or a non-functioning pituitary tumour causing stalk disconnection hyperprolactinaemia: levels of above 5000 mU/L in the presence of a macroadenoma, or above 2000 mU/L in the presence of a microadenoma (or with no radiological abnormality), strongly suggest a prolactinoma (see p. 972). Macroprolactinoma refers to tumours above 10 mm diameter, microprolactinoma to smaller ones.

Occasionally very large prolactinomas can be associated with such high serum prolactin levels that some assays give an artifactual falsely low result (known as the ‘hook effect’). If suspected, this can be excluded by serial dilutions of the serum sample.

If patients have no clinical features of hyperprolactinaemia but have an apparently elevated prolactin level, the possibility of ‘macroprolactinaemia’ should be considered. This is a higher molecular weight complex of prolactin bound to IgG which is physiologically inactive but occurs in a small proportion of normal people and can therefore lead to unnecessary treatment. Macroprolactinaemia can be diagnosed in the laboratory by precipitation of IgG with polyethylene glycol, after which prolactin levels will be normal on testing.

Treatment

Hyperprolactinaemia is usually treated to avoid the long-term effects of oestrogen deficiency (even if the patient would otherwise welcome the lack of periods!) or testosterone deficiency in the male. Exceptions include minor elevations (400–1000 mU/L) with preservation of normal regular menstruation (or normal male testosterone levels) and postmenopausal patients with microprolactinomas who are not taking oestrogen replacement.

Medical treatment. Hyperprolactinaemia is controlled with a dopamine agonist.

- **Cabergoline** (500 µg once or twice a week judged on clinical response and prolactin levels) is the best tolerated and longest-acting drug.
- **Bromocriptine** is the longest-established therapy and therefore preferred if pregnancy is planned: initial doses should be small (e.g. 1 mg), taken with food and gradually increased to 2.5 mg two or three times daily. Side-effects, which prevent effective therapy in a minority of cases, include nausea and vomiting, dizziness and syncope, constipation and cold peripheries.
- **Quinagolide** (75–150 µg once daily) is an alternative.

Complications include pulmonary, retroperitoneal and pericardial fibrotic reactions and cardiac valve lesions (when used in higher doses in Parkinson’s disease). Patients need careful monitoring although such adverse effects appear to be very rare in patients on ‘endocirc’ doses.

In most cases a dopamine agonist will be the first and only therapy and can be used in the long term. Prolactinomas usually shrink in size on a dopamine agonist, and in macroadenomas any pituitary mass effects commonly resolve. Microprolactinomas may not recur after several years of dopamine agonist therapy in a minority of cases, but in the majority hyperprolactinaemia will recur if treatment is stopped.

**Trans-sphenoidal surgery** may restore normoprolactinaemia in patients with microadenoma, but is rarely completely successful with macroadenomas and risks damage to normal pituitary function. Therefore most patients and physicians elect to continue medical therapy rather than proceed to surgery. Prolactin should therefore always be measured before surgery on any mass in the pituitary region. Some surgeons believe that long-term bromocriptine increases the hardness of the adenoma and makes resection more difficult, but others dissent from this view.

**Radiotherapy** usually controls adenoma growth and is slowly effective in lowering prolactin but causes progressive hypopituitarism. It may be advocated after medical tumour shrinkage or after surgery in larger tumours, especially where families are complete, but most workers simply advocate continuation of dopamine agonist therapy in responsive cases.

In patients planning pregnancy, it is useful to know the size of the pituitary lesion before starting dopamine agonist therapy. Rarely, tumours enlarge during pregnancy to produce headaches and visual field defects. Dopamine agonists, which are traditionally stopped after conception, should be restarted if there are any signs of tumour growth during pregnancy.

**HYPERSECRETION OF OTHER PITUITARY HORMONES**

Pituitary tumours may rarely secrete TSH (and cause thyrotoxicosis). Such ‘TSHomas’ lead to the unusual biochemical pattern of elevated T₄ levels with normal or high circulating TSH levels. FSH and LH secreting pituitary tumours may cause elevated sex steroids but are extremely uncommon.

**ACTH Hypersecretion**

Cushing’s disease and Nelson’s syndrome are discussed in the adrenal disease section (p. 1012).

**THE THYROID AXIS**

The metabolism of virtually all nucleated cells of many tissues is controlled by the thyroid hormones. Overactivity or underactivity of the gland are the most common of all endocrine problems.

**Anatomy**

The thyroid gland consists of two lateral lobes connected by an isthmus. It is closely attached to the thyroid cartilage and to the upper end of the trachea, and thus moves on swallowing. It is often palpable in normal women.

Embryologically it originates from the base of the tongue and descends to the middle of the neck. Remnants of thyroid tissue can sometimes be found at the base of the tongue (lingual thyroid) and along the line of descent. The gland has a rich blood supply from superior and inferior thyroid arteries.
The thyroid gland consists of follicles lined by cuboidal epithelioid cells. Inside is the colloid (the iodinated glycoprotein thyroglobulin) which is synthesized by the follicular cells. Each follicle is surrounded by basement membrane, between which are parafollicular cells containing calcitonin-secreting C cells.

**Physiology**

**Synthesis.** The thyroid synthesizes two hormones, L-thyroxine (T₄) and triiodothyronine (T₃), of which T₄ acts at the cellular level and T₃ is the prohormone. Inorganic iodide is trapped by the gland by an enzyme dependent system, oxidized and incorporated into the glycoprotein thyroglobulin to form mono- and diiodothyrosine and then T₄ and T₃ (Fig. 18.14).

More T₃ than T₄ is produced, but T₄ is converted in some peripheral tissues (liver, kidney and muscle) to the more active T₃ by 5'-monodeiodination; an alternative 3'-monodeiodination yields the inactive reverse T₃ (rT₃). The latter step occurs particularly in severe non-thyroidal illness (see below).

In plasma, more than 99% of all T₄ and T₃ is bound to hormone-binding proteins (thyroxine-binding globulin, TBG; thyroid-binding prealbumin, TBPA; and albumin). Only free hormone is available for tissue action, where T₃ binds to specific nuclear receptors within the cell. Many drugs and other factors affect TBG; all may result in confusing total T₄ levels in blood, and most laboratories therefore now measure free T₄ levels.

**Control of the hypothalamic–pituitary–thyroid axis.** The control and feedback of the thyroidal axis is discussed in Figure 18.2 and page 967. Thyrotrophin-releasing hormone (TRH), a peptide produced in the hypothalamus, stimulates TSH from the pituitary. TSH stimulates growth and activity of the thyroid follicular cells via the G-protein coupled TSH membrane receptor (Table 18.3). Circulating T₄ is peripherally de-iodinated to T₃ which binds to the thyroid hormone nuclear receptor (TR) on target organ cells to cause modified gene transcription. Two TR receptors exist (TRα and TRβ) and the tissue-specific effects of T₃ are dependent upon the local expression of these TR receptors. TRα knockout mice show poor growth, bradycardia and hypothermia, whilst TRβ knockout mice show thyroid hyperplasia and high T₄ levels in the presence of inappropriately normal circulating TSH, suggesting a role for the latter receptors in thyroid hormone resistance (see p. 995).

**Physiological effects of thyroid hormones:**
- Cardiovascular system – increased heart rate and cardiac output.
- Skeletal – increased bone turnover and resorption.
- Respiratory – maintains normal hypoxic and hypercapnic drive in respiratory centre.
- Gastrointestinal – increases gut motility.
- Blood – increases red blood cell 2,3-BPG facilitating oxygen release to tissues.
- Neuromuscular – increases speed of muscle contraction and relaxation and muscle protein turnover.

![Fig. 18.14 Synthesis and metabolism of the thyroid hormones.](image-url)
Iodine
Globally, dietary iodine deficiency is a major cause of thyroid disease, as iodine is an essential requirement for thyroid hormone synthesis. The recommended daily intake of iodine should be at least 140 μg, and dietary supplementation of salt and bread has reduced the number of areas where ‘endemic goitre’ still occurs (see below).

Thyroid function tests
Immunooasys for free T₄, free T₃ and TSH are widely available. There are only minor circadian rhythms, and measurements may be made at any time. Particular uses of the tests are summarized in Table 18.10, with typical findings in common disorders.

TSH measurement
TSH levels can discriminate between hyperthyroidism, hypothyroidism and euthyroidism. There are pitfalls, however. These are mainly with hypopituitarism, with the ‘sick euthyroid’ syndrome and with dysthyroid eye disease, all of which may give ‘false’ (i.e. misleading, not incorrect) low results implying hyperthyroidism. As a single test of thyroid function it is the most sensitive in most circumstances, but accurate diagnosis requires at least two tests – for example, TSH plus free T₄ or free T₃ where hypothyroidism is suspected, TSH plus serum free T₄ where hypothyroidism is likely.

TRH test
This has been rendered almost obsolete by modern sensitive TSH assays except for investigation of hypothalamic–pituitary dysfunction. TRH (prorelin) is occasionally used to differentiate between thyroid hormone resistance and TSHoma in the context of raised rT₃ and TSH levels. Typically, there is a rise in TSH in thyroid hormone resistance, whilst in TSHoma there is a flat response due to continued autonomous TSH secretion which does not respond to TRH.

Problems in interpretation of thyroid function tests
There are three major areas of difficulty.

Serious acute or chronic illness
Thyroid function is affected in several ways:
- reduced concentration and affinity of binding proteins,
- decreased peripheral conversion of T₂ to T₃ with more rT₃
- reduced hypothalamic–pituitary TSH production.

Systemically ill patients can therefore have an apparently low total and free T₄ and T₃ with a normal or low basal TSH (the ‘sick euthyroid’ syndrome). Levels are usually only mildly below normal and are thought to be mediated by interleukins IL-1 and IL-6; the tests should be repeated after resolution of the underlying illness.

Pregnancy and oral contraceptives
These lead to greatly increased TBG levels and thus to high or high-normal total T₄. Free T₄ is usually normal. Normal ranges for free T₄ and TSH alter with the normal physiological changes during pregnancy and TSH is often slightly suppressed in the first trimester, but this rarely causes clinical problems.

Drugs
Amiodarone decreases T₄ to T₃ conversion and free T₄ levels may therefore be above normal in a euthyroid patient; conversely amiodarone may induce both hyper- and hypothyroidism – the TSH level is usually reliable.

Many drugs affect thyroid function tests by interfering with protein binding but this now rarely causes a problem with free T₄ assays.

Antithyroid antibodies
Serum antibodies to the thyroid are common and may be either destructive or stimulating; both occasionally coexist in the same patient.

Destructive antibodies are directed against the microsomes or against thyroglobulin; the antigen for thyroid microsomal antibodies is the thyroid peroxidase (TPO) enzyme. TPO antibodies are found in up to 20% of the normal population, especially older women, but only 10–20% of these develop overt hypothyroidism.

TSH receptor IgG antibodies (TRAb) typically stimulate, but occasionally block, the receptor; they can be measured in two ways:
- by the inhibition of binding of TSH to its receptors (TSH-binding inhibitory immunoglobulin, TBI)
- by demonstrating that they stimulate the release of cyclic AMP (thyroid-stimulating immunoglobulin/antibody TSI, TSAb).

**Hypothyroidism**

**Pathophysiology**

Underactivity of the thyroid is usually primary, from disease of the thyroid, but may be secondary to hypothalamic–pituitary disease (reduced TSH drive) (Table 18.11). Primary hypothyroidism is one of the most common endocrine conditions with an overall UK prevalence of over 1% in women, but under 0.1% in men; lifetime prevalence for an individual is higher – perhaps as high as 9% for women and 1% for men with mean age at diagnosis around 60 years. The worldwide prevalence of subclinical hypothyroidism varies from 1 to 10%.

**Causes of primary hypothyroidism** (Table 18.11)

**Autoimmune**

**Atrophic (autoimmune) hypothyroidism.** This is the most common cause of hypothyroidism and is associated with antithyroid autoantibodies leading to lymphoid infiltration of the gland and eventual atrophy and fibrosis. It is six times more common in females and the incidence increases with age. The condition is associated with other autoimmune disease such as pernicious anaemia, vitiligo and other endocrine deficiencies (p. 965). In some instances intermittent hypothyroidism occurs with recovery from disease; antibodies which block the TSH receptor may sometimes be involved in the aetiology.

**Hashimoto’s thyroiditis.** This form of autoimmune thyroiditis, again more common in women and most common in late middle age, produces atrophic changes with regeneration, leading to goitre formation. The gland is usually firm and rubbery but may range from soft to hard. TPO antibodies are present, often in very high titres (>1000 IU/L). Patients may be hypothyroid or euthyroid, though they may go through an initial toxic phase, ‘Hashi-toxicity’. Liothyronine therapy may shrink the goitre even when the patient is not hypothyroid.

**Postpartum thyroiditis.** This is usually a transient phenomenon observed following pregnancy. It may cause hyperthyroidism, hypothyroidism or the two sequentially. It is believed to result from the modifications to the immune system necessary in pregnancy, and histologically is a lymphocytic thyroiditis. The process is normally self-limiting, but when conventional antibodies are found there is a high chance of this proceeding to permanent hypothyroidism. Postpartum thyroiditis may be misdiagnosed as postnatal depression, emphasizing the need for thyroid function tests in this situation.

**Defects of hormone synthesis**

**Iodine deficiency.** Dietary iodine deficiency still exists (p. 225) in some areas as ‘endemic goitre’ where goitre, occasionally massive, is common. The patients may be euthyroid or hypothyroid depending on the severity of iodine deficiency. The mechanism is thought to be borderline hypothyroidism leading to TSH stimulation and thyroid enlargement in the face of continuing iodine deficiency. Iodine deficiency is still a problem in the Netherlands, Western Pacific, South East Asia (e.g. the mountainous areas of the Himalayas) and Africa. Some countries affected by iodine deficiency, e.g. China and Kazakhstan, are taking action by providing iodine in salt but others, e.g. Russia, have so far not done so. Of the 500 million with iodine deficiency in India, about 2 million have cretinism.

**Dyshormonogenesis.** This rare condition is due to genetic defects in the synthesis of thyroid hormones; patients develop hypothyroidism with a goitre. One particular familial form is associated with sensorineural deafness due to a deletion mutation in chromosome 7, causing a defect of the transporter pendrin (Pendred’s syndrome) (see Fig. 18.14).

**Clinical features** (Fig. 18.15)

Hypothyroidism produces many symptoms. The alternative term ‘myxoedema’ refers to the accumulation of mucopolysaccharide in subcutaneous tissues. The classic picture of the slow, dry-haired, thick-skinned, deep-voiced patient with weight gain, cold intolerance, bradycardia and constipation makes the diagnosis easy. Milder symptoms are, however, more common and hard to distinguish from other causes of non-specific tiredness. Many cases are detected on biochemical screening.

Special difficulties in diagnosis may arise in certain circumstances:

- **Children with hypothyroidism** may not show classic features but often have a slow growth velocity, poor school performance and sometimes arrest of pubertal development.
- **Young women with hypothyroidism** may not show obvious signs. Hypothyroidism should be excluded in all patients with oligomenorrhea/amenorrhea, menorrhagia, infertility or hyperprolactinaemia.
- **The elderly** show many clinical features that are difficult to differentiate from normal ageing.

**Investigation of primary hypothyroidism**

Serum TSH is the investigation of choice; a high TSH level confirms primary hypothyroidism. A low free $T_4$ level confirms the hypothyroid state (and is also essential to exclude TSH deficiency if clinical hypothyroidism is strongly suspected and TSH is normal or low).

Thyroid and other organ-specific antibodies may be present. Other abnormalities include the following:

*Fig. 18.15* Hypothyroidism – symptoms and signs. Bold type indicates signs of greater discriminant value. A history from a relative is often revealing. Symptoms of other autoimmune disease may be present.

- **anaemia**, which is usually normochromic and normocytic in type but may be macrocytic (sometimes this is due to associated pernicious anaemia) or microcytic (in women, due to menorrhagia)
- **increased serum aspartate transferase levels**, from muscle and/or liver
- **increased serum creatine kinase levels**, with associated myopathy
- **hypercholesterolaemia and hypertriglyceridaemia**
- **hyponatraemia** due to an increase in ADH and impaired free water clearance.

### Treatment

*Replacement therapy* with levothyroxine (thyroxine, i.e. $T_4$) is given for life. The starting dose will depend upon the severity of the deficiency and on the age and fitness of the patient, especially their cardiac performance: 100 μg daily for the young and fit, 50 μg (increasing to 100 μg after 2–4 weeks) for the small, old or frail. Patients with ischaemic heart disease require even lower initial doses, especially if the hypothyroidism is severe and long-standing. Most physicians would then begin with 25 μg daily and perform serial ECGs, increasing the dose at 3- to 4-week intervals if angina does not occur or worsen and the ECG does not deteriorate.

**Monitoring.** The aim is to restore $T_4$ and TSH to well within the normal range. Adequacy of replacement is assessed clinically and by thyroid function tests after at least 6 weeks on a steady dose. If serum TSH remains high, the dose of $T_4$ should be increased in increments of 25–50 μg with the tests repeated at 6–8 weeks intervals until TSH becomes normal. Complete suppression of TSH should be avoided because of the risk of atrial fibrillation and osteoporosis. The usual maintenance dose is 100–150 μg given as a single daily dose. An annual thyroid function test is recommended – this is usually performed in the primary care setting, often assisted and prompted by district ‘thyroid registers’.

Clinical improvement on $T_4$ may not begin for 2 weeks or more, and full resolution of symptoms may take 6 months. The necessity of lifelong therapy must be emphasized and the possibility of other autoimmune endocrine disease developing, especially Addison’s disease or pernicious anaemia, should be considered. During pregnancy, an increase in $T_4$ dosage of about 25–50 μg is often needed to maintain normal TSH levels, and the necessity of optimal replacement during pregnancy is emphasized by the finding of reductions in cognitive function in children of mothers with elevated TSH during pregnancy.

A few patients with primary hypothyroidism complain of incomplete symptomatic response to $T_4$ replacement. Combination $T_4$ and $T_3$ replacement has been advocated in this context, but randomized clinical trials show no consistent benefit in quality of life symptoms.

### Borderline hypothyroidism or ‘compensated euthyroidism’

Patients are frequently seen with low-normal serum $T_4$ levels and slightly raised TSH levels. Sometimes this follows surgery or radioactive iodine therapy when it can reasonably be seen as ‘compensatory’. Treatment with levothyroxine is normally recommended where the TSH is consistently above 10 mU/L, or when possible symptoms, high-titre thyroid antibodies, or lipid abnormalities are present. Where the TSH is only marginally raised, the tests should be repeated 3–6 months later. Conversion to overt hypothyroidism is more common in men or when TPO antibodies are present. In practice, vague symptoms in patients with marginally elevated TSH (below 10 mU/L) rarely respond to treatment, but a ‘therapeutic trial’ of replacement may be needed to
confirm that symptoms are unrelated to the thyroid. It is also considered best to normalize TSH during (and ideally before) pregnancy to avoid fetal adverse effects.

**Myxoedema coma**

Severe hypothyroidism, especially in the elderly, may present with confusion or even coma. Myxoedema coma is very rare: hypothermia is often present and the patient may have severe cardiac failure, hypoventilation, hypoglycaemia and hyponatraemia. The mortality was previously at least 50% and patients require full intensive care. Optimal treatment is controversial and data lacking; most physicians would advise T₃ orally or intravenously in doses of 2.5–5 μg every 8 hours, then increasing as above. Large intravenous doses should not be used. Additional measures, though unproven, should include:

- oxygen (by ventilation if necessary)
- monitoring of cardiac output and pressures
- gradual rewarming
- hydrocortisone 100 mg i.v. 8-hourly
- glucose infusion to prevent hypoglycaemia.

‘Myxoedema madness’ Depression is common in hypothyroidism but rarely with severe hypothyroidism in the elderly the patient may become frankly demented or psychotic, sometimes with striking delusions. This may occur shortly after starting T₄ replacement.

**Screening for hypothyroidism**

- The incidence of congenital hypothyroidism is approximately 1 in 3500 births. Untreated, severe hypothyroidism produces permanent neurological and intellectual damage (‘cretinism’). Routine screening of the newborn using a blood spot, as in the Guthrie test, to detect a high TSH level as an indicator of primary hypothyroidism is efficient and cost-effective; cretinism is prevented if T₄ is started within the first few months of life.

- Screening of elderly patients for thyroid dysfunction has a low pick-up rate and is controversial and not currently recommended. However, patients who have undergone thyroid surgery or received iodine or amiodarone should have regular thyroid function tests, as should those receiving lithium or amiodarone therapy.

**HYPERTHYROIDISM**

Hyperthyroidism (thyroid overactivity, thyrotoxicosis) is common, affecting perhaps 2–5% of all females at some time and with a sex ratio of 5:1, most often between the ages of 20 and 40 years. Nearly all cases (>99%) are caused by intrinsic thyroid disease; a pituitary cause is extremely rare (Table 18.12).

**Graves’ disease**

This is the most common cause of hyperthyroidism and is due to an autoimmune process. Serum IgG antibodies bind to TSH receptors in the thyroid, stimulating thyroid hormone production, i.e. they behave like TSH. These TSH receptor antibodies (TSHR-Ab) are specific for Graves’ disease, can be measured in serum, are present in 85–90% of cases and decline with treatment. Persistent high levels predict a relapse when drug treatment is stopped. There is an association with HLA-B8, DR3 and DR2 and a 40% concordance rate amongst monozygotic twins with a 5% concordance rate in dizygotic twins. There is a weak association with cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), HLA-DRB*08 and DRB3*0202 on chromosome 6.

*Yersinia enterocolitica, Escherichia coli* and other Gram-negative organisms contain TSH binding sites. This raises the possibility that the initiating event in the pathogenesis may be an infection with possible ‘molecular mimicry’ in a genetically susceptible individual, but the precise initiating mechanisms remain unproven in most cases.

Thyroid eye disease accompanies the hyperthyroidism in many cases (see below) but other components of Graves’ disease, e.g. Graves’ dermopathy, are very rare. Rarely lymphadenopathy and splenomegaly may occur. Graves’ disease is also associated with other autoimmune disorders such as pernicious anaemia, vitiligo and myasthenia gravis.

The natural history is one of fluctuation, many patients showing a pattern of alternating relapse and remission; perhaps only 40% of subjects have a single episode. Many patients eventually become hypothyroid.

**Other causes of hyperthyroidism/thyrotoxicosis**

**Solitary toxic adenoma/nodule**

This is the case of about 5% of cases of hyperthyroidism. It does not usually remit after a course of antithyroid drugs.

**Toxic multinodular goitre**

This commonly occurs in older women. Again, antithyroid drugs are rarely successful in inducing a remission, although they can control the hyperthyroidism.

de Quervain’s thyroiditis
This is transient hyperthyroidism from an acute inflammatory process, probably viral in origin. Apart from the toxicosis, there is usually fever, malaise and pain in the neck with tachycardia and local thyroid tenderness. Thyroid function tests show initial hyperthyroidism, the erythrocyte sedimentation rate (ESR) and plasma viscosity are raised, and thyroid uptake scans show suppression of uptake in the acute phase. Hypothyroidism, usually transient, may then follow after a few weeks. Treatment of the acute phase is with aspirin, using short-term prednisolone in severely symptomatic cases.

Postpartum thyroiditis
This is described on page 985.

Amiodarone-induced thyrotoxicosis
Amiodarone, a class III antiarrhythmic drug (see p. 730), causes two types of hyperthyroidism.

Type I amiodarone-induced thyrotoxicosis (AIT) is associated with pre-existing Graves’ disease or multinodular goitre. In this situation hyperthyroidism is probably triggered by the high iodine content of amiodarone.

Type II AIT is not associated with previous thyroid disease and is thought to be due to a direct effect of the drug on thyroid follicular cells leading to a destructive thyroiditis with release of T4 and T3. Type II AIT may be associated with a hypothyroid phase several months after presentation. Because amiodarone inhibits the deiodination of T4 to T3, biochemical presentation of both types of AIT may be associated with higher T4:T3 ratios than usual.

Clinical features of hyperthyroidism
The symptoms and signs of hyperthyroidism affect many systems (Fig. 18.16).

Symptomatology and signs vary with age and with the underlying aetiology.

The eye signs, pretibial myxoedema and thyroid acropathy occur only in Graves’ disease. Pretibial myxoedema is an infiltration on the shin, essentially occurring only with eye disease (see below). Thyroid acropathy is very rare and consists of clubbing, swollen fingers and periosteal new bone formation.

In the elderly, a frequent presentation is with atrial fibrillation, other tachycardias and/or heart failure, often with few other signs. Thyroid function tests are mandatory in any patient with atrial fibrillation.

Children frequently present with excessive height or excessive growth rate, or with behavioural problems such as hyperactivity. They may also show weight gain rather than loss.

So-called ‘apathetic thyrotoxicosis’ in some elderly patients presents with a clinical picture more like hypothyroidism. There may be very few signs and a high degree of clinical suspicion is essential.

Differential diagnosis
Hyperthyroidism is often clinically obvious but treatment should never be instituted without biochemical confirmation.

Differentiation of the mild case from anxiety states may be difficult; useful positive clinical markers are eye signs, a diffuse goitre, proximal myopathy and wasting. Weight loss despite a normal or increased appetite is a very useful clinical symptom of hyperthyroidism. The hyperdynamic circulation with warm peripheries seen with hyperthyroidism can be contrasted with the clammy hands of anxiety.

Investigations
- Serum TSH is suppressed in hyperthyroidism (<0.05 mU/L), except for the very rare instances of TSH hypersecretion.
- A raised free T4 or T3 confirms the diagnosis; T4 is almost always raised but T3 is more sensitive as there are occasional cases of isolated ‘T3 toxicosis’.

Fig. 18.16 Hyperthyroidism – symptoms and signs. Bold type indicates signs of greater discriminant value.
TPO and thyroglobulin antibodies are present in most cases of Graves’ disease.

TSH receptor antibodies are not measured routinely, but are commonly present: thyroid-stimulating immunoglobulin (TSI) 80% positive, TSH-binding inhibitory immunoglobulin (TBI) 60–90% in Graves’ disease (see p. 987).

**Treatment**

Three possibilities are available: antithyroid drugs, radioiodine and surgery. Practices and beliefs differ widely within and between countries.

**Antithyroid drugs**

Carbimazole is most often used in the UK, and propylthiouracil is also used. Thiamazole (methimazole), the active metabolite of carbimazole, is used in the USA. These drugs inhibit the formation of thyroid hormones and also have other minor actions; carbimazole/thiamazole is also an immunosuppressive agent. Initial doses and side-effects are detailed in Table 18.13.

Although thyroid hormone synthesis is reduced very quickly, the long half-life of T₄ (7 days) means that clinical benefit is not apparent for 10–20 days. As many of the manifestations of hyperthyroidism are mediated via the sympathetic system, beta-blockers are used to provide rapid partial symptomatic control; they also decrease peripheral conversion of T₄ to T₃. Drugs preferred are those without intrinsic sympathomimetic activity, e.g. propranolol (Table 18.13). They should not be used alone for hyperthyroidism except when the condition is self-limiting, as in subacute thyroiditis.

Subsequent management is either by gradual dose titration or a ‘block and replace’ regimen. Neither regimen has been shown to be unequivocally superior. TSH often remains suppressed for many months after clinical improvement and normalization of T₄ and T₃.

**Gradual dose titration**

1. Start carbimazole 20–40 mg daily.
2. Review after 4–6 weeks and reduce dose of carbimazole depending on clinical state and T₄/T₃ levels. TSH levels may remain suppressed for several months and are unhelpful at this stage.
3. When clinically and biochemically euthyroid, stop beta-blockers.
4. Review after 2–3 months and, if controlled, reduce carbimazole.

5. Gradually reduce dose to 5 mg daily over 6–24 months if hyperthyroidism remains controlled.
6. When the patient is euthyroid on 5 mg daily carbimazole, discontinue.

Propylthiouracil is used in similar fashion (Table 18.13).

**‘Block and replace’ regimen**

With this policy, full doses of antithyroid drugs, usually carbimazole 40 mg daily, are given to suppress the thyroid completely while replacing thyroid activity with 100 μg of levothyroxine daily once euthyroidism has been achieved. This is continued usually for 18 months, the claimed advantages being the avoidance of over- or undertreatment and the better use of immunosuppressive action of carbimazole. This regimen is contraindicated in pregnancy as T₄ crosses the placenta less well than carbimazole.

**Relapse**

About 50% of patients will relapse after a course of carbimazole or propylthiouracil, mostly within the following 2 years but occasionally much later. Long-term antithyroid therapy is then used or surgery or radiotherapy is considered (see below). Most patients (90%) with hyperthyroidism have a diffuse goitre but those with large single or multinodular goitres are unlikely to remit after a course of antithyroid drugs and will usually require definitive treatment. Severe biochemical hyperthyroidism is also less likely to remain in remission.

**Toxicity**

The major side-effect of drug therapy is agranulocytosis that occurs in approximately 1 in 1000 patients, usually within 3 months of treatment. All patients must be warned to seek immediate medical attention for a white blood cell count if they develop unexplained fever or sore throat – written information is essential. Rash is more frequent and usually require a change of drug. If toxicity occurs on carbimazole, propylthiouracil may be used and vice versa; side-effects are only occasionally repeated on the other drug.

**Radioactive iodine**

Radioactive iodine (RAI) is given to patients of all ages, although it is contraindicated in pregnancy and while breast-feeding. RAI is the most common treatment modality in the USA whereas antithyroid drugs tend to be favoured in Europe.

Choice of therapy
Indications for either surgery or radioiodine are:
- patient choice
- persistent drug side-effects
- poor compliance with drug therapy
- recurrent hyperthyroidism after drugs.

Particular indications for surgery include:
- a large goitre, which is unlikely to remit after antithyroid medication.

Special situations in hyperthyroidism

Thyroid crisis or ‘thyroid storm’
This rare condition, with a mortality of 10%, is a rapid deterioration of hyperthyroidism with hyperpyrexia, severe tachycardia, extreme restlessness, cardiac failure and liver dysfunction. It is usually precipitated by stress, infection or surgery in an unprepared patient, or radioiodine therapy. With careful management it should no longer occur and most cases referred as ‘crisis’ are simply severe but uncomplicated thyrotoxicosis.

Treatment is urgent. Propranolol in full doses is started immediately together with potassium iodide, antithyroid drugs, corticosteroids (which suppress many of the manifestations of hyperthyroidism) and full supportive measures. Control of cardiac failure and tachycardia is also necessary.

Hyperthyroidism in pregnancy and neonatal life
The high level of HCG found in pregnancy is a weak stimulator of the TSH receptor, commonly causing suppressed TSH with slightly elevated fT₄/fT₃ in the first trimester which may be associated with hyperemesis gravidarum. True maternal hyperthyroidism during pregnancy is however uncommon and usually mild. Diagnosis can be difficult because of the overlap with symptoms of normal pregnancy and misleading thyroid function tests, although TSH is largely reliable. The pathogenesis is almost always Graves’ disease. Thyroid-stimulating immunoglobulin (TSI) crosses the placenta to stimulate the fetal thyroid. Carbimazole also crosses the placenta, but T₃ does so poorly, so a ‘block-and-replace’ regimen is contraindicated. The smallest dose of carbimazole necessary is used and the fetus must be monitored (see below). The paediatrician should be informed and the infant checked immediately after birth – overtreatment with carbimazole can cause fetal goitre. Breast-feeding while on usual doses of carbimazole or propylthiouracil appears to be safe.

If necessary (high doses needed, poor patient compliance or drug side-effects), surgery can be performed, preferably in the second trimester. Radioactive iodine is absolutely contraindicated.

The fetus and maternal Graves’ disease
Any mother with a history of Graves’ disease may have circulating TSI. Even if she has been treated (e.g. by surgery), the immunoglobulin may still be present to stimulate the fetal thyroid, and the fetus can thus become hyperthyroid, while the mother remains euthyroid.

Any such patient should therefore be monitored during pregnancy. Fetal heart rate provides a direct biological assay
of fetal thyroid status, and monitoring should be performed at least monthly. Rates above 160 per minute are strongly suggestive of fetal hyperthyroidism, and maternal treatment with carbimazole and/or propranolol is used. Direct measurement of TSHR-Ab may be helpful to predict neonatal thyroidotoxicosis in this situation. To prevent the mother becoming hypothyroid, T₄ may be given as this does not easily cross the placenta. Sympathomimetics, used to prevent premature labour, are contraindicated as they may provoke fetal tachycardia in the fetus.

Hyperthyroidism may also develop in the neonatal period as TSI has a half-life of approximately 3 weeks. Manifestations in the newborn include irritability, failure to thrive and persisting weight loss, diarrhoea and eye signs. Thyroid function tests are difficult to interpret as neonatal normal ranges vary with age.

Untreated neonatal hyperthyroidism is probably associated with hyperactivity in later childhood.

**Thyroid hormone resistance**

Thyroid hormone resistance is an inherited condition caused by an abnormality of the thyroid hormone receptor. Mutations to the receptor (TRβ1) result in the need for higher levels of thyroid hormones to achieve the same intracellular effect. As a result, the normal feedback control mechanisms (see Fig. 18.2, p. 967) result in high blood levels of T₄ with a normal TSH in order to maintain a euthyroid state. This has two consequences:

1. First, thyroid function tests appear abnormal even when the patient is euthyroid and requires no treatment. Specialist review is required to differentiate from hyperthyroidism due to inappropriate TSH secretion.
2. Second, different tissues contain different thyroid hormone receptors and, in some families, receptors in certain tissues may have normal activity. In this case the level of thyroid hormones to maintain euthyroidism at pituitary and hypothalamic levels (which controls secretion of TSH) may be higher than that required in other tissues such as heart and bone, so that these tissues may exhibit ‘thyroxic’ effects in spite of a normal serum TSH. This ‘partial thyroid hormone resistance’ can be very difficult to manage effectively.

**Long-term consequences of hyperthyroidism**

Long-term follow-up studies of hyperthyroidism show a slight increase in overall mortality, which affects all age groups, is not fully explained and tends to occur in the first year after diagnosis. Thereafter, the only long-term risk of adequately treated hyperthyroidism appears to be an increased risk of osteoporosis. Patients with persistently suppressed TSH levels have an increased likelihood of developing atrial fibrillation which may predispose to thromboembolic disease.

**THYROID EYE DISEASE**

This is also known as dysthyroid eye disease or ophthalmic Graves’ disease.

**Pathophysiology**

The ophthalmopathy of Graves’ disease is due to a specific immune response that causes retro-orbital inflammation. Swelling and oedema of the extraocular muscles lead to limitation of movement and to proptosis which is usually bilateral but can sometimes be unilateral. Ultimately increased pressure on the optic nerve may cause optic atrophy. Histology shows focal oedema and glycaminoglycan deposition followed by fibrosis. The precise autoantigen which leads to the immune response remains to be identified, but it appears to be an antigen in retro-orbital tissue with similar immuno-reactivity to the TSH receptor.

Eye disease is a manifestation of Graves’ disease and can occur in patients who may be hyperthyroid, euthyroid or hypothyroid. Thyroid dysfunction and ophthalmopathy usually occur within two years of each other although sometimes a gap of many years is seen. TSH receptor antibodies are almost invariably found in the serum but their role in the pathogenesis is unclear. Ophthalmopathy is more common and more severe in smokers.

**Clinical features**

The clinical appearances are characteristic (Fig. 18.16) but thyroid eye disease demonstrates a wide range of severity. A high proportion of patients with Graves’ disease notice some soreness, painful watering or prominence of the eyes, and the ‘stare’ of lid retraction is relatively common. More severe proptosis occurs in a minority of cases, and limitation and discomfort of eye movement and visual impairment due to optic nerve compression are relatively uncommon. Proptosis and lid retraction may limit the ability to close the eyes completely so that corneal damage may occur. There is periorbital oedema and conjunctival oedema and inflammation.

Eye manifestations do not parallel the degree of biochemical thyrotoxicosis, or the need for antithyroid therapy, but exacerbation of eye disease is more common after radiiodine treatment (15% vs 3% on antithyroid drugs). Sight is threatened in only 5–10% of cases, but the discomfort and cosmetic problems cause great patient anxiety.

**Investigations**

Few investigations are necessary if the appearances are characteristic and bilateral. TSH, T₃ and free T₄ are measured.

There are a variety of grading systems but none is universally accepted. It is essential to clearly document eye movements and the degree of oedema and inflammation. The exophthalmos should be measured to allow progress to be monitored. MRI or CT of the orbits will exclude retro-orbital space-occupying lesions and show enlarged muscles and oedema, and may show a taut optic nerve due to raised intra-orbital pressure.

**Treatment**

If the patient is thyrotoxic this should be treated, but this will not directly result in an improvement of the ophthalmopathy, and hypothyroidism must be avoided as it may exacerbate the eye problem. Smoking should be stopped. Treatment of the eyes may be either local or systemic, and always requires close liaison between specialist endocrinologist and ophthalmologist:

- **Methylcellulose or hypromellose eyedrops** are given to aid lubrication and improve comfort.
- **Some patients gain relief by sleeping upright.**
- **The eyelids can be taped to ensure closure at night.** In the rare case, a tarsorrhaphy (eyelids partly sewn together) is required.
- Systemic steroids (prednisolone 30–120 mg daily) usually reduce inflammation if more severe symptoms are present. Pulse intravenous methylprednisolone may be more rapidly effective in severe cases.
- Irradiation of the orbits (20 Gy in divided doses) is used in severe instances. This improves inflammation and ocular motility but has little effect on proptosis and its precise role is debated.
- Lid surgery will protect the cornea if lids cannot be closed.
- Surgical decompression of the orbit(s) may be required, particularly if pressure of orbital contents on the optic nerve threatens vision, and at a later, stable stage for cosmetic reasons.
- Corrective eye muscle surgery may improve diplopia due to muscle changes, but should be deferred until the situation has been stable for 6 months and should follow any orbital decompression. Plastic surgery around the eyes may also be of value.

**GOITRE (THYROID ENLARGEMENT)**

Goitre is more common in women than in men and may be either physiological or pathological.

**Clinical features**

Goitres are present on examination in up to 9% of the population. Most commonly a goitre is noticed as a cosmetic defect by the patient or by friends or relatives. The majority are painless, but pain or discomfort can occur in acute varieties. Large goitres can produce dysphagia and difficulty in breathing, implying oesophageal or tracheal compression.

A small goitre may be more easily visible (on swallowing) than palpable. Clinical examination should record the size, shape, consistency and mobility of the gland as well as whether its lower margin can be demarcated (thus implying the absence of retrosternal extension). A bruit may be present. Associated lymph nodes should be sought and the tracheal position determined if possible. Examination should never omit an assessment of the patient’s clinical thyroid status.

Specific enquiry should be made about any medication, especially iodine-containing preparations, and possible exposure to radiation.

Particular points of note are:

- Puberty and pregnancy may produce a diffuse increase in size of the thyroid.
- Pain in a goitre may be caused by thyroiditis, bleeding into a cyst or (rarely) a thyroid tumour.
- Excessive doses of carbimazole or propylthiouracil will induce goitre.
- Iodine deficiency and dyshormonogenesis (see above) can also cause goitre.

**Assessment**

There are two major aspects of any goitre: its pathological nature and the patient’s thyroid status.

The nature can often be judged clinically. Goitres (Table 18.14) are usually separable into diffuse and nodular types, the causes of which differ.

**Diffuse goitre**

**Simple goitre**

In this instance no clear cause is found for enlargement of the thyroid, which is usually smooth and soft. It may be associated with thyroid growth-stimulating antibodies.

**Autoimmune thyroid disease**

Hashimoto’s thyroiditis and thyrotoxicosis are both associated with firm diffuse goitre of variable size. A bruit is often present in thyrotoxicosis.

**Thyroiditis**

Acute tenderness in a diffuse swelling, sometimes with severe pain, is suggestive of an acute viral thyroiditis (de Quervain’s). It may produce transient clinical hyperthyroidism with an increase in serum $T_4$ (see p. 968).

**Nodular goitres**

**Multinodular goitre**

Most common is the multinodular goitre, especially in older patients. The patient is usually euthyroid but may be hyperthyroid or borderline with suppressed TSH levels but normal $T_4$ and $T_3$. Multinodular goitre is the most common cause of tracheal and/or oesophageal compression and can cause laryngeal nerve palsy. It may also extend retrosternally. The classical ‘multinodular goitre’ is usually readily apparent clinically, but it should be noted that modern, high-resolution ultrasound frequently reports multiple small nodules in glands which are clinically diffusely enlarged and associated with autoimmune thyroid disease. These nodules are also found in up to 40% of the normal population.

**Solitary nodular goitre**

Such a goitre presents a difficult problem of diagnosis. Malignancy should be considered in any solitary nodule –
however, the majority of such nodules are cystic or benign and, indeed, may simply be the largest nodule of a multi-nodular goitre. The diagnostic challenge is to identify the small minority of malignant nodules, which require surgery, from the majority of benign nodules, which do not. A history of rapid enlargement, associated lymph nodes or occasionally pain in such a situation suggests the possibility of thyroid carcinoma, but investigations are paramount. Risk factors for malignancy include previous irradiation, long-standing iodine deficiency and occasional familial cases.

Solitary toxic nodules are quite uncommon and may be associated with T₃ toxicosis.

**Fibrotic goitre**
Fibrotic goitre (Riedel’s thyroiditis) is a rare condition, usually producing a ‘woody’ gland. It is associated with other midline fibrosis and is often difficult to distinguish from carcinoma, being irregular and hard. Clinical clues include systemic symptoms of inflammation and elevation in inflammatory markers.

**Malignancy**
In addition to thyroid carcinomas (see below), the thyroid is rarely the site of a metastatic deposit or the site of origin of a lymphoma.

**Investigations**
Clinical findings will dictate appropriate initial tests:

- **Thyroid function tests** – TSH plus free T₄ or T₃ (see Table 18.10).
- **Thyroid antibodies** – to exclude autoimmune aetiology.
- **Ultrasound.** Ultrasound with high resolution is a sensitive method for delineating nodules and can demonstrate whether they are cystic or solid. In addition, a multinodular goitre may be demonstrated when only a single nodule is palpable. Unfortunately, even cystic lesions can be malignant and thyroid tumours may arise within a multinodular goitre; therefore fine-needle aspiration (see below) is often required and performed under ultrasound control at the same time as the scan.

- **Chest and thoracic inlet X-rays** to detect tracheal compression and large retrosternal extensions in patients with very large goitre or clinical symptoms.

- **Fine-needle aspiration (FNA).** In patients with a solitary nodule or a dominant nodule in a multinodular goitre, there is a 5% chance of malignancy; in view of this, FNA should be performed. This can be done in the outpatient clinic. Cytology in expert hands can usually differentiate the suspicious or definitely malignant nodule.

FNA reduces the necessity for surgery, but there is a 5% false-negative rate which must be borne in mind (and the patient appropriately counselled). Continued observation is required when an isolated thyroid nodule is assumed to be benign without excision.

**Thyroid scan** (¹³¹I or ¹²³I) can be useful to distinguish between functioning (hot) or non-functioning (cold) nodules. A hot nodule is only rarely malignant; however, a cold nodule is malignant in only 10% of cases and FNA has largely replaced isotope scans in the diagnosis of thyroid nodules.

**Treatment**

**Euthyroid goitre**
Many goitres are small, cause no symptoms and can be observed (including self-monitoring by the patient in the long term). In particular, during puberty and pregnancy a goitre associated with euthyroidism rarely requires intervention and the patient can be reassured that spontaneous resolution is likely. When thyroid function is abnormal the patient should be rendered euthyroid. Indications for surgical intervention are:

- **The possibility of malignancy.** A history of rapid growth, pain, cervical lymphadenopathy, change in voice or previous irradiation to the neck are worrying features. A positive or suspicious FNA makes surgery mandatory and surgery may be necessary if doubt persists even in the presence of a negative FNA (especially if the patient is concerned by the false negative rate).

- **Pressure symptoms on the trachea or, more rarely, oesophagus.** The possibility of retrosternal extension should be excluded.

- **Cosmetic reasons.** A large goitre is often a considerable anxiety to the patient even though functionally and anatomically benign.

Recent guidelines suggest possible use of RAI in euthyroid goiter, particularly when surgery is an unattractive option.

**Toxic nodule**
This is initially with antithyroid drugs but surgery or radioiodine is often required.

**THYROID CARCINOMA**
Types of thyroid carcinoma, their characteristics and treatment are listed in Table 18.15. While not common, these tumours are responsible for 400 deaths annually in the UK and an annual incidence of 30,000 cases in the USA. Over 75% occur in women. In 90% of cases they present as thyroid nodules (see above), but occasionally with cervical lymphadenopathy (about 5%), or with lung, cerebral, hepatic or bone metastases.

</tbody>
</table>
Carcinomas derived from thyroid epithelium may be papillary or follicular (differentiated) or anaplastic (undifferentiated), while medullary carcinomas (about 5% of all thyroid cancers) arise from the calcitonin-producing C cells. The pathogenesis of thyroid epithelial carcinomas is not understood except for occasional familial papillary carcinoma and those cases related to previous head and neck irradiation or ingestion of radioactive iodine (e.g. post Chernobyl). These tumours are minimally active hormonally and are extremely rarely associated with hyperthyroidism; over 90%, however, secrete thyroglobulin, which can therefore act as a tumour marker.

Papillary and follicular carcinomas

The primary treatment is surgical, normally total or near-total thyroidectomy for local disease. Regional or more extensive neck dissection is needed where there is local nodal spread or involvement of local structures.

Most tumours will take up iodine, and UK guidelines currently recommend radioactive iodine (RAI) ablation of residual thyroid tissue post-operatively for most patients with differentiated thyroid cancer. After ablation of normal thyroid in this way, RAI may be used to localize residual disease (scanning using low doses) or to treat it (using high doses – 5.5–7.5 GBq). When recurrence does occur, local invasion and lymph node involvement is most common, and lungs and bone are the most common sites of distant metastases.

Patients are treated with suppressive doses of levothyroxine (sufficient to suppress TSH levels below the normal range) in order to minimize risk of recurrence. Patient progress is monitored both clinically and biochemically using serum thyroglobulin levels as a tumour marker. The measurement of thyroglobulin is most sensitive when TSH is high but this requires the withdrawal of levothyroxine therapy. Recombinant TSH (thyrotropin alfa, rhTSH) 900 μg (2 doses over 48 hours) is used to stimulate thyroglobulin without stopping thyroxine therapy. Detectable thyroglobulin suggests recurrence, in which case whole body 131I scanning is required.

The prognosis is extremely good when these types of tumour are excised while confined to the thyroid gland, and the specific therapies available lead to a relatively good prognosis even in the presence of metastases at diagnosis. Accepted markers of high risk include greater age (>40 years), larger primary tumour size (>4 cm) and macroscopic invasion of capsule and surrounding tissues.

Anaplastic carcinomas and lymphoma

These do not respond to radioactive iodine, and external radiotherapy produces only a brief respite.

Medullary carcinoma

Medullary carcinoma (MTC) is a neuroendocrine tumour of the calcitonin-producing C cells of the thyroid. This condition is often associated with multiple endocrine neoplasia type 2 (MEN 2, see p. 1026), although the other manifestations of MEN 2 may be absent. Approximately 25% of patients diagnosed with MTC have a mutation of the RET proto-oncogene, hence the importance of genetic counselling and family screening. Total thyroidectomy and wide lymph node clearance is usually indicated in MTC. Local invasion or metastasis is frequent, and the tumour responds poorly to treatment, although progression is often slow.

FURTHER READING

REPRODUCTION AND SEX

The normal physiology of the female and male reproductive systems will be considered first, followed by their common disorders. Some relevant terminology is set out in Box 18.4.

Embryology

Up to 8 weeks of gestation the sexes share a common development, with a primitive genital tract including the Wolffian and Müllerian ducts. There are additionally a primitive perineum and primitive gonads.

□ In the presence of a Y chromosome, the potential testis develops while the ovary regresses.

□ In the absence of a Y chromosome, the potential ovary develops and related ducts form a uterus and the upper vagina.

Production of Müllerian inhibitory factor from the early ‘testis’ produces atrophy of the Müllerian duct, while, under the influence of testosterone and dihydrotestosterone, the Wolffian duct differentiates into an epididymis, vas deferens, seminal vesicles and prostate. Androgens induce transformation of the perineum to include a penis, penile urethra and scrotum containing the testes, which descend in response to androgenic stimulation. At birth, testicular volume is 0.5–1 mL.

Physiology

The male

An outline of the hypothalamic–pituitary–testicular axis is shown in Figure 18.17.

1. Pulses of gonadotrophin releasing hormone (GnRH) are released from the hypothalamus and stimulate LH and FSH release from the pituitary. LH and FSH are composed of two glycoprotein chains (α and β subunits). The α subunits are identical and are shared with TSH, whilst the β subunit confers specific biological activity.

2. LH stimulates testosterone production from Leydig cells of the testis.

3. Testosterone acts via nuclear androgen receptors which interact with co-regulatory proteins to produce the appropriate tissue responses – male secondary sexual characteristics, anabolism and the maintenance of
**Fig. 18.17** Male and female hypothalamic-pituitary-gonadal axes. LH and FSH are secreted in pulses in response to hypothalamic GnRH and have differential effects on the gonads (see text). Testosterone and oestrogens have multiple peripheral effects and exert negative feedback on LH secretion. Inhibin exerts negative feedback on FSH secretion.

**Box 18.4** Definitions in reproductive medicine

- **Menarche**: Age at first period
- **Primary amenorrhoea**: Failure to begin spontaneous menstruation by age 16
- **Secondary amenorrhoea**: Absence of menstruation for 3 months in a woman who has previously had cycles
- **Oligomenorrhoea**: Irregular long cycles; often used for any length of cycle above 32 days
- **Dyspareunia**: Pain or discomfort in the female during intercourse
- **Libido**: Sexual interest or desire; often difficult to assess and is greatly affected by stress, tiredness and psychological factors
- **Menstruation**: Onset of spontaneous (usually regular) uterine bleeding in the female
- **Erectile dysfunction**: Inability of the male to achieve or sustain an erection adequate for satisfactory intercourse
- **Azoospermia**: Absence of sperm in the ejaculate
- **Oligospermia**: Reduced numbers of sperm in the ejaculate; normal values are disputed
- **Virilization**: Occurrence of male secondary sexual characteristics in the female

libido. It also acts locally within the testis to aid spermatogenesis. Testosterone circulates largely bound to sex hormone-binding globulin (SHBG) (see p. 966). Testosterone feeds back on the hypothalamus/pituitary to inhibit GnRH secretion.

4. FSH stimulates the Sertoli cells in the seminiferous tubules to produce mature sperm and the inhibins A and B.

5. Inhibin feeds back to the pituitary to decrease FSH secretion. Activin, a related peptide, counteracts inhibin.

**Fig. 18.18** Hormonal and follicular changes during the normal menstrual cycle.

The secondary sexual characteristics of the male for which testosterone is necessary are the growth of pubic, axillary and facial hair, enlargement of the external genitalia, deepening of the voice, sebum secretion, muscle growth and frontal balding.

**The female**

The female situation is more complex (Figs 18.17 and 18.18).

1. In the adult female, higher brain centres impose a menstrual cycle of 28 days upon the activity of hypothalamic GnRH.

2. Pulses of GnRH, at about 2-hour intervals, stimulate release of pituitary LH and FSH.
3. LH stimulates ovarian androgen production by the ovarian theca cells.
4. FSH stimulates follicular development and aromatase activity (an enzyme required to convert ovarian androgens to estrogens) in the ovarian granulosa cells. FSH also stimulates release of inhibin from ovarian stromal cells, which inhibits FSH release. Activin counteracts inhibin (Fig. 18.17).
5. Although many follicles are ‘recruited’ for development in early folliculogenesis, by day 8–10 a ‘leading’ (or ‘dominant’) follicle is selected for development into a mature Graafian follicle.
6. Oestrogens show a double feedback action on the pituitary (Fig. 18.17), initially inhibiting gonadotrophin secretion (negative feedback), but later high-level exposure results in increased GnRH secretion and increased LH sensitivity to GnRH (positive feedback), which leads to the mid-cycle LH surge inducing ovulation from the leading follicle (Fig. 18.18).
7. The follicle then differentiates into a corpus luteum, which secretes both progesterone and oestadiol during the second half of the cycle (luteal phase).
8. Oestrogen initially and then progesterone cause uterine endometrial proliferation in preparation for possible implantation; if implantation does not occur, the corpus luteum regresses and progesterone secretion and inhibin levels fall so that the endometrium is shed (menstruation) allowing increased GnRH and FSH secretion.
9. If implantation and pregnancy follow, human chorionic gonadotrophin (HCG) production from the trophoblast maintains corpus luteum function until 10–12 weeks of gestation, by which time the placenta will be making sufficient oestrogen and progesterone to support itself.

Oestrogens also induce secondary sexual characteristics, especially development of the breast and nipples, vaginal and vulval growth and pubic hair development. They also induce growth and maturation of the uterus and Fallopian tubes. They circulate largely bound to SHBG.

**Puberty**

The mechanisms initiating puberty are poorly understood but are thought to result from withdrawal of central inhibition of GnRH release. Environmental and physical factors are involved in the timing of puberty (including body fat changes, physical exercise) as well as genetic factors (e.g. a G protein-coupled receptor gene, GPR54) required for pubertal maturation. Kisspeptin is the endogenous ligand for GPR54 and this peptide is believed to play a crucial role in the regulation of GnRH production and the timing of puberty.

LH and FSH are both low in the prepubertal child. In early puberty, FSH begins to rise first, initially in nocturnal pulses; this is followed by a rise in LH with a subsequent increase in testosterone/estrogen levels. The milestones of puberty in the two sexes are shown in Figure 18.19.

**In boys**, pubertal changes begin at between 10 and 14 years and are complete at between 15 and 17 years. The genitalia develop, testes enlarge and the area of pubic hair increases. Peak height velocity is reached between ages 12 and 17 years during stage 4 of testicular development. Full spermatogenesis occurs comparatively late.

**In girls**, events start a year earlier. Breast bud enlargement begins at age 9–13 years and continues to 12–18 years.

Pubic hair growth commences at ages 9–14 years and is completed at 12–16 years. Menarche occurs relatively late (age 11–15 years) but peak height velocity is reached earlier (at age 10–13 years), and growth is completed much earlier than in boys.

**Precocious puberty**

Development of secondary sexual characteristics, or menarche in girls, at or before the age of 9 years is premature. All cases require assessment by a paediatric endocrinologist.

*Idiopathic (true) precocity* is most common in girls and very rare in boys. This is a diagnosis of exclusion. With no apparent cause for premature breast or pubic hair development, and an early growth spurt, it may be normal and may run in families. Treatment with long-acting GnRH analogues (given by nasal spray, by subcutaneous injection or by implant) causes suppression of gonadotrophin release via downregulation of the receptor – and therefore reduced sex hormone production – and is moderately effective; cyproterone acetate, an antiandrogen with progesterational activity, is also used.

Other forms of precocity include:

- **Cerebral precocity.** Many causes of hypothalamic disease, especially tumours, present in this way. In boys this must be rigorously excluded. MRI scan is almost always indicated to exclude this diagnosis.
- **McCune-Albright syndrome.** This usually occurs in girls, with precocity, polyostotic fibrous dysplasia and skin pigmentation (cafe-au-lait). See also page 1026.
- **Premature thelarche.** This is early breast development alone, usually transient, at age 2–4 years. It may regress or persist until puberty. There is no evidence of follicular development.
- **Premature adrenarche.** This is early development of pubic hair without significant other changes, usually after the age of 5 years and more commonly in girls.
It is also more common in obese children due to reduced SHBG levels leading to higher free circulating androgens. In boys with precocious adrenarche, the rare possibility of an androgen-secreting testicular tumour should be looked for if serum androgens are high and LH is suppressed.

Delayed puberty
Over 95% of children show signs of pubertal development by the age of 14 years. In its absence, investigation should begin by the age of 15 years. Causes of hypogonadism (see below) are clearly relevant but most cases represent constitutional delay.

In constitutional delay, pubertal development, bone age and stature are in parallel. A family history may confirm that other family members experienced the same delayed development, which is common in boys but very rare in girls.

In boys, a testicular volume >5 mL indicates the onset of puberty. A rising serum testosterone is an earlier clue.

In girls, the breast bud is the first sign. Ultrasound allows accurate assessment of ovarian and uterine development.

Basal LH/FSH levels may identify the site of a defect, and GnRH (LHRH) tests can indicate the stage of early puberty.

If any progression into puberty is evident clinically, investigations are not required. When delay is great and problems are serious (e.g. severe teasing at school), low-dose short-term sex hormone therapy is used.

The menopause
The menopause, or cessation of periods, naturally occurs at about the age of 45–55 years. During the late forties, FSH initially, and then LH concentrations begin to rise, probably as follicle supply diminishes. Oestrogen levels fall and the cycle becomes disrupted. Most women notice irregular scanty periods coming on over a variable period, though in some sudden amenorrhea or amenorrhagia occurs. Eventually the menopausal pattern of low oestriadiol levels with grossly elevated LH and FSH levels (usually >50 and >25 U/L, respectively) is established. Premature menopause may also occur surgically, with radiotherapy to the ovaries and with ovarian disease.

Clinical features and treatment
Features of oestrogen deficiency are hot flushes (which occur in most women and can be disabling), vaginal dryness and atrophy of the breasts. There may also be vague symptoms of loss of libido, loss of self-esteem, non-specific aches and pains, irritability, depression, loss of concentration and weight gain.

Women show a rapid loss of bone density in the 10 years following the menopause (osteoporosis, see p. 561) and the premenopausal protection from ischaemic heart disease disappears.

Hormone replacement therapy (HRT). Symptomatic patients should usually be treated but the previous widespread use of HRT has been thrown into doubt by a number of large prospective studies which have reported in recent years. Although there is no universal agreement, the overall benefits and risks are summarized as follows (percentages are from the Women’s Health Initiative (WHI) study of 16600 women):

- Symptomatic improvement in most menopausal symptoms for the majority of women. Oestrogen-deficient symptoms respond well to oestrogen replacement, the vaguer symptoms generally, but not always, less well. Vaginal symptoms also respond to local oestrogen preparations.
- Protection against fractures of wrist, spine and hip, secondary to osteoporosis (~24–33%) (see Ch. 10), owing to protection of predominantly trabecular bone (p. 557). However, this is not a recommended indication for therapy.
- A significant reduction in the risk of large bowel cancer (~33%).
- A significant increase in the risk of breast cancer (~26%), but no change in breast cancer mortality, and some studies suggest that breast cancers diagnosed on HRT are easier to treat effectively. This increased risk has been disputed.
- A significant increase in the risk of endometrial cancer when unopposed oestrogens are given to women with a uterus.
- A significant increase in the risk of ischaemic heart disease (~29%) and stroke (~41%).
- The inconvenience of withdrawal bleeds, unless a hysterectomy has been performed or regimens which include continuous oestrogen and progesterone are used.
- Other disputed effects include possible increase in general well-being but there is no reduction in the incidence of Alzheimer’s disease.

Absolute risks and benefits for individual women clearly depend on their background risk of that disease, and there is as yet no evidence on the relative risks of different hormone preparations or routes of administration (oral, transdermal or implant). Overall, the WHI study estimated that, over 5 years of treatment, an extra 1 woman in every 100 would develop an illness that would not have occurred had she not been taking HRT. However, the decision about whether or not a woman takes HRT is now very much an individual decision based on the severity of that woman’s menopausal symptoms, her personal risk of conditions which may be prevented or made more likely by HRT, and ultimately individual patient choice. HRT is not recommended purely for prevention of postmenopausal osteoporosis in the absence of menopausal symptoms.

Symptomatic treatment is the main indication with the lowest effective dose given for short-term rather than long-term treatment.

Selective oestrogen receptor modulators, SERMs (e.g. raloxifene), offer a potentially attractive combination of positive oestrogen effects on bone and cardiovascular system with no effects on oestrogen receptors of uterus and breast and possible reduction in breast cancer incidence; long-term outcome studies, however, are still awaited.

Premature menopause
The most common cause of premature menopause in women (before age 40) is ovarian failure, which may be autoimmune. It is rarely caused by identifiable genetic causes such as the fragile X pre-mutation but is most commonly of unknown aetiology (although often familial). Repeat LH/FSH levels are necessary before giving a diagnosis of premature menopause because of the psychological impact of this diagnosis
and the possibility that a single elevation of LH/FSH might simply be the mid-cycle ovulatory surge. Bilateral oophorectomy causes the same oestrogen deficiency state. HRT should almost always be given, as the risk of osteoporosis and other conditions related to oestrogen deficiency almost always outweighs the risks of HRT at this younger age. HRT may still be also be actively recommended when normal menopause occurs relatively early (e.g. before the age of 50).

The ageing male

In the male there is no sudden ‘change of life’. However, there is a progressive loss in sexual function with reduction in morning erections and frequency of intercourse.

The age of onset varies widely, but overall testicular volume diminishes and sex hormone-binding globulin (SHBG) and gonadotrophin levels gradually rise. If premature hypogonadism is present for any reason, replacement testosterone therapy should be given to prevent osteoporosis (see p. 565). More widespread androgen replacement of the ageing male is under evaluation, primarily in the USA, with variable results in earlier, small studies, but no long-term follow-up data are available. However, the increasing choice of preparations for testosterone replacement largely reflects the interest of the pharmaceutical industry in this situation.

Conversely, lowering of androgens forms part of the therapy of prostate hypertrophy and prostate cancer. Finasteride, an inhibitor of 5α-reductase, is used in benign prostatic hypertrophy. It prevents the conversion of testosterone to dihydrotestosterone, which causes prostatic hypertrophy, and is effective, though somewhat delayed in action (see p. 645). GnRH analogues are used to lower testosterone levels and induce disease remission in patients with prostate cancer (p. 492).

CLINICAL FEATURES OF DISORDERS OF SEX AND REPRODUCTION

A detailed history and examination of all systems is required (Box 18.5). A man having regular satisfactory intercourse or a woman with regular ovulatory periods is most unlikely to have significant endocrine disease, assuming the history is accurate (check with the partner!).

**Tests of gonadal function**

Basal measurements of the gonadotrophins, oestrogens/testosterone and prolactin:

- Low testosterone or oestradiol with high gonadotrophins indicates primary gonadal disease.
- Low levels of testosterone/oestradiol with low or normal LH/FSH imply hypothalamic–pituitary disease.
- Demonstration of ovulation (by measurement of luteal phase serum progesterone and/or by serial ovarian ultrasound in the follicular phase) or a healthy sperm count (20–200 million/mL, >60% grade 1 motility and <20% abnormal forms), provide absolute confirmation of normal female or male reproductive endocrinology, but these tests are not always essential.
- Pregnancy provides complete demonstration of normal male and female function.
- Hyperprolactinaemia can be confirmed or excluded by direct measurement. Levels may increase with stress; if this is suspected, a cannula should be inserted and samples taken through it 30 minutes later.

More detailed tests are indicated in Table 18.16.

**DISORDERS IN THE MALE**

**Hypogonadism**

**Clinical features**

Male hypogonadism may be a presenting complaint or an incidental finding, such as during investigation for subfertility. The testes may be small and soft and there may be gynae-
Comastia. Except with subfertility, the symptoms are usually of androgen deficiency, primarily poor libido, erectile dysfunction and loss of secondary sexual hair (Table 18.17) rather than deficiency of semen production. Sperm makes up only a very small proportion of seminal fluid volume; most is prostatic fluid.

Causes of male hypogonadism are shown in Table 18.18.

Investigations

Testicular disease may be immediately apparent but basal levels of testosterone, LH and FSH should be measured. These will allow the distinction between primary gonadal (testicular) failure and hypothalamic–pituitary disease to be made. Depending on the causes, semen analysis, chromosomal analysis (e.g. to exclude Klinefelter’s syndrome) and bone age estimation are required.

In clear-cut gonadotrophin deficiency, pituitary MRI scan, prolactin levels and other pituitary function tests are needed.

Table 18.17

However, equivocal lowering of serum testosterone (7–10 nmol/L) without elevation of gonadotrophins is a relatively common biochemical finding, and is a frequent cause of referral in men with poor libido or erectile dysfunction. Such tests are compatible with mild gonadotrophin deficiency, but may also be seen in acute illness of any cause and often simply represent the lower end of the normal range or the normal circadian rhythm of testosterone when bloods are checked in afternoon or evening surgeries. A therapeutic trial of testosterone replacement is often justified and forms part of the investigation in many patients; full pituitary evaluation may be required in such cases to exclude other pituitary disease. ‘Anabolic’ steroid (i.e. androgen) abuse causes similar biochemical findings, and is likely if the patient appears well virilized.

Treatment

The cause can rarely be reversed. Replacement therapy should be commenced (Table 18.19). Primary gonadal failure should be treated with testosterone. Patients with hypothalamic–pituitary disease are routinely given testosterone replacement, but should be given LH and FSH (purified or synthetic) or pulsatile GnRH when fertility is required.

Special instances of hypogonadism

Cryptorchidism
By the age of 5 years both testes should be in the scrotum. After that age, the germinal epithelium is increasingly at risk, and lack of descent by puberty is associated with subfertility. Surgical exploration and orchidopexy are usually undertaken but a short trial of HCG occasionally induces descent: an HCG test with a testosterone response 72 hours later excludes anorchia. Intra-abdominal testes have an increased risk of developing malignancy; if presentation is after puberty, orchidectomy is advised.

Klinefelter’s syndrome
Klinefelter’s syndrome is a common congenital abnormality, affecting 1 in 1000 males. It is a chromosomal disorder (47XXY and variants, e.g. 46XY/47XXY mosaicism), i.e. a male with an extra X chromosome. There is both a loss of Leydig cells and seminiferous tubular dysgenesis. Patients usually present in adolescence with poor sexual development, small or undescended testes, gynaecomastia or infertility. In 47XXY there is long leg length with tall stature. The androgen deficiency leads to lack of epiphyseal closure in puberty. Patients occasionally have behavioural problems and learning difficulties. There is also a predisposition to diabetes mellitus, breast cancer, emphysema and bronchiectasis; these are all unrelated to the testosterone deficiency.

Clinical examination shows a wide spectrum of features with small pea-sized but firm testes, usually gynaecomastia and other signs of androgen deficiency. Some patients have a normal puberty and may present later with infertility. Confirmation is by chromosomal analysis. Treatment is androgen replacement therapy unless testosterone levels are normal. No treatment is possible for the abnormal seminiferous tubules and infertility.

Kallmann’s syndrome
This is isolated GnRH deficiency. It is associated with decreased or absent sense of smell (anosmia), and sometimes with other bony (cleft palate), renal and cerebral abnormalities (e.g. colour blindness). It is often familial and is usually X-linked, resulting from a mutation in the KAL1 gene which encodes anosmin-1 (producing loss of smell); one sex-linked form is due to an abnormality of a cell adhesion molecule. Management is that of secondary hypogonadism (see p. 999). Fertility is possible.

Normosmic idiopathic hypogonadotropic hypogonadism
This refers to isolated GnRH deficiency in the absence of anosmia. Known mutations account for less than 15% of normosmic idiopathic hypogonadotropic hypogonadism (nIHH). Mutations include the KISS1 gene which codes for kisspeptin, the protein which acts on GPR54 receptor, and the FGFR1 gene.

Oligospermia or azoospermia
These may be secondary to androgen deficiency and can be corrected by androgen replacement. More often they result from primary testicular diseases, in which case they are rarely treatable.

Azoospermia with normal testicular size and low FSH levels suggests a vas deferens block, which is sometimes reversible by surgical intervention.

Lack of libido and erectile dysfunction
Lack of libido is a loss of sexual desire which may in turn lead to erectile dysfunction (ED). ED may be psychological, neurogenic, vascular, endocrine or related to drugs, and often includes contributions from several causes. ED is a common symptom in hypogonadism, but most patients with ED have normal hormones and many have no definable organic cause. Vascular disease is a common aetiology, especially in smokers, and is often associated with vascular problems elsewhere. Autonomic neuropathy, most commonly from diabetes mellitus, is a common partial, if not total, identifiable cause (see p. 1056). Many drugs produce ED (see Table 22.28). The endocrine causes are those of hypogonadism (see above) and can be excluded by normal testosterone, gonadotrophin and prolactin levels. The presence of nocturnal emissions and frequent satisfactory morning erections makes endocrine disease unlikely.

Psychogenic erectile dysfunction is frequently a diagnosis of exclusion, though complex tests of penile vasculature and function are available in some centres.

Treatment. Offending drugs should be stopped. Phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, vardenafil) which increase penile blood flow (see p. 1056) are first choice for therapy. Other treatments include apomorphine, intracavernosal injections of alprostadil, papaverine or phentolamine, vacuum expanders and penile implants.

If no organic disease is found, or if there is clear evidence of psychological problems, the couple should receive psychosexual counselling.

Gynaecomastia
Gynaecomastia is development of breast tissue in the male. Causes are shown in Table 18.20. It is due to an imbalance

between free oestrogen and free androgen effects on breast tissue.

*Pubertal gynaecomastia* occurs in perhaps 50% of normal boys, often asymmetrically. It usually resolves spontaneously within 6–18 months, but after this duration may require surgical removal, as fibrous tissue will have been laid down. The cause is thought to be relative oestrogen excess, and the oestrogen antagonist tamoxifen is occasionally helpful.

In the older male, gynaecomastia requires a full assessment to exclude potentially serious underlying disease, such as bronchial carcinoma and testicular tumours (e.g. Leydig cell tumour). However, aromatase activity (p. 996) increases with age and may be the cause of gynaecomastia in this group. Aromatase is an enzyme of the cytochrome P450 family and converts androgens to produce oestrogens. Drug effects are common (especially digoxin and spironolactone), and once these and significant liver disease are excluded most cases have no definable cause. Surgery is occasionally necessary.

## DISORDERS IN THE FEMALE

### Hypogonadism

Impaired ovarian function, whether primary or secondary, will lead both to oestrogen deficiency and abnormalities of the menstrual cycle. The latter is very sensitive to disruption, cycles becoming anovulatory and irregular before disappearing altogether. Symptoms will depend on the age at which the failure develops. Thus, before puberty, primary amenorrhoea will occur, possibly with delayed puberty; if after puberty, secondary amenorrhoea and hypogonadism will result.

### Oestrogen deficiency

The physiological effects of oestrogens and symptoms/signs of deficiency are shown in Table 18.21.

### Amenorrhoea

Absence of periods or markedly irregular infrequent periods (oligomenorrhoea) is the commonest presentation of female gonadal disease. The clinical assessment of such patients is shown in Box 18.6, and common causes are listed in Table 18.22.

### Polycystic ovary syndrome

Polycystic ovary syndrome is the most common cause of oligomenorrhoea and amenorrhoea (see below).

### Weight-related amenorrhoea

A minimum body weight is necessary for regular menstruation. While anorexia nervosa is the extreme form of weight loss (see p. 1219), amenorrhoea is common and may be seen at weights within the ‘normal’ range. The biochemistry is indistinguishable from gonadotrophin deficiency and some patients have additional mild endocrine disease (e.g. polycystic ovarian disease). Restoration of bodyweight to above the 50th centile for height is usually effective in restoring menstruation, but in the many cases where this cannot be achieved then oestrogen replacement is necessary. Similar problems occur with intensive physical training in athletes and dancers.

### Hypothalamic amenorrhoea

Amenorrhoea with low oestrogen and gonadotrophins in the absence of organic pituitary disease, weight loss or excessive exercise is described as hypothalamic amenorrhoea. This may be related to ‘stress’, to previous weight loss or stopping the contraceptive pill, but some patients appear to have defective cycling mechanisms without apparent explanation.

### Hypothyroidism

Oligomenorrhoea and amenorrhoea are frequent findings in severe hypothyroidism in young women.

</table>

* These conditions may present as primary amenorrhoea.

LH, Luteinizing hormone; FSH, follicle-stimulating hormone; E₂, oestradiol; PRL, prolactin; T, testosterone; DHEAS, dehydroepiandrosterone sulphate; SHBG, sex hormone-binding globulin; HCG, human chorionic gonadotrophin; LHRH, luteinizing hormone-releasing hormone; nIHH, normosmic idiopathic hypogonadotropic hypogonadism.

**Other**

Other causes include pregnancy. Genital tract abnormalities, such as an imperfect hymen, can cause primary amenorrhoea.

Severe illness, even in the absence of weight loss, can lead to amenorrhoea.

**Turner’s syndrome** (p. 1007) is a cause of primary amenorrhoea. The phenotype is female with female external genitalia. There is gonadal dysgenesis with streak ovaries. Features include short stature, webbing of the neck (up to 40%), a wide carrying angle of the elbows, high arched palate and low-set ears. These patients also have an increased incidence of autoimmune disease (2%), bicuspid aortic valves aortic coarctation and dissection and coronary artery disease, hypertension, type 2 diabetes, abnormal biochemistry, horseshoe kidneys, lymphoedema, reduced bone density and inflammatory bowel disease (0.3%).

**Investigations**

Basal levels of FSH, LH, oestrogen and prolactin allow initial distinction between primary gonadal and hypothalamic–pituitary causes (Table 18.22). Ovarian biopsy may occasionally be necessary to confirm the diagnosis of primary ovarian failure, although elevation of LH and FSH to menopausal levels is usually adequate. Subsequent investigations are shown in Table 18.22.

**Treatment**

Treatment is that of the cause wherever possible (e.g. hypothyroidism, low weight, stress, excessive exercise).

Primary ovarian disease is rarely treatable except in the rare condition of ‘resistant’ ovary, where high-dose gonadotrophin therapy can occasionally lead to folliculogenesis. Hyperprolactinaemia should be corrected (see below). Polycystic ovary syndrome is discussed in detail below. In all other cases oestrogen replacement is usually indicated to prevent the long-term consequences of deficiency.
Hirsutism and polycystic ovary syndrome

Normal hair vs hirsutism
The extent of normal hair growth varies between individuals, families and races, being more extensive in the Mediterranean and some Asian subcontinent populations. These normal variations in body hair, and the more extensive hair growth seen in patients complaining of hirsutism, represent a continuum from no visible hair to extensive cover with thick dark hair. It is therefore impossible to draw an absolute dividing line between ‘normal’ and ‘abnormal’ degrees of facial and body hair in the female. Soft vellus hair is normally present all over the body, and this type of hair on the face and elsewhere is ‘normal’ and is not sex hormone dependent. Hair in the beard, moustache, breast, chest, axilla, abdominal midline, pubic and thigh areas is sex-hormone dependent. Any excess in the latter regions is thus a marker of increased ovarian or adrenal androgen production, most commonly polycystic ovary syndrome (PCOS) but occasionally other rarer causes.

Causes of hirsutism

Polycystic ovary syndrome. PCOS is the most common cause of hirsutism in clinical practice affecting about 1 in 5 women world-wide. It is characterized by multiple small cysts within the ovary (which represent arrested follicular development) and by excess androgen production from the ovaries (and to a lesser extent from the adrenals). It was originally described in its severe form as the Stein–Leventhal syndrome.

Measured levels of androgens in blood vary widely from patient to patient and may remain within the normal range but SHBG levels are often low (due to high insulin levels), and therefore free androgen levels are high. In PCOS there is thought to be increased frequency of the GnRH pulse generator, leading to an increase in LH pulses and androgen secretion. In addition, androgens are normally converted to oestrogens in adipose tissue, but aromatase levels are low (partly due to decreased FSH levels) so that, instead of androgen (mainly androstenedione) being converted to oestrogen, androstenedione is secreted and converted to testosterone in peripheral tissue. The response of the hair follicle to circulating androgens also seems to vary between individuals with otherwise identical clinical and biochemical features, and the reason for this variation in end-organ response remains poorly understood.

PCOS is frequently associated with hyperinsulinaemia and insulin resistance. The prevalence of type 2 diabetes is ten times higher than in normal women. It is also associated with hypertension, hyperlipidaemia and increased cardiovascular disease (the metabolic syndrome, p. 231), which is 2–3 times higher in PCOS. Obesity with PCOS is an additional risk factor for insulin resistance. The precise mechanisms which link the aetiology of polycystic ovaries, hyperandrogenism, anovulation and insulin resistance remain to be elucidated and whether the basic defect is in the ovary, adrenal, pituitary or a more generalized metabolic defect remains unknown.

In routine clinical practice, the majority of patients with objective signs of androgen-dependent hirsutism will have PCOS, and investigation is mainly required to exclude rarer and more serious causes of virilization.

Idiopathic hirsutism. Patients with hirsutism, no elevation of serum androgen levels and no other clinical features are sometimes labelled as having ‘idiopathic hirsutism’. However, studies suggest that most patients with ‘idiopathic hirsutism’ have some radiological or biochemical evidence of PCOS on more detailed investigation, and several studies have demonstrated evidence of mild PCOS in up to 20% of the normal female population.

Familial or idiopathic hirsutism does occur, but usually involves a distribution of hair growth which is not typically androgenic.

Other causes. Rarer and more serious endocrine causes of hirsutism and virilization include congenital adrenal hyperplasia (CAH, see p. 1014), Cushing’s syndrome (p. 1012) and virilizing tumours of the ovary and adrenal.

Ovarian hyperthecosis is a non-malignant ovarian disorder characterized by luteinized thecal cells in the ovarian stroma which secrete testosterone. The clinical features are similar to PCOS but tend to present in perimenopausal women, and serum testosterone levels are higher than typically seen in PCOS.

Iatrogenic hirsutism also occurs after treatment with androgens, or more weakly androgenic drugs such as progestogens or danazol.

Non-androgen-dependent hair growth (hypertrichosis) occurs with drugs such as phenytoin, diazoxide, minoxidil and ciclosporin.

Clinical features of PCOS

PCOS presents with amenorrhea/oligomenorrhoea, hirsutism and acne (alone or in combination), usually beginning shortly after menarche. Clinical, biochemical and radiological features of PCOS merge imperceptibly into those of the normal populations. The development of hirsutism commonly provokes severe distress in young women and may lead to avoidance of normal social activities.

- **Hirsutism** should be recorded objectively, ideally using a scoring system, to document the problem and to monitor treatment. The method and frequency of physical removal (e.g. shaving, plucking) should also be recorded. Most patients who complain of hirsutism will have an objective excess of hair on examination, but occasionally very little will be found (and appropriate counselling is then indicated).

- **Age and speed of onset.** Hirsutism related to PCOS usually begins around the time of the menarche and increases slowly and steadily in the teens and twenties. Rapid progression and prepubertal or late onset suggest a more serious cause.

- **Accompanying virilization.** Hirsutism due to PCOS may be severe and affect all androgen-dependent areas on the face and body. However, more severe virilization (clitoromegaly, recent-onset frontal balding, male phenotype) implies substantial androgen excess, and usually indicates a rarer cause rather than PCOS. Thinning of head hair in a male pattern – androgenic alopecia – occurs in a proportion of women with uncomplicated PCOS, typically with a familial tendency for premature androgen-related hair loss in both sexes.

- **Menstruation.** Most patients with hirsutism will have some disturbance of menstruation, typically oligo-amenorrhoea, although more frequent erratic bleeding...
can also occur. However, PCOS can present as hirsutism with regular periods, or as irregular periods with no evidence of hirsutism or acne.

- **Weight.** Many patients with hirsutism are also overweight or obese. This worsens the underlying androgen excess and insulin resistance and inhibits the response to treatment, and is an indication for appropriate advice on diet and exercise. In severe cases the insulin resistance may have a visible manifestation as acanthosis nigricans on the neck and in the axillae (see Fig. 23.24).

**Investigations and differential diagnosis**

A variety of investigations aid the diagnosis of patients with hirsutism:

- **Serum total testosterone** is often elevated in PCOS and is invariably substantially raised in virilizing tumours (usually >5 nmol/L). Patients with hirsutism and normal testosterone levels frequently have low levels of sex hormone-binding globulin (SHBG), leading to high free androgen levels. The free androgen index (total testosterone/SHBG concentration) is often used and is high; free testosterone is difficult to measure.

- **Other androgens.** Androstenedione and dehydroepiandrosterone sulphate are frequently elevated in PCOS, and even more elevated in congenital adrenal hyperplasia (CAH) and virilizing tumours.

- **17α-Hydroxyprogesterone** is elevated in classical CAH, but may be apparent in late-onset CAH only after stimulation tests.

- **Gonadotrophin levels.** LH hypersecretion is a frequent feature of PCOS, but the pulsatile nature of secretion of this hormone means that a ‘classic’ increased LH/FSH ratio is not always observed on a random sample.

- **Oestrogen levels.** Oestradiol is usually normal in PCOS, but oestrone levels (which are rarely measured) are elevated because of peripheral conversion. Levels are variable in other causes.

- **Ovarian ultrasound** is a useful investigation (Fig. 18.20). Typical features are those of a thickened capsule, multiple 3–5 mm cysts and a hyperechogenic stroma. Prolonged hyperandrogenization from any cause may lead to polycystic changes in the ovary. Ultrasound may also reveal virilizing ovarian tumours, although these are often small.

- **Serum prolactin.** Mild hyperprolactinaemia is common in PCOS but rarely exceeds 1500 mU/L.

---

**Fig. 18.20** Polycystic ovary syndrome. (a) Longitudinal transvaginal ultrasound of ovary, revealing multiple cysts with central ovarian stroma showing increased echo texture. (b) MR image (coronal) of polycystic ovaries, also showing pelvic anatomy. Reproduced by kind permission of Barbara Hochstein and Geoffrey Cox, Auckland Radiology Group.
If a virilizing tumour is suspected clinically or after investigation, then more complex tests include dexamethasone suppression tests, CT or MRI of adrenals, and selective venous sampling.

**Diagnosis**
Most patients presenting with a combination of hirsutism and menstrual disturbance will be shown to have polycystic ovary syndrome, but the rarer alternative diagnoses should be excluded, e.g. late-onset congenital adrenal hyperplasia (early-onset, raised serum 17α-OH-progesterone), Cushing’s syndrome (look for other clinical features) and virilizing tumours of the ovary or adrenals (severe virilization, markedly elevated serum testosterone).

The consensus (Rotterdam) criteria 2003 for diagnosis of PCOS are at least two of:
- clinical or biochemical evidence of hyperandrogenism
- evidence of oligo- or anovulation
- presence of polycystic ovaries on ultrasound.

**Treatments**
The underlying cause should be removed in the rare instances where this is possible (e.g. drugs, adrenal or ovarian tumours). Treatment of CAH and Cushing’s is discussed on page 1014 and page 1012, respectively. Other therapy depends upon whether the aim is to reduce hirsutism, regularize periods or produce fertility.

**Local therapy for hirsutism**
Regular plucking, bleaching, depilatory cream, waxing or shaving is used. Such removal neither worsens nor improves the underlying severity of hirsutism. More ‘permanent’ solutions include electrolysis and a variety of ‘laser’ hair removal systems – all appear effective but have not been evaluated in long-term studies, are expensive, and still often require repeated long-term treatment. **Efflorescence cream** (an antiprotozoal) inhibits hair growth by inhibiting ornithine decarboxylase but is effective in only a minority of cases and should be discontinued if there is no improvement after four months.

**Systemic therapy for hirsutism**
This always requires a year or more of treatment for maximal benefit, and long-term treatment is frequently required as the problem tends to recur when treatment is stopped. The patient must therefore always be an active participant in the decision to use systemic therapy and must understand the rare risks as well as the benefits.

- **Oestrogens** (e.g. oral contraceptives) suppress ovarian androgen production and reduce free androgens by increasing SHBG levels. Combined hormone pills, which contain ethinylestradiol and a non-androgenic progestogen, e.g. desogestrel dospirenone, or cyproterone acetate (co-cyprindiol), will result in a slow improvement in hirsutism in a majority of cases and should normally be used first unless there is a contraindication, e.g. history of thrombosis. The risk of venous thrombosis appears to be 2–4-fold higher than on other low-dose oral contraceptive pills. After the menopause, HRT preparations which contain medroxyprogesterone (rather than more androgenic progestogens) may be helpful.
- **Cyproterone acetate** (50–100 mg daily) is an antiandrogen but is also a progestogen, teratogenic and a weak glucocorticoid. Given continuously it produces amenorrhoea, and so is normally given for days 1–14 of each cycle. In women of childbearing age, contraception is essential.
  - **Spironolactone** (200 mg daily) also has antiandrogen activity and can cause useful improvements in hirsutism.
  - **Finasteride** (5 mg daily), a 5α-reductase inhibitor which prevents the formation of dihydrotestosterone in the skin, has also been shown to be effective but long-term experience is limited.
- **Flutamide**, another antiandrogen, is less commonly used owing to the high incidence of hepatic side-effects.

**Treatment of menstrual disturbance**
- Cyclical oestrogen/progestogen administration will regulate the menstrual cycle and remove the symptom of oligo- or amenorrhoea. This is most frequently an additional benefit of the treatment of hirsutism, but may also be used when menstrual disturbance is the only symptom.
- Drugs to improve the hyperinsulinaemia associated with PCOS and obesity are increasingly used (and requested by patients). Metformin (500 mg three times daily) improves menstrual cyclicity and ovulation in short-term studies, and some patients also report improvement in hirsutism and ease of weight loss, but gastrointestinal upset may limit use.
- Thiazolidinediones are also effective, but there are relatively few studies which are mostly short-term, and there are concerns about the long-term cardiovascular effects of these agents.

**Treatment for fertility**
- Metformin alone may improve ovulation and achieve conception.
- Clomifene 50–100 mg can be given daily on days 2–6 of the cycle and is more effective than metformin alone in achieving ovulation. This can occasionally cause the **ovarian hyperstimulation syndrome**, an iatrogenic complication of ovulation induction therapy, consisting of ovarian enlargement, oedema, hypovolaemia, renal failure, and possibly shock; specialist supervision is essential. It is recommended that clomifene should not normally be used for longer than six cycles (owing to a possible increased risk of ovarian cancer in patients treated for longer than recommended).
- **Reverse circadian rhythm.** Prednisolone (2.5 mg in the morning, 5 mg on retiring) suppresses pituitary production of ACTH, upon which adrenal androgens partly depend. Regular ovulatory cycles often ensue. A steroid instruction leaflet and a card must be supplied. More intensive techniques to stimulate ovulation may also be indicated in specialist hands, including low-dose gonadotrophin therapy, and ovarian hyperstimulation techniques associated with in vitro fertilization.

Wedge resection of the ovary was a traditional therapy but is now rarely required, although laparoscopic ovarian electrodiathermy may be helpful.

**Oral contraception**
The combined oestrogen–progestogen pill is widely used for contraception and has a low failure rate (<1 per 100 woman-years). ‘Pills’ contain 20–40 μg of oestrogen, usually ethinyl-
estradiol, together with a variable amount of one of several progestogens. The mechanism of action is twofold:

- suppression by oestrogen of gonadotrophins, thus preventing follicular development, ovulation and luteinization
- progestogen effects on cervical mucus, making it hostile to sperm, and on tubal motility and the endometrium.

Side-effects of these preparations are shown in Box 18.7. Most of the serious ones are rare and are less common with typical modern 20–30 μg oestrogen pills, although evidence suggests that thromboembolism may be slightly more common with ‘third-generation pills’ containing desogestrel and gestodene (approximately 30/100000 woman-years compared with 15/100000 on older pills and 5/100000 on no treatment). While some problems require immediate cessation of the pill, other milder side-effects must be judged against the hazards of pregnancy occurring with inadequate contraception, especially if other effective methods are not practicable or acceptable.

Hazards of the combined pill are increased in smokers, in obesity and in those with other risk factors for cardiovascular disease (e.g. hypertension, hyperlipidaemia, diabetes) especially in women aged over 35 years (avoid if over 50 years). The ‘mini-pill’ (progestogen only, usually norethisterone) is less effective but is often suitable where oestrogens are contraindicated (Box 18.7). A progestosterone antagonist, mifepristone, in combination with a prostaglandin analogue (vaginal gemeprost), induces abortion of pregnancy at up to 9 weeks’ gestation. It prevents progesterone-induced inhibition of uterine contraction.

### SUBFERTILITY

Subfertility, or ‘infertility’, is defined as the inability of a couple to conceive after 1 year of unprotected intercourse. Investigation requires the combined skills of gynaecologist, endocrinologist and, ideally, andrologist. Both partners must be involved and every aspect of the physiology critically examined.

#### Causes

(Fig. 18.21)

A significant proportion of couples have both male and female contributing factors.

- Inadequate intercourse, hostile cervical mucus and vaginal factors are uncommon (5%). Fifteen per cent of cases appear to be idiopathic, and natural fertility decreases with increasing age.

#### Male factors

About 30–40% of couples have a major identifiable male factor. There is some evidence that male sperm counts are declining in many populations. Untreated male hypogonad-ism of any cause (see Table 18.18) is likely to be associated with subfertility.

#### Female factors

Female tubal problems account for perhaps 20%; a similar proportion have ovulatory disorders. Any cause of oligomenorrhoea or amenorrhoea (see Table 18.22) is likely to be associated with suboptimal ovulation or anovulation.

#### Clinical assessment

Both partners should be seen and the following factors checked:

- **The man.** Look for previous testicular damage (orchitis, trauma), undescended testes, urethral symptoms and evidence of sexually transmitted infection, local surgery, and use of alcohol and drugs. A semen analysis early in the investigations is essential.
- **The woman.** Look for previous pelvic infection, regularity of periods, previous surgery, alcohol intake and smoking, and bodyweight (see p. 1001).
- **Together.** Check the frequency and adequacy of intercourse, and the use of lubricants.

#### Investigations

See Figure 18.21.

**Treatment**

Counselling of both partners is essential. Any defect(s) found should be treated if possible. Ovulation can usually be induced by exogenous hormones if simpler measures fail, while in vitro fertilization (IVF) and similar techniques are widely used, especially where there is tubal blockage, oligospernia or ‘idiopathic subfertility’. Intracytoplasmic sperm injection (ICSI) appears particularly effective for severe oligospernia and poor sperm function.

**DISORDERS OF SEXUAL DIFFERENTIATION**

Disorders of sexual differentiation are rare but may affect chromosomal, gonadal, endocrine and phenotypic development (Table 18.23). Such cases always require extensive,

**FURTHER READING**

multidisciplinary clinical management. An individual’s sex can be defined in several ways:

- **Chromosomal sex.** The normal female is 46XX, the normal male 46XY. The Y chromosome confers male sex; if it is not present, development follows female lines.
- **Gonadal sex.** This is obviously determined predominantly by chromosomal sex, but requires normal embryological development.
- **Phenotypic sex.** This describes the normal physical appearance and characteristics of male and female body shape. This in turn is a manifestation of gonadal sex and subsequent sex hormone production.
- **Social sex (gender).** This is heavily dependent on phenotypic sex and normally assigned on appearance of the external genitalia at birth.
- **Sexual orientation – heterosexual, homosexual or bisexual.**

## THE GLUCOCORTICOID AXIS

### Adrenal gland – anatomy and function
(see Table 18.3)

The human adrenals weigh 8–10 g together and comprise an outer cortex with three zones (reticularis, fasciculata and glomerulosa) producing steroids, and an inner medulla that synthesizes, stores and secretes catecholamines (see adrenal medulla, p. 1024).

The adrenal steroids are grouped into three classes based on their predominant physiological effects.

### Glucocorticoids

These are so named after their effects on carbohydrate metabolism. Major actions are listed in Table 18.24. They act on intracellular corticosteroid receptors and combine with coactivating proteins to bind the ‘glucocorticoid response element’ (GRE) in specific regions of DNA to cause gene transcription. Glucocorticoid action is modified locally by the action of 11\(\beta\)-hydroxysteroid dehydrogenase (11\(\beta\)HSD). 11\(\beta\)HSD Type 1 converts inactive cortisol to cortisone, hence amplifying the hormone signal, whilst 11\(\beta\)HSD type 2 does the opposite.

The relative potency of common steroids is shown in Table 18.25.

### Mineralocorticoids

The predominant effect of mineralocorticoids is on the extracellular balance of sodium and potassium in the distal tubule of the kidney. Aldosterone, produced solely in the zona glomerulosa, is the predominant mineralocorticoid in humans (about 50%); corticosterone makes a small contribution. Mineralocorticoids act on type 1 corticosteroid receptors, whilst glucocorticoids act on type 2 receptors, both having a very similar structure. The mineralocorticoid activity of cortisol is weak but it is present in considerable excess. The mineralocorticoid receptor in the kidney is largely protected from this excess by the intrarenal conversion (‘shuttle’) of cortisol to cortisone by 11\(\beta\)-hydroxysteroid dehydrogenase type 2.

### Androgens

Although secreted in considerable quantities, most androgens have only relatively weak intrinsic androgenic activity until metabolized peripherally to testosterone or dihydrotestosterone. Dihydrotestosterone is metabolized from testosterone by 5\(\alpha\)-reductase and is a potent androgen receptor agonist. The androgen receptor has been well characterized (p. 966) and mutations within this gene may cause androgen insensitivity syndromes.

### Biochemistry

All steroids have the same basic skeleton (Fig. 18.22b) and the chemical differences between them are slight. The major biosynthetic pathways are shown in Figure 18.22a.

### Physiology

Glucocorticoid production by the adrenal is under hypothalamic–pituitary control (Fig. 18.23).

Corticotrophin-releasing hormone (CRH) is secreted in the hypothalamus in response to circadian rhythm, stress and other stimuli. CRH travels down the portal system to stimulate adrenocorticotropic hormone (ACTH) release from the anterior pituitary. ACTH is derived from the prohormone pro-opiomelanocortin (POMC), which undergoes complex processing within the pituitary to produce ACTH and a number of other peptides including beta-lipotrophin and beta-endorphin. Many of these peptides, including ACTH, contain melanocyte-stimulating hormone (MSH)-like sequences which cause pigmentation when levels of ACTH are markedly raised.

Circulating ACTH stimulates cortisol production in the adrenal. The cortisol secreted (or any other synthetic corti-

* Cortisol is arbitrarily defined as 1.
The glucocorticoid axis

**Fig. 18.22** (a) The major steroid biosynthetic pathways. Steroid hormones are synthesized in adrenal and gonads from the initial substrate cholesterol via a series of interconnected enzymatic steps. The reactions catalysed are shown by shaded boxes with italic labels. The molecular identity of the enzymes is shown in red – some catalyse more than one reaction. p450 enzymes are in mitochondria, 3βHSD (hydroxysteroid dehydrogenase) in cytoplasm. 17βHSD and p450_aro (aromatase) are found mainly in gonads. (b) The steroid molecule.

cortisol administered to the patient) causes negative feedback on the hypothalamus and pituitary to inhibit further CRH/ACTH release. The set-point of this system clearly varies throughout the day according to the circadian rhythm, and is usually overridden by severe stress. Unlike cortisol, mineralocorticoids and sex steroids do not cause negative feedback on the CRH/ACTH axis.

Following adrenalectomy or other adrenal damage (e.g. Addison’s disease), cortisol secretion will be absent or reduced; ACTH levels will therefore rise.

**Mineralocorticoid** secretion is mainly controlled by the renin–angiotensin system (see p. 1023).

**Investigation of glucocorticoid abnormalities**

**Basal levels**

ACTH and cortisol are released episodically and in response to stress. When taking a blood sample, remember:

- Sampling time should be recorded. Basal levels should be taken between 0800 h and 0900 h near the peak of the circadian variation.
- Stress should be minimized.
- Appropriate reference ranges (for time and assay method) should be used.

Suppression and stimulation tests are used in suspected excess and deficient cortisol production, respectively.

**Dexamethasone suppression tests**

Administration of a synthetic glucocorticoid to a normal subject produces prompt feedback suppression of CRH and ACTH levels and thus of endogenous cortisol secretion (dexamethasone is not measured by most cortisol assays).

Plasma cortisol values are very dependent upon the assay used – local reference ranges must be consulted.

Three forms of the test, used in the diagnosis and differential diagnosis of Cushing’s syndrome, are available (Table 18.26).

**ACTH stimulation tests**

Synthetic ACTH (tetracosactide, which consists of the first 24 amino acids of human ACTH) is given to stimulate adrenal cortisol production. Details are given in Table 18.26 and Box 18.1 on page 968.

**Addison’s disease: primary hypoadrenalism**

**Pathophysiology and causes**

In this condition there is destruction of the entire adrenal cortex. Glucocorticoid, mineralocorticoid and sex steroid production are therefore all reduced. (This differs from hypothalamic–pituitary disease, in which mineralocorticoid secretion remains largely intact, being predominantly stimulated by angiotensin II. Adrenal sex steroid production is also largely independent of pituitary action.) In Addison’s disease reduced cortisol levels lead, through feedback, to increased CRH and ACTH production, the latter being directly responsible for the hyperpigmentation.

**Incidence.** Addison’s disease is rare, with an incidence of 3–4/million/year and prevalence of 40–60/million. Primary hypoadrenalism shows a marked female preponderance and is most often caused by autoimmune disease (>90% in UK) but in countries with a high prevalence of HIV/AIDS, tuberculosis is an increasing cause. Autoimmune adrenalitis results from the destruction of the adrenal cortex by organ-specific autoantibodies, with 21-hydroxylase as the common antigen. There are associations with other autoimmune con-

ditions in the polyglandular autoimmune syndromes types I and II (e.g. type 1 diabetes mellitus, pernicious anaemia, thyroiditis, hypoparathyroidism, premature ovarian failure) (p. 1026).

All other causes are rare (Table 18.27).

**Clinical features**

These are shown in Figure 18.24. The symptomatology of Addison’s disease is often vague and non-specific. These symptoms may be the prelude to an Addisonian crisis with severe hypotension and dehydration precipitated by intercurrent illness, accident or operation.

Pigmentation (dull, slyt, grey-brown) is the predominant sign in over 90% of cases.

Postural systolic hypotension, due to hypovolaemia and sodium loss, is present in 80–90% of cases, even if supine blood pressure is normal. Mineralocorticoid deficiency is the cause of the hypotension.

**Investigations**

Once Addison’s disease is suspected, investigation is urgent. If the patient is seriously ill or hypotensive, hydrocortisone
100 mg should be given intramuscularly together with intravenous saline. Ideally this should be done immediately after a blood sample is taken for later measurement of plasma cortisol. Alternatively, an ACTH stimulation test can be performed immediately. Full investigation should be delayed until emergency treatment (see below) has improved the patient’s condition. Otherwise, tests are as follows:

- **Single cortisol measurements** are of little value, although a random cortisol below 100 nmol/L during the day is highly suggestive, and a random cortisol >550 nmol/L makes the diagnosis unlikely (but not impossible).

- **The short ACTH stimulation test** should be performed (see Table 18.26). Note that an absent or impaired cortisol response confirms the presence of hypoadrenalism but does not differentiate Addison’s disease from ACTH deficiency or iatrogenic suppression by steroid medication.

- A **0900 h plasma ACTH level** – a high level (>80 ng/L) with low or low-normal cortisol confirms primary hypoadrenalism.

- A **long ACTH stimulation test** can also exclude adrenal suppression by steroids or ACTH deficiency.

- **Electrolytes and urea** classically show hyponatraemia, hyperkalaemia and a high urea, but they can be normal.

- **Blood glucose** may be low, with symptomatic hypoglycaemia.

- **Adrenal antibodies** are present in many cases of autoimmune adrenalitis.

- **Chest and abdominal X-rays** may show evidence of tuberculosis and/or calcified adrenals.

- **Serum aldosterone** is reduced with high plasma renin activity.

- **Hypercalcaemia and anaemia** (after rehydration) are sometimes seen. They resolve on treatment, but are occasionally the first clue to the diagnosis.

### Treatment

Acute hypoadrenalism needs urgent treatment (Emergency box 18.1).

Long-term treatment is with replacement glucocorticoid and mineralocorticoid; tuberculosis must be treated if present or suspected. Replacement dosage details are shown in Table 18.28. Dehydroepiandrosterone (DHEA) replacement has also been advocated, and studies suggest that this may cause symptomatic improvements, although long-term results are awaited.

### Management of acute hypoadrenalism

- Clinical context: hypotension, hyponatraemia, hyperkalaemia, hypoglycaemia, dehydration, pigmentation often with precipitating infection, infarction, trauma or operation. The major deficiencies are of salt, steroid and glucose.

- Assuming normal cardiovascular function, the following are required:
  - One litre of 0.9% saline should be given over 30–60 minutes with 100 mg of intravenous bolus hydrocortisone.
  - Subsequent requirements are several litres of saline within 24 hours (assessing with central venous pressure line if necessary) plus hydrocortisone, 100 mg i.m., 6-hourly, until the patient is clinically stable.

- Glucose should be infused if there is hypoglycaemia.

- Oral replacement medication is then started, unless unable to take oral medication, initially hydrocortisone 20 mg, 8-hourly, reducing to 20–30 mg in divided doses over a few days (Table 18.28).

- Fludrocortisone is unnecessary acutely as the high cortisol doses provide sufficient mineralocorticoid activity – it should be introduced later.

### Patient advice

All patients requiring replacement steroids should:

---

**Table 18.28** Dehydroepiandrosterone (DHEA) replacement has also been advocated, and studies suggest that this may cause symptomatic improvements, although long-term results are awaited.

- Adequacy of glucocorticoid dose is judged by:
  - clinical well-being and restoration of normal, but not excessive, weight
  - normal cortisol levels during the day while on replacement hydrocortisone (cortisol levels cannot be used for synthetic steroids).

- Fludrocortisone replacement is assessed by:
  - restoration of serum electrolytes to normal
  - blood pressure response to posture (it should not fall >10 mmHg systolic after 2 minutes’ standing)
  - suppression of plasma renin activity to normal.
know how to increase steroid replacement dose for intercurrent illness
- carry a ‘Steroid Card’
- wear a Medic-Alert bracelet (or similar), which gives details of their condition so that emergency replacement therapy can be given if found unconscious
- keep an (up-to-date) ampoule of hydrocortisone at home in case oral therapy is impossible, for administration by self, family or GP.

Secondary hypoadrenalism

This may arise from hypothalamic–pituitary disease (inadequate ACTH production) or from long-term steroid therapy leading to hypothalamic–pituitary–adrenal suppression.

Most patients with the former have panhypopituitarism (see p. 974) and need $T_4$ replacement as well as cortisol; in this case hydrocortisone must be started before $T_4$. The most common cause of secondary hypoadrenalism is long-term corticosteroid medication for non-endocrine disease. The hypothalamic–pituitary axis and the adrenal may both be suppressed and the patient may have vague symptoms of feeling unwell. The long ACTH stimulation test should demonstrate a delayed cortisol response. Weaning off steroids is often a long and difficult process.

Cushing's syndrome

Cushing's syndrome is the term used to describe the clinical state of increased free circulating glucocorticoid. It occurs most often following the therapeutic administration of synthetic steroids or ACTH (see below). All the spontaneous forms of the syndrome are rare.

Pathophysiology and causes

Spontaneous Cushing's syndrome is rare, with an incidence of <5/million/year.

Causes of Cushing's syndrome are usually subdivided into two groups (Table 18.29):

- increased circulating ACTH from the pituitary (65% of cases), known as Cushing's disease, or from an 'ectopic', non-pituitary, ACTH-producing tumour elsewhere in the body (10%) with consequent glucocorticoid excess ('ACTH dependent' Cushing's)
- a primary excess of endogenous cortisol secretion (25% of spontaneous cases) by an adrenal tumour or nodular hyperplasia, with subsequent (physiological) suppression of ACTH. Rare cases are due to aberrant expression of receptors for other hormones (e.g. glucose-dependent insulinotrophic peptide (GIP), LH or catecholamines) in adrenal cortical cells ('ACTH independent' Cushing's).

Clinical features

The clinical features of Cushing’s syndrome are those of glucocorticoid excess and are illustrated in Figure 18.25.

- Pigmentation occurs only with ACTH-dependent causes.
- A Cushingoid appearance can be caused by excess alcohol consumption (pseudo-Cushing's syndrome) – the pathophysiology is poorly understood.
- Impaired glucose tolerance or frank diabetes is common, especially in the ectopic ACTH syndrome.
- Hypokalaemia due to the mineralocorticoid activity of cortisol is common with ectopic ACTH secretion.

Diagnosis

There are two phases to the investigation:

1. Confirmation

Most obese, hirsute, hypertensive patients do not have Cushing’s syndrome, and some cases of genuine Cushing’s have relatively subtle clinical signs. Confirmation rests on demonstrating inappropriate cortisol secretion, not suppressed by exogenous glucocorticoids: difficulties occur with obesity and depression where cortisol dynamics are often abnormal. Random cortisol measurements are of no value. Occasional patients are seen with so-called ‘cyclical Cushing’s’ where the abnormalities come and go.

Investigations to confirm the diagnosis include:

- 48-hour low-dose dexamethasone test (see Table 18.26). Normal individuals suppress plasma cortisol to <50 nmol/L. Patients with Cushing’s syndrome fail to show complete suppression of plasma cortisol levels (although levels may fall substantially in a few cases). This test is highly sensitive (>97%). The overnight dexamethasone test is slightly simpler, but has a higher false-positive rate.
- 24-hour urinary free cortisol measurements. This is simple, but less reliable – repeatedly normal values render the diagnosis most unlikely, but some patients with Cushing’s have normal values on some collections (approximately 10%).
- Circadian rhythm. After 48 hours in hospital, cortisol samples are taken at 0900 h and 2400 h (without

- Prolonged suppression of endogenous ACTH (probably due to an ACTH-producing tumour)
- Abnormal stimulation of endogenous ACTH (e.g. by glucose or GIP)
warning the patient). Normal subjects show a pronounced circadian variation (see Fig. 18.3, p. 968); those with Cushing’s syndrome have high midnight cortisol levels (>100 nmol/L), though the 0900 h value may be normal. Midnight salivary cortisol collected at home gives the same information more simply where the assay is available.

**Other tests.** There are frequent exceptions to the classic responses to diagnostic tests in Cushing’s syndrome. If any clinical suspicion of Cushing’s remains after preliminary tests then specialist investigations are still indicated. These may include insulin stress test, desmopressin stimulation test (p. 1017) and CRH tests.

### 2. Differential diagnosis of the cause

This can be extremely difficult since all causes can result in clinically identical Cushing’s syndrome. The classical ectopic ACTH syndrome is distinguished by a short history, pigmentation and weight loss, unprovoked hypokalaemia, clinical or chemical diabetes and plasma ACTH levels above 200 ng/L, but many ectopic tumours are benign and mimic pituitary disease closely, both clinically and biochemically. Severe hirsutism/virilization suggests an adrenal tumour.

Biochemical and radiological procedures for diagnosis include:

- **Adrenal CT or MRI scan.** Adrenal adenomas and carcinomas causing Cushing’s syndrome are relatively large and always detectable by CT scan. Carcinomas are distinguished by large size, irregular outline and signs of infiltration or metastases. Bilateral adrenal hyperplasia may be seen in ACTH-dependent causes or in ACTH-independent nodular hyperplasia.

- **Pituitary MRI.** A pituitary adenoma may be seen but the adenoma is often small and not visible in a significant proportion of cases.

**Fig. 18.25 Cushing’s syndrome – symptoms and signs.** Bold type indicates signs of most value in discriminating Cushing’s syndrome from simple obesity and hirsutism.

**Plasma potassium levels.** Hypokalaemia is common with ectopic ACTH secretion. (All diuretics must be stopped.)

**High-dose dexamethasone** test (Table 18.26). Failure of significant plasma cortisol suppression suggests an ectopic source of ACTH or an adrenal tumour.

**Plasma ACTH levels.** Low or undetectable ACTH levels (<10 ng/L) on two or more occasions are a reliable indicator of non-ACTH-dependent disease.

**CRH test.** An exaggerated ACTH and cortisol response to exogenous CRH suggests pituitary-dependent Cushing’s disease, as ectopic sources rarely respond.

**Chest X-ray** to look for a carcinoma of the bronchus or a bronchial carcinoid. Carcinoid lesions may be very small; if ectopic ACTH is suspected, whole-lung, mediastinal and abdominal CT scanning should be performed.

Further investigations may involve selective catheterization of the inferior petrosal sinus to measure ACTH for pituitary lesions, or blood samples taken throughout the body in a search for ectopic sources. Radiolabelled octreotide (111In octreotide) is occasionally helpful in locating ectopic ACTH sites.

**Treatment**

Untreated Cushing’s syndrome has a very bad prognosis, with death from hypertension, myocardial infarction, infection and heart failure. Whatever the underlying cause, cortisol hypersecretion should be controlled prior to surgery or radiotherapy. Considerable morbidity and mortality is otherwise associated with operating on unprepared patients, especially when abdominal surgery is required. The usual drug is metyrapone, an 11β-hydroxylase blocker, which is given in doses of 750 mg to 4 g daily in three to four divided doses. Ketoconazole (200 mg three times daily) is also used and is synergistic with metyrapone. Plasma cortisol should be monitored, aiming to reduce the mean level during the day.
to 150–300 nmol/L, equivalent to normal production rates. Aminogluthethimide and triostane (which reversibly inhibits 3-hydroxysteroid dehydrogenase/δ-5,4 isomers) are occasionally used. Choice of further treatment depends upon the cause.

**Cushing's disease (pituitary-dependent hyperadrenalism)**

- *Trans-sphenoidal removal of the tumour* is the treatment of choice. Selective adenomectomy nearly always leaves the patient ACTH deficient immediately postoperatively, and this is a good prognostic sign. Overall, pituitary surgery results in remission in 75–80% of cases, but results vary considerably and an experienced surgeon is essential.
- *External pituitary irradiation* alone is slow acting, only effective in 50–60% even after prolonged follow-up and mainly used after failed pituitary surgery. Children, however, respond much better to radiotherapy, 80% being cured.
- *Medical therapy* to reduce ACTH (e.g. bromocriptine, cyproheptadine) is rarely effective.
- *Bilateral adrenalectomy* is an effective last resort if other measures fail to control the disease (see Nelson’s syndrome). This can be performed laparoscopically.

**Other causes**

Adrenal adenomas should be resected after achievement of clinical remission with metyrapone or ketoconazole. Contralateral adrenal suppression may last for a year or more.

Adrenal carcinomas are highly aggressive and the prognosis is poor. In general, if there are no widespread metastases, tumour bulk should be reduced surgically. The adrenolytic drug mitotane may inhibit growth of the tumour and prolong survival, though it can cause nausea and ataxia. Some would also give radiotherapy to the tumour bed after surgery.

Tumours secreting ACTH ectopically should be removed if possible. Otherwise chemotherapy/radiotherapy may be used, depending on the tumour. Control of the Cushing’s syndrome with metyrapone or ketoconazole is beneficial for symptoms, and bilateral adrenalectomy may be appropriate to give complete control of the Cushing’s syndrome if prognosis from the tumour itself is reasonable.

If the source of ACTH is not clear, cortisol hypersecretion should be controlled with medical therapy until a diagnosis can be made.

**Nelson’s syndrome**

Nelson’s syndrome is increased pigmentation (because of high levels of ACTH) associated with an enlarging pituitary tumour, which occurs in about 20% of cases after bilateral adrenalectomy for Cushing’s disease. The syndrome is rare now that adrenalectomy is an uncommon primary treatment, and its incidence may be reduced by pituitary radiotherapy soon after adrenalectomy. The Nelson’s adenoma may be treated by pituitary surgery and/or radiotherapy (unless given previously).

**Incidental adrenal tumours (‘incidentalomas’)**

With the advent of abdominal CT, MRI and high-resolution ultrasound scanning, unsuspected adrenal masses have been discovered in 3–10% of scans (increasing with age). These obviously include the adrenal tumours described above, but cysts, myelolipomas and metastases are also seen. Functional tests to exclude secretory activity should be performed (adenomas often secrete cortisol at a low level); if none is found then most authorities recommend removal of large (>4–5 cm) and functional tumours but observation of smaller hormonally inactive lesions. Phaeochromocytoma must be excluded before surgery due to the risk of perioperative hypertensive or hypotensive crises (see p. 1025).

**Congenital adrenal hyperplasia (CAH)**

**Pathophysiology**

This condition results from an autosomal recessive deficiency of an enzyme in the cortisol synthetic pathways. There are six major types, but most common is 21-hydroxylase deficiency (CYP21A2) which occurs in about 1 in 15 000 births and which has been shown to be due to defects on chromosome 6 near the HLA region affecting one of the cytochrome p450 enzymes (p450c21).

As a result, cortisol secretion is reduced and feedback leads to increased ACTH secretion to maintain adequate cortisol – leading to adrenal hyperplasia. Diversion of the steroid precursors into the androgenic steroid pathways occurs (see Fig. 18.22a). Thus, 17-hydroxyprogesterone, androstenedione and testosterone levels are increased, leading to virilization. Aldosterone synthesis may be impaired with resultant salt wasting.

The other forms affect 11β-hydroxylase, 17α-hydroxylase, 3β-hydroxysteroid dehydrogenase and a cholesterol side-chain cleavage enzyme (p450scd) (see Fig. 18.22a).

**Clinical features**

If severe, CAH presents at birth with sexual ambiguity or adrenal failure (collapse, hypotension, hypoglycaemia), sometimes with a salt-losing state (hypotension, hyponatraemia). In the female, clitoral hypertrophy, urogenital abnormalities and labioscrotal fusion are common, but the syndrome may be unrecognized in the male.

Precocious puberty with hirsutism is a later presentation, whereas rare, milder cases only present in adult life, usually accompanied by primary amenorrhoea. Hirsutism developing before puberty is suggestive of CAH.

**Investigations**

Expert advice is essential in the confirmation and differential diagnosis of 21-hydroxylase deficiency, and with ambiguous genitalia such advice must be sought urgently before any assignment of gender is made.

A profile of adrenocortical hormones is measured before and one hour after ACTH administration.

- 17-Hydroxyprogesterone levels are increased.
- Urinary pregnanetriol excretion is increased.
- Androstenedione levels are raised
- Basal ACTH levels are raised

**Treatment**

Glucocorticoid activity must be replaced, as must mineralocorticoid activity if deficient. In CAH the larger dose of glucocorticoid is given at night to suppress the morning ACTH peak with a smaller dose in the morning (cf. Addison’s disease, p. 1012; Table 18.28). Correct dosage is often difficult to establish in the child but should ensure normal 17-
hydroxyprogesterone levels while allowing normal growth; excessive replacement leads to stunting of growth. In adults, clinical features and biochemistry (plasma renin and 17-OH-progesterone) are used to modify treatment. Genetic counselling (p. 45) and antenatal diagnosis is essential, particularly in 21-hydroxylase deficiency. The mother of an affected fetus can take dexamethasone daily to prevent virilization.

**Uses and problems of therapeutic steroid therapy**

Apart from their use as therapeutic replacement for endocrine deficiency states, synthetic glucocorticoids are widely used for many non-endocrine conditions (Box 18.8). Short-term use (e.g. for acute asthma) carries only small risks of significant side-effects except for the simultaneous suppression of immune responses. The danger lies in their continuance, often through medical oversight or patient default. In general, therapy for 3 weeks or less, or a dose of prednisolone less than 5 mg per day, will not result in significant long-term suppression of the normal adrenal axis.

Long-term therapy with synthetic or natural steroids will, in most respects, mimic endogenous Cushing’s syndrome. Exceptions are the relative absence of hirsutism, acne, hypertension and severe sodium retention, as the common synthetic steroids have low androgenic and mineralocorticoid activity.

Excessive doses of steroids may also be absorbed from skin when strong dermatological preparations are used, but inhaled steroids rarely cause Cushing’s syndrome, although they commonly cause adrenal suppression.

The major hazards are detailed in Box 18.9. In the long term, many are of such severity that the clinical need for high-dose steroids should be continually and critically assessed. Steroid-sparing agents (e.g. azathioprine) should always be considered and screening and prophylactic therapy for osteoporosis introduced (see p. 565). New targeted biological therapies for inflammatory conditions may reduce the incidence of steroid-induced adrenal suppression.

**Supervision of steroid therapy**

All patients receiving steroids should carry a ‘Steroid Card’. They should be made aware of the following points:

- Long-term steroid therapy must never be stopped suddenly.
- Doses should be reduced very gradually, with most being given in the morning at the time of withdrawal –

---

This minimizes adrenal suppression. Many authorities believe that ‘alternate-day therapy’ produces less suppression.

- Doses need to be increased in times of serious intercurrent illness (defined as presence of a fever, accident and stress. Double doses should be taken during these times.
- Other physicians, anesthetists and dentists must be told about steroid therapy.
- Patients should also be informed of potential side-effects and this information should be documented in the clinical record.
- Rationale for prophylactic use of bisphosphonate therapy to prevent the development of osteoporosis (NICE guidance).

### Steroids and surgery

Any patient receiving steroids or who has recently received them (within the last 12 months) and may still have adrenal suppression requires careful control of steroid medication around the time of surgery. Details are shown in Table 18.30.

### THE THIRST AXIS

Thirst and water regulation are largely controlled by vasopressin, also known as antidiuretic hormone (ADH), which is synthesized in the hypothalamus and then migrates in neurosecretory granules along axonal pathways to the posterior pituitary. Pituitary disease alone without hypothalamic involvement therefore does not lead to ADH deficiency as the hormone can still ‘leak’ from the damaged end of the intact axon.

At normal concentrations the kidney is the predominant site of action of vasopressin. Vasopressin stimulation of the V1 receptors allows the collecting ducts to become permeable to water via the migration of aquaporin-2 water channels, thus permitting reabsorption of hypotonic luminal fluid (p. 654). Vasopressin therefore reduces diuresis and results in overall retention of water. At high concentrations vasopressin also causes vasoconstriction via the V2 receptors in vascular tissue.

Changes in plasma osmolality are sensed by osmoreceptors in the anterior hypothalamus. Vasopressin secretion is suppressed at levels below 280 mOsm/kg, thus allowing maximal water diuresis. Above this level, plasma vasopressin increases in direct proportion to plasma osmolality. At the upper limit of normal (295 mOsm/kg) maximum antidiuresis is achieved and thirst is experienced at about 298 mOsm/kg (Fig. 18.26).

Other factors affecting vasopressin release are shown in Table 18.31.

Disorders of vasopressin secretion or activity include:
- deficiency as a result of hypothalamic disease (‘cranial’ diabetes insipidus)
- inappropriate excess of the hormone
- ‘nephrogenic’ diabetes insipidus – a rare condition in which the renal tubules are insensitive to vasopressin, an example of a receptor abnormality.

While all these are uncommon, they need to be distinguished from the occasional patient with ‘primary polydipsia’ and those whose renal tubular function has been impaired by

electrolyte abnormalities, such as hypokalaemia or hypercalcaemia.

**Diabetes insipidus (DI)**

**Clinical features**

Deficiency of vasopressin or insensitivity to its action leads to polyuria, nocturia and compensatory polydipsia. Daily urine output may reach as much as 10–15 L, leading to dehydration that may be very severe if the thirst mechanisms or consciousness are impaired or the patient is denied fluid.

Causes of DI are listed in Table 18.32. The most common is hypothalamic–pituitary surgery, following which transient DI is common, frequently remitting after a few days or weeks.

DI may be masked by simultaneous cortisol deficiency – cortisol replacement allows a water diuresis and DI then becomes apparent. Familial isolated vasopressin deficiency causes DI from early childhood and is dominantly inherited. DIDMOAD (Wolfram) syndrome is a rare autosomal recessive disorder comprising Diabetes Insipidus, Diabetes Mellitus, Optic Atrophy and Deafness due to mutations in the WFS1 gene on chromosome 4. MR scanning may show an absent or poorly developed posterior pituitary.

**Biochemistry**

- High or high-normal plasma osmolality with low urine osmolality (in primary polydipsia plasma osmolality tends to be low).
- Resultant high or high-normal plasma sodium.
- High 24-h urine volumes (less than 2 L excludes the need for further investigation).
- Failure of urinary concentration with fluid deprivation.
- Restoration of urinary concentration with vasopressin or an analogue.

The latter two points are studied with a formal water-deprivation test (Box 18.10). In normal subjects, plasma osmolality remains normal while urine osmolality rises above 600 mOsm/kg. In DI, plasma osmolality rises while the urine remains dilute, only concentrating after exogenous vasopressin is given (in ‘cranial’ DI) or not concentrating after vasopressin if nephrogenic DI is present. An alternative is measurement of plasma vasopressin during hypertonic saline infusion, but these measurements are not widely available.

**Sickle cell disease**

Mid temporary nephrogenic DI can occur after prolonged polyuria due to any cause, including cranial DI and primary polydipsia.

**Box 18.10 Water-deprivation test**

**Indication**

Diagnosis or exclusion of diabetes insipidus

**Procedure**

Fasting and no fluids from 0730 h (or overnight if only mild DI is expected and polyuria is only modest)

Monitor serum and urine osmolality, urine volume and weight hourly for up to 8 hours

Abandon fluid deprivation if weight loss >3% occurs

If serum osmolality >300 mOsm/kg and/or urine osmolality <600 mOsm/kg give desmopressin 2 μg i.m. at end of test. Allow free fluid but measure urine osmolality for 2–4 hours

**Interpretation**

*Normal response.* Serum osmolality remains within normal range (275–295 mOsm/kg). Urine osmolality rises to >600 mOsm/kg.

*Diabetes insipidus (DI).* Serum osmolality rises above normal without adequate concentration of urine osmolality (i.e. serum osmolality >300 mOsm/kg; urine osmolality <600 mOsm/kg).

*Nephrogenic DI* – if DDAVP does not concentrate urine.

*Cranial DI* – if urine osmolality rises by >50% after desmopressin.
Treatment
The synthetic vasopressin analogue desmopressin is the treatment of choice. It is most reliably given intranasally as a spray 10–40 μg once or twice daily, but can also be given orally as 100–200 μg three times daily, or intramuscularly 2–4 μg daily. Response is variable and must be monitored carefully with enquiry about fluid input/output and plasma osmolality measurements. Where there is a reversible underlying cause (e.g., a hypothalamic tumour) this should be investigated and treated.

Alternative agents in mild DI, probably working by sensitizing the renal tubules to endogenous vasopressin, include thiazide diuretics, carbamazepine (200–400 mg daily) or chlorpropamide (200–350 mg daily) but these are rarely used.

Nephrogenic diabetes insipidus
In this condition, renal tubules are resistant to normal or high levels of plasma vasopressin. It may be inherited as a rare sex-linked recessive, with an abnormality in the vasopressin-2 receptor, or as an autosomal post-receptor defect in an ADH-sensitive water channel, aquaporin-2. More commonly it can be acquired as a result of renal disease, sickle cell disease, drug ingestion (e.g., lithium), hypercalcaemia or hypokalaemia. Wherever possible the cause should be reversed. Polyuria is helped by thiazide diuretics.

Other causes of polyuria and polydipsia
Diabetes mellitus, hypokalaemia and hypercalcaemia should be excluded. In the case of diabetes mellitus the cause is an osmotic diuresis secondary to glycosuria which leads to dehydration and an increased perception of thirst owing to hypertonicity of the extracellular fluid.

Primary polydipsia
This is a relatively common cause of thirst and polyuria. It is a psychiatric disturbance characterized by the excessive intake of water. Plasma sodium and osmolality fall as a result and the urine produced is appropriately dilute. Vasopressin levels become virtually undetectable. Prolonged primary polydipsia may lead to the phenomenon of 'renal medullary washout', with a fall in the concentrating ability of the kidney.

Characteristically the diagnosis is made by a water-deprivation test. A low plasma osmolality is usual at the start of the test, and since vasopressin secretion and action can be stimulated, the patient's urine becomes concentrated (albeit 'maximum' concentrating ability may be impaired; the initially low urine osmolality gradually increases with the duration of the water deprivation.

Syndrome of inappropriate antidiuretic hormone (SIADH)
Clinical features
Inappropriate secretion of ADH leads to retention of water and hyponatraemia. The presentation is usually vague, with confusion, nausea, irritability and, later, fits and coma. There is no oedema. Mild symptoms usually occur with plasma sodium levels below 125 mmol/L and serious manifestations are likely below 115 mmol/L. The elderly may show symptoms with milder abnormalities.

The syndrome must be distinguished from dilutional hyponatraemia due to excess infusion of dextrose/water solutions or diuretic administration (thiazides or amiloride, see p. 657).

Diagnosis
The usual features are:
- dilutional hyponatraemia due to excessive water retention
- euolaemia (in contrast to hypovolaemia of sodium and water depletion states)
- low plasma osmolality with 'inappropriate' urine osmolality >100 mOsm/kg (and typically higher than plasma osmolality)
- continued urinary sodium excretion >30 mmol/L (lower levels suggest sodium depletion and should respond to 0.9% saline infusion)
- absence of hypokalaemia (or hypotension)
- normal renal and adrenal and thyroid function.

The causes are listed in Table 18.33.

Hyponatraemia is very common during illness in frail elderly patients and it may sometimes be clinically difficult to distinguish SIADH from salt and water depletion, particularly when mixed clinical features are present. Under these circumstances a triad infusion of 1–2 L 0.9% saline is given. SIADH will not respond (but will excrete the sodium and water load effectively) – sodium depletion will respond.

Treatment
The underlying cause should be corrected where possible. Symptomatic relief can be obtained by the following measures:

</table>
Fluid intake should be restricted to 500–1000 mL daily. If tolerated, and complied with, this will correct the biochemical abnormalities in almost every case.

- Plasma osmolality, serum sodium and bodyweight should be measured frequently.
- If water restriction is poorly tolerated or ineffective, demeclocycline (600–1200 mg daily) is given; this inhibits the action of vasopressin on the kidney, causing a reversible form of nephrogenic diabetes insipidus. It often, however, causes photosensitive rashes.
- When the syndrome is very severe (i.e. acute and symptomatic), hypertonic saline may be indicated but this is potentially dangerous and should only be used with extreme caution (p. 663).
- Vasopressin V₂ antagonists, e.g. tolvaptan, are being used with good initial results.

DISORDERS OF CALCIUM METABOLISM

Serum calcium levels are mainly controlled by parathyroid hormone (PTH) and vitamin D. Hypercalcaemia is much more common than hypocalcaemia and is frequently detected incidentally with multichannel biochemical analysers. Mild asymptomatic hypercalcaemia occurs in about 1 in 1000 of the population, with an incidence of 25–30 per 100,000 population. It occurs mainly in elderly females, and is usually due to primary hyperparathyroidism (primary HPT).

Parathyroid hormone

There are normally four parathyroid glands which are situated posterior to the thyroid, but occasionally additional glands exist or they may be found elsewhere in the neck or mediastinum. PTH, an 84-amino-acid hormone derived from a 115-residue preprohormone, is secreted from the chief cells of the parathyroid glands. PTH levels rise as serum ionized calcium falls. The latter is detected by specific G protein-coupled calcium-sensing receptors on the plasma membrane of the parathyroid cells. PTH has several major actions, all serving to increase plasma calcium by:

- increasing osteoclastic resorption of bone (occurring rapidly)
- increasing intestinal absorption of calcium (a slow response)
- increasing synthesis of 1,25-(OH)₂D₃
- increasing renal tubular reabsorption of calcium
- increasing excretion of phosphate.

PTH effects are mediated at specific membrane receptors on the target cells, resulting in an increase of adenyl cyclase messenger activity.

Vitamin D metabolism is discussed on page 559.

PTH measurements

PTH measurements use two-site immunometric assays that measure only the intact PTH molecule; interpretation requires a simultaneous calcium measurement in order to differentiate most causes of hyper- and hypocalcaemia.

Long-term immobility

Familial hypocalciuric hypercalcaemia

---

**Hypercalcaemia**

Pathophysiology and causes

The major causes of hypercalcaemia are listed in Table 18.34; primary hyperparathyroidism and malignancies are by far the most common (>90% of cases). Hyperparathyroidism itself may be primary, secondary or tertiary. Primary hyperparathyroidism is caused by single (>80%) parathyroid adenomas or by diffuse hyperplasia of all the glands (15–20%); multiple parathyroid adenomas are rare. Involvement of multiple parathyroid glands may be part of a familial syndrome (e.g. multiple endocrine neoplasia (MEN) syndrome type 1 or 2a). Parathyroid carcinoma is rare (<1%), though it usually produces severe and intractable hypercalcaemia. Hyperparathyroidism–jaw tumour syndrome is a rare familial cause of hyperparathyroidism which may be associated with parathyroid carcinoma and maxillary or mandibular tumours.

**Primary hyperparathyroidism** is of unknown cause, though it appears that adenomas are monoclonal. Hyperplasia may also be monoclonal. Chromosomal rearrangements in the 5′ regulatory region of the parathyroid hormone gene have been identified, and inactivation of some tumour suppressor genes at a variety of sites may also be involved.

**Secondary hyperparathyroidism** (see p. 628) is physiological compensatory hypertrophy of all parathyroids because of hypocalcaemia, such as occurs in renal failure or vitamin D deficiency. PTH levels are raised but calcium levels are low or normal, and PTH falls to normal after correction of the cause of hypocalcaemia where this is possible.
Tertiary hyperparathyroidism is the development of apparently autonomous parathyroid hyperplasia after longstanding secondary hyperparathyroidism, most often in renal failure. Plasma calcium and phosphate are both raised, the latter often grossly so. Parathyroidectomy is necessary at this stage.

Symptoms and signs
Mild hypercalcaemia (e.g. adjusted calcium <3 mmol/L) is frequently asymptomatic, but more severe hypercalcaemia can produce a number of symptoms:

- **General features.** There may be tiredness, malaise, dehydration and depression.
- **Renal features.** Renal colic from stones, polyuria or nocturia, haematuria and hypertension occurs. The polyuria results from the effect of hypercalcaemia on renal tubules, reducing their concentrating ability – a form of mild nephrogenic diabetes insipidus. Primary hyperparathyroidism is present in about 5% of patients who present with renal calculi.
- **Bones.** There may be bone pain. Hyperparathyroidism mainly affects cortical bone, and bone cysts and locally destructive ‘brown tumours’ occur but only in advanced disease. Only 5–10% of all cases have definite bony lesions even when sought. Bone disease may be more apparent when there is coexisting vitamin D deficiency.
- **Abdominal.** There may be abdominal pain.
- **Chondrocalcinosis** and ectopic calcification. These are occasional features.
- **Corneal calcification.** This is a marker of long-standing hypercalcaemia but causes no symptoms.

There may also be symptoms from the underlying cause. Malignant disease is usually advanced by the time hypercalcaemia occurs, typically with bony metastases. The common primary tumours are bronchus, breast, myeloma, oesophagus, thyroid, prostate, lymphoma and renal cell carcinoma. True ‘ectopic PTH secretion’ by the tumour is very rare, and most cases are associated with raised levels of PTH-related protein. This is a 144-amino-acid polypeptide, the initial sequence of which shows an approximate homology with the biologically active part of PTH, which is necessary in fetal development but does not have a clearly defined role in the adult. Local bone-resorbing cytokines and prostaglandins may be involved locally where there are metastatic skeletal lesions, leading to local mobilization of calcium by osteolysis with subsequent hypercalcaemia.

Severe hypercalcaemia (>3 mmol/L) is usually associated with malignant disease, hyperparathyroidism, renal failure or vitamin D therapy.

Investigations and differential diagnosis
Biochemistry
- Several fasting serum calcium and phosphate samples should be performed.
- **Serum PTH.** The hallmark of primary hyperparathyroidism is hypercalcaemia and hypophosphataemia with detectable or elevated intact PTH levels during hypercalcaemia. When this combination is present in an asymptomatic patient then further investigation is usually unnecessary.
- There is often a mild hyperchloaemic acidosis.
- **Renal function** is usually normal but should be measured as a baseline.
- **24-hour urinary calcium** or single calcium creatinine ratio should be measured in a young patient with modest elevation in calcium and PTH to exclude familial hypocalciuric hypercalcaemia (see p. 1021).
- **Elevated serum alkaline phosphatase** is found in severe parathyroid bone disease, but otherwise it suggests an alternative cause for hypercalcaemia.

Where PTH is undetectable or equivocal, a number of other tests may lead to the diagnosis:
- protein electrophoresis: to exclude myeloma
- serum TSH: to exclude hyperthyroidism
- 0900 h cortisol and/or ACTH test: to exclude Addison’s disease
- serum ACE: helpful in the diagnosis of sarcoidosis
- hydrocortisone suppression test: hydrocortisone 40 mg three times daily for 10 days leads to suppression of plasma calcium in sarcoidosis, vitamin D-mediated hypercalcaemia and some malignancies.

Imaging
Abdominal X-rays may show renal calculi or nephrocalcinosis. High-definition hand X-rays can show subperiosteal erosions in the middle or terminal phalanges. DXA bone density scan is useful to detect bone effects in asymptomatic patients with hyperparathyroidism (HPT) in whom conservative management is planned.

The success of parathyroid imaging is highly operator dependent and choice therefore depends on local skills and experience. Imaging is frequently far less accurate than parathyroid exploration by an expert surgeon where the success rate is at least 90%. However, with the advent of minimally invasive surgery, preoperative imaging is increasingly used. Methods include:

- ultrasound which, though insensitive for small tumours, is simple and safe
- high-resolution CT scan or MRI (more sensitive)
- radioisotope scanning using $^{99m}$Tc-sestamibi, which is approximately 90% sensitive in detecting adenomas.

Treatment of hypercalcaemia
Details of emergency treatment for severe hypercalcaemia are given in Emergency box 18.2. This should be followed by oral therapy unless the underlying disease can be treated.

Treatment of primary hyperparathyroidism
Medical management
There are no effective medical therapies at present for primary hyperparathyroidism, but a high fluid intake should be maintained, a high calcium or vitamin D intake avoided, and exercise encouraged. New therapeutic agents that target the calcium-sensing receptors (e.g. cinacalcet) are of proven value in parathyroid carcinoma and in dialysis patients (p. 633).

Surgery
Indications for surgery in primary hyperparathyroidism remain controversial. There is agreement that surgery is indicated for:

- patients with renal stones or impaired renal function
- bone involvement or marked reduction in cortical bone density
Emergency Box 18.2

Treatment of acute severe hypercalcaemia

Acute hypercalcaemia often presents with dehydration, nausea and vomiting, nocturia and polyuria, drowsiness and altered consciousness. The serum Ca" is over 3 mmol/L and sometimes as high as 5 mmol/L. While investigation of the cause is under way, immediate treatment is mandatory if the patient is seriously ill or if the Ca" is above 3.5 mmol/L.

- Rehydrate at least 4–6 L of 0.9% saline on day 1, and 3–4 L for several days thereafter. Central venous pressure (CVP) may need to be monitored to control the hydration rate.
- Intravenous bisphosphonates are the treatment of choice for hypercalcaemia of malignancy or of undiagnosed cause. Pamidronate is preferred (60–90 mg as an intravenous infusion in 0.9% saline or dextrose 2–4 hours or, if less urgent, over 2–4 days). Levels fall after 24–72 hours, lasting for approximately two weeks. Zoledronate is an alternative.
- Prednisolone (30–60 mg daily) is effective in some instances (e.g. in myeloma, sarcoidosis and vitamin D excess) but in most cases is ineffective.
- Calcitriol (200 units i.v. daily) has an short-lived action and is little used.
- Oral phosphate (sodium cellulose phosphate 5 g three times daily) produces diarrhoea.

- unequivocal marked hypercalcaemia (in UK typically >3.0 mmol/L; USA guidelines state >1 mg/dL above reference range)
- the uncommon younger patient, below age 50 years
- a previous episode of severe acute hypercalcaemia.

The situation where plasma calcium is mildly raised (2.65–3.00 mmol/L) is more controversial. Most authorities feel that young patients should be operated on, as should those who have reduced cortical bone density or significant hypercalciuria, as this is associated with stone formation.

In older patients without these problems, or in those unfit for or unwilling to have surgery, conservative management is indicated. Regular measurement of serum calcium and of renal function is necessary. Bone density of cortical bone should be monitored if conservative management is used.

Surgical technique and complications

Parathyroid surgery should be performed only by experienced surgeons, as the minute glands may be very difficult to define, and it is difficult to distinguish between an adenoma and normal parathyroid. In expert centres over 90% of operations are successful, involving removal of the adenoma, or removal of all four hyperplastic parathyroids. Minimal access surgery is increasingly used, and some centres measure PTH levels intra-operatively to ensure the adenoma has been removed.

Other than postoperative hypocalcaemia (see below), the other rare complications are those of thyroid surgery – bleeding and recurrent laryngeal nerve palsies (<1%). Vocal cord function should be checked preoperatively.

If initial exploration is unsuccessful, a full work-up including venous catheterization and scanning is essential, remembering that parathyroid tissue can be ectopic.

Postoperative care

The major danger after operation is hypocalcaemia, which is more common in patients with significant bone disease – the 'hungry bone' syndrome. Some authorities treat such patients with calcitriol 2 μg daily from 2 days preoperatively for 10–14 days. Chvostek’s and Trousseau’s signs (see p. 1022) are monitored as well as biochemistry. Plasma calcium measurements are performed at least daily until stable – with or without replacement – a mild transient hypoparathyroidism often continues for 1–2 weeks. Depending on its severity, oral or intravenous calcium should be given temporarily, as only a few patients (<1%) will develop long-standing surgical hypoparathyroidism.

Familial hypocalciuric hypercalcaemia

This uncommon autosomal dominant, and usually asymptomatic, condition demonstrates increased renal reabsorption of calcium despite hypercalcaemia. PTH levels are normal or slightly raised and urinary calcium is low. It is caused by loss of function mutations in the gene on the long arm of chromosome 3 encoding for the calcium-ion-sensing G protein-coupled receptor in the kidney and parathyroid gland. Family members are often affected, detected by genetic analysis. Parathyroid surgery is not indicated as the course appears benign. This diagnosis can be differentiated from hyperparathyroidism in an isolated case by the calcium creatinine ratio in blood and urine.

Hypocalcaemia and hypoparathyroidism

Pathophysiology

Hypocalcaemia may be due to deficiencies of calcium homeostatic mechanisms, secondary to high phosphate levels or other causes of hypocalcaemia (Table 18.35). All forms of hypoparathyroidism, except transient surgical effects, are uncommon.

**Ask the authors**

Causes

- **Chronic Kidney disease** is the most common cause of hypocalcaemia.
- **Hypocalcaemia after thyroid or parathyroid surgery** is common but usually transient – fewer than 1% of thyroidectomies leave permanent damage (see above).
- **Idiopathic hypoparathyroidism** is one of the rarer autoimmune disorders, often accompanied by vitiligo, cutaneous candidiasis and other autoimmune disease.

The DiGeorge syndrome (p. 70) is a familial condition in which the hypoparathyroidism is associated with intellectual impairment, cataracts and calcified basal ganglia, and occasionally with specific autoimmune disease.

**Pseudohypoparathyroidism** is a syndrome of end-organ resistance to PTH owing to a mutation in the GNAS1 protein (GNAS1) which is coupled to the PTH receptor. It is associated with short stature, short metacarpals, subcutaneous calcification and sometimes intellectual impairment. Variable degrees of resistance involving other G protein-linked hormone receptors may also be seen (TSH, LH, FSH).

Pseudo-pseudohypoparathyroidism describes the phenotypic defects but without any abnormalities of calcium metabolism. These individuals may share the same gene defect as patients with pseudohypoparathyroidism and be members of the same families.

Clinical features

Hypoparathyroidism presents as neuromuscular irritability and neuropsychiatric manifestations. Paraesthesiae, circumoral numbness, cramps, anxiety and tetany (Box 18.11) are followed by convulsions, laryngeal stridor, dystonia and psychosis. Two signs of hypocalcaemia are Chvostek’s sign (gentle tapping over the facial nerve causes twitching of the ipsilateral facial muscles) and Trousseau’s sign, where inflation of the sphygmomanometer cuff above systolic pressure for 3 minutes induces tetanic spasm of the fingers and wrist. Severe hypocalcaemia may cause papilloedema and frequently a prolonged QT interval on the ECG.

Investigations

The clinical history and picture is usually diagnostic and is confirmed by a low serum calcium (after correction for any albumin abnormality). Additional tests include:

- serum and urine creatinine for renal disease
- PTH levels in the serum: absent or inappropriately low in hypoparathyroidism, high in other causes of hypocalcaemia
- parathyroid antibodies (present in idiopathic hypoparathyroidism)
- 25-hydroxy vitamin D serum level (low in vitamin D deficiency)

**Box 18.11 Causes of tetany**

- In the presence of alkalosis
  - Hyperventilation
  - Excess antacid therapy
  - Persistent vomiting
  - Hypochloaemic alkalosis, e.g. primary hyperaldosteronism

- In the presence of hypocalcaemia (see Table 18.35)

- **magnesium level** – severe hypomagnesaemia results in functional hypoparathyroidism which is reversed by magnesium replacement.
- **X-rays of metacarpals**, showing short fourth metacarpals which occur in pseudohypoparathyroidism.

Treatment

Alpha-hydroxylated derivatives of vitamin D are preferred for their shorter half-life, and especially in renal disease as the others require renal hydroxylation. Usual daily maintenance doses are 0.25–2 μg for alfalcacidol (1α-OH-D₃). During treatment, plasma calcium must be monitored frequently to detect hypercalcaemia.

**ENDOCRINOLOGY OF BLOOD PRESSURE CONTROL**

The control of blood pressure (BP) is complex, involving neural, cardiac, hormonal and many other mechanisms.

BP is dependent upon cardiac output and peripheral resistance. Although cardiac output can be increased in endocrine disease (e.g. hyperthyroidism), the main role of hormonal mechanisms is control of peripheral resistance and of circulating blood volume. The oral contraceptive pill is a common endocrine cause of mild hypertension.

When to investigate for secondary hypertension

Endocrine causes account for 5–10% of all hypertension (Table 18.36). It is impracticable and unnecessary to screen all hypertensive patients for secondary causes. The highest chances of detecting such causes are in:

- subjects under 35 years, especially those without a family history of hypertension
- those with accelerated (malignant) hypertension
- those with indications of renal disease (e.g. proteinuria, unequal renal sizes)
- those with hypokalaemia

**Table 18.36 Endocrine causes of hypertension**

those resistant to conventional antihypertensive therapy (e.g. more than three drugs)
- those with unusual symptoms (e.g. sweating attacks or weakness).

The renin–angiotensin–aldosterone axis: biochemistry and actions

The renin–angiotensin–aldosterone system is illustrated in Figure 18.27.

Angiotensinogen, an α₂-globulin of hepatic origin, circulates in plasma. The enzyme, renin, is secreted by the kidney in response to decreased renal perfusion pressure or flow. It cleaves the decapptide angiotensin I from angiotensinogen. Angiotensin I is inactivated by subsequent cleavage by angiotensin-converting enzyme (ACE; present in lung and vascular endothelium) into the active decapeptide angiotensin II, which has two major actions (mediated by two types of receptor, AT₁ and AT₂). The AT₁ subtype which is found in the heart, blood vessels, kidney, adrenal cortex, lung and brain mediates the vasoconstrictor effect. AT₂ is probably involved in vascular growth. Angiotensin II:
- causes rapid, powerful vasoconstriction
- stimulates the adrenal zona glomerulosa to increase aldosterone production (over hours or days).

As BP increases and sodium is retained, the stimuli to renin secretion are reduced. Dietary sodium excess also suppresses renin secretion, whereas sodium deprivation or urinary sodium loss will increase it.

The renin–angiotensin system can be blocked at several points with renin inhibitors, angiotensin-converting enzyme inhibitors (ACEI) and angiotensin II receptor antagonists (A-II-RA). These are useful agents in treatment of hypertension and heart failure (see pp. 738 and 739) but have differences in action: ACEIs also block kinin production while A-II-RAs are specific for the AT-II receptors.

Atrial and brain natriuretic factors/peptides (ANP and BNP)

Atrial natriuretic peptides, a family of varying length forms, are secreted from atrial granules in response to atrial stretch. They produce marked effects on the kidney, increasing sodium and water excretion and glomerular filtration rate and lowering BP, plasma renin activity and plasma aldosterone (p. 652).

Brain natriuretic peptide is found in the ventricle as well as the brain and has moderate sequence homology with ANP; normally its circulating level is much less than for ANP but may exceed it in congestive cardiac failure.

ANP and BNP appear to play a significant role in cardiovascular and fluid homeostasis, but there is no evidence of primary defects in their secretion causing disease. Serum BNP levels accurately reflect the presence and severity of heart failure and are useful in defining prognosis and the need for adjustment of treatment (p. 735).

Agents that both inhibit the endopeptidases that break down ANP and inhibit ACE (the receptors concerned are similar) are becoming available.

**RENIN (AND ANGIOTENSIN) DEPENDENT HYPERTENSION**

Many forms of unilateral and bilateral renal diseases are associated with hypertension. The classic example is renal artery stenosis: the major hypertensive effects of this and other situations such as renin-secreting tumours are directly or indirectly due to angiotensin II.

Angiotensin II receptor antagonists (e.g. losartan, valsartan, candesartan and irbesartan) are effective in hypertension and congestive cardiac failure, similar to angiotensin-converting enzyme inhibitors (ACEI). They produce much the same clinical effects, though with fewer side-effects (e.g. no cough and less hyperkalaemia). Direct renin inhibitors (e.g. aliskiren) have also been introduced for the treatment of hypertension.

**Renal artery stenosis**

This is discussed on page 607.

**DISORDERS OF ALDOSTERONE SECRETION**

**Primary hyperaldosteronism**

**Pathophysiology**

This condition is caused by excess aldosterone production leading to sodium retention, potassium loss and the combination of hypokalaemia and hypertension.
Causes (see Table 18.36)

Adrenal adenomas (Conn’s syndrome) originally accounted for 60% of cases of primary hyperaldosteronism but represented a rare cause of hypertension. In recent series the increasing use of aldosterone:renin ratios in investigation of hypertension has led to an increased diagnosis of hyperaldosteronism due to bilateral adrenal hyperplasia of uncertain aetiology. Some claim that this is the cause of up to 10% of cases of ‘essential’ hypertension, but adenomas represent a minority of cases when diagnosed in this way.

Clinical features

The usual presentation is simply hypertension. Hypokalaemia (<3.5 mmol/L) was a hallmark of the condition as originally described but is now frequently absent. The few symptoms are non-specific; rarely muscle weakness, nocturia and tetany are seen. The hypertension may be severe and associated with renal, cardiac and retinal damage.

Adenomas, often very small, are more common in young females, while bilateral hyperplasia rarely occurs before age 40 years and is more common in males.

Investigations

Beta-blockers and other drugs may interfere with renin activity, and spironolactone, ACE inhibitors and AR-R antagonists will all affect results and all should be discontinued if possible. The characteristic features are as follows:

- Plasma aldosterone:renin ratio (ARR) is now most frequently used as a screening test for the condition, but raised ARR alone does not confirm the diagnosis (if the renin is low enough ARR will always be high). Note that normal ranges are highly assay dependent.

- Elevated plasma aldosterone levels that are not suppressed with 0.9% saline infusion (2 L over 4 hours) or fludrocortisone administration. Between 30% and 50% of patients with raised ARR on screening will suppress normally, excluding the diagnosis.

- Suppressed plasma renin activity or immunoreactivity.

- Hypokalaemia is often present but a normal serum potassium does not exclude the diagnosis.

- Urinary potassium loss. Levels >30 mmol daily during hypokalaemia are inappropriate.

Once a diagnosis of hyperaldosteronism is established, differentiation of adenoma from hyperplasia involves adrenal CT or MRI, but small adenomas may be missed and non-functioning incidentalomas also occur. Further information may be obtained from diurnal/postural changes in plasma aldosterone levels (which tend to rise with adenomas between 0900 h supine and 1300 h erect samples; in contrast, they fall with hyperplasia), measurement of 18-OH cortisol levels (raised in adenoma) and venous catheterization for aldosterone levels. All of these tests have their pitfalls and exceptions.

Glucocorticoid (or dexamethasone)-suppressible hyperaldosteronism is rare and is caused by a chimeric gene on chromosome 8. A fusion gene resulting from an unusual cross-over at meiosis between the genes encoding aldosterone synthase and adrenal 11β-hydroxylase produces aldosterone which is under ACTH control. Treatment with glucocorticoid resolves the problem.

Treatment

An adenoma can be removed surgically – usually laparoscopically; BP falls in 70% of patients. Those with hyperplasia should be treated with the aldosterone antagonist spironolactone (100–400 mg daily); frequent side-effects include nausea, rashes and gynaecomastia, and the pure aldosterone receptor antagonist eplerenone is a useful alternative (p. 657). Spironolactone metabolites have been linked with tumour development in animals. Amiloride and calcium-channel blockers are moderately effective in controlling the hypertension but do not correct the hyperaldosteronism.

Secondary hyperaldosteronism

This situation arises when there is excess renin (and hence angiotensin II) stimulation of the zona glomerulosa. Common causes are accelerated hypertension and renal artery stenosis, when the patient will be hypertensive. Causes associated with normotension include congestive cardiac failure and cirrhosis, where excess aldosterone production contributes to sodium retention.

Angiotensin-converting enzyme inhibitors (e.g. captopril, enalapril or lisinopril) and angiotensin II antagonists (e.g. losartan, candesartan) are effective in heart failure, both symptomatically and in increasing life expectancy (see p. 737). Spironolactone is of value in both situations, and 25 mg/day has been shown to improve survival in heart failure (see p. 739).

Syndrome of apparent mineralocorticoid excess

This causes the clinical syndrome of primary hyperaldosteronism but with low renin and aldosterone levels. Reduced activity of the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) prevents the normal conversion in the kidney of cortisol (which is active at the mineralocorticoid receptor) to cortisone (which is not) and therefore ‘exposes’ the mineralocorticoid receptor in the kidney to the usual molar excess of cortisol over aldosterone in the blood. While the inherited syndrome is rare, the same clinical syndrome can occur with excessive ingestion of liquorice, which inhibits the 11β-HSD2 enzyme.

Hypoaldosteronism

Except as part of primary hypoadrenalism (Addison’s disease, see p. 1010), this is very uncommon. Causes include hyporeninaemic hypoaldosteronism, aldosterone biosynthetic defects, and drugs (e.g. ACE inhibitors, heparin).

The Adrenal Medulla

The major catecholamines, noradrenaline (norepinephrine) and adrenaline (epinephrine), are produced in the adrenal medulla (Fig. 18.28), although most noradrenaline is derived from sympathetic neuronal release. While noradrenaline and adrenaline undoubtedly produce hypertension when infused, they probably play little part in BP regulation in normal humans.
Phaeochromocytoma

Phaeochromocytomas, tumours of the sympathetic nervous system, are very rare (less than 1 in 1000 cases of hypertension). Ninety per cent arise in the adrenal, while 10% occur elsewhere in the sympathetic chain. Some are associated with MEN 2 syndromes (see below) and the von Hippel–Lindau syndrome (p. 644). Most tumours release both noradrenaline (norepinephrine) and adrenaline (epinephrine) but large tumours and extra-adrenal tumours produce almost entirely norepinephrine.

Paragangliomas are related catecholamine-secreting tumours, typically in the head and neck but also found in the thorax, pelvis and bladder. They are more closely associated with other genetic associations of phaeochromocytoma. The association of paraganglioma, bilateral adrenal phaeochromocytomas, positive family history or young age at presentation is seen in multiple endocrine neoplasms (p. 1026).

Pathology

Oval groups of cells occur in clusters and stain for chromogranin A. Twenty-five per cent are multiple and 10% malignant, the latter being more frequent in the extra-adrenal tumours. Malignancy cannot be determined on simple histological examination alone.

Clinical features

The clinical features are those of catecholamine excess and are frequently, but not necessarily, intermittent (Table 18.37).

Diagnosis

Specific tests are:

- Measurement of urinary catecholamines and metabolites (metanephrines are most sensitive and specific – Fig. 18.28) is a useful screening test; normal levels on three 24-hour collections of metanephrines virtually exclude the diagnosis. Many drugs and dietary vanilla interfere with these tests.

(Signs of hypertensive damage)

- **Resting plasma catecholamines** are raised.
- **Plasma chromogranin A** (a storage vesicle protein) is raised.
- **Clonidine suppression test** may be appropriate, but should only be performed in specialist centres.
- **CT scans**, initially of the abdomen, are helpful to localize the tumours which are often large.
- **MRI** usually shows the lesion clearly.
- **Scanning with [¹¹¹]metiodobenzylguanidine (mIBG)** produces specific uptake in sites of sympathetic activity with about 90% success. It is particularly useful with extra-adrenal tumours.

Treatment

Tumours should be removed if this is possible; 5-year survival is about 95% for non-malignant tumours. Medical pre-operative and perioperative treatment is vital and includes complete alpha- and beta-blockade with phenoxybenzamine (20–80 mg daily initially in divided doses), then propranolol (120–240 mg daily), plus transfusion of whole blood to expand the contracted plasma volume. The alpha-blockade must precede the beta-blockade, as worsened hypertension may otherwise result. Labelotol is not recommended. Surgery in the unprepared patient is fraught with dangers of both hypertension and hypotension; expert anaesthesia and an experienced surgeon are both vital, and sodium nitroprusside should be available in case sudden severe hypertension develops.

When operation is not possible, combined alpha- and beta-blockade can be used long term. Radionucleotide treatment with mIBG has been used but with limited success in malignant phaeochromocytoma.

Patients should be kept under clinical and biochemical review after tumour resection as over 10% recur or develop a further tumour. Catecholamine excretion measurements should be performed at least annually.
OTHER ENDOCRINE DISORDERS

DISEASES OF MANY GLANDS

Multiple gland failure (polyglandular autoimmune syndromes)

These are caused by autoimmune disease as detailed in Table 18.2 on page 965. Most common are the associations of primary hypothyroidism and type 1 diabetes, and either of these with Addison’s disease or pernicious anaemia.

Autoimmune polyendocrinopathy type 1 (APS-1) is an autosomal recessive disorder and is caused by AIRE gene mutations. The AIRE gene is present in the epithelium of the thymus and is involved in the presentation of self-antigens to thymocytes. Mutations will allow persistence of lymphocytes from the thymus to react against self antigens and cause development of autoimmune disorders. Mucocutaneous candidiasis often develops before the onset of endocrine deficiencies, such as Addison’s disease, type 1 diabetes, hyperparathyroidism, nail dystrophy, vitiligo and dental enamel hypoplasia.

APS-2 is not associated with candidiasis and is also known as Schmidt’s syndrome, typically when hypothyroidism, Addison’s disease and type 1 diabetes are present in combination; coeliac disease is also an association.

Multiple endocrine neoplasia

This is the name given to the simultaneous or metachronous occurrence of tumours involving a number of endocrine glands (Table 18.38). The condition is inherited in an auto-

</table>

somal dominant manner and arise from the expression of recessive oncogenic mutations, most of which have been isolated. Affected persons may pass on the mutation to their offspring in the germ cell, but for the disease to become evident a somatic mutation must also occur, such as deletion or loss of a normal homologous chromosome. The defect in MEN 1 is in a novel gene (menin) on the long arm of chromosome 11 which encodes for a 610-amino-acid protein. Menin represses a transcription factor (JunD) and lack of JunD suppression leads to decreased apoptosis and oncogenesis. Patients with the MEN1 gene carry one mutant gene and a wild type gene (i.e. are heterozygous). When the wild type gene undergoes a random somatic mutation during life, this leads to loss of heterozygosity and explains the late onset of tumours at any stage (the “two hit” hypothesis). MEN 2a and 2b are caused by mutations of the RET proto-oncogene on chromosome 10 (see medullary thyroid cancer, p. 994). This gene encodes for a transmembrane glycoprotein receptor. For MEN 2a the mutation is in the extracellular domain; for 2b it is in the intracellular domain.

Management

Treatment of established tumours in MEN is largely the same as treatment for similar tumours occurring sporadically. In MEN 1 four-gland parathyroidectomy is usually recommended when surgery is needed since all glands are typically involved. However, the essence of management in MEN is annual screening to detect tumours at an early, treatable stage.

Screening

A careful family history is essential. If the precise gene mutation has been identified in a particular family, then family members at risk can be offered genetic screening for the presence of the mutation, ideally in childhood. In affected individuals, biochemical screening and periodic imaging is then required.

Screening for type 1

Hyperparathyroidism is usually the first manifestation, and serum calcium is the simplest screening test in families with no identified mutation. In an established case (or gene-positive family member) other screening bloods include prolactin, GH/IGF-1 and ‘gut hormones’ (p. 272). Periodic imaging of pancreas, adrenals and pituitary is usually performed.

Screening for type 2

Serum calcium levels will easily detect hyperparathyroidism.

- **Medullary carcinoma of thyroid (MCT)** – with the known presence of the gene defect, total thyroidectomy is recommended in early childhood or as soon as the gene defect is identified. Calcitonin is a useful tumour marker.
- **Phaeochromocytoma** – metanephrine or catecholamine estimations.

McCune–Albright syndrome

This condition is associated with autonomous hypersecretion of a number of endocrine glands at a young age.
Gonadotrophin-independent puberty with Leydig cell hyperplasia in males and ovarian oestrogen production in girls occurs. Pituitary hypersecretion may lead to hyperprolactinaemia, acromegaly or gigantism. Cushing’s syndrome due to nodular hyperplasia of the adrenal cortex is observed, as well as autonomous functioning thyroid nodules. Non-endocrine manifestations include café-au-lait patches and hypophosphataemic rickets. A point mutation of the GNAS1 gene inhibits GTPase activity, leading to persistent activation of cAMP-mediated endocrine secretion.

ECTOPIC HORMONE SECRETION

This terminology refers to hormone synthesis, and normally secretion, from a neoplastic non-endocrine cell, most usually seen in tumours that have some degree of embryological resemblance to specialist endocrine cells. The clinical effects are those of the hormone produced, with or without manifestations of systemic malignancy. The most common situations seen are the following:

- **Hypercalcaemia of malignant disease**, often from squamous cell tumours of lung and breast, often with bone metastases. Where metastases are not present, most cases are mediated by secretion of PTH-related protein (PTHrP), which has considerable sequence homology to PTH; a variety of other factors may sometimes be involved, but very rarely PTH itself (see p. 1019). Treatment is also discussed on page 1020.
- **SIADH** (see p. 1018). Again, this is most common from a primary lung tumour.
- **Ectopic ACTH syndrome** (see p. 1012). Small-cell carcinoma of the lung, carcinoid tumours and medullary thyroid carcinomas are the most common causes, though many other tumours rarely cause it.
- **Production of insulin-like activity** may result in hypoglycaemia (see p. 1059).
Diabetes mellitus (DM) is a syndrome of chronic hyperglycaemia due to relative insulin deficiency, resistance, or both. It affects more than 120 million people worldwide, and it is estimated that it will affect 370 million by the year 2030. Diabetes is usually irreversible and, although patients can have a reasonably normal lifestyle, its late complications result in reduced life expectancy and major health costs. These include macrovascular disease, leading to an increased prevalence of coronary artery disease, peripheral vascular disease and stroke, and microvascular damage causing diabetic retinopathy and nephropathy. Neuropathy is another major complication.

Insulin structure and secretion

Insulin is the key hormone involved in the storage and controlled release within the body of the chemical energy available from food. It is coded for on chromosome 11 and synthesized in the beta-cells of the pancreatic islets (Fig. 19.1). The synthesis, intracellular processing and secretion of insulin by the beta-cell is typical of the way that the body produces and manipulates many peptide hormones. Figure 19.2 illustrates the cellular events triggering the release of insulin-containing granules. After secretion, insulin enters the portal circulation and is carried to the liver, its prime target organ. About 50% of secreted insulin is extracted and degraded in the liver; the residue is broken down by the kidneys. C-peptide is only partially extracted by the liver (and hence provides a useful index of the rate of insulin secretion), but is mainly degraded by the kidneys.

An outline of glucose metabolism

Blood glucose levels are closely regulated in health and rarely stray outside the range of 3.5–8.0 mmol/L (63–144 mg/dL), despite the varying demands of food, fasting and exercise. The principal organ of glucose homeostasis is the liver, which absorbs and stores glucose (as glycogen) in the post-absorptive state and releases it into the circulation between meals to match the rate of glucose utilization by peripheral tissues. The liver also combines 3-carbon molecules derived from breakdown of fat (glycerol), muscle glycogen (lactate) and protein (e.g. alanine) into the 6-carbon glucose molecule by the process of gluconeogenesis.

Glucose production

About 200 g of glucose is produced and utilized each day. More than 90% is derived from liver glycogen and hepatic gluconeogenesis, and the remainder from renal gluconeogenesis.

Glucose utilization

The brain is the major consumer of glucose. Its requirement is 1 mg/kg bodyweight per minute, or 100 g daily in a 70 kg man. Glucose uptake by the brain is obligatory and is not dependent on insulin, and the glucose used is oxidized to carbon dioxide and water. Other tissues, such as muscle and fat, are facultative glucose consumers. The effect of insulin peaks associated with meals is to lower the threshold for glucose entry into cells; at other times, energy requirements are largely met by fatty-acid oxidation. Glucose taken up by

DIABETES MELLITUS

HYPERGLYCAEMIA, INSULIN AND INSULIN ACTION

Introduction

Diabetes mellitus (DM) is a syndrome of chronic hyperglycaemia due to relative insulin deficiency, resistance, or both. It affects more than 120 million people worldwide, and it is estimated that it will affect 370 million by the year 2030. Diabetes is usually irreversible and, although patients can have a reasonably normal lifestyle, its late complications result in reduced life expectancy and major health costs. These include macrovascular disease, leading to an increased prevalence of coronary artery disease, peripheral vascular disease and stroke, and microvascular damage causing diabetic retinopathy and nephropathy. Neuropathy is another major complication.

Insulin structure and secretion

Insulin is the key hormone involved in the storage and controlled release within the body of the chemical energy available from food. It is coded for on chromosome 11 and synthesized in the beta-cells of the pancreatic islets (Fig. 19.1). The synthesis, intracellular processing and secretion of insulin by the beta-cell is typical of the way that the body produces and manipulates many peptide hormones. Figure 19.2 illustrates the cellular events triggering the release of insulin-containing granules. After secretion, insulin enters the portal circulation and is carried to the liver, its prime target organ. About 50% of secreted insulin is extracted and degraded in the liver; the residue is broken down by the kidneys. C-peptide is only partially extracted by the liver (and hence provides a useful index of the rate of insulin secretion), but is mainly degraded by the kidneys.

An outline of glucose metabolism

Blood glucose levels are closely regulated in health and rarely stray outside the range of 3.5–8.0 mmol/L (63–144 mg/dL), despite the varying demands of food, fasting and exercise. The principal organ of glucose homeostasis is the liver, which absorbs and stores glucose (as glycogen) in the post-absorptive state and releases it into the circulation between meals to match the rate of glucose utilization by peripheral tissues. The liver also combines 3-carbon molecules derived from breakdown of fat (glycerol), muscle glycogen (lactate) and protein (e.g. alanine) into the 6-carbon glucose molecule by the process of gluconeogenesis.

Glucose production

About 200 g of glucose is produced and utilized each day. More than 90% is derived from liver glycogen and hepatic gluconeogenesis, and the remainder from renal gluconeogenesis.

Glucose utilization

The brain is the major consumer of glucose. Its requirement is 1 mg/kg bodyweight per minute, or 100 g daily in a 70 kg man. Glucose uptake by the brain is obligatory and is not dependent on insulin, and the glucose used is oxidized to carbon dioxide and water. Other tissues, such as muscle and fat, are facultative glucose consumers. The effect of insulin peaks associated with meals is to lower the threshold for glucose entry into cells; at other times, energy requirements are largely met by fatty-acid oxidation. Glucose taken up by
Diabetes mellitus and other disorders of metabolism

Fig. 19.1 Part of a beta-cell. The ribosomes manufacture pre-pro-insulin from insulin mRNA. The hydrophobic ‘pre’ portion of pre-pro-insulin allows it to transfer to the Golgi apparatus, and is subsequently enzymatically cleaved off. Proinsulin is parcellled into secretory granules in the Golgi apparatus. These mature and pass towards the cell membrane where they are stored before release. The proinsulin molecule folds back on itself and is stabilized by disulphide bonds. The biochemically inert peptide fragment known as connecting (C) peptide splits off from proinsulin in the secretory process, leaving insulin as a complex of two linked peptide chains. Equimolar quantities of insulin and C-peptide are released into the circulation. A small amount of insulin is secreted by the beta-cell directly via the ‘constitutive pathway’, which bypasses the secretory granules.

Fig. 19.2 Local forces regulating insulin secretion from beta-cells. Glucose enters the beta-cell via the GLUT-2 transporter protein, which is closely associated with the glycolytic enzyme glucokinase. Metabolism of glucose within the beta-cell generates ATP. ATP closes potassium channels in the cell membrane (A). If a sulphonylurea binds to its receptor, this also closes potassium channels. Closure of potassium channels predisposes to cell membrane depolarization, allowing calcium ions to enter the cell via calcium channels in the cell membrane (B). The rise in intracellular calcium triggers activation of calcium-dependent phospholipid protein kinase which, via intermediary phosphorylation steps, leads to fusion of the insulin-containing granules with the cell membrane and exocytosis of the insulin-rich granule contents. Similar mechanisms produce hormone-granule secretion in many other endocrine cells.

muscle is stored as glycogen or broken down to lactate, which re-enters the circulation and becomes a major substrate for hepatic gluconeogenesis. Glucose is used by fat tissue as a source of energy and as a substrate for triglyceride synthesis; lipolysis releases fatty acids from triglyceride together with glycerol, another substrate for hepatic gluconeogenesis.

Hormonal regulation

Insulin is a major regulator of intermediary metabolism, although its actions are modified in many respects by other hormones. Its actions in the fasting and postprandial states differ (Fig. 19.3). In the fasting state its main action is to regulate glucose release by the liver, and in the postprandial state it additionally facilitates glucose uptake by fat and muscle. The effect of counter-regulatory hormones (glucagon, epinephrine (adrenaline), cortisol and growth hormone) is to cause greater production of glucose from the liver and less utilization of glucose in fat and muscle for a given level of insulin.

Glucose transport

Cell membranes are not inherently permeable to glucose. A family of specialized glucose-transporter (GLUT) proteins carry glucose through the membrane into cells.

- GLUT-1 – enables basal non-insulin-stimulated glucose uptake into many cells (see Fig. 6.26).
- GLUT-2 – transports glucose into the beta-cell: a prerequisite for glucose sensing.
- GLUT-3 – enables non-insulin-mediated glucose uptake into brain neurons and placenta.
- GLUT-4 – enables much of the peripheral action of insulin. It is the channel through which glucose is taken up into muscle and adipose tissue cells following stimulation of the insulin receptor (Fig. 19.4).

The insulin receptor

This is a glycoprotein (400 kDa), coded for on the short arm of chromosome 19, which straddles the cell membrane of...
many cells (Fig. 19.4). It consists of a dimer with two alpha-subunits, which include the binding sites for insulin, and two beta-subunits, which traverse the cell membrane. When insulin binds to the alpha-subunits it induces a conformational change in the beta-subunits, resulting in activation of tyrosine kinase and initiation of a cascade response involving a host of other intracellular substrates. One consequence of this is migration of the GLUT-4 glucose transporter to the cell surface and increased transport of glucose into the cell. The insulin-receptor complex is then internalized by the cell, insulin is degraded, and the receptor is recycled to the cell surface.

**CLASSIFICATION OF DIABETES**

Diabetes may be primary (idiopathic) or secondary (Table 19.1). Although secondary diabetes accounts for barely 1–2% of all new cases at presentation, it should not be missed because the cause can sometimes be treated. The classification of primary diabetes continues to evolve. Monogenic forms have been identified (see p. 1035), in some cases with significant therapeutic implications. The polygenic forms known as type 1 and type 2 diabetes are still distinguished to some extent by age of onset, or perceived need for insulin, but more formal classification is based around the balance between insulin deficiency and resistance, and the presence or absence of immunogenic markers associated with type 1 diabetes. Type 1 and type 2 diabetes represent two distinct diseases from the epidemiological point of view, but clinical distinction can sometimes be difficult. The two diseases should therefore be seen as a spectrum, distinct at the two ends but overlapping to some extent in the middle (Table 19.2). Hybrid forms are increasingly recognized, and patients with immune-mediated diabetes (type 1) may, for example, also be overweight and insulin resistant. It is more relevant to give the patient the right treatment on clinical grounds than to worry about how to label their diabetes. All forms of diabetes derive from inadequate insulin secretion relative to the needs of the body, and progressive insulin secretory failure is characteristic of both forms of diabetes. Thus, some patients with immune-mediated diabetes type 1 may not at first require insulin, whereas many with type 2 diabetes will eventually do so.

Type 1 diabetes mellitus

Epidemiology
Type 1 diabetes is a disease of insulin deficiency. In western countries almost all patients have the immune-mediated form of the disease (type 1A). Type 1 diabetes is prominent as a disease of childhood, reaching a peak incidence around the time of puberty, but can present at any age. A ‘slow-burning’ variant with slower progression to insulin deficiency occurs in later life and is sometimes called latent autoimmune diabetes in adults (LADA). This may be difficult to distinguish from type 2 diabetes. Clinical clues are: hyperglycaemia which fails to correct with diet and tablet treatment, and autoantibody tests indicating autoimmune disease. The highest rates of type 1 diabetes in the world are seen in Finland and other Northern European countries, with the exception of the island of Sardinia, which for unknown reasons has the second highest rate in the world (Fig. 19.5). The incidence of type 1 diabetes appears to be increasing in most populations. In Europe the annual increase is of the order of 2–3%, and is most marked in children under the age of 5 years. WHO (1995) estimated that there are 19.4 million people with type 1 diabetes and that the number will rise to 57.2 million by 2025.

Causes
Type 1 diabetes belongs to a family of HLA-associated immune-mediated organ-specific diseases. Genetic susceptibility is polygenic, with the greatest contribution from the HLA region. Autoantibodies directed against pancreatic islet constituents appear in the circulation within the first few years of life, and often predate clinical onset by many years. Autoantibodies are also found in older patients with LADA and carry an increased risk of progression to insulin therapy.

Genetic susceptibility and inheritance
Increased susceptibility to type 1 diabetes is inherited, but the disease is not genetically predetermined. The identical twin of a patient with type 1 diabetes has a 30–50% chance of developing the disease, which implies that non-genetic factors must also be involved. The risk of developing diabetes by age 20, curiously, is greater with a diabetic father (3–7%) than with a diabetic mother (2–3%). If one child in a

Published incidence rates of type 1 diabetes in children (0–14 age range) (cases per 100,000 population per year)
family has type 1 diabetes, each sibling has a – 6% risk of developing diabetes by age 20. This risk rises to about 20% in HLA-identical siblings who have the same HLA type as the proband. Since type 1 diabetes can present at any age, the lifetime risk for a sibling or child is at least double the risk by age 20.

**HLA system**

The HLA genes on chromosome 6 are highly polymorphic and modulate the immune defence system of the body. More than 90% of patients with type 1 diabetes carry HLA-DR3-DQ2, HLA-DR4-DQ8, or both, as compared with some 35% of the background population. All DQB1 alleles with an aspartic acid at residue 57 confer neutral to protective effects with the strongest effect from DQB1*0602 (DQ6), while DQB1 alleles with an alanine at the same position (i.e. DQ2 and DQ8) confer strong susceptibility. Genotypic combinations have a major influence upon risk of disease. For example, HLA DR3-DQ2/HLA DR4-DQ8 heterozygotes have a considerably increased risk of disease, and some HLA class I alleles also modify the risk conferred by class II susceptibility genes.

**Other genes or gene regions**

Genome-wide association studies have greatly broadened our understanding of the genetic background to type 1 diabetes and 11 genes or gene regions have been identified to date. These studies have confirmed that by far the greatest genetic contribution comes from the HLA region, but this is modulated by a large number of genes with small effects. These include the gene encoding insulin (INS) on chromosome 11 and a number of genes involved in immune responses, including the protein tyrosine phosphatase PTPN22 which appears to be involved in a variety of HLA-associated autoimmune conditions.

**Autoimmunity and type 1 diabetes**

Type 1 diabetes overlaps with other organ-specific autoimmune diseases including autoimmune thyroid disease, coeliac disease, Addison’s disease and pernicious anaemia. Autopsies of patients who died following diagnosis show infiltration of the pancreatic islets by mononuclear cells. This appearance, known as insulinitis, resembles that in other autoimmune diseases such as thyroiditis. Autoantibodies directed against islet constituents precede the onset of clinical disease by many years and can be used to predict it; they are present in 95% of newly presenting patients. Several islet antigens have been characterized, and these include insulin itself, the enzyme glutamic acid decarboxylase (GAD), protein tyrosine phosphatase (IA-2) (Fig. 19.6) and the cation transporter ZnT8. Animal models of autoimmune diabetes such as the non-obese diabetic (NOD) mouse have been extensively studied. The observation that treatment with immunosuppressive agents such as cyclosporin prolongs beta-cell survival in newly diagnosed patients has confirmed that the disease is immune-mediated.

**Environmental factors**

The incidence of childhood type 1 diabetes is rising across Europe at the rate of 2–3% each year, suggesting that environmental factor(s) are involved in its pathogenesis. Islet autoantibodies (see above) appear in the first few years of life, indicating prenatal or early postnatal interactions with the environment. Exposures to dietary constituents, enterovi-...
life-time risk in these groups exceeds 30%. High rates also affect people of middle Eastern and Latin or Hispanic American origin living western lifestyles. Obesity increases the risk of type 2 diabetes 80–100 fold, and this is reflected by the increasing prevalence of diabetes in different populations. The inhabitants of affluent countries gain on average nearly 1 gram in weight every day of their adult life between the ages of 25 and 55 years. This gain, due to a tiny excess in energy intake over expenditure – 90 kcal or one chocolate-coated digestive biscuit per day – is often due to reduced exercise rather than increased food intake. Further, our sedentary lifestyle means that the proportion of obese young adults is rising rapidly, and epidemic obesity will create a huge public health problem for the future. The increasing numbers of obese adolescents presenting with type 2 diabetes, particularly within high-risk ethnic groups, is a matter for concern.

Type 2 diabetes is associated with central obesity, hypertension, hypertriglyceridaemia, a decreased HDL-cholesterol, disturbed haemostatic variables and modest increases in a number of pro-inflammatory markers. Insulin resistance is strongly associated with many of these variables, as is increased cardiovascular risk. This group of conditions is referred to as the metabolic syndrome (see p. 231). The International Diabetes Federation has proposed criteria based on increased waist circumference (or BMI > 30) plus two of the following: diabetes (or fasting glucose > 6.0 mmol/L), hypertension, raised triglycerides or low HDL cholesterol. On this definition, about a third of the adult population have features of the syndrome, not necessarily associated with diabetes. Critics would argue that the metabolic syndrome is not a distinct entity, but one end of a continuum in the relationship between exercise, lifestyle and bodyweight on the one hand, and genetic make-up on the other, and that diagnosis adds little to standard clinical practice in terms of diagnosis, prognosis or therapy.

Causes of type 2 diabetes

Inheritance

Population-based studies show that identical twins of patients with type 2 diabetes have >50% chance of developing diabetes; the risk to non-identical twins or siblings is of the order of 25%. These observations confirm a strong genetic component to the disease. Type 2 diabetes is a polygenic disorder, and, as with type 1 diabetes, genome-wide association data have allowed identification of numerous susceptibility loci (16 at the time of writing). These loci, many of which are related to genes subserving beta-cell development or function, do not overlap with those identified for type 1 diabetes. Another difference is that there is no major gene susceptibility, equivalent to the HLA region, in type 2 diabetes. Thus the allelic odds ratio for TCLF7, the most common variant for type 2 diabetes, is a mere ~1.35, and other common variants have odds ratios which range between 1.1 and 1.2. Paradoxically, the new genes for type 2 diabetes account for a relatively small fraction of its observed heritability; nor do they allow subtypes of the condition to be identified with any confidence, as was previously anticipated.

Environmental factors: early and late

An association has been noted between low weight at birth and at 12 months of age and glucose intolerance later in life, particularly in those who gain excess weight as adults. The concept is that poor nutrition early in life impairs beta-cell development and function, predisposing to diabetes in later life. Low birthweight has also been shown to predispose to heart disease and hypertension.

Immunology and inflammation

There is no evidence of immune involvement in the pathogenesis of type 2 diabetes but, as noted earlier, a proportion of late-onset patients carry islet autoantibodies directed against GAD at diagnosis, and these are more likely to progress to insulin therapy. Such cases probably represent type 1 diabetes masquerading as type 2 diabetes.

Subclinical inflammatory changes are characteristic of both type 2 diabetes and obesity, and in diabetes, high-sensitivity C-reactive protein (CRP) levels are elevated in association with raised fibrinogen and increased plasminogen activator inhibitor-1 (PAI-1), and contribute to cardiovascular risk. Circulating levels of the proinflammatory cytokines TNF-α and IL-6 are elevated in both diabetes and obesity. Use of anti-inflammatory agents might potentially reduce the vascular risk associated with both conditions, but this has yet to be demonstrated.

Abnormalities of insulin secretion and action

Diabetes develops when the body can no longer secrete sufficient insulin to meet its requirements. The relative role of secretory failure versus insulin resistance in the pathogenesis of type 2 diabetes has been much debated, but even massively obese individuals with a fully functioning beta-cell mass do not necessarily develop diabetes, which implies that some degree of beta-cell dysfunction is necessary. Insulin can bind normally to its receptor on the surface of cells in type 2 diabetes, and the mechanisms of ‘insulin resistance’ are still poorly understood. Insulin resistance is however associated with central obesity and accumulation of intracellular triglyceride in muscle and liver in type 2 diabetes, and a high proportion of patients have non-alcoholic fatty liver disease (NAFLD), see page 344. It has long been maintained that patients with type 2 diabetes retain up to 50% of their beta-cell mass at the time of diagnosis, as compared with healthy controls, but the shortfall is greater than this when they are matched with healthy individuals who are equally obese. In addition, patients with type 2 diabetes almost all show islet amyloid deposition at autopsy, derived from a peptide known as amylin or islet amyloid polypeptide (IAPP) which is co-secreted with insulin. It is not known if this is a cause or consequence of beta-cell secretory failure.

Abnormalities of insulin secretion manifest early in the course of type 2 diabetes. One of the earliest signs is loss of the first phase of the normal biphasic response to intravenous insulin. The onset of diabetes is associated with hypersecretion of insulin by a depleted beta-cell mass. Circulating insulin levels are therefore higher than in healthy controls, although still inadequate to restore glucose homeostasis. Relative insulin lack is associated with increased glucose production from the liver (owing to inadequate suppression of gluconeogenesis) and reduced glucose uptake by peripheral tissues. Hyperglycaemia and lipid excess are toxic to beta-cells, at least in vitro, a phenomenon known as glucotoxicity, and this is thought to result in further beta-cell loss and further deterioration of glucose homeostasis. Circulating insulin levels thus peak with increasing duration of diabetes.
and then decline due to secretory failure, an observation sometimes known as the ‘Starling curve’ of the pancreas. Type 2 diabetes is thus a condition in which relative insulin deficiency tends to progress towards absolute insulin deficiency requiring insulin therapy.

It has recently been shown that short-term intensive insulin therapy, given early in the course of type 2 diabetes, improves the recovery and maintenance of beta-cell function.

**Overview and prevention**

Genetic predisposition determines whether an individual is susceptible to type 2 diabetes; if and when diabetes develops largely depends upon lifestyle. A dramatic reduction in the incidence of new cases of adult-onset diabetes was documented in World War II when food was scarce, and clinical trials in individuals with impaired glucose tolerance have shown that diet, exercise or agents such as metformin have a marked effect in deferring the onset of type 2 diabetes. Established diabetes can be reversed, even if temporarily, by successful diet or bariatric surgery. Diabetes is therefore largely preventable, although the most effective measures would be directed at the whole population and implemented early in life. Prevention is well worth while, for diabetes diagnosed in a man between the ages of 40 and 59 reduces life expectancy by 5–10 years. By contrast, type 2 diabetes diagnosed after the age of 70 has little effect on life expectancy in men.

**Monogenic diabetes mellitus**

The genetic causes of some rare forms of diabetes are shown in Table 19.3. Considerable progress has been made in understanding these rare variants of diabetes. Genetic defects of beta-cell function (previously called ‘maturity-onset diabetes of the young’ (MODY)) are dominantly inherited, and seven variants have been described, each associated with different clinical phenotypes (Table 19.4). These should be considered in people presenting with early-onset diabetes in association with an affected parent and early-onset diabetes in ~50% of relatives. They can often be treated with a sulphonylurea.

Infants who develop diabetes before 6 months of age are likely to have a monogenic defect and not true type 1 diabetes. Transient neonatal diabetes mellitus (TNDM) occurs soon after birth, resolves at a median of 12 weeks, and 50% of cases ultimately relapse later in life. Most have an abnormality of imprinting of the ZAC and HYMAI genes on chromosome 6q. The commonest cause of permanent neonatal diabetes mellitus (PNDM) is mutations in the KCNJ11 gene encoding the Kir6.2 subunit of the beta-cell potassium-ATP channel.

The glucokinase gene is intimately involved in the glucose-sensing mechanism within the pancreatic beta-cell. The hepatic nuclear factor (HNF) genes and the insulin promoter factor-1 (IPF-1) gene control nuclear transcription in the beta-cell where they regulate its development and function. Abnormal nuclear transcription genes may cause pancreatic agenesis or more subtle progressive pancreatic damage. A handful of families with autosomal dominant diabetes have been described with mutations in NeuroD1 and recently the carboxyl ester lipase (CEL) gene.
channel. Neurological features are seen in 20% of patients. Diabetes is due to defective insulin release rather than beta-cell destruction, and patients can be treated successfully with sulfonylureas, even after many years of insulin therapy.

Clinical Presentation of Diabetes
Presentation may be acute, subacute or asymptomatic.

Acute Presentation
Young people often present with a 2- to 6-week history and report the classic triad of symptoms:
- polyuria – due to the osmotic diuresis that results when blood glucose levels exceed the renal threshold
- thirst – due to the resulting loss of fluid and electrolytes
- weight loss – due to fluid depletion and the accelerated breakdown of fat and muscle secondary to insulin deficiency.

Ketonuria is often present in young people and may progress to ketoacidosis if these early symptoms are not recognized and treated.

Subacute Presentation
The clinical onset may be over several months or years, particularly in older patients. Thirst, polyuria and weight loss are typically present but patients may complain of such symptoms as lack of energy, visual blurring (owing to glucose-induced changes in refraction), or pruritus vulvae or balanitis that is due to Candida infection.

Complications as the Presenting Feature
These include:
- staphylococcal skin infections
- retinopathy noted during a visit to the optician
- a polyneuropathy causing tingling and numbness in the feet
- erectile dysfunction
- arterial disease, resulting in myocardial infarction or peripheral gangrene.

Asymptomatic Diabetes
Glycosuria or a raised blood glucose may be detected on routine examination (e.g. for insurance purposes) in individuals who have no symptoms of ill-health. Glycosuria is not diagnostic of diabetes but indicates the need for further investigations. About 1% of the population have renal glycosuria. This is an inherited low renal threshold for glucose, transmitted either as a Mendelian dominant or recessive trait.

Physical Examination at Diagnosis
Evidence of weight loss and dehydration may be present, and the breath may smell of ketones. Older patients may present with established complications, and the presence of the characteristic retinopathy is diagnostic of diabetes. In occasional patients there will be physical signs of an illness causing secondary diabetes (Table 19.1). Patients with severe insulin resistance may have acanthosis nigricans, which is characterized by blackish pigmentation at the nape of the neck and in the axillae.

Diagnosis and Investigation of Diabetes
Diabetes is easy to diagnose when overt symptoms are present, and a glucose tolerance test is hardly ever necessary for clinical purposes. The oral glucose tolerance test has,

Box 19.1 WHO Diagnostic Criteria – 1999
WHO criteria for the diagnosis of diabetes are:
- Fasting plasma glucose >7.0 mmol/L (126 mg/dL)
- Random plasma glucose >11.1 mmol/L (200 mg/dL)
- One abnormal laboratory value is diagnostic in symptomatic individuals; two values are needed in asymptomatic people.

The glucose tolerance test is only required for borderline cases and for diagnosis of gestational diabetes.

The Glucose Tolerance Test – WHO Criteria

</tbody>
</table>

- Adult: 75 g glucose in 300 mL water
- Child: 1.75 g glucose/kg body weight
- Only a fasting and a 120-min sample are needed
- Results are for venous plasma – whole blood values are lower.

Note: There is no such thing as mild diabetes. All patients who meet the criteria for diabetes are liable to disabling long-term complications.
however, allowed more detailed epidemiological characterization based on the existence of separate glucose thresholds for macrovascular and microvascular disease. These correspond with the levels for the diagnosis of impaired glucose tolerance (IGT) and diabetes as specified by the WHO criteria set out in Box 19.1. Epidemiological studies show that for every person with known diabetes, there is another undiagnosed in the population. A much larger proportion fall into the intermediate category of impaired glucose tolerance.

**Impaired glucose tolerance (IGT)**

This is not a clinical entity but a risk factor for future diabetes and cardiovascular disease. Obesity and lack of regular physical exercise make progression to frank diabetes more likely. The classification is complicated by the poor reproducibility of the key two-hour value in the oral glucose tolerance test. The group is heterogeneous; some patients are obese, some have liver disease, and others are on medication that impairs glucose tolerance. Individuals with IGT have the same risk of cardiovascular disease as in frank diabetes but do not develop the specific microvascular complications.

**Impaired fasting glucose (IFG)**

This diagnostic category (fasting plasma glucose between 6.1 and 6.9 mmol/L) was introduced by the American Diabetes Association (ADA), with the practical advantage that it avoids the need for a glucose tolerance test. This is not a clinical entity, but does predict future risk of frank diabetes and cardiovascular disease. This category only overlaps with IGT to a limited extent, and therefore the associated risks of cardiovascular disease and future diabetes are not directly comparable. A lower cut-off of 5.6 mmol/L (rather than 6.1 mmol/L) has been recommended by the ADA, which will of course greatly increase the number of those affected.

**Other investigations**

No further tests are needed to diagnose diabetes. Other routine investigations include screening the urine for protein, a full blood count, urea and electrolytes, liver biochemistry and random lipids. The latter test is useful to exclude an associated hyperlipidaemia and, if elevated, should be repeated fasting after diabetes has been brought under control. Diabetes may be secondary to other conditions (Table 19.1), may be precipitated by underlying illness and be associated with autoimmune disease or hyperlipidaemia. Hypertension is present in 50% of patients with type 2 diabetes and even more in African and Caribbean patients.

### Treatment of Diabetes

**The role of patient education and community care**

The care of diabetes is based on self-management by the patient, who is helped and advised by those with specialized knowledge. The quest for improved glycaemic control has made it clear that whatever the technical expertise applied, the outcome depends on willing cooperation by the patient. This in turn depends on an understanding of the risks of diabetes and the potential benefits of glycaemic control and other measures such as maintaining a lean weight, stopping smoking and taking care of the feet. If accurate information is not supplied, misinformation from friends and other patients will take its place. For this reason the best time to educate the patient is soon after diagnosis. Organized education programmes involve all healthcare workers, including nurse specialists, dieticians and podiatrists, and should include ongoing support and updates wherever possible.

**Diet**

The diet for people with diabetes is no different from that considered healthy for everyone. Table 19.5 lists recommendations on the ideal composition of this diet. To achieve this, food for people with diabetes should be:
low in sugar (though not sugar free)
- high in starchy carbohydrate (especially foods with a low glycaemic index) i.e. slower absorption
- high in fibre
- low in fat (especially saturated fat).

The overweight or obese should be encouraged to lose weight by a combination of changes in food intake and physical activity.

**Carbohydrates**

Slowly absorbed carbohydrates (i.e. those with a low glycaemic index) prevent rapid swings in circulating glucose. For example, the glucose peak seen in the blood after eating pasta is much flatter than that seen after eating the same amount of carbohydrate as white potato.

**Prescribing a diet**

Most people find it extremely difficult to modify their eating habits, and repeated advice and encouragement are needed if this is to be achieved. A diet history is taken, and the diet prescribed should involve the least possible interference with the person’s lifestyle. Advice from dieticians is more likely to affect medium-term outcome than advice from doctors. People taking insulin or oral agents have traditionally been advised to eat roughly the same amount of food (particularly carbohydrate) at roughly the same time each day, so that treatment can be balanced against food intake and exercise. Knowledgeable and motivated patients with type 1 diabetes, who get feedback from regular blood glucose monitoring, can vary the amount of carbohydrate consumed, or meal times, by learning to adjust their exercise pattern and treatment. This is the basis of the DAFNE (Dose Adjustment For Normal Eating) regimen.

**Exercise**

Diet treatment is incomplete without exercise. Any increase in activity levels is to be encouraged, but participation in more formal exercise programmes is best. Where facilities for this exist, exercise should be prescribed for everyone with diabetes. Several trials have shown that regular exercise reduces the risk of progression to type 2 diabetes by 30–60%, and the lowest long-term morbidity and mortality is seen in those with established disease who have the highest levels of cardiorespiratory fitness. Both aerobic and resistance training improve insulin sensitivity and metabolic control in type 1 and type 2 diabetes, although reported effects on metabolic control are inconsistent. Patients on insulin or sulfonylureas should be warned that there is an increased risk of hypoglycaemia for up to 6–12 hours following heavy exertion.

**Tablet treatment for type 2 diabetes**

Diet and lifestyle changes are the key to successful treatment of type 2 diabetes, and no amount of medication will succeed where these have failed. The concept is that controlling diabetes is not just a matter of swallowing tablets, and these should in general never be prescribed until lifestyle changes have been implemented. Tablets will however be needed if satisfactory metabolic control (see ‘Measuring control’ below) is not established within 4–6 weeks. A consensus treatment pathway is shown in Figure 19.9 (p. 1041). The three main options are metformin, a sulfonylurea or a thiazolidinedione.

### Biguanide (Metformin)

Metformin is the only biguanide currently in use, and remains the best validated primary treatment for type 2 diabetes. It activates the enzyme AMP-kinase, which is involved in GLUT4 metabolism and fatty acid oxidation, but its mechanism of action remains unclear at a cellular level. It reduces the rate of gluconeogenesis, and hence hepatic glucose output, and increases insulin sensitivity. It does not affect insulin secretion, does not induce hypoglycaemia and does not predispose to weight gain. It is thus particularly helpful in the overweight, although normal weight individuals also benefit, and may be given in combination with sulfonylureas or thiazolidinediones. Metformin was as effective as sulfonylurea or insulin in glucose control and reduction of microvascular risk in the United Kingdom Prospective Diabetic Study (UKPDS), but proved unexpectedly beneficial in reducing cardiovascular risk, an effect that could not be fully explained by its glucose-lowering actions. Metformin is currently the only oral agent to have demonstrated unequivocal cardiovascular protection within a randomized controlled trial. Adverse effects include anorexia, epigastric discomfort and diarrhoea, and these prohibit its use in 5–10% of patients. Diarrhoea should never be investigated in a diabetic patient without testing the effect of stopping metformin! Lactic acidosis has occurred in patients with severe hepatic or renal disease, and metformin is contraindicated when these are present. A Cochrane review showed little risk of lactic acidosis with standard clinical use, but most clinicians withdraw the drug when serum creatinine exceeds 150 µmol/L.

### Sulfonylureas (Table 19.6)

These act upon the beta-cell to promote insulin secretion in response to glucose and other secretagogues. They are ineffective in patients without a functional beta-cell mass, and

</tbody>
</table>
they are usually avoided in pregnancy. Their action is to bind to the sulfonylurea receptor on the cell membrane, which closes ATP-sensitive potassium channels and blocks potassium efflux. The resulting depolarization promotes influx of calcium, a signal for insulin release (Fig. 19.2). Sulfonylureas are cheap and more effective than the other main agents in achieving short-term (1–3 years) glucose control, but their effect wears off as the beta-cell mass declines. There are theoretical concerns that they might hasten beta-cell apoptosis and promote weight gain, and are therefore best avoided in the overweight. They can also cause hypoglycaemia and although the episodes are generally mild, fatal hypoglycaemia may occur. Severe cases should always be admitted to hospital, monitored carefully, and treated with a continuous glucose infusion since rebound hypoglycaemia may occur after single injections of glucose. Sulfonylureas should be used with care in patients with liver disease. Patients with renal impairment should only be given those primarily excreted by the liver. Tolbutamide is the safest drug in the very elderly because of its short duration of action.

**Thiazolidinediones**

The thiazolidinediones (more conveniently known as the ‘glitazones’) reduce insulin resistance by interaction with peroxisome proliferator-activated receptor-gamma (PPAR-gamma), a nuclear receptor which regulates large numbers of genes including those involved in lipid metabolism and insulin action. The paradox that glucose metabolism should respond to a drug that binds to nuclear receptors mainly found in fat cells is still not fully understood. Fatty tissue is redistributed in patients taking a glitazone, with a reduction of central adiposity but an increase in peripheral fat. One suggestion as to their action is that they act indirectly via the glucose–fatty acid cycle, lowering free fatty acid levels and thus promoting glucose consumption by muscle. The glitazones lower circulating insulin relative to plasma glucose, but do not return glucose levels to normal. They can be used alone or in combination with other agents. The glitazones reduce hepatic glucose production, an effect that is synergistic with that of metformin, and also enhance peripheral glucose uptake. Like metformin, the glitazones potentiate the effect of endogenous or injected insulin. The glitazones have yet to demonstrate unique advantages in the treatment of diabetes, and their place in routine diabetes care remains uncertain. Long-term clinical trials show that the glucose-lowering effect of rosiglitazone in monotherapy persists longer than that of glibenclamide, but is comparable to that of metformin. **Unwanted effects** include weight gain of 5–6 kg, together with fluid retention and increased risk of heart failure, anaemia and osteoporosis. Rosiglitazone and pioglitazone should not be used in patients with heart failure. A meta-analysis of clinical trials with rosiglitazone has suggested that it might cause an increased cardiovascular risk; it should not be used in patients with ischaemic heart disease. Pioglitazone has not been shown to have this effect so far.

**Meglitinides**, e.g. repaglinide and nateglinide, are insulin secretagogues. Meglitinides are the non-sulfonylurea moiety of glibenclamide. As with the sulfonylureas, they act via closure of the K⁺-ATP channel in the beta-cells (Fig. 19.2). They are short-acting agents that promote insulin secretion in response to meals. They are more expensive than standard sulfonylureas. Whether they have advantages over established short-acting sulfonylureas such as tolbutamide has not been addressed by clinical trials.

**Injection therapies**

**Incretins**

It has long been known that the insulin response to oral glucose is greater than the response to intravenous glucose. This is known as the incretin effect, and is due to release of two peptide hormones, glucose-dependent insulinosotropic peptide (GIP) and glucagon-like peptide-1 (GLP-1) from the L cells in the intestine. The incretin effect is diminished in type 2 diabetes.

GLP-1 has a very short half-life, and exenatide and liraglutide, longer-acting analogues, are now available. Exenatide, which must be given by twice-daily subcutaneous injection, promotes insulin release, inhibits glucagon release, reduces appetite and delays gastric emptying, thus blunting the postprandial rise in plasma glucose. Its main clinical disadvantage is the need for injection, and its advantage is that it improves glucose control whilst inducing useful weight reduction. **Side-effects** include nausea, and acute pancreatitis has been reported. At present it is used as an alternative to insulin, particularly in the overweight. A new long-acting preparation is now available and can be given once-weekly as additional therapy for type 2 patients on maximal oral medication.

The enzyme dipeptidyl peptidase 4 (DPP4) rapidly inactivates GLP-1 as this is released into the circulation, and inhibition of this enzyme thus potentiates the effect of endogenous GLP-1 secretion. DDP4 inhibition is an alternative approach to incretin-based therapy. The two agents currently available, sitagliptin and vildagliptin, are moderately effective in lowering blood glucose but do not induce weight loss. They are likely to be most effective in the early stages of type 2 diabetes when insulin secretion is relatively preserved. The main **side-effect** is nausea. Although incretin-based therapies are currently enjoying a vogue, their place in the management of type 2 diabetes has yet to be established.

**Other therapies**

- **Intestinal enzyme inhibitors** include **acarbose**, a sham sugar that competitively inhibits alpha-glucosidase enzymes situated in the brush border of the intestine, reducing absorption of dietary carbohydrate. Undigested starch may then enter the large intestine where it will be broken down by fermentation. Abdominal discomfort, flatulence and diarrhoea can result, and dosage needs careful adjustment to avoid these side-effects.

- **Orlistat** is a lipase inhibitor which reduces the absorption of fat from the diet. It benefits diabetes indirectly by promoting weight loss in patients under careful dietary supervision on a low fat diet. This is necessary to avoid unpleasant steatorrhea.

- **Rimonabant** is a cannabinoid that promotes weight loss in people with type 2 diabetes. At least half of all patients using it experience a mood change whilst on the medication, and it should not be routinely used in those with a past history of depression. It can help those type 2 patients who gain a lot of weight when they go onto insulin, but its place in therapy is not yet clear.

- **Gastric banding and gastric bypass surgery** (see p. 233) have been used in those with marked obesity unresponsive to 6 months’ intensive attempts at dieting and graded exercise. The risks of surgery are not insignificant, but need to be balanced against the risks
of patients staying as they are. About a third of patients become non-diabetic after gastric bypass.

**Insulin treatment**

Insulin is found in every creature with a backbone, and the key parts of the molecule show few species differences. Small differences in the amino acid sequence may alter the antigenicity of the molecule. The glucose and insulin profiles in normal subjects are shown in Figure 19.7.

**Short-acting insulins**

Insulins derived from beef or pig pancreas are still used but have largely been replaced in most developed countries by biosynthetic human insulin. This is produced by adding a DNA sequence coding for insulin or proinsulin into cultured yeast or bacterial cells. Short-acting insulins are used for pre-meal injection in multiple dose regimens, for continuous intravenous infusion in labour or during medical emergencies, and in patients using insulin pumps. Human insulin is absorbed slowly, reaching a peak 60–90 minutes after subcutaneous injection, and its action tends to persist too long after meals, predisposing to hypoglycaemia. Absorption is delayed because soluble insulin is in the form of stable hexamers (six insulin molecules around a zinc core) and needs to dissociate to monomers or dimers before it can enter the circulation. Short-acting insulin analogues have been engineered to dissociate more rapidly following injection without altering the biological effect. Insulin analogues (Fig. 19.8) such as insulin lispro, insulin aspart and insulin glulisine enter the circulation more rapidly than human soluble insulin, and also disappear more rapidly. Although widely used, the short-acting analogues have little effect upon overall glucose control in most patients, mainly because improved postprandial glucose is balanced by higher levels before the next meal. A Cochrane review has concluded that there is no evidence as to their benefit in type 2 diabetes.

**Longer-acting insulins**

The action of human insulin can be prolonged by the addition of zinc or protamine derived from fish sperm. The most widely used form is NPH (isophane insulin), which has the advantage that it can be premixed with soluble insulin to form stable mixtures, of which the combination of 30% soluble with 70% NPH is most widely used. Long-acting analogues have their structure modified to delay absorption or to prolong their duration of action. Insulin glargine is soluble in the vial as a slightly acidic (pH 4) solution, but precipitates at subcutaneous pH, thus prolonging its duration of action. Insulin detemir has a fatty acid ‘tail’ which allows it to bind to serum albumin, and its slow dissociation from the bound state prolongs its duration of action. Although popular and widely used, these insulins have little advantage over NPH in most clinical situations, although useful in those on intensified therapy or with troublesome hypoglycaemia.

**Inhaled insulin**

The first inhaled insulin was withdrawn from the market in 2007, mainly because of limited clinical demand. An alterna-

---

**Fig. 19.7** Glucose and insulin profiles in normal subjects.

**Fig. 19.8** Amino acid structure of human insulin. Lispro is a genetically engineered rapidly acting insulin analogue created by reversing the order of the amino acids proline and lysine in positions 28 and 29 of the B chain. Insulin aspart is a similar analogue created by replacing proline at position 28 of the B chain with an aspartic acid residue. Insulin glargine is a genetically engineered long-acting insulin created by replacing asparagine in position 21 of the A chain with a glycine residue and adding two arginines to the end of the B chain. Insulin detemir discards threonine in position 30 of the B chain and adds a fatty acyl chain to lysine in position B29.
tive may become available, but the main limitation is that only about 10% of the inhaled dose reaches the circulation, and this has cost implications. Variability of absorption and possible long-term adverse effects on the lungs are also of concern.

**Practical management of diabetes**

All patients with diabetes require advice about diet and lifestyle. Lifestyle changes, i.e. controlling weight, stopping smoking and taking regular exercise, can prevent or delay the onset of type 2 diabetes in people with glucose intolerance. Good glycaemic control is unlikely to be achieved with insulin or oral therapy when diet is neglected, especially when the patient is also overweight. Regular exercise helps to control weight and reduces cardiovascular risk. Blood pressure control is vital using an angiotensin converting enzyme (ACE) inhibitor or angiotensin II receptor (AT1R) antagonist (see p. 804); Most patients will also benefit from a statin and low-dose aspirin (see p. 1050).

**Type 2 diabetes**

The great majority of patients presenting over the age of 40 will have type 2 diabetes, but do not miss the occasional type 1 patient presenting late. An approach to their management is illustrated in Figure 19.9. Recently it has been suggested that a GLP-1 agonist can be added to oral therapy. Goals of treatment are described on page 1044. Type 2 diabetes is characterized by progressive beta-cell failure, and glucose control deteriorates over time, requiring a progressive and pre-emptive escalation of diabetes therapy. Regular review is essential for this to be achieved. Most patients on tablets will eventually require insulin, and it is helpful to explain this from the outset. The most widespread error in management at this stage is procrastination; the patient whose control is inadequate on oral therapy should start insulin without undue delay. Insulin should also be considered in all type 2 patients with an HbA1c >8%, and in patients with high cardiovascular risk factors when HbA1c >7%.

There is little consensus regarding the optimal insulin regimen in type 2 diabetes, but an intermediate insulin given at night with metformin during the day is initially as effective as multidose insulin regimens in controlling glucose levels, and is less likely to promote weight gain. Metformin is a useful adjunct to insulin in those able to tolerate it. A second morning dose of insulin may become necessary to control postprandial hyperglycaemia. Twice-daily injections of premixed soluble and isophane insulins (i.e. biphasic isophane insulin) are widely used and reasonably effective (Fig. 19.10a). Once-daily insulin glargine showed good control of blood glucose in one study. More aggressive treatment, with multiple injections or continuous infusion pumps, is increasingly being used in younger patients with type 2 diabetes.

**Type 1 diabetes**

Insulin is always indicated in a patient who has been in ketoacidosi, and is usually indicated in lean patients who present under the age of 40 years.

---

**Fig. 19.9** A treatment pathway for type 2 diabetes mellitus. Note that discussion of lifestyle changes and compliance should be undertaken at every stage. **Fig. 19.10** Insulin regimens. Profiles of soluble insulins are shown as: dashed lines; intermediate- or long-acting insulin as solid lines (purple); and rapid-acting insulin as dotted lines (blue). The arrows indicate when the injections are given. B, breakfast; L, lunch; S, supper; Sn, snack (bedtime).
**Principles of insulin treatment**

**Injections**

The needles used to inject insulin are very fine and sharp. Even though most injections are virtually painless, patients are understandably apprehensive and treatment begins with a lesson in injection technique. Insulin is usually administered by a pen injection device but can be drawn up from a vial into special plastic insulin syringes marked in units (100 U in 1 mL). Injections are given into the fat below the skin on the abdomen, thighs or upper arm, and the needle is usually inserted to its full length. Slim adults and children usually use a 31 gauge 6 mm needle and fatter adults a 30 gauge 8 mm needle. Both reusable and disposable pen devices are available, together with a range of devices to aid injection. The injection site used should be changed regularly to prevent areas of lipohypertrophy (fatty lumps). The rate of insulin absorption depends on local subcutaneous blood flow, and is accelerated by exercise, local massage or a warm environment. Absorption is more rapid from the abdomen than from the arm, and is slowest from the thigh. All these factors can influence the shape of the insulin profile.

**Insulin administration**

In healthy individuals a sharp increase in insulin occurs after meals; this is superimposed on a constant background of secretion (Fig. 19.7). Insulin therapy attempts to reproduce this pattern, but ideal control is difficult to achieve for four reasons:

- In normal subjects, insulin is secreted directly into the portal circulation and reaches the liver in high concentration; about 50% of the insulin produced by the pancreas is cleared by the liver. By contrast, insulin injected subcutaneously passes into the systemic circulation before passage to the liver. Insulin-treated patients therefore have lower portal levels of insulin and higher systemic levels relative to the physiological situation.
- Subcutaneous soluble insulin takes 60–90 minutes to achieve peak plasma levels, so the onset and offset of action are too slow.
- The absorption of subcutaneous insulin into the circulation is variable.
- Basal insulin levels are constant in normal people, but injected insulin invariably peaks and declines in people with diabetes, with resulting swings in metabolic control.

A multiple injection regimen with short-acting insulin and a longer-acting insulin at night is appropriate for most younger patients (Fig. 19.10b). The advantages of multiple injection regimens are that the insulin and the food go in at roughly the same time so that meal times and sizes can vary, without greatly disturbing metabolic control. The flexibility of multiple injection regimens is of great value to patients with busy jobs, shift workers and those who travel regularly. Some recovery of endogenous insulin secretion may occur over the first few months (the ‘honeymoon period’) in type 1 patients and the insulin dose may need to be reduced or even stopped for a period. Requirements rise thereafter. Strict glucose control from diagnosis in type 1 diabetes prolongs beta-cell function, resulting in better glucose levels and less hypoglycaemia. Some type 1 diabetes patients will opt for twice-daily mixed insulin injections (Fig. 19.10a) and put up with the lifestyle restrictions that this imposes (with twice-daily regimens, the size and timing of meals are fixed more rigidly). Target blood glucose values should normally be 4–7 mmol/L before meals, 4–10 mmol/L after meals.

All patients need careful training for a life with insulin. This is best achieved outside hospital, provided that adequate facilities exist for outpatient diabetes education. A scheme for adjusting insulin regimens is given in Table 19.7. DAFNE is described on p. 1038.

**When to use insulin analogues**

Hypoglycaemia between meals and particularly at night is the limiting factor for many patients on multiple injection regimens. The more expensive rapid-acting insulin analogues (Fig. 19.10c) are a useful substitute for soluble insulin in some patients. They reduce the frequency of nocturnal hypoglycaemia due to reduced carry-over effect from the day-time. They are often used on grounds of convenience, since patients can inject shortly before meals but this is illogical since standard insulins injected at the same time give an equivalent overall control. High or erratic morning blood sugar readings can prove a problem for about a quarter of all patients on conventional multiple injection regimens, because the bedtime intermediate-acting insulin falls and the absorption is variable. The long-acting insulin analogues insulin glargine and insulin detemir help to overcome these problems and reduce the risk of nocturnal hypoglycaemia.

**Infusion devices**

CSII (continuous subcutaneous insulin infusion) is delivered by a small pump strapped around the waist that infuses a constant trickle of insulin via a needle in the subcutaneous tissues. Meal-time doses are delivered when the patient touches a button on the side of the pump. This approach is particularly useful in the overnight period, since the basal overnight infusion rate can be programmed to fit each patient’s needs. Disadvantages include the nuisance of being attached to a gadget, skin infections, the risk of ketoacidosis if the flow of insulin is broken (since these patients have no protective reservoir of depot insulin) and cost. Infusion pumps should only be used by specialized centres able to offer a round-the-clock service to their patients. This form of treatment has revolutionized the lives of some patients.

Complications of insulin therapy

At the injection site
Shallow injections result in intradermal insulin delivery and painful, reddened lesions or even scarring. Injection site abscesses occur but are extremely rare. Local allergic responses sometimes occur early in therapy but usually resolve spontaneously. Generalized allergic responses are exceptionally rare. Fatty lumps, known as lipohypertrophy, may occur as the result of overuse of a single injection site with any type of insulin.

Insulin resistance
The most common cause of mild insulin resistance is obesity. Occasional unstable patients require massive insulin doses, often with a fluctuating requirement. There are often associated behavioural problems. Insulin resistance associated with antibodies directed against the insulin receptor has been reported in patients with acanthosis nigricans (Table 19.3).

Weight gain
Many patients show weight gain on insulin treatment, especially if the insulin dose is increased inappropriately—insulin makes you feel hungry! Sticking to a careful dietary regimen is vital when on insulin. Patients who are in poor control when insulin is started tend to gain most weight.

Hypoglycaemia during insulin treatment
This is the most common complication of insulin therapy, and limits what can be achieved with insulin treatment. It is a major cause of anxiety for patients and relatives. It results from an imbalance between injected insulin and a patient’s normal diet, activity and basal insulin requirement. The times of greatest risk are before meals and during the night. Irregular eating habits, unusual exertion and alcohol excess may precipitate episodes; other cases appear to be due simply to variation in insulin absorption.

Symptoms develop when the blood glucose level falls below 3 mmol/L and typically develop over a few minutes, with most patients experiencing ‘adrenergic’ features of sweating, tremor and a pounding heartbeat. Virtually all patients experience intermittent symptoms and one in three will go into a coma at some stage in their lives. A small minority suffer attacks that are so frequent and severe as to be virtually disabling.

Physical signs include pallor and a cold sweat. Many patients with longstanding diabetes report loss of these warning symptoms and are at a greater risk of progressing to more severe hypoglycaemia. Such patients appear pale, drowsy or detached, signs that their relatives quickly learn to recognize. Behaviour is clumsy or inappropriate, and some become irritable or even aggressive. Others slip rapidly into hypoglycaemic coma. Occasionally, patients develop convulsions during hypoglycaemic coma. This must not be confused with idiopathic epilepsy. Another presentation is with a hemiparesis that resolves when glucose is administered. Hypoglycaemia is a common problem.

Hypoglycaemic unawareness. People with diabetes have an impaired ability to counter-regulate glucose levels after hypoglycaemia. The glucagon response is invariably deficient, even though the alpha-cells are preserved and respond normally to other stimuli. The epinephrine (adrenaline) response may also fail in patients with a long duration of diabetes, and this is associated with loss of warning symptoms. Recurrent hypoglycaemia may itself induce a state of hypoglycaemia unawareness, and the ability to recognize this condition may sometimes be restored by relaxing control for a few weeks.

Nocturnal hypoglycaemia. Basal insulin requirements fall during the night but increase again from about 4 a.m. onwards, at a time when levels of injected insulin are falling. As a result many patients wake with high blood glucose levels, but find that injecting more insulin at night increases the risk of hypoglycaemia in the early hours of the morning. The problem may be helped by the following:

- checking that a bedtime snack is taken regularly
- for patients taking twice-daily mixed insulin to separate their evening dose and take the intermediate insulin at bedtime rather than before supper
- reducing the dose of soluble insulin before supper, since the effects of this persist well into the night
- changing patients on a multiple injection regimen with soluble insulin to a rapid-acting insulin analogue
- changing to a long-acting insulin analogue at night.

Mild hypoglycaemia
Any form of rapidly absorbed carbohydrate will relieve the early symptoms, and sufferers should always carry glucose or sweets. Drowsy individuals will be able to take carbohydrate in liquid form (e.g. Lucozade). All patients and their close relatives need training about the risks of hypoglycaemia. Patients should not take more carbohydrate than necessary during the recovery period, since this causes a rebound to hyperglycaemia. Alcohol excess increases the risk of hypoglycaemia, and this requires careful explanation, together with the need to guard against hypoglycaemia while driving.

Severe hypoglycaemia
The diagnosis of severe hypoglycaemia resulting in confusion or coma is simple and can usually be made on clinical grounds, backed by a bedside blood test. If real doubt exists, blood should be taken for glucose estimation before treatment is given. Patients should carry a card or wear a bracelet or necklace identifying themselves as diabetic, and these should be looked for in unconscious patients.

Unconscious patients should be given either intramuscular glucagon (1 mg) or intravenous glucose (25–50 mL of 50% dextrose solution) followed by a flush of 0.9% saline to preserve the vein (since 50% dextrose scleroses veins). Glucagon acts by mobilizing hepatic glycogen, and works almost as rapidly as glucose. It is simple to administer and can be given at home by relatives. It does not work after a prolonged fast. Oral glucose is given to replenish glycogen reserves once the patient revives.

Whole pancreas and pancreatic islet transplantation
Whole pancreas transplantation has been performed for some 30 years, usually in diabetic patients who require immunosuppression for a kidney transplant. Surgical
advances have greatly improved the outcome of this procedure. In experienced hands graft function lasts longer with considerable improvement in quality of life. The procedure, however, adds to the risks of renal transplantation. Whole pancreas transplants survive better if grafted together with a kidney than when the pancreas alone is transplanted. There is evidence of protection against or reversal of some complications of diabetes.

*Islet transplantation* is performed by harvesting pancreatic islets from cadavers (two or three pancreata are usually needed); these are then injected into the portal vein and seed themselves into the liver. This form of treatment was attempted for many years with poor results, but better results have been achieved by an improved protocol developed in Edmonton, Canada. The main indication is disabling hypoglycaemia, and the main disadvantage is the need for powerful immunosuppressive therapy, with associated costs and complications.

**Measuring the metabolic control of diabetes**

**Urine tests**

Some patients will not perform capillary blood glucose monitoring at home. Urine tests using dipsticks give such patients some feedback on whether their diet and treatment are achieving reasonable metabolic control. If they have consistently negative tests with no symptoms of hypoglycaemia, one can assume that they are fairly well controlled. Nevertheless, the correlation between urine tests and simultaneous blood glucose is poor for three reasons:

- Changes in urine glucose lag behind changes in blood glucose.
- The mean renal threshold is around 10 mmol/L but the range is wide (7–13 mmol/L). The threshold also rises with age.
- Urine tests can give no guidance concerning blood glucose levels below the renal threshold.

**Home blood glucose testing**

The home provides the best place for assessment of day-to-day control and this is an essential aid to good glycaemic control. The fasting blood glucose concentration is a useful guide to therapy in tablet-treated type 2 diabetes, but random blood glucose testing (e.g. in the clinic) is of limited value. Patients can be easily taught to provide their own profiles by testing finger-prick blood samples with reagent strips and reading these with the aid of a meter. Blood is taken from the side of a finger tip (not from the tip, which isdensely innervated) using a special lancet usually fitted to a spring-loaded device. Patients can talk through the use of various devices with a diabetes nurse specialist to select the most appropriate devices for them. Patients should take regular profiles (e.g. four daily samples on two days each week) and note these in a diary or record book. Patients on insulin are encouraged to adjust their insulin dose as appropriate (Table 19.7) and should ideally be able to obtain advice over the telephone when needed.

**Glycosylated haemoglobin (HbA1c)** and fructosamine

Glycosylation of haemoglobin occurs as a two-step reaction, resulting in the formation of a covalent bond between the glucose molecule and the terminal valine of the β chain of the haemoglobin molecule. The rate at which this reaction occurs is related to the prevailing glucose concentration. Glycosylated haemoglobin is expressed as a percentage of the normal haemoglobin (standardized range 4–6.2%). This test provides an index of the average blood glucose concentration over the life of the haemoglobin molecule (approximately 6 weeks). The figure will be misleading if the life-span of the red cell is reduced or if an abnormal haemoglobin or thalassaemia is present. There is considerable interindividual variation in HbA1c levels, even in health. Although the glycosylated haemoglobin test provides a rapid assessment of the level of glycaemic control in a given patient, blood glucose testing is needed before the clinician can know what to do about it.

Glycosylated plasma proteins (fructosamine) may also be measured as an index of control. Glycosylated albumin is the major component, and fructosamine measurement relates to glycaemic control over the preceding 2–3 weeks. It is useful in patients with anaemia or haemoglobinopathy and in pregnancy (when haemoglobin turnover is changeable) and other situations where changes of treatment need a swift means of assessing progress.

**Targets**

Data from the UK Prospective Diabetic Study (UKPDS) and the Diabetes Control and Complications Trial (DCCT) suggest that under ideal circumstances patients with both type 1 diabetes and type 2 diabetes should aim to run their glycosylated haemoglobin readings below 7.5% in order to reduce the risk of long-term microvascular complications (Table 19.8). Hypoglycaemia, patterns of eating and lifestyle, weight problems and problems accepting and coping with diabetes limit what can be achieved (see p. 1046). Some will, but most will not, be able to reach these target values, particularly as their duration of diabetes increases. Realistic goals should be set for each patient, taking into account what is likely to be achievable.

Statin therapy reduces cardiovascular events in both primary and secondary prevention studies. More intensive statin therapy to lower LDL-C to <1.8 mmol/L is advocated by some. Ezetimibe can be added to statin therapy.

**Does good metabolic control of diabetes matter?**

Blood glucose is just one measure of the diverse metabolic consequence of diabetes which not only affects carbohydrate metabolism but also the metabolism of lipids and proteins.

---

**Table 19.8**

Target goals of risk factors for diabetic patients.
The DCCT in the USA compared standard and intensive insulin therapy in a large prospective controlled trial of young patients with type 1 diabetes. Despite intensive therapy, mean blood glucose levels were still 40% above the non-diabetic range, but even at this level of control, the risk of progression to retinopathy was reduced by 60%, nephropathy by 30% and neuropathy by 20% over the 7 years of the study. Near-normoglycaemia should, therefore, be the goal for all young patients with type 1 diabetes. The unwanted effects of this policy include weight gain and a two- to three-fold increase in the risk of severe hypoglycaemia. Control should be less strict in those with a history of recurrent severe hypoglycaemia.

The UKPDS compared standard and intensive treatment in a large prospective controlled trial of type 2 diabetes patients. There was a 25% overall reduction in microvascular disease end-points, a 33% reduction in albuminuria and a 30% reduction in the need for laser treatment for retinopathy in the more intensively treated patients. This study also showed blood pressure control to be equally necessary in the prevention of retinopathy. However, a recent UKPDS study shows that good blood pressure control needs to be continued to maintain the benefits (i.e. there is no ‘legacy’ effect). There appeared to be little difference in outcome between the agents used to achieve good metabolic control (metformin, sulphonylurea or insulin). Intensive blood pressure control very considerably reduced the cardiovascular risk.

**Can established complications be halted or reversed by intensive insulin therapy?**

Insulin infusion devices have made near-normal blood glucose control possible for closely supervised groups of patients. Studies in patients with established retinopathy have shown that patients with early retinopathy benefit from intensive therapy, but that patients with more advanced retinal changes generally do not. These observations suggest that microvascular lesions are self-perpetuating once a threshold level of damage has been reached.

**Regular checks for patients with diabetes**

Box 19.2 is modified from the guidelines set out in *The European Patients’ Charter* published by the St Vincent Declaration Committee of the WHO. The charter sets out goals for both the healthcare team and the patient.

**FURTHER READING**

**PSYCHOSOCIAL IMPLICATIONS OF DIABETES**

Patients starting tablet or insulin treatment should be encouraged to live as normal a life as possible, but this is not easy. Tact, empathy, encouragement and practical support are needed from all members of the clinical team. Diabetes, like any chronic disease, has psychological sequelae. Most patients will experience periods of not coping, of helplessness, of denial and of acceptance often fluctuating over time. Other problems include:

- *The impossibility to take a ‘holiday’ from diabetes* – yet the human psyche is poorly developed to cope with unremitting adversity.
- *Concessions or sympathy are often denied* to the person with diabetes, since its presence is invisible.
- *The treatment is complex and demanding,* and the person with diabetes is expected to make trade-offs between short-term and long-term well-being.
- *Embarassing loss of control over personal behaviour* or consciousness can occur in insulin-treated patients after only a slight miscalculation.
- *Risk-taking behaviour* is indulged in by all humans when emotion is in conflict with logical thought, but its effects can be much greater for the person with diabetes (particularly the risks of unplanned pregnancy, alcohol and tobacco).
- *Poor self-image* is a very common problem.
- *Eating disorders* are more common in people with diabetes – 30–40% of young women with diabetes will exhibit a clinically significant eating disorder.
Omission of tablets or insulin is common since non-adherence to treatment regimens is universal in all illness. Between one in four and one in five tablets prescribed for diabetes is not consumed within the designated treatment period. Insulin omission is very common in young women where the pressure to lose weight overcomes concerns about long-term complications.

Adolescence

Adolescence is a difficult time of life. A period of poor metabolic control, or dropping out of medical care for a time and re-emerging with complications, is very common. Diabetic Summer Camps (e.g. run by Diabetes UK) help prevent a feeling of isolation and not knowing anyone else with the same problem. Separate adolescent clinics allow:

- treatment without marginalization in a larger group of older people
- meeting peers with similar problems in the waiting room
- gradual separation from parents and assumption of personal responsibility for the illness
- age-appropriate literature to be available.

Practical aspects

Patients need to inform the driving and vehicle licensing authority and their insurance companies after diagnosis. They would also be wise to inform their family, friends and employers in case unexpected hypoglycaemia occurs. Insulin treatment can be undertaken by people in most walks of life. A few jobs are unsuitable; these include driving Heavy Goods or Public Service vehicles, working at heights, piloting aircraft or working close to dangerous machinery in motion. Certain professions such as the police and the armed forces are barred to all diabetic patients. There are few other limitations, although a considerable amount of ill-informed prejudice exists. Doctors can sometimes help support patients in the face of misinformed work practices.

**DIABETIC METABOLIC EMERGENCIES**

The main terms used are defined in Table 19.9.

**Diabetic ketoacidosis**

Diabetic ketoacidosis is the hallmark of type 1 diabetes. It is usually seen in the following circumstances:

- previously undiagnosed diabetes
- interruption of insulin therapy
- the stress of intercurrent illness.

The majority of cases reaching hospital could have been prevented by earlier diagnosis, better communication between patient and doctor, and better patient education. The most common error of management is for patients to reduce or omit insulin because they feel unable to eat owing to nausea or vomiting. This is a factor in at least 25% of all hospital admissions. Insulin may need adjusting up or down but should never be stopped.

**Pathogenesis**

Ketoacidosis is a state of uncontrolled catabolism associated with insulin deficiency. Insulin deficiency is a necessary pre-condition since only a modest elevation in insulin levels is sufficient to inhibit hepatic ketogenesis, and stable patients do not readily develop ketoacidosis when insulin is withdrawn. Other factors include counter-regulatory hormone excess and fluid depletion. The combination of insulin deficiency with excess of its hormonal antagonists leads to the parallel processes shown in Figure 19.11. In the absence of insulin, hepatic glucose production accelerates, and periph-

---

Fig. 19.11 Dehydration occurs during ketoacidosis as a consequence of two parallel processes. Hyperglycaemia results in osmotic diuresis, and hyperketonaemia results in acidosis and vomiting. Renal hypoperfusion then occurs and a vicious circle is established as the kidney becomes less able to compensate for the acidosis.
eral uptake by tissues such as muscle is reduced. Rising glucose levels lead to an osmotic diuresis, loss of fluid and electrolytes, and dehydration. Plasma osmolality rises and renal perfusion falls. In parallel, rapid lipolysis occurs, leading to elevated circulating free fatty-acid levels. The free fatty acids are broken down to fatty acyl-CoA within the liver cells, and this in turn is converted to ketone bodies within the mitochondria (Fig. 19.12). Accumulation of ketone bodies produces a metabolic acidosis. Vomiting leads to further loss of fluid and electrolytes. The excess ketones are excreted in the urine but also appear in the breath, producing a distinctive smell similar to that of acetone. Respiratory compensation for the acidosis leads to hyperventilation, graphically described as ‘air hunger’. Progressive dehydration impairs renal excretion of hydrogen ions and ketones, aggravating the acidosis. As the pH falls below 7.0 (\( [H^+] > 100 \text{ nmol/L} \)), pH-dependent enzyme systems in many cells function less effectively. Untreated, severe ketoacidosis is invariably fatal.

**Clinical features**

The features of ketoacidosis are those of uncontrolled diabetes with acidosis, and include prostration, hyperventilation (Kussmaul respiration), nausea, vomiting and, occasionally, abdominal pain. The latter is sometimes so severe that it can be confused with a surgical acute abdomen.

Some patients are mentally alert at presentation, but confusion and stupor are present in more severe cases. Up to 5% present in coma. Evidence of marked dehydration is present and the eyeball is lax to pressure in severe cases. Hyperventilation is present but becomes less marked in very severe acidosis owing to respiratory depression. The smell of ketones on the breath allows an instant diagnosis to be made by those able to detect the odour. The skin is dry and the body temperature is often subnormal, even in the presence of infection; in such cases, pyrexia may develop later.

**Diagnosis**

This is confirmed by demonstrating hyperglycaemia with ketonaemia or heavy ketonuria, and acidosis. No time should be lost, and treatment is started as soon as the first blood sample has been taken. Hyperglycaemia is demonstrated by dipstick, while a blood sample is sent to the laboratory for confirmation. Ketonaemia is confirmed by centrifuging a blood sample and testing the plasma with a dipstick that measures ketones. Hand-held sensors measuring β-hydroxybutyrate in 30 seconds are available. An arterial blood sample is taken for blood gas analysis.

**Management**

The principles of management are as follows (Emergency box 19.1); these should be carried out in a high dependency area.

- Replace the fluid losses with 0.9% saline. Average loss of water is 5–7 litres with a sodium loss of 500 mmol.
- Replace the electrolyte losses. Potassium levels need to be monitored. Patients have a total body potassium deficit of 350 mmol, although initial plasma levels may not be low. Insulin therapy leads to uptake of potassium by the cells with a consequent fall in plasma K⁺ levels. Potassium is therefore given as soon as insulin is started.
- **Restore the acid–base balance.** A patient with healthy kidneys will rapidly compensate for the metabolic acidosis once the circulating volume is restored. Bicarbonate is seldom necessary and is only considered if the pH is below 7.0 (\( [H^+] > 100 \text{ nmol/L} \)), and is best given as an isotonic (1.26%) solution.
- **Replace the deficient insulin.** Modern treatment is with relatively modest doses of insulin, which lower blood glucose by suppressing hepatic glucose output rather than by stimulating peripheral uptake, and are therefore much less likely to produce hypoglycaemia. Soluble insulin is given as an intravenous infusion where facilities for adequate supervision exist, or as hourly intramuscular injections. The subcutaneous route is avoided because subcutaneous blood flow is reduced in shocked patients.
- **Monitor blood glucose closely.** Hourly measurement is needed in the initial phases of treatment.
- **Replace the energy losses.** When plasma glucose falls to near-normal values (12 mmol/L), saline infusion should be replaced with 5% dextrose containing 20 mmol/L of potassium chloride. The insulin infusion rate is reduced and adjusted according to blood glucose.
- Seek the underlying cause. Physical examination may reveal a source of infection (e.g. a perianal abscess). Two common markers of infection are misleading: fever is unusual even when infection is present, and polymorphonuclear neutrophilia is present even in the absence of infection. Relevant investigations include a chest X-ray, urine and blood cultures, and an ECG (to exclude myocardial infarction). If infection is suspected, broad-spectrum antibiotics are started once the appropriate cultures have been taken.

**Problems of management**

- **Hypotension.** This may lead to renal shutdown. Plasma expanders (or whole blood) are therefore given if the systolic blood pressure is below 80 mmHg. A central venous pressure line is useful in this situation. A bladder catheter is inserted if no urine is produced within 2
Emergency Box 19.1

Guidelines for the diagnosis and management of diabetic ketoacidosis

**Diagnosis**
- Hyperglycaemia: measure blood glucose.
- Ketonaemia: test plasma with ketostix. Finger prick sample for β-hydroxybutyrate measurement.
- Acidosis: measure pH and blood gases.

**Investigations**
- Blood glucose.
- Urea and electrolytes.
- Full blood count.
- Blood gases.
- Blood and urine culture.
- Chest X-ray.
- ECG.
- Cardiac enzymes.

**Phase 1 Management**
- Admit to HDU.
- Insulin: soluble insulin i.v. 6 units/h by infusion, or 20 units i.m. stat. followed by 6 units i.m. hourly.
- Fluid replacement: 0.9% sodium chloride with 20 mmol KCl per litre. An average regimen would be 1 L in 30 minutes, then 1 L in 1 hour, then 1 L in 2 hours, then 1 L in 4 hours, then 1 L in 6 hours.
- Adjust KCl concentration depending on results of 2 hourly blood K+ measurement.

IF:
- Blood pressure below 80 mmHg, give plasma expander.
- pH below 7.0 give 500 mL of sodium bicarbonate 1.26% plus 10 mmol KCl. Repeat if necessary to bring pH up to 7.0.

**Phase 2 Management**
- When blood glucose falls to 10–12 mmol/L change infusion fluid to 1 L 5% dextrose plus 20 mmol KCl 6-hourly. Continue insulin with dose adjusted according to hourly blood glucose test results (e.g. i.v. 3 units/h glucose 15 mmol/L; 2 units/h when glucose 10 mmol/L).

**Phase 3 Management**
- Once stable and able to eat and drink normally, transfer patient to four times daily subcutaneous insulin regimen (based on previous 24 hours’ insulin consumption, and trend in consumption).

**Special measures**
- Broad-spectrum antibiotic if infection likely.
- Bladder catheter if no urine passed in 2 hours.
- Nasogastric tube if drowsy.
- Consider CVP pressure monitoring if shocked or if previous cardiac or renal impairment.
- Give s.c. prophylactic LMW heparin.

**Subsequent management**
- Monitor glucose hourly for 8 hours.
- Monitor electrolytes 2-hourly for 8 hours.
- Adjust K replacement according to results.

**Hyperosmolar hyperglycaemic state**

This condition, in which severe hyperglycaemia develops without significant ketosis, is the metabolic emergency characteristic of uncontrolled type 2 diabetes. Patients present in middle or later life, often with previously undiagnosed diabetes. Common precipitating factors include consumption of glucose-rich fluids, concurrent medication such as thiazide diuretics or steroids, and intercurrent illness. The hyperosmolar hyperglycaemic state and ketoacidosis represent two ends of a spectrum rather than two distinct disorders (Box 19.3). The biochemical differences may partly be explained as follows:

- **Age.** The extreme dehydration characteristic of hyperosmolar hyperglycaemic state may be related to age. Older people experience thirst less acutely, and more readily become dehydrated. In addition, the mild renal impairment associated with age results in increased urinary losses of fluid and electrolytes.
- **The degree of insulin deficiency.** This is less severe in the hyperosmolar hyperglycaemic state. Endogenous insulin levels are sufficient to inhibit hepatic ketogenesis, whereas glucose production is unrestrained.
**Complications of diabetes**

**Lactic acidosis**

Lactic acidosis may occur in diabetic patients on biguanide therapy. The risk in patients taking metformin is extremely low provided that the therapeutic dose is not exceeded and the drug is withheld in patients with advanced hepatic or renal dysfunction.

Patients present in severe metabolic acidosis with a large anion gap (normally less than 17 mmol/L), usually without significant hyperglycaemia or ketosis. Treatment is by rehydration and infusion of isotonic 1.26% bicarbonate. The mortality is in excess of 50%.

---

**COMPLICATIONS OF DIABETES**

Insulin-treated patients still have a considerably reduced life expectancy. The major cause of death in treated patients is due to cardiovascular problems (70%) followed by renal failure (10%) and infections (6%). There is no doubt that the duration and degree of hyperglycaemia play a major role in the production of complications. Better diabetic control can reduce the rate of progression of both nephropathy and retinopathy and the DCCT showed a 60% reduction in developing complications over 9 years when the HbA1c was kept at around 7% in type 1 diabetes.

**Pathophysiology**

The mechanisms leading to damage are ill defined. The following are consequences of hyperglycaemia and may play a role:

- **Non-enzymatic glycosylation** of a wide variety of proteins, e.g. haemoglobin, collagen, LDL and tubulin in peripheral nerves. This leads to an accumulation of advanced glycosylated end-products causing injury and inflammation via stimulation of pro-inflammatory factors, e.g. complement, cytokines.

- **Polyol pathway.** The metabolism of glucose by increased intracellular aldose reductase leads to accumulation of sorbitol and fructose. This causes changes in vascular permeability, cell proliferation and capillary structure via stimulation of protein kinase C and TGF-β.

- **Abnormal microvascular blood flow** impairs supply of nutrients and oxygen. Microvascular occlusion is due to vasoconstrictors, e.g. endothelins and thrombogenesis, and leads to endothelial damage.

- **Other factors** include the formation of reactive oxygen species and growth factors stimulation (TGF-β) and vascular endothelial growth factor (VEGF). These growth factors are released by ischaemic tissues and cause endothelial cells to proliferate.

- **Haemodynamic changes,** e.g. in kidney (see p. 1053).

It has been proposed that all of the above mechanisms stem from a single hyperglycaemia-induced process of overproduction of superoxide by the mitochondrial electron chain. This new paradigm offers an integrated explanation of how complications of diabetes develop.
**Macrovascular complications** (Table 19.10)

Diabetes is a risk factor in the development of atherosclerosis. This risk is related to that of the background population. For example, Japanese diabetics are much less likely than patients in Europe to develop atherosclerosis, but are much more likely to develop it than are non-diabetic Japanese. The excess risk to diabetics compared with the general population increases as one moves down the body:

- Stroke is twice as likely.
- Myocardial infarction is three to five times as likely, and women with diabetes lose their premenopausal protection from coronary artery disease.
- Amputation of a foot for gangrene is 50 times as likely.

The UKPDS and DCCT studies have shown that intensive treatment of diabetes has only a small effect upon the cardiovascular risk of type 2 or type 1 diabetes patients.

Cardiovascular risk factors occurring together tend to have a multiplicative effect on the overall level of cardiovascular risk. It is vital to tackle all cardiovascular risk factors together in diabetes, and not just to focus on glucose levels.

- **Hypertension.** The UKPDS demonstrated that aggressive treatment of hypertension produces a marked reduction in adverse cardiovascular outcomes, both microvascular and macrovascular. To achieve the target for blood pressure (Table 19.8), the UKPDS found that one-third of patients needed three or more antihypertensive drugs in combination, and two-thirds of treated patients needed two or more.

- **Smoking:** the avoidable risk factor (see p. 829). Never give up efforts to help diabetic patients stop smoking.

- **Lipid abnormalities.** Clinical trials suggest that there is no ‘safe’ cut-off for serum cholesterol. The lowest achievable level seems best to aim for, and in practice this means that almost all people with type 2 diabetes will be treated with a statin.

- **Low-dose aspirin** can reduce macrovascular risk, but is associated with a morbidity and mortality from bleeding. The benefits of aspirin outweigh the bleeding risk when the risk of a cardiovascular end-point is >30% in the next 10 years. This risk is reached in patients aged under 45 with three strong additional cardiovascular risk factors, aged 45–54 with three additional risk factors, aged 54–65 with two additional risk factors or aged over 65 with just one additional risk factor.

- **ACE inhibitors/angiotensin II receptor antagonists.**

  Treating people with diabetes and at least one other major cardiovascular risk factor with an ACE-inhibitor produces a 25–35% lowering of the risk of heart attack, stroke, overt nephropathy or cardiovascular death. Angiotensin II receptor antagonists are sometimes preferred initially and are also used for those intolerant to ACE inhibitors.

**Microvascular complications**

In contrast to macrovascular disease, which is prevalent in the West as a whole, microvascular disease is specific to diabetes. Small blood vessels throughout the body are affected but the disease process is of particular danger in three sites:

- retina
- renal glomerulus
- nerve sheaths.

Diabetic retinopathy, nephropathy and neuropathy tend to manifest 10–20 years after diagnosis in young patients. They present earlier in older patients, probably because these have had unrecognized diabetes for months or even years prior to diagnosis. Genetic factors appear to contribute to the susceptibility to microvascular disease. Diabetic siblings of diabetic patients with renal and eye disease have a three- to fivefold increased risk of the same complication in both type 1 and type 2 patients. There are racial differences in the overall prevalence of nephropathy. In the USA prevalence is: Pima American Indians > Hispanic/Mexican > US black > US white people.

**Diabetic eye disease**

About one in three young people in this patient population is likely to develop visual problems, and in the UK 5% have in the past become blind after 30 years of diabetes. Diabetes is still the commonest cause of blindness in under 65 year old people despite the widespread use of laser photoagulation and control of blood pressure.

It affects the eye in a variety of ways:

- **Diabetic retinopathy** with lesions developing in the retina and in the iris.

- **Cataract** which develops earlier in diabetes than in the general population. Fluctuations in blood sugar can in addition give rise to some alterations in the refractive error as a result of osmotic changes within the lens. With the absorption of water into the lens the eye becomes more hypermetropic. This change occurs most commonly in young type 1 diabetics resulting in difficulty in reading. With control of blood sugar this is frequently reversed. However with high levels of blood sugar often associated with a degree of ketosis an acute cataract may develop (snowflake cataract) which comes on very rapidly and does not clear.

- **External ocular palsies** (p. 1104).

- The sixth and the third nerve are the most commonly affected. Third nerve palsy is not associated with pain. These nerve palsies usually recover spontaneously within a period of 3–6 months.

**Natural history**

**Cataracts**

Diabetic cataracts occur at an earlier stage than in non-diabetics.

Diabetic retinopathy

Diabetic retinopathy (Fig. 19.13) increases with the length of diabetes, 20% will have retinal changes after 10 years, rising to 80% after 20 years (see Table 19.11).

The effects on the retina initially differ with the different types of diabetes. In type 1 diabetes the progression may be fairly rapid to proliferative retinopathy (Fig. 19.14), often accelerated with poor control of diabetes and blood pressure. With good control the progression is slower (DCCT study). In type 2 diabetes the progression is much slower and initially in the macular and paramacular region. These changes are associated with macular oedema and consequent loss of vision. This maculopathy again can be slowed by good control of diabetes and blood pressure (UKPDS). Patients with type 2 diabetes may go on to develop proliferative retinopathy and patients with type 1 may go on to develop maculopathy although this is less common.

Background diabetic retinopathy. The first sign is the development of microaneurysms (small red dots) within the retina around the posterior pole. On fluorescein angiography they are associated with areas of capillary non-perfusion. Other features are superficial haemorrhages in the ganglion cell layer and outer plexiform layer. These haemorrhages are blotch-like in appearance (like ink on a blotter) and are the consequence of capillary closure. Cotton wool spots are micro-infarcts within the retina and the spot itself is the accumulation of axoplasmic debris. This debris is removed by macrophages and as this occurs there may be white dots at the site of the previous cotton wool spot (cytoid bodies).

Cotton wool spots may be associated with high blood pressure but may be entirely due to the diabetes. The cotton wool spots of hypertension tend to resolve quickly whereas those in diabetes can last over 3–6 months.

Pre-proliferative and proliferative retinopathy Proliferative retinopathy is preceded by the widespread development of capillary non-perfusion. This ischaemia induces new blood vessels to grow. Some of these blood vessels are inside the retina and therefore represent a healing process. These intraretinal new vessels (IRMA) do not give rise to any symptoms.

Preretinal new vessels (when the vessel has come through the retina) lie on the surface of the retina and usually occur at the margin of the area of capillary closure. They represent aborted attempts at revascularization: they are induced to grow because of the accumulation of VEGF (vascular endothelial growth factor). However these new vessels are prone to bleed, particularly if there is vitreous traction. Small haemorrhages give rise to the preretinal haemorrhage (boat-shaped haemorrhage) that lies on the inferior half of the retina. With further bleeding or traction, the blood seeps into the vitreous with the consequent loss of vision. Once new vessels have developed they undergo evolution with collagen tissue growing along the margins of the vessel and giving rise to fibrotic traction bands. These bands may pull on the retina and cause further haemorrhaging and possible retinal detachment. Abnormalities in the veins may be a strong indication of capillary non-perfusion. Beading occurs as the vein passes through an area of ischaemia and venous loops result from closure of the vein at the margin of an area of capillary non-perfusion. These two are clinical signs which are a good indication of advanced capillary closure.

![Fig. 19.13 Features of diabetic eye disease. (a) The normal macula (centre) and optic disc. (b) Dot and blot haemorrhages (early background retinopathy). (c) Hard exudates are present in addition in background retinopathy. (d) Multiple cotton-wool spots indicate pre-proliferative retinopathy requiring routine ophthalmic referral. (e) Multiple frond-like new vessels, the hallmark of proliferative retinopathy. White fibrous tissue is forming near the new vessels, a feature of advanced retinopathy (this eye also illustrates multiple xenon arc laser burns superiorly). (f) Exudates appearing within a disc-width of the macula are a feature of an exudative maculopathy. (g) Central and (h) cortical cataracts can be seen against the red reflex with the ophthalmoscope.](image)

If the capillary non-perfusion is rapidly developing and widespread then vessels may be induced to grow on the pupil margin and ultimately in the angle of the anterior chamber giving rise to rapid increase in intraocular pressure (thrombotic glaucoma). If the capillary closure should extend across the macular area, there will be associated loss of central vision.

Maculopathy. In type 2 diabetics the aneurysms increase in number and leak, giving rise to fluid accumulation within the
retina. If these aneurysms are localized they are associated with the deposition of fat and protein in the surrounding area (circinate retinopathy). If the oedema extends into the macula then the retina becomes thickened, visual function deteriorates and there is loss of central vision. Later new vessels may develop giving rise again to recurrent progressive vitreous haemorrhages. The final outcome in patients with maculopathy is for a large exudative plaque to be present in the central macular area.

**Mixed retinopathy.** Although proliferative and maculopathy are fairly distinct, frequently there is a combination of both types of retinopathy.

### Examination

**Examination of the eye.** Visual acuity should be checked with the best distance glasses using a pinhole. The ocular movements are assessed to detect any ocular motor palsies. The iris is examined for rubecosis and then the pupils dilated with 1% tropicamide. About 20 minutes later the eye is examined for the presence of a cataract by looking at the lens with a +10.00 lens in the ophthalmoscope and viewing the lens against the red reflex. If there is any opacity in the central area then this will be the cause of visual loss. The retina is then examined and a systematic examination should always be carried out, looking at the disc, in all quadrants, and then finally the macula. The macula is examined last because this induces the greatest pupillary constriction.

**Screening for sight.** Threatening eye disease with universal access is now seen as offering the best hope of displacing diabetes as the commonest cause of blindness in those under 65 years of age. The National Screening Committee in the UK has helped establish digital photography-based screening across the country based on a national set of standards. All patients with diabetes, over the age of 12 years, have annual measurements of their acuity, and photographs of their retina taken. Box 19.4 shows standardized criteria for screening schemes; these are regularly inspected.

**Fig. 19.14** Prevalence of retinopathy in relation to duration of the disease in patients with type 1 diabetes mellitus diagnosed under the age of 33 years. Almost all eventually develop background change and 60% progress to proliferative retinopathy. From *Archives of Ophthalmology* 1984; 102: 520.

...to view the retina adequately. Cataract extraction is straightforward if there is no retinopathy present. However, if there is retinopathy and/or iris neovascularization, both of these can progress. In addition the development of macular oedema if not pre-existing is more common and in the presence of existing macular oedema this can deteriorate fairly rapidly. Cataract extraction is indicated for visual reasons and also if it obstructs the view of the retina.

**Retinopathy.** The DCCT and UKPDS show that the risk of developing diabetic eye disease can be reduced by striving for aggressive metabolic control of the diabetes. There is no specific medical treatment for background retinopathy. Smoking and hypertension worsen the rate of progression, and blood pressure control is of particular importance. Development or progression of retinopathy may be accelerated by rapid improvement in glycaemic control, pregnancy and in those with nephropathy, and these groups need frequent monitoring. An ophthalmologist may perform fluorescein angiography (a fluoroscein dye is injected into an arm vein and photographed in transit through the retinal vessels) to define the extent of the potentially sight-threatening diabetic retinopathy.

**Proliferative retinopathy.** Once new vessels have developed this is an indication for laser therapy. The laser should be directed at the new vessels and, in addition, to the associated areas of capillary non-perfusion (ischaemia). If the proliferative retinopathy has progressed to new vessels developing on the optic disc then a technique known as panretinal photocoagulation (PRP) is carried out. This involves multiple laser burns to the peripheral retinopathy again to the areas of capillary non-perfusion. The presence of new vessels on the disc carries the worst prognosis and therefore laser therapy should be carried out as rapidly as possible. If bleeding has occurred and there is a good view then laser treatment should be applied. If the bleeding is recurrent and affecting vision and/or if there is the presence of fibrous tissue giving rise to traction on the retina, then...

Note: Hard exudates have a bright yellowish white colour and are often irregular in outline with a sharply defined margin. Cotton-wool spots are greyish white, have indistinct margins and a dull matt surface, unlike the glossy appearance of hard exudates.

The diabetic kidney

The kidney may be damaged by diabetes in three main ways:

- glomerular damage
- ischaemia resulting from hypertrophy of afferent and efferent arterioles
- ascending infection.

Diabetic nephropathy

Epidemiology

Clinical nephropathy secondary to glomerular disease usually manifests 15–25 years after diagnosis of diabetes and affects 25–35% of patients diagnosed under the age of 30 years. It is the leading cause of premature death in young diabetic patients. Older patients also develop nephropathy, but the proportion affected is smaller. Some centres have reported a falling incidence rate of diabetic nephropathy in type 1 diabetes. This may reflect good-quality local care for diabetics rather than a change in the natural history of the disease itself. As people with type 2 diabetes develop diabetes progressively younger, a rising incidence rate of nephropathy is seen.

Pathophysiology

The earliest functional abnormality in the diabetic kidney is renal hypertrophy associated with a raised glomerular filtration rate. This appears soon after diagnosis and is related to poor glycaemic control. As the kidney becomes damaged by diabetes, the afferent arteriole (leading to the glomerulus) becomes vasodilated to a greater extent than the efferent glomerular arteriole. This increases the intraglomerular filtration pressure, further damaging the glomerular capillaries. This increased intraglomerular pressure also leads to increased shearing forces locally which are thought to contribute to mesangial cell hypertrophy and increased secretion of extracellular mesangial matrix material. This process eventually leads to glomerular sclerosis. The initial structural lesion in the glomerulus is thickening of the basement membrane. Associated changes result in disruption of the protein cross-linkages which normally make the membrane an effective filter. In consequence, there is a progressive leak of large molecules (particularly protein) into the urine.
Albuminuria

The earliest evidence of this is ‘microalbuminuria’ – amounts of urinary albumin so small as to be undetectable by standard dipsticks (see p. 579). Microalbuminuria may be tested for by radioimmunoassay or by using special dipsticks. It is a predictive marker of progression to nephropathy in type 1 diabetes, and of increased cardiovascular risk in type 2 diabetes. Microalbuminuria may, after some years, progress to intermittent albuminuria followed by persistent proteinuria. Light-microscopic changes of glomerulosclerosis become manifest; both diffuse and nodular glomerulosclerosis can occur. The latter is sometimes known as the Kimmelstiel–Wilson lesion. At the later stage of glomerulosclerosis, the glomerulus is replaced by hyaline material.

At the stage of persistent proteinuria, the plasma creatinine is normal but the average patient is only some 5–10 years from end-stage kidney disease. The proteinuria may become so heavy as to induce a transient nephrotic syndrome, with peripheral oedema and hypoalbuminaemia.

Patients with nephropathy typically show a normochromic normocytic anaemia and a raised erythrocyte sedimentation rate (ESR). Hypertension is a common development and may itself damage the kidney still further. A rise in plasma creatinine is a late feature that progresses inevitably to renal failure, although the rate of progression may vary widely between individuals.

The natural history of this process is shown in Figure 19.15.

Ischaemic lesions

Arteriolar lesions, with hypertrophy and hyalinization of the vessels, can occur in patients with diabetes. The appearances are similar to those of hypertensive disease and lead to ischaemic damage to the kidneys.

Infective lesions

Urinary tract infections are relatively more common in women with diabetes, but this does not apply to men. Ascending infection may occur because of bladder stasis resulting from autonomic neuropathy, and infections more easily become established in damaged renal tissue. Autopsy material frequently reveals interstitial changes suggestive of infection, but ischaemia may produce similar changes and the true frequency of pyelonephritis in diabetes is uncertain. Untreated infections in diabetics can result in renal papillary necrosis, in which renal papillae are shed in the urine, but this complication is rare.

Diagnosis

The urine of all diabetic patients should be checked regularly for the presence of protein. Many centres also screen younger patients for microalbuminuria since there is evidence that meticulous glycaemic control or early antihypertensive treatment at this stage may delay the onset of frank proteinuria.

Once proteinuria is present, other possible causes for this should be considered (see below), but once these are excluded, a presumptive diagnosis of diabetic nephropathy can be made. For practical purposes this implies inevitable progression to end-stage kidney disease, although the time course can be markedly slowed by early aggressive antihypertensive therapy. Clinical suspicion of a non-diabetic cause of nephropathy may be provoked by an atypical history, the absence of diabetic retinopathy (usually but not invariably present with diabetic nephropathy) and the presence of red-cell casts in the urine. Renal biopsy should be considered in such cases, but in practice is rarely necessary or helpful. A 24-hour urine collection is performed to quantify protein loss. Regular measurement is made of the plasma creatinine level with estimated glomerular filtration rate (GFR).

Management

The management of diabetic nephropathy is similar to that of other causes of chronic kidney disease, with the following provisos:

- Aggressive treatment of blood pressure with a target below 130/80 mmHg has been shown to slow the rate of deterioration of renal failure considerably. Angiotensin-converting enzyme inhibitors or an angiotensin receptor II antagonist are the drugs of choice (see p. 804). These drugs should also be used in normotensive patients with persistent microalbuminuria. Reduction in albuminuria occurs with this treatment.
- Oral hypoglycaemic agents partially excreted via the kidney (e.g. glibenclamide and metformin) should be avoided.
- Insulin sensitivity increases and drastic reductions in insulin dosage may be needed.
- Associated diabetic retinopathy tends to progress rapidly, and frequent ophthalmic supervision is essential.

Management of end-stage disease is made more difficult by the fact that patients often have other complications of diabetes such as blindness, autonomic neuropathy or peripheral vascular disease. Vascular shunts tend to calcify rapidly and hence chronic ambulatory peritoneal dialysis may be preferable to haemodialysis. The failure rate of renal transplants is somewhat higher than in non-diabetic patients. A segmental pancreatic graft is sometimes performed at the same time as a renal graft. Although pancreatic transplants

![Fig. 19.15 Schematic representation of the natural history of nephropathy. The typical onset is 15 years after diagnosis. Intermittent proteinuria leads to persistent proteinuria. In time, the plasma creatinine rises as the glomerular filtration rate falls.](image-url)
have a limited viability, owing to progressive fibrosis within the graft, they may give the patient a year or so of freedom from insulin injections.

**Diabetic neuropathy**

Diabetes can damage peripheral nervous tissue in a number of ways. The vascular hypothesis postulates occlusion of the vasa nervorum as the prime cause. This seems likely in isolated mononeuropathies, but the diffuse symmetrical nature of the common forms of neuropathy implies a metabolic cause. Since hyperglycaemia leads to increased formation of sorbitol and fructose in Schwann cells, accumulation of these sugars may disrupt function and structure.

The earliest functional change in diabetic nerves is delayed nerve conduction velocity; the earliest histological change is segmental demyelination, caused by damage to Schwann cells. In the early stages axons are preserved, implying prospects of recovery, but at a later stage irreversible axonal degeneration develops.

The following varieties of neuropathy occur (Fig. 19.16):

- symmetrical mainly sensory polyneuropathy (distal)
- acute painful neuropathy
- mononeuropathy and mononeuritis multiplex
  - (a) cranial nerve lesions
  - (b) isolated peripheral nerve lesions
- diabetic amyotrophy (asymmetrical motor diabetic neuropathy)
- autonomic neuropathy.

**Symmetrical mainly sensory polyneuropathy**

This is often unrecognized by the patient in its early stages. Early clinical signs are loss of vibration sense, pain sensation (deep before superficial) and temperature sensation in the feet. At later stages patients may complain of a feeling of ‘walking on cotton wool’ and can lose their balance when washing the face or walking in the dark owing to impaired proprioception. Involvement of the hands is much less common and should prompt a search for non-diabetic causes. Complications include unrecognized trauma, beginning as blistering due to an ill-fitting shoe or a hot-water bottle, and leading to ulceration.

**Sequelae of neuropathy.** Involvement of motor nerves to the small muscles of the feet gives rise to interosseous wasting. Unbalanced traction by the long flexor muscles leads to a characteristic shape of the foot, with a high arch and clawing of the toes, which in turn leads to abnormal distribution of pressure on walking, resulting in callus formation under the first metatarsal head or on the tips of the toes and perforating neuropathic ulceration. Neuropathic arthropathy (Charcot’s joints) may sometimes develop in the ankle. The hands show small-muscle wasting as well as sensory changes, but these signs and symptoms must be differentiated from those of the carpal tunnel syndrome, which occurs with increased frequency in diabetes and may be amenable to surgery.

**Acute painful neuropathy**

A diffuse, painful neuropathy is less common. The patient describes burning or crawling pains in the feet, shins and anterior thighs. These symptoms are typically worse at night, and pressure from bedclothes may be intolerable. It may present at diagnosis or develop after sudden improvement in glycaemic control (e.g. when insulin is started). It usually remits spontaneously after 3–12 months if good control is maintained. A more chronic form, developing later in the course of the disease, is sometimes resistant to almost all forms of therapy. Neurological assessment is difficult because of the hyperaesthesia experienced by the patient, but muscle wasting is not a feature and objective signs can be minimal.

Management is firstly to explore for non-diabetic causes (see p. 1175). Explanation and reassurance about the high likelihood of remission within months may be all that is needed. Tricyclics, gabapentin, pregabalin, duloxetine, mexiletine, valproate and carbamazepine all reduce the perception of neuritic pain somewhat, but usually not as much as patients hope for. Transepidermal nerve stimulation (TENS) benefits some patients. Topical capsaicin-containing creams help occasionally. A few report that acupuncture has helped.

---

**Fig. 19.16 The neuropathic man.**
Mononeuritis and mononeuritis multiplex (multiple mononeuropathy)

Any nerve in the body can be involved in diabetic mononeuropathy; the onset is typically abrupt and sometimes painful. Radiculopathy (i.e. involvement of a spinal root) may also occur.

Isolated palsies of nerves to the external eye muscles, especially the third and sixth nerves, are more common in diabetes. A characteristic feature of diabetic third nerve lesions is that pupillary reflexes are retained owing to sparing of pupillomotor fibres. Full spontaneous recovery is the rule for most episodes of mononeuropathy over 3–6 months. Lesions are more likely to occur at common sites for external pressure palsies or nerve entrapment (e.g. the median nerve in the carpal tunnel, see p. 1172).

Diabetic amyotrophy

This condition is usually seen in older men with diabetes. Presentation is with painful wasting, usually asymmetrical, of the quadriceps muscles or occasionally in the shoulders. The wasting may be very marked and knee reflexes are diminished or absent. The affected area is often extremely tender. Extensor plantar responses sometimes develop and CSF protein content is elevated. Diabetic amyotrophy is usually associated with periods of poor glycaemic control and may be present at diagnosis. It often resolves in time with careful metabolic control of the diabetes.

Autonomic neuropathy

Asymptomatic autonomic disturbances can be demonstrated on laboratory testing in many patients, but symptomatic autonomic neuropathy is rare. It affects both the sympathetic and parasympathetic nervous systems and can cause disabling postural hypotension.

The cardiovascular system

Vagal neuropathy results in tachycardia at rest and loss of sinus arrhythmia. At a later stage, the heart may become denervated (resembling a transplanted heart). Cardiovascular reflexes such as the Valsalva manoeuvre are impaired. Postural hypotension occurs owing to loss of sympathetic tone to peripheral arterioles. A warm foot with a bounding pulse is sometimes seen in a polyneuropathy as a result of peripheral vasodilatation.

Gastrointestinal tract

Vagal damage can lead to gastroparesis, often asymptomatic, but sometimes leading to intractable vomiting. Implantable devices which stimulate gastric emptying, and injections of botulinum toxin into the pylorus (to partly paralyse the sphincter), have each shown benefit in cases of this previously intractable problem. Autonomic diarrhoea often occurs at night accompanied by urgency and incontinence. Diarrhoea and steatorrhoea may occur owing to small bowel bacterial overgrowth; treatment is with antibiotics such as tetracycline.

Bladder involvement

Loss of tone, incomplete emptying and stasis (predisposing to infection) can occur, and may ultimately result in an atomic, painless, distended bladder. Treatment is with intermittent self-catheterization, permanent catheterization if that fails and prophylactic antibiotic therapy for those prone to recurrent infection.

Male erectile dysfunction

This is common. The first manifestation is incomplete erection which may in time progress to total failure; retrograde ejaculation also occurs in patients with autonomic neuropathy. Erectile dysfunction in diabetes has many causes including anxiety, depression, alcohol excess, drugs (e.g. thiazides and beta-blockers), primary or secondary gonadal failure, hypothyroidism, and inadequate vascular supply owing to atheroma in pudendal arteries. The history and examination should focus on these possible causes. Blood is taken for LH, FSH, testosterone, prolactin and thyroid function. Treatment should ideally include sympathetic counselling of both partners.

Phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, vardenafil), which enhance the effects of nitric oxide on smooth muscle and increase penile blood flow, are used in those who do not take nitrates for angina. Sixty per cent of diabetic patients can be expected to benefit from this therapy.

Alternatives for those who fail to improve with a phosphodiesterase inhibitor, who dislike the side-effects (headache and a green tinge to vision the next day), or those in whom it is contraindicated, are:

- Apomorphine 2 or 3 mg sublingually 20 minutes before sexual activity.
- Alprostadil (prostaglandin E1 preparation) given as a small pellet inserted with a device into the urethra (125 µg initially with a maximum of 500 µg). If the partner is pregnant, barrier contraception must be used to keep prostaglandin away from the fetus.
- Intracavernosal injection of alprostadil urethra (2.5 µg initially with a maximum of 40 µg). Side-effects include priapism which needs urgent treatment should erection last more than 3 hours.
- Vacuum devices.

The diabetic foot

Ten to fifteen per cent of diabetic patients develop foot ulcers at some stage in their lives. Diabetic foot problems are responsible for nearly 50% of all diabetes-related hospital admissions. Many diabetic limb amputations could be delayed or prevented by more effective patient education and medical supervision. Ischaemia, infection and neuropathy combine to produce tissue necrosis. Although all these factors may coexist, the ischaemic and the neuropathic foot (Table 19.12) can be distinguished. In rural India foot ulcers

are common due to neuropathic and infective causes rather than vascular causes.

**Management**

Many diabetic foot problems are avoidable, so patients need to learn the principles of foot care (Table 19.13). Older patients should visit a chiropodist regularly and should not cut their own toe-nails. Once tissue damage has occurred in the form of ulceration or gangrene, the aim is preservation of viable tissue. The four main threats to the skin and subcutaneous tissues are:

- **Infection.** This can take hold rapidly in a diabetic foot. Early antibiotic treatment is essential, with antibiotic therapy adjusted in the light of culture results. The organisms grown from the skin surface may not be the organism causing deeper infection. Collections of pus are drained and excision of infected bone is needed if osteomyelitis develops and does not respond to appropriate antibiotic therapy. Regular X-rays of the foot are needed to check on progress.

- **Ischaemia.** The blood flow to the feet is assessed clinically and with Doppler ultrasound. Femoral angiography is used to localize areas of occlusion amenable to bypass surgery or angioplasty. Relatively few patients fall into this category, and the risks (deterioration leading to amputation) and benefits of surgical intervention are finely balanced.

- **Abnormal pressure.** An ulcerated site must be kept non-weight-bearing. Resting the affected leg may need to be supplemented with special deep shoes and insoles to move pressure away from critical sites, or by removable or non-removable casts of the leg. After healing, special shoes and insoles are likely to continue to be needed to protect the feet and prevent abnormal pressure repeating damage to a healed area. In neuropathic feet particularly, sharp surgical debridement by a chiropodist is necessary to prevent callus distorting the local wound architecture and causing damage through abnormal pressure on normal skin nearby.

- **Wound environment.** Dressings are used to absorb or remove exudate, maintain moisture, and protect the wound from contaminating agents, and should be easily removable. Expensive new dressings containing growth factors and other biologically active agents may have a role to play in future, but their place is still being assessed.

Good liaison between physician, chiropodist and surgeon is essential if periods in hospital are to be used efficiently. When irreversible arterial insufficiency is present, it is often quicker and kinder to opt for an early major amputation rather than subject the patient to a debilitating sequence of conservative procedures.

**Infections**

There is no evidence that diabetic patients with good glycaemic control are more prone to infection than normal subjects. However, poorly controlled diabetes entails increased susceptibility to the following infections:

- **Skin**
  - (a) staphylococcal infections (boils, abscesses, carbuncles)
  - (b) mucocutaneous candidiasis

- **Gastrointestinal tract**
  - (a) chronic periodontitis
  - (b) rectal and ischiorectal abscess formation (when control very poor)

- **Urinary tract**
  - (a) urinary tract infections (in women)
  - (b) pyelonephritis
  - (c) perinephric abscess

- **Lungs**
  - (a) staphylococcal and pneumococcal pneumonia
  - (b) Gram-negative bacterial pneumonia
  - (c) tuberculosis.

One reason why poor control leads to infection is that chemotaxis and phagocytosis by polymorphonuclear leucocytes are impaired because at high blood glucose concentrations neutrophil superoxide generation is impaired.

Conversely, infections may lead to loss of glycaemic control, and are a common cause of ketoacidosis. Insulin-treated patients need to increase their dose by up to 25% in the face of infection, and non-insulin-treated patients may need insulin cover while the infection lasts. Patients should be told never to omit their insulin dose, even if they are nauseated and unable to eat; instead they should test their blood glucose frequently and seek urgent medical advice. Diabetic patients should receive pneumococcal vaccine and yearly influenza vaccine.

**Skin and joints** (see also p. 1254)

Joint contractures in the hands are a common consequence of childhood diabetes. The signs may be demonstrated by asking the patient to join the hands as if in prayer; the metacarpophalangeal and interphalangeal joints cannot be opposed. Thickened, waxy skin can be noted on the backs of the fingers. These features may be due to glycosylation of collagen and are not progressive. The condition is sometimes referred to as diabetic cheiroarthropathy.

Osteopenia in the extremities is also described in type 1 diabetes but rarely leads to clinical consequences.

NOTES ON SPECIAL SITUATIONS IN DIABETES

Surgery
Smooth control of diabetes minimizes the risk of infection and balances the catabolic response to anaesthesia and surgery. The procedure for insulin-treated patients is simple:

- Long-acting and/or intermediate insulin should be stopped the day before surgery, with soluble insulin substituted.
- Whenever possible, diabetic patients should be first on the morning theatre list.
- An infusion of glucose, insulin and potassium is given during surgery. The insulin can be mixed into the glucose solution or administered separately by syringe pump. A standard combination is 16 U of soluble insulin with 10 mmol of KCl in 500 mL of 10% glucose, infused at 100 mL/h.
- Postoperatively, the infusion is maintained until the patient is able to eat. Other fluids needed in the perioperative period must be given through a separate intravenous line and must not interrupt the glucose/insulin/potassium infusion. Glucose levels are checked every 2–4 hours and potassium levels are monitored. The amount of insulin and potassium in each infusion bag is adjusted either upwards or downwards according to the results of regular monitoring of the blood glucose and serum potassium concentrations.

The same approach is used in the emergency situation, with the exception that a separate variable-rate insulin infusion may be needed to bring blood glucose under control before surgery.

Non-insulin-treated patients should stop medication 2 days before the operation. Patients with mild hyperglycaemia (fasting blood glucose below 8 mmol/L) can be treated as non-diabetic. Those with higher levels are treated with soluble insulin prior to surgery, and with glucose, insulin and potassium during and after the procedure, as for insulin-treated patients.

Pregnancy and diabetes
Meticulous metabolic control of the diabetes and careful medical and obstetric management is required.

Metabolic control of diabetes in pregnancy
The patient should perform daily home blood glucose profiles, recording blood tests before and 2 hours after meals.

The renal threshold for glucose falls in pregnancy, and urine tests are therefore of little or no value. Insulin requirements rise progressively, and intensified insulin regimens are generally used. The aim is to maintain blood glucose and fructosamine (or HbA1c) levels as close to the normal range as can be tolerated. Oral anti-diabetic therapy should not be used.

General management
The patient is seen at intervals of 2 weeks or less at a clinic managed jointly by physician and obstetrician. Circumstances permitting, the aim should be outpatient management with a spontaneous vaginal delivery at term. Retinopathy and nephropathy may deteriorate during pregnancy. Digital photographic eye screening and urine testing for protein should be undertaken at booking, at 28 weeks and before delivery.

Obstetric problems associated with diabetes
Poorly controlled diabetes is associated with stillbirth, mechanical problems in the birth canal owing to fetal macrosomia, hydramnios and pre-eclampsia. Ketoacidosis in pregnancy carries a 50% fetal mortality, but maternal hypoglycaemia is relatively well tolerated.

Neonatal problems
Maternal diabetes, especially when poorly controlled, is associated with fetal macrosomia. The infant of a diabetic mother is more susceptible to hyaline membrane disease than non-diabetic infants of similar maturity. In addition, neonatal hypoglycaemia may occur. The mechanism is as follows: maternal glucose crosses the placenta, but insulin does not; the fetal islets hypersecrete to combat maternal hyperglycaemia, and a rebound to hypoglycaemic levels occurs when the umbilical cord is severed.

These complications are due to hyperglycaemia in the third trimester. Poor glycaemic control around the time of conception carries an increased risk of major congenital malformations. When a pregnancy is planned, optimal metabolic control should be sought before conception.

Gestational diabetes
This term refers to glucose intolerance that develops in the course of pregnancy and usually remits following delivery. The condition is typically asymptomatic. Women who have a previous history of gestational diabetes, older or overweight women, those with a history of large for gestational age babies and women from certain ethnic groups are at particular risk, but many cases occur in women who are not in any of these categories. For this reason some advocate screening of all pregnant women on the basis of random plasma glucose testing in each trimester and by oral glucose tolerance testing if the glucose concentration is, for example, 7 mmol/L or more. There is no consensus concerning the level of blood glucose which is harmful for the baby, and therefore no consensus concerning cut-off levels for screening and intervention.

Treatment is with diet in the first instance, but most patients require insulin cover during the pregnancy. Insulin does not cross the placenta. Many oral agents cross the placenta and are usually avoided because of the potential risk to the fetus.

Gestational diabetes has been associated with all the obstetric and neonatal problems described above for pre-
existing diabetes, except that there is no increase in the rate of congenital abnormalities. Gestational diabetes is often the harbinger of type 2 diabetes in later life.

Not all diabetes presenting in pregnancy is gestational. True type 1 diabetes may develop, and swift diagnosis is essential to prevent the development of ketoacidosis. Hospital admission is required if the patient is symptomatic, or has ketonuria or a markedly elevated blood glucose level.

**Unstable diabetes**

This term is used to describe patients with recurrent ketoacidosis and/or recurrent hypoglycaemic coma. Of these, the largest group is made up of those who experience recurrent severe hypoglycaemia.

**Recurrent severe hypoglycaemia**

This affects 1–3% of insulin-dependent patients. Most are adults who have had diabetes for more than 10 years. By this stage, endogenous insulin secretion is negligible in the great majority of patients. Pancreatic alpha-cells are still present in undiminished numbers, but the glucagon response to hypoglycaemia is virtually absent. Long-term patients are thus subject to fluctuating hyperinsulinaemia owing to erratic absorption of insulin from injection sites, and lack a major component of the hormonal defence against hypoglycaemia. In this situation adrenaline (epinephrine) secretion becomes vital, but this too may become impaired in the course of diabetes. Loss of adrenaline (epinephrine) secretion has been attributed to autonomic neuropathy, but this is unlikely to be the sole cause; central adaptation to recurrent hypoglycaemia may also be a factor.

The following factors may also predispose to recurrent hypoglycaemia:

- **Overtreatment with insulin.** Frequent biochemical hypoglycaemia lowers the glucose level at which symptoms develop. Symptoms often reappear when overall glucose control is relaxed.
- **An unrecognized low renal threshold for glucose.** Attempts to render the urine sugar-free will inevitably produce hypoglycaemia.
- **Excessive insulin doses.** A common error is to increase the dose when a patient needs more frequent injections to overcome a problem of timing.
- **Endocrine causes.** These include pituitary insufficiency, adrenal insufficiency and premenstrual insulin sensitivity.
- **Alimentary causes.** These include exocrine pancreatic failure and diabetic gastroparesis.
- **Chronic kidney disease.** Clearance of insulin is diminished.
- **Patient causes.** Patients may be unintelligent, uncooperative or may manipulate their therapy.

**Recurrent ketoacidosis**

This usually occurs in adolescents or young adults, particularly girls. Metabolic decompensation may develop very rapidly. A combination of chaotic food intake and insulin omission, whether conscious or unconscious, is now regarded as the primary cause of this problem. It almost always occurs in the context of considerable psychosocial problems, particularly eating disorders. This area needs careful and sympathetic exploration in any patient with recurrent ketoacidosis. It is perhaps not surprising that in an illness where much of one’s life is spent thinking of and controlling food intake, 30% of women with diabetes have had some features of an eating disorder at some time. Other causes include:

- **Iatrogenic.** Inappropriate insulin combinations may be a cause of swinging glycaemic control. For example, a once-daily regimen may cause hypoglycaemia during the afternoon or evening and pre-breakfast hyperglycaemia due to insulin deficiency.
- **Intercurrent illness.** Unsuspected infections, including urinary tract infections and tuberculosis, may be present. Thyrotoxicosis can also manifest as unstable glycaemic control.

---

**HYPOGLYCAEMIA IN THE NON-DIABETIC**

Hypoglycaemia develops when hepatic glucose output falls below the rate of glucose uptake by peripheral tissues. Hepatic glucose output may be reduced by:

- the inhibition of hepatic glycogenolysis and gluconeogenesis by insulin
- depletion of hepatic glycogen reserves by malnutrition, fasting, exercise or advanced liver disease
- impaired gluconeogenesis (e.g. following alcohol ingestion).

In the first of these categories, insulin levels are raised, the liver contains adequate glycogen stores, and the hypoglycaemia can be reversed by injection of glucagon. In the other two situations, insulin levels are low and glucagon is ineffective. Peripheral glucose uptake is accelerated by high insulin levels and by exercise, but these conditions are normally balanced by increased glucose output.

The most common symptoms and signs of hypoglycaemia are neurological. The brain consumes about 50% of the total glucose produced by the liver. This high energy requirement is needed to generate ATP used to maintain the potential difference across axonal membranes.

**Insulinomas**

Insulinomas are pancreatic islet cell tumours that secrete insulin. Most are sporadic but some patients have multiple tumours arising from neural crest tissue (multiple endocrine neoplasia). Some 95% of these tumours are benign. The classic presentation is with fasting hypoglycaemia, but early symptoms may also develop in the late morning or afternoon. Recurrent hypoglycaemia is often present for months or years before the diagnosis is made, and the symptoms may be atypical or even bizarre; the presenting features in one series are given in Table 19.14. Common misdiagnoses include psychiatric disorders, particularly pseudodementia in

</table>
elderly people, epilepsy and cerebrovascular disease. Whipple’s triad remains the basis of clinical diagnosis. This is satisfied when:

- symptoms are associated with fasting or exercise
- hypoglycaemia is confirmed during these episodes
- glucose relieves the symptoms.

A fourth criterion – demonstration of inappropriately high insulin levels during hypoglycaemia – may usefully be added to these.

The diagnosis is confirmed by the demonstration of hypoglycaemia in association with inappropriate and excessive insulin secretion. Hypoglycaemia is demonstrated by:

- Measurement of overnight fasting (16 hours) glucose and insulin levels on three occasions. About 90% of patients with insulinomas will have low glucose and non-suppressed (normal or elevated) insulin levels.
- A prolonged 72-hour supervised fast if overnight testing is inconclusive and symptoms persist.

Autonomous insulin secretion is demonstrated by lack of the normal feedback suppression during hypoglycaemia. This may be shown by measuring insulin, C-peptide or pro-insulin during a spontaneous episode of hypoglycaemia.

Treatment of insulinoma

The most effective therapy is surgical excision of the tumour, but insulinomas are often very small and difficult to localize. Many techniques can be used to attempt to localize insulinomas. Sensitivity and specificity vary between centres and between operators. These include highly selective angiography, contrast-enhanced high-resolution CT scanning, scanning with radio-labelled somatostatin (some insulinomas express somatostatin receptors), and endoscopic and intra-operative ultrasound scanning. Venous sampling for the detection of ‘hot spots’ of high insulin concentration in the various intra-abdominal veins is still used occasionally.

Medical treatment with diazoxide is useful when the insulinoma is malignant, in patients in whom a tumour cannot be located, and in elderly patients with mild symptoms. Symptoms may also remit on treatment with a somatostatin analogue (octreotide or lanreotide).

Hypoglycaemia with other tumours

Hypoglycaemia may develop in the course of advanced neoplasia and cachexia, and has been described in association with many tumour types. Certain massive tumours, especially sarcomas, may produce hypoglycaemia owing to the secretion of insulin-like growth factor-1. True ectopic insulin secretion is extremely rare.

Postprandial hypoglycaemia

If frequent venous blood glucose samples are taken following a prolonged glucose tolerance test, about one in four subjects will have at least one value below 3 mmol/L. The arterial glucose difference is quite marked during this phase, so that very few are truly hypoglycaemic in terms of arterial (or capillary) blood glucose content. Failure to appreciate this simple fact led some authorities to believe that postprandial (or reactive) hypoglycaemia was a potential ‘organic’ explanation for a variety of complaints that might otherwise have been considered psychosomatic. An epidemic of false ‘hypoglycaemia’ followed, particularly in the USA. Later work showed a poor correlation between symptoms and biochemical hypoglycaemia. Even so, a number of otherwise normal people occasionally become pale, weak and sweaty at times when meals are due, and report benefit from advice to take regular snacks between meals.

True postprandial hypoglycaemia may develop in the presence of alcohol, which ‘primes’ the cells to produce an exaggerated insulin response to carbohydrate. The person who substitutes alcoholic beverages for lunch is particularly at risk. Postprandial hypoglycaemia sometimes occurs after gastric surgery, owing to rapid gastric emptying and mismatching of nutrient absorption and insulin secretion. This is referred to as ‘dumping’ but it is now rarely encountered (see p. 262).

Hepatic and renal causes of hypoglycaemia

The liver can maintain a normal glucose output despite extensive damage, and hepatic hypoglycaemia is uncommon. It is particularly a problem with fulminant hepatic failure.

The kidney has a subsidiary role in glucose production (via gluconeogenesis in the renal cortex), and hypoglycaemia is sometimes a problem in terminal renal failure.

Hereditary fructose intolerance occurs in 1 in 20000 live births and can cause hypoglycaemia (see p. 1068).

Endocrine causes of hypoglycaemia

Deficiencies of hormones antagonistic to insulin are rare but well-recognized causes of hypoglycaemia. These include hypopituitarism, isolated adrenocorticotrophic hormone (ACTH) deficiency and Addison’s disease.

Drug-induced hypoglycaemia

Many drugs have been reported to produce isolated cases of hypoglycaemia, but usually only when other predisposing factors are present:

- Sulfonylureas may be used in the treatment of diabetes or may be taken by non-diabetics in suicide attempts.
- Quinine may produce severe hypoglycaemia in the course of treatment for falciparum malaria.
- Salicylates may cause hypoglycaemia; usually accidental ingestion by children.
- Propranolol can induce hypoglycaemia in the presence of strenuous exercise or starvation.
- Pentamidine used in the treatment of resistant pneumocystis pneumonia (see p. 200).

Alcohol-induced hypoglycaemia

Alcohol inhibits gluconeogenesis. Alcohol-induced hypoglycaemia occurs in poorly nourished chronic alcoholics, binge drinkers and in children who have taken relatively small amounts of alcohol, since they have a diminished hepatic glycogen reserve. They present with coma and hypothermia.
Factitious hypoglycaemia

This is a relatively common variant of self-induced disease and is more common than an insulinoma. Hypoglycaemia is produced by surreptitious self-administration of insulin or sulfonylureas. Many patients in this category have been extensively investigated for an insulinoma. Measurement of C-peptide levels during hypoglycaemia should identify patients who are injecting insulin; sulfonylurea abuse can be detected by chromatography of plasma or urine.

**DISORDERS OF LIPID METABOLISM**

**Lipid physiology**

Lipids are insoluble in water, and are transported in the bloodstream as macromolecular complexes. In these complexes, lipids (principally triglyceride, cholesterol and cholesterol esters) are surrounded by a stabilizing coat of phospholipid. Proteins (called apoproteins) embedded into the surface of these ‘lipoprotein’ particles exert a stabilizing function and allow the particles to be recognized by receptors in the liver and the peripheral tissues. The structure of a chylomicron (one type of lipoprotein particle) is illustrated in Figure 19.17.

Five principal types of lipoprotein particles are found in the blood (Fig. 19.18). They are structurally different and can be separated in the laboratory by their density and electrophoretic mobility. The larger particles give postprandial plasma its cloudy appearance. More than half of all patients aged under 60 with angiographically confirmed coronary artery disease have a lipoprotein disorder.

The genes for all the major apoproteins and that for the low-density lipoprotein (LDL) receptor have been isolated, sequenced and their chromosomal sites mapped. Production of abnormal apoproteins is known to produce, or predispose to, several types of lipid disorder, and it is likely that others will be discovered.

**Chylomicrons** (Fig. 19.18)

Chylomicrons are synthesized in the small intestine postprandially, passing initially into the lymphatic lymphatic drainage, then along the thoracic duct into the bloodstream. They contain triglyceride and a small amount of cholesterol and its ester, and provide the main mechanism for transporting the digestion products of dietary fat to the liver and peripheral tissues. Each newly formed chylomicron contains several different apoproteins (B-48, A-I, A-II), and acquires apoproteins C-II and E by transfer from high-density lipoprotein (HDL) particles in the bloodstream. Apoprotein C-II binds to specific receptors in adipose tissue and skeletal muscle and the liver and allows the endothelial enzyme, lipoprotein lipase, to remove most of the triglyceride from the particle. The remaining chylomicron remnant particle, which contains the bulk of the original cholesterol, is taken up by the liver by mechanisms which are not fully understood, possibly mediated by apoprotein E.

**Very-low-density lipoprotein (VLDL) particles** (Fig. 19.18)

These are synthesized continuously in the liver and contain most of the body’s endogenously synthesized triglyceride and a smaller quantity of cholesterol. They are the body’s main source of energy during prolonged fasting. Apoprotein B-100 is an essential component of VLDL. Apoproteins C-II and E are incorporated later into VLDL by transfer from HDL particles. As they pass round the circulation, VLDL particles bind through apoprotein C-II allowing triglyceride to be progressively removed by lipoprotein lipase in the capillary endothelium. This leaves a particle, now depleted of triglyceride and apoprotein C-II, called an intermediate-density lipoprotein (IDL) particle.

**Intermediate-density lipoprotein (IDL) particles** (Fig. 19.18)

These have apoprotein B-100 and apoprotein E molecules on the particle surface. Most IDL particles bind to liver LDL receptors through the apoprotein E molecule and are then

---

*Fig. 19.17 Schematic diagram of a chylomicron particle (75–1200 nm) showing apoproteins lying in the surface membrane.*

*Fig. 19.18 Schematic representation of the sites of origin, interaction between, and fate of, the major lipoprotein particles.*
catabolized. Some IDL particles have further triglyceride removed (by the enzyme hepatic lipase), producing LDL particles.

**Low-density lipoprotein (LDL) particles**

(Fig. 19.18)

LDL particles are the main carrier of cholesterol, and deliver it both to the liver and to peripheral cells. The surface of the LDL particle contains apoprotein B-100, and also apoprotein E. The apoprotein B-100 is the principal ligand for the LDL clearance receptor. This receptor lies within coated pits on the surface of the hepatocyte. Once bound to the receptor, the coated pit invaginates and fuses with liposomes which destroy the LDL particle (Fig. 19.19). The number of hepatic LDL clearance receptors regulates the circulating LDL concentration, which is also influenced by controlling the activity of the rate-limiting enzyme in the cholesterol synthetic pathway, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase (Fig. 7.4).

LDL particles can deposit lipid into the walls of the peripheral vasculature. Not all the cholesterol synthesized by the liver is packaged immediately into lipoprotein particles. Some is oxidized into bile salts. Both bile salts and cholesterol are excreted in the bile: both are then reabsorbed through the terminal ileum and recirculated (enterohepatic circulation).

LDL particles become Lp(a) lipoproteins as a result of the linkage of apoprotein (a) to apoprotein B-100 with a single disulphide bond. Raised levels of Lp(a) lipoprotein are a risk factor for cardiovascular disease.

**High-density lipoprotein (HDL) particles**

(Fig. 19.18)

Nascent HDL particles are produced in both the liver and intestine. They are disc shaped, seemingly inert and contain apoprotein A-I. They are transmuted into mature particles by the acquisition of phospholipids, and the E and C apoproteins from chylomicrons and VLDL particles in the circulation. The more mature HDL particles take up cholesterol from cells in the peripheral tissues aided by cholesterol-efflux regulatory protein (ABCD1 gene). As it is taken up, the enzyme lecithin-cholesterol acyltransferase (LCAT), activated by the apoprotein A on the particle’s surface, esterifies the sequestered cholesterol. The HDL particle transports cholesterol away from the periphery and may transfer it indirectly to other particles such as VLDL in the circulation or deliver its cholesterol directly to the liver (reverse cholesterol transport) and steroid-synthetic tissues (ovaries, testes, adrenal cortex).

This direct delivery takes place through scavenger receptor B1. In experimental animals the absence of scavenger receptor B1 dramatically accelerates the development of atheroma, and genetically programmed overproduction suppresses atheroma formation.

**Measurement**

When a laboratory measures fasting serum lipids, the majority of the total cholesterol concentration consists of LDL particles with a 20–30% contribution from HDL particles. The triglyceride concentration largely reflects the circulating number of VLDL particles, since chylomicrons are not normally present in the fasted state. If the patient is not fasted, the total triglyceride concentration will be raised owing to the additional presence of triglyceride-rich chylomicrons.

**Epidemiology and lipids**

**LDL and total cholesterol**

Population studies have repeatedly demonstrated a strong association between both total and LDL cholesterol concentration and coronary heart risk. There is a strong link between mean fat consumption, mean serum cholesterol concentration and the prevalence of coronary heart disease between countries. The exception is France where the cardiovascular risk is only moderate – perhaps owing to high alcohol consumption. Studies of migrants, particularly of Japanese men migrating to Hawaii, have shown that as diet changes, and cholesterol concentrations rise, so does the cardiovascular risk. Such studies show the role of the environment rather than the genetic make-up of a population.

The Multiple Risk Factor Intervention Trial (MRFIT) screened one-third of a million American men for various cardiovascular risk factors and then followed them for 6 years. Data from this study have shown that although cardiovascular risk rises progressively as total cholesterol concentration increases (Fig. 19.20), the risk increase is modest for individuals with no other cardiovascular risk factors. With each additional risk factor the effect produced by the same difference in cholesterol concentration becomes greatly magnified. The Framingham Study has reproduced these findings in a separate population.

**HDL cholesterol**

Epidemiological studies have shown that higher HDL concentrations protect against cardiovascular disease. Raising HDL by pharmacological means does not, however, necessarily reduce cardiovascular risk. HDL also has effects on the function of platelets and of the haemostatic cascade. These properties may favourably influence thrombogenesis.

**VLDL particles (triglycerides)**

There is a relatively weak independent link between raised concentrations of (triglyceride-rich) VLDL particles and car-
diovascular risk. Very raised triglyceride concentrations (>6 mmol/L) cause a greatly increased risk of acute pancreatitis and retinal vein thrombosis. Hypertriglyceridaemia tends to occur in association with a reduced HDL concentration. Much of the cardiovascular risk associated with ‘hypertriglyceridaemia’ turns out on multivariate analysis to be due to the associated low HDL levels and not to the hypertriglyceridaemia itself.

Chylomicrons
Excess chylomicrons do not confer an excess cardiovascular risk, but raise the total plasma triglyceride concentration.

Hyperlipidaemia results from genetic predisposition interacting with an individual’s diet.

Secondary hyperlipidaemia
If a lipid disorder has been detected it is vital to carry out a clinical history, examination and simple special investigations to detect causes of secondary hyperlipidaemia (Table 19.15), which may need treatment in their own right. Hypothyroidism, diabetes, renal disease and abnormal liver function can all raise plasma lipid levels.

We have used the functional/genetic classification which has the advantage that the genetic disorders may be grouped by the results of simple lipid biochemistry into causes of:
- disorders of VLDL and chylomicrons – hypertriglyceridaemia alone

* disorders of LDL – hypercholesterolaemia alone
- disorders of HDL
- combined hyperlipidaemia.

Disorders of VLDL and chylomicrons – hypertriglyceridaemia alone

The majority of cases appear to be due to multiple genes acting together to produce a modest excess of circulating concentration of VLDL particles, such cases being termed polygenic hypertriglyceridaemia.

In a proportion of cases there will be a family history of a lipid disorder or its effects (e.g. pancreatitis). Such cases are often classified as familial hypertriglyceridaemia. The defect underlying the vast majority of such cases is not understood. The main clinical feature is a history of attacks of pancreatitis or retinal vein thrombosis in some individuals.

Lipoprotein lipase deficiency and apoprotein C-II deficiency
These are rare diseases which produce greatly elevated triglyceride concentrations owing to the persistence of chylomicrons (and not VLDL particles) in the circulation. The chylomicrons persist because the triglyceride within cannot be metabolized if the enzyme lipoprotein lipase is defective, or because the triglycerides cannot gain access to the normal enzyme owing to deficiency of the apoprotein C-II on their surface. Patients present in childhood with eruptive xanthomas, lapaemia retinalis and retinal vein thrombosis, pancreatitis and hepatosplenomegaly. If not identified in childhood, it can present in adults with gross hypertriglyceridaemia resistant to simple measures. The presence of chylomicrons floating like cream on top of fasting plasma suggests this diagnosis. It is confirmed by plasma electrophoresis or ultracentrifugation. An abnormality of apoprotein C can be deduced if the hypertriglyceridaemia improves temporarily after infusing fresh frozen plasma, and lipoprotein lipase deficiency is likely if it does not.

Disorders of LDL – hypercholesterolaemia alone

Heterozygous familial hypercholesterolaemia is an autosomal dominant monogenic disorder present in 1 in 500 of the normal population. The average primary care physician would therefore be expected to have four such patients, but because of clustering within families the prevalence varies.
There is an increased prevalence in some racial groups (e.g. French Canadians, Finns, South Africans). Surprisingly, most individuals with this disorder remain undetected. Patients may have no physical signs, in which case the diagnosis is made on the presence of very high plasma cholesterol concentrations which are unresponsive to dietary modification and are associated with a typical family history of early cardiovascular disease. Diagnosis can more easily be made if typical clinical features are present. These include xanthomatous thickening of the Achilles tendons and xanthomas over the extensor tendons of the fingers. Xanthelasma may be present, but is not diagnostic of familial hypercholesterolaemia.

The genetic defect is the underproduction or malproduction of the LDL cholesterol uptake receptor in the liver (Table 19.16). Over 150 different mutations in the LDL receptor have been described to date. Fifty per cent of men with the disease will die by the age of 60, most from coronary artery disease, if untreated.

**Homozygous familial hypercholesterolaemia** is very rare indeed. Affected children have no LDL receptors in the liver. They have a hugely elevated LDL cholesterol concentration, and massive deposition of lipid in arterial walls, the aorta and the skin. The natural history is for death from ischaemic heart disease in late childhood or adolescence. Repeated plasmapheresis has been used to remove LDL cholesterol with some success. Liver transplantation is a ‘cure’. Plasma lipids normalize and xanthomata regress after transplantation, but the numbers of patients having undergone this procedure is small.

**Mutations in the apoprotein B-100 gene** cause another relatively common single gene disorder. Since LDL particles bind to their clearance receptor in the liver through apoprotein B-100, this defect also results in high LDL concentrations in the blood, and a clinical picture which closely resembles classical heterozygous familial hypercholesterolaemia. The two disorders can be distinguished clearly only by genetic tests. The approach to treatment is the same.

**Polygenic hypercholesterolaemia** is a term used to lump together patients with raised serum cholesterol concentrations, but without one of the monogenic disorders above. They exist in the right-hand tail of the normal distribution of cholesterol concentration. The precise nature of the polygenic variation in plasma cholesterol concentration remains unknown. Variations in the apoprotein E gene (chromosome 19), and in Sterol-regulatory element-binding protein (SREBP)-2 gene, are involved in some individuals in this heterogeneous group.

## Disorders of HDL (very low HDL, low total cholesterol)

**Tangier disease** is an autosomal recessive disorder characterized by a low HDL cholesterol concentration. Cholesterol accumulates in reticuloendothelial tissue and arteries causing enlarged orange-coloured tonsils and hepatosplenomegaly. Cardiovascular disease, corneal opacities and a polyneuropathy also occur. It is due to a gene mutation (ABC1 gene – see HDL physiology above and Table 19.16) which normally promotes cholesterol uptake from cells by HDL particles.

Other mutations in this gene have been found in a few families with autosomal dominant HDL deficiency. It is as yet unknown whether abnormalities of this gene contribute to the low HDL cholesterol concentrations commonly seen in cardiovascular disease patients.

## Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia)

The most common patient group is a polygenic combined hyperlipidaemia. Patients have an increased cardiovascular risk due to both high LDL concentrations and suppression of HDL by the hypertriglyceridaemia.

**Familial combined hyperlipidaemia**

This is relatively common, affecting 1 in 200 of the general population. The genetic basis for the disorder has not yet been characterized. It is diagnosed by finding raised cholesterol and triglyceride concentrations in association with a typical family history. There are no typical physical signs.

**Remnant hyperlipidaemia**

This is a rare (1 in 5000) cause of combined hyperlipidaemia. It is due to accumulation of LDL remnant particles and is associated with an extremely high risk of cardiovascular disease. It may be suspected in a patient with raised total cholesterol and triglyceride concentrations by finding xan-

</table>
Thomases in the palmar creases (diagnostic) and the presence of tuberous xanthomas, typically over the knees and elbows (Fig. 19.21). Remnant hyperlipidaemia is almost always due to the inheritance of a variant of the apoprotein E allele (apoE2) together with an aggravating factor such as another primary hyperlipidaemia. When suspected clinically the diagnosis can be confirmed using ultracentrifugation of plasma, or phenotyping apoprotein E.

THERAPIES AVAILABLE TO TREAT HYPERLIPIDAEIA

The lipid-lowering diet
Studies have shown that dieticians helping patients to adjust their own diet to meet the nutritional targets set out below produce a better lipid-lowering effect than does the issuing of standard diet sheets and advice from a doctor. The main elements of a lipid-lowering diet are set out below.

Reduce the total fat intake
Dairy products and meat are the principal sources of saturated fat in the diet. Intake of these products should therefore be reduced, and fish and poultry should be substituted. Visible fat and skin should be removed before cooking and preparing meat dishes. Meat products including sausages and reconstituted meats (such as ‘luncheon meat’) should be avoided since the concentration of fat is unknown and often high. Baking and grilling of meats reduces the fat content and is preferred to frying. Low-fat or cottage cheese and skimmed or semi-skimmed milk should be substituted for the standard full-fat varieties. Pastries and cakes contain large quantities of fat and should be avoided. The overall aim should be to decrease fat intake such that it is providing approximately 30% of the total energy intake in the diet. Further reduction in fat intake is unacceptable to many patients.

Substitution with monounsaturates and polyunsaturates
Monounsaturated oils, particularly olive oil, and polyunsaturated oils such as sunflower, safflower, corn and soya oil, should be used in cooking instead of saturated fat-rich alternatives.

Reduce the dietary cholesterol intake
Liver, offal and fish roes should be avoided. Although eggs and prawns are rich in cholesterol their total contribution to the body’s cholesterol pool is small and they can still be part of a balanced lipid-lowering diet.

Increase the intake of fibre (non-starch polysaccharides, NSPs)
Foods high in soluble fibre, such as pulses, legumes, root vegetables, leafy vegetables and unprocessed cereals, help reduce circulating lipid concentrations. These should be substituted in the diet in the place of higher-fat alternatives.

Reduce alcohol consumption
Excess alcohol is a cause of secondary hyperlipidaemia, and may worsen primary lipid disorders.

Achieve an ideal body weight
Treatment of obesity is part of the management of hyperlipidaemia, both because it will help the lipid disorder itself, and because obesity is an independent cardiovascular risk factor.

Foods containing stanol esters
Plant stanols reduce the absorption of cholesterol from the intestine by competing for space in the micelles that deliver lipid to the mucosal cells of the gut. They are largely unabsorbed and excreted in the stool. Increasing the amount of plant stanol in the diet 10-fold by using a margarine (e.g. Benecol) containing added stanol esters lowers LDL cholesterol by approximately 0.35–0.5 mmol/L. A reduction in the risk of heart disease of about 25% would be expected if this reduction in LDL cholesterol was applied to a population.

Drugs
The classes of drugs used to treat hyperlipidaemia are listed in Table 19.17. The statins are the most widely used drugs. Anacetrapib, an inhibitor of cholesteryl ester transfer protein, has recently been introduced. It lowers LDL-C levels similar to statins with increase in HDL-C. Torcetrapib also lowers LDL-C and raises HDL-C but does not reduce atherogenesis, as judged by vascular intraluminal ultrasound.

MANAGEMENT OF SPECIFIC HYPERLIPIDAEIAS

Screening
Most patients with hyperlipidaemia are asymptomatic and have no clinical signs. Many are discovered during the screening of high-risk individuals. Whose lipids should be measured?

There are great doubts as to whether blanket screening of plasma lipids is warranted. Selective screening of people at high risk of cardiovascular disease should be undertaken:

- a family history of coronary heart disease (especially below 50 years of age)
- a family history of lipid disorders
- the presence of a xanthoma
- the presence of xanthelasma or corneal arcus before the age of 40 years
### Table 19.17 Drugs used in the management of hyperlipidaemia

<tbody>
<tr>
<td><strong>Statins</strong></td>
<td>Inhibit the rate-limiting step in cholesterol synthesis (HMG 6A reductase)</td>
<td>Contraindications: Active liver disease, pregnancy, lactation</td>
<td>30–60% reduction in LDL cholesterol</td>
<td>Simvastatin, Atorvastatin and Pravastatin have good long-term safety in large-scale trials and in clinical practice. Avoid if possible in women of childbearing age</td>
</tr>
<tr>
<td>e.g.</td>
<td></td>
<td>Adverse effects: Derangement of liver biochemistry, diarrhoea, myositis. Raise ciclosporin level in blood</td>
<td>Modest triglyceride lowering</td>
<td></td>
</tr>
<tr>
<td>Simvastatin</td>
<td></td>
<td></td>
<td>Tiny effect on HDL cholesterol</td>
<td></td>
</tr>
<tr>
<td>Pravastatin</td>
<td></td>
<td></td>
<td>Atorvastatin and particularly rosuvastatin have the most potent cholesterol-lowering effects (HMG CoA reductase)</td>
<td></td>
</tr>
<tr>
<td>Fluvasstatin</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Atorvastatin</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Rosuvastatin</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Cholesterol absorption inhibitors</td>
<td>Inhibition of gut absorption of cholesterol from food and also from bile. Mechanism of this inhibition is unclear</td>
<td>Contraindications: Lactation</td>
<td>Reduce LDL cholesterol by additional 10–15% if given with a statin. Triglyceride concentrations reduced by 10%. Increase HDL cholesterol by 5%</td>
<td>Mostly act in gut and little is absorbed Short term safety good. Long term safety unknown</td>
</tr>
<tr>
<td>e.g. Ezetimibe</td>
<td></td>
<td>Adverse effects: Occasional diarrhoea, abdominal discomfort</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Cholesterol-binding resins</td>
<td>Bind bile acids in the gut preventing enterohepatic circulation. Liver makes more bile acids from cholesterol, depleting the cholesterol pool</td>
<td>Adverse effects: Gastrointestinal side-effects predominate. Palatability is a problem</td>
<td></td>
<td></td>
</tr>
<tr>
<td>e.g. Colestyramine</td>
<td></td>
<td>Counselling: Other drugs bind to resins and should be taken 1 h before or 4 h afterwards</td>
<td></td>
<td></td>

</table>
- obesity
- diabetes mellitus
- hypertension
- acute pancreatitis
- those undergoing renal replacement therapy.

Where one family member is known to have a monogenic disorder such as familial hypercholesterolaemia (1 in 500 of the population), siblings and children must have their plasma lipid concentrations measured. It is also worth screening the prospective partners of any patients with this heterozygous monogenic lipid disorder because of the small risk of producing children homozygous for the condition.

Acute severe illnesses such as myocardial infarction can derange plasma lipid concentrations for up to 3 months. Plasma lipid concentrations should be measured either within 48 hours of an acute myocardial infarction (before derangement has had time to occur) or 3 months later.

Serum cholesterol concentration does not change significantly after a meal and as a screening test a random blood sample is sufficient. If the total cholesterol concentration is raised, HDL cholesterol, triglyceride and LDL cholesterol concentrations should be quantitated on a fasting sample. If a test for hypertriglyceridaemia is needed, a fasting blood sample is mandatory.

Hypertriglyceridaemia

A serum triglyceride concentration below 2.0 mmol/L is normal. In the range 2.0–6.0 mmol/L no specific intervention will be needed unless there are coincident cardiovascular risk factors, and in particular a strong family history of early cardiovascular death. In general, patients should be advised that they have a minor lipid problem, offered advice on weight reduction if obese, and advice on correcting other cardiovascular risk factors.

If the triglyceride concentration is above 6.0 mmol/L there is a risk of pancreatitis and retinal vein thrombosis. Patients should be advised to reduce their weight if overweight and start a formal lipid-lowering diet (see below). A proportion of individuals with hypertriglyceridaemia have livers which respond to even moderate degrees of alcohol intake by allowing accumulation or excess production of VLDL particles. If hypertriglyceridaemia persists, lipid measurements should be repeated before and after a 3-week interval of complete abstinence from alcohol. If a considerable improvement results, lifelong abstinence may prove necessary. Other drugs, including thiazides, oestrogens and glitazones, can have a similar effect to alcohol in susceptible patients.

If the triglyceride concentration remains elevated above 6.0 mmol/L, despite the above measures, drug therapy is warranted. A fibrate acid derivative is the agent of first choice. Nicotinic acid may be used in addition but its side-effects are often a problem. Fish oil capsules which contain ω-3 long-chain fatty acids are also effective in lowering triglyceride concentrations.

The severe hypertriglyceridaemia associated with the rare disorders of lipoprotein lipase deficiency and apoprotein C-II deficiency may require restriction of dietary fat to 10–20% of total energy intake and the use of special preparations of medium-chain triglycerides in cooking in place of oil or fat. Medium-chain triglycerides are not absorbed via chylomicrons (see p. 273).

Hypercholesterolaemia (without hypertriglyceridaemia)

Familial hypercholesterolaemia

Individuals often require treatment with diet and more than one cholesterol-lowering drug. The cholesterol absorption inhibitor ezetimibe is a logical addition to a statin and has a low side-effect profile (Table 19.17). Bile acid sequestrants are an alternative to ezetimibe, but have greater problems with tolerability. Concurrent therapy with statins and fibrates is usually avoided, in view of their overlapping side-effects, but in very severe cases such mixed therapy has been undertaken under close supervision.

Primary prevention for people with risk factors

Lipid-lowering therapy using a statin, or alternatives as above, should be considered in asymptomatic individuals irrespective of the total or LDL cholesterol level in type 2 diabetes alone, or with two or more of: positive family history of cardiovascular disease, albuminuria, hypertension, smoking.

Primary prevention for people without risk factors

In the absence of risk factors, lipid-lowering therapy should be used in asymptomatic men with LDL cholesterol levels persistently above 6.5 mmol/L despite dietary change. The situation for women is less clear.

Secondary prevention

As a generality, statin treatment is warranted for any patient with known macrovascular disease (coronary artery disease, TIA or stroke, peripheral vascular disease), irrespective of the total or LDL cholesterol level (treatment target is total cholesterol under 4.0, LDL-CK 1.8 mmol/L). If a statin is not tolerated, a fibrate, ezetimibe or fibrate/cholesterol absorption inhibitor combination are alternatives.

Risk prevention tables (see p. 748)

An array of risk prediction tables (see p. 748) are available to allow quantification of the risk of a patient having a cardiovascular event within the next 10 years. Some advocate the use of these risk tables as a guide to treatment – for example if the 10-year risk reaches the 15% or the 30% level. We side with those who have reservations over their use. Such risk analyses are a useful approach in helping to decide whether to use treatments such as aspirin. Aspirin probably has no effect until the day an atherosclerotic plaque ruptures, when it may then prevent thrombosis leading to a heart attack or stroke. Furthermore it has a significant associated morbidity and mortality (from bleeding). At a 10-year cardiovascular risk level of 15% the benefit/risk ratio for aspirin becomes favourable. At the 30% level the benefits are clear.

By contrast, the use of lipid-lowering agents, if initially tolerated, has a low associated morbidity and mortality. These agents probably reduce the rate of atheroma accumulation over a period of decades. When a patient is young, the chance that atheroma will be bad enough to cause a heart attack or stroke within the next 10 years will be small, even if atheroma is accumulating at a swift rate. The level of cardiovascular risk will only rise to the 15% or 30% level when the patient gets older. Yet it seems bizarre not to treat the gradual accumulation of atheroma when the patient is young.
with a low 10-year risk, and then to start treatment when age causes the 10-year risk levels to rise to a particular threshold, if all other factors are the same. In choosing whether or not to prescribe, we prefer to consider ‘will he/she live long enough to collect some pension and see his/her grandchildren?’ rather than ‘will he/she have a heart attack or stroke within the next 10 years?’. The answers to these two questions are very different.

**Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia)**

Treatment is the same for all varieties of combined hyperlipidaemia. For any given cholesterol concentration the hypertriglyceridaemia found in the combined hyperlipidaemias increases the cardiovascular risk considerably. Treatment is aimed at reducing serum cholesterol below 4.0 mmol/L and triglycerides below 2.0 mmol/L. Therapy is with diet in the first instance and with drugs if an adequate response has not occurred. Fibrates are the treatment of choice since these reduce both cholesterol and triglyceride concentrations, and also have the benefit of raising cardioprotective HDL concentrations. The combination of a fibrate and ezetimibe or a bile acid-binding resin is of considerable use when a fibrate alone produces an insufficient reduction in LDL cholesterol. Nicotinic acid can be used in addition, although its unwanted effects render it a third-line agent.

**OTHER LIPID DISORDERS**

**Hypolipidaemia**

Low lipid levels can be found in severe protein–energy malnutrition. They are also seen occasionally with severe malabsorption and in intestinal lymphangiectasia.

Hypobetalipoproteinaemia (Table 19.16) is a benign familial condition which is being increasingly recognized. The cholesterol levels are in the range 1–3.5 mmol/L.

**Abetalipoproteinaemia**

This is described on page 284.

**INBORN ERRORS OF CARBOHYDRATE METABOLISM**

**Glycogen storage disease**

All mammalian cells can manufacture glycogen, but the main sites of its production are the liver and muscle. Glycogen is a high-molecular-weight glucose polymer made up of 1–4 linked glucose units, with a 1–6 branch point every 4–10 residues. In glycogen storage disease there is either an abnormality in the molecular structure or an increase in glycogen concentration owing to a specific enzyme defect. Almost all these conditions are autosomal recessive in inheritance and present in infancy, except for McArdle’s disease, which presents in adults.

Table 19.18 shows the classification and clinical features of some of these diseases.

**Galactosaemia**

Galactose is normally converted to glucose. However, a deficiency of the enzyme galactose-1-phosphate uridyltransferase or, less commonly, uridine diphosphate galactose-4-epimerase, results in accumulation of galactose-1-phosphate in the blood. The transferase deficiency, inherited as an autosomal recessive, is due in 70% of patients to a glutamine to arginine missense mutation in Q188R. Galactose ingestion (i.e. milk) leads to inanition, failure to thrive, vomiting, hepatomegaly and jaundice, diabetes, cataracts and developmental delay. A lactose-free diet stops the acute toxicity but poor growth and problems with speech and mental development still occur with the transferase deficiency. A newborn screening programme to detect galactosaemia is used in parts of the USA and other countries.

Prenatal diagnosis and diagnosis of the carrier state are possible by measurement of the level of galactose-1-phosphate in the blood.

**Galactokinase deficiency** also results in galactosaemia and early cataract formation.

**Defects of fructose metabolism**

Absorbed fructose is chiefly metabolized in the liver to lactic acid or glucose. Three defects of metabolism in the liver and intestine occur; all are inherited as autosomal recessive traits:

- **Fructosuria** is due to fructokinase deficiency. It is a benign asymptomatic condition.
- **Hereditary fructose intolerance** is due to fructose-1-phosphate aldolase deficiency. Fructose-1-phosphate accumulates after fructose ingestion, inhibiting both glycogenolysis and gluconeogenesis, resulting in symptoms of severe hypoglycaemia. Hepatomegaly and renal tubular defects occur but are reversible on a fructose- and sucrose-free diet. Intelligence is normal and there is an absence of dental caries.
- **Hereditary fructose-1,6-diphosphatase deficiency** leads to a failure of gluconeogenesis. Infants present with hypoglycaemia, ketosis and lactic acidosis. Dietary control can lead to normal growth.

### Pentosuria

Pentosuria is due to reduced activity of NADP-linked sylitol dehydrogenase. It has no clinical significance.

### INBORN ERRORS OF AMINO ACID METABOLISM

Inborn errors of amino acid metabolism are chiefly inherited as autosomal recessive conditions. The major ones are shown in Table 19.19.

### Amino acid transport defects

Amino acids are filtered by the glomerulus, but 95% of the filtered load is reabsorbed in the proximal convoluted tubule by an active transport mechanism. Aminoaciduria results from:

- abnormally high plasma amino acid levels (e.g. phenylketonuria)
- any inherited disorder that damages the tubules secondarily (e.g. galactosaemia)

### GENERALIZED AMINOACIDURIAS

#### Fanconi syndrome

This occurs in a juvenile form (De Toni–Fanconi–Debré syndrome); in adult life it is often acquired through, for example, heavy metal poisoning, drugs or some renal diseases. There is a generalized defective proximal tubular reabsorption of:

- most amino acids
- glucose
- urate
- phosphate, resulting in hypophosphataemic rickets
- bicarbonate, with failure to transport hydrogen ions, causing a renal tubular acidosis that then produces a hyperchloraemic acidosis (see p. 676).

Other abnormalities include:
Table 19.19 The major inborn errors of amino acid metabolism

</table>

There are many other enzyme defects producing, for example, alaniinaemia, ammonaemia, argninaemia, citrullinaemia, isovaleric acidinaemia, lysinaemia, ornithinaemia or tyrosinaemia.

- potassium depletion, primary or secondary to the acidosis
- polyuria
- increased excretion of immunoglobulins and other low-molecular-weight proteins.

Various combinations of the above abnormalities have been described.

The juvenile form begins at the age of 6–9 months, with failure to thrive, vomiting and thirst. The clinical features are as a result of fluid and electrolyte loss and the characteristic vitamin D-resistant rickets.

In the adult, the disease is similar to the juvenile form, but osteomalacia is a major feature.

Treatment of the bone disease is with large doses of vitamin D (e.g. 1–2 mg of 1α-hydroxycholecalciferol with regular blood calcium monitoring). Fluid and electrolyte loss need to be corrected.

Lowe's syndrome (oculocerebrorenal dystrophy)

In this syndrome there is generalized aminoaciduria combined with mental retardation, hypotonia, congenital cataracts and an abnormal skull shape.

SPECIFIC AMINOACIDURIAS

Cystinuria

There is a defective tubular reabsorption and jejunal absorption of cystine and the dibasic amino acids, lysine, ornithine and arginine. Inheritance is either completely or incompletely recessive, so that only heterozygotes who have increased excretion of lysine and cystine can occur. Cystine absorption from the jejunum is impaired but, nevertheless, cystine in peptide form can be absorbed. Cystinuria leads to urinary
stones and is responsible for approximately 1–2% of all urinary calculi. The disease often starts in childhood, although most cases present in adult life.

Treatment is with a high fluid intake in order to keep the urinary cystine concentration low. Patients are encouraged to drink up to 3 L over 24 hours and to drink even at night. Penicillamine should be used for patients who cannot keep the cystine concentration of their urine low.

The condition cystinosis must not be confused with cystinuria.

**Hartnup’s disease**

There is defective tubular reabsorption and jejunal absorption of most neutral amino acids but not their peptides. The resulting tryptophan malabsorption produces nicotinamide deficiency (see p. 222). Patients can be asymptomatic, but others develop evidence of pellagra, with cerebellar ataxia, psychiatric disorders and skin lesions. Treatment is with nicotinamide, which often brings about considerable improvement.

**Tryptophan malabsorption syndrome (blue diaper syndrome)**

This is due to an isolated transport defect for tryptophan: the tryptophan excreted oxidizes to a blue colour on the baby’s diaper.

**Familial iminoglycinuria**

This occurs when there is defective tubular reabsorption of glycine, proline and hydroxyproline. It seems to have few clinical effects.

**Methionine malabsorption syndrome**

This is due to failure to absorb and excrete methionine, and results in diarrhoea, vomiting and mental retardation. Patients characteristically have an oast-house smell.

**LYSOSOMAL STORAGE DISEASES**

Lysosomal storage diseases are due to inborn errors of metabolism which are mainly inherited in an autosomal recessive manner. See Table 19.18.

**Glucosylceramide lipidoses: Gaucher’s disease**

This is the most prevalent lysosomal storage disease and is due to a deficiency in glucocerebrosidase, a specialized lysosomal acid β-glucosidase. This results in accumulation of glucosylceramide in the lysosomes of the reticuloendothelial system, particularly the liver, bone marrow and spleen. Over 300 mutations have been characterized in the glucocerebrosidase gene, the most common being a single base change (N370S) causing the substitution of arginine for serine; this is seen in 70% of Jewish patients. The typical Gaucher cell, a glucocerebroside-containing reticuloendothelial histiocyte, is found in the bone marrow, producing many cytokines such as CD14.

There are three clinical types, the most common presenting in childhood or adult life with an insidious onset of hepatosplenomegaly (type 1). There is a high incidence in Ashkenazi Jews (1 in 3000 births), and patients have a characteristic pigmentation on exposed parts, particularly the forehead and hands. The clinical spectrum is variable, with patients developing anaemia, evidence of hypersplenism and pathological fractures that are due to bone involvement. Nevertheless, many have a normal life-span.

The diagnosis is made on finding a deficiency of lysosomal A glucocerebrosidase in leucocytes. Plasma chitotriosidase (an enzyme secreted by activated macrophages) is grossly elevated in Gaucher’s disease and other lysosomal disorders: it is used to monitor enzyme replacement therapy. Acute Gaucher’s disease (type 2) presents in infancy with rapid onset of hepatosplenomegaly, with neurological involvement owing to the presence of Gaucher cells in the brain. The outlook is very poor. Type 3 presents in childhood or adolescence with a variable progression of hepatosplenomegaly, neurodegeneration and bone disease. Again, the outlook is poor.

Some patients with non-neuropathic Gaucher’s disease show considerable improvement with infusion of human recombinant glucocerebrosidase (miglitolase – a human recombinant enzyme). Oral miglustat (an inhibitor of glucosylceramide synthase) is used for mild to moderate type 1 Gaucher’s disease.

**Sphingomyelin cholesterol lipidoses: Niemann–Pick disease**

The disease is due to a deficiency of lysosomal sphingomyelinase which results in the accumulation of sphingomyelin cholesterol and glycosphingolipids in the reticuloendothelial macrophages of many organs, particularly the liver, spleen, bone marrow and lymph nodes. The disease usually presents within the first 6 months of life with mental retardation and hepatosplenomegaly; a particular type (11c) presents in adults with dementia. The gene frequency is 1:100 in Ashkenazi Jews. Typical foam cells are found in the marrow, lymph nodes, liver and spleen.

**The mucopolysaccharidoses (MPSs)**

This is a group of disorders caused by the deficiency of lysosomal enzymes (e.g. α-L-iduronidase) required for the catabolism of glycosaminoglycans (mucopolysaccharides).

The catabolism of dermatan sulphate, heparan sulphate, keratin sulphate or chondroitin sulphate may be affected either singularly or together.

Accumulation of glycosaminoglycans in the lysosomes of various tissues results in the disease. Ten forms of MPS have been described; all are chronic but progressive, and a wide spectrum of clinical severity can be seen within a single enzyme defect. The MPS types show many clinical features though in variable amounts, with dysostosis, abnormal facies, poor vision and hearing and joint dysmobility (either stiff or hypermobile) being frequently seen. Mental retardation is present in, for example, Hurler (MPS IH) and San Filippo A (MPS III A) types, but normal intelligence and life-span are seen in Scheie (MPS IS). L-aronidase
infusion reduces lysosomal storage, resulting in clinical improvement.

The GM2 gangliosidoses

In these conditions there is accumulation of GM2 gangliosides in the central nervous system and peripheral nerves. It is particularly common (1 in 2000) in Ashkenazi Jews. Tay–Sachs disease is the severest form, where there is a progressive degeneration of all cerebral function, with fits, epilepsy, dementia and blindness, and death usually occurs before 2 years of age. The macula has a characteristic cherry spot appearance.

Fabry’s disease

This X-linked recessive condition involves the glycosphinoglycolipid pathway. There is a deficiency of lysosomal hydrolase (α-galactosidase A) causing an accumulation of globotriaosylsaccharide with terminal α-galactosyl moieties in the lysosomes of various tissues including the liver, kidney, blood vessels and the ganglion cells of the nervous system. The patients present with peripheral nerve involvement, gastrointestinal symptoms/abdominal pain, diarrhoea and early safety, but eventually most patients have cardiac strokes and kidney disease in adult life. An absent or very low level of alpha-gal A in leucocytes confirms the diagnosis. Genetic testing is available. Treatment is with agalsidase alpha beta infusions.

Diagnosis

Many of the sphingolipidoses can be diagnosed by demonstrating the enzyme deficiency, usually in peripheral blood leucocytes.

Prenatal diagnosis is possible in a number of the conditions by obtaining specimens of amniotic cells. Carrier states can also be identified, so that sensible genetic counselling can be given.

AMYLOIDOSIS

Amyloidosis is a disorder of protein metabolism in which there is an extracellular deposition of pathological insoluble fibrillar proteins in organs and tissues. Characteristically, the amyloid protein consists of β-pleated sheets that are responsible for its insolubility and resistance to proteolysis.

Amyloidosis can be acquired or inherited. Classification is based on the nature of the precursor plasma proteins (at least 20) that form the fibrillar deposits. The process for the production of these fibrils appears to be multifactorial and differs amongst the various types of amyloid.

AL amyloidosis (immunoglobulin light chain-associated)

This is a plasma cell dyscrasia, related to multiple myeloma, in which clonal plasma cells in the bone marrow produce immunoglobulins that are amyloidogenic. This may be the outcome of destabilization of light chains owing to substitution of particular amino acids into the light chain variable region. There is a clonal dominance of amyloid light (AL) chains – either the dominant κ or λ isotype – which are excreted in the urine (Bence Jones proteins). This type of amyloid is often associated with lymphoproliferative disorders, such as myeloma, Waldenström’s macroglobulinaemia or non-Hodgkin’s lymphoma. It rarely occurs before the age of 40 years.

The clinical features are related to the organs involved. These include the kidneys (presenting with proteinuria and the nephrotic syndrome) and the heart (presenting with heart failure). Autonomic and sensory neuropathies are relatively common, and carpal tunnel syndrome with weakness and paraesthesia of the hands may be an early feature. Sensory neuropathy is common. There is an absence of central nervous system involvement.

On examination, hepatomegaly and rarely splenomegaly, cardiomyopathy, polyneuropathy and bruising may be seen. Macroglossia occurs in about 10% of cases and periorbital purpura in 15%.

Familial amyloidoses (transthyretin-associated (ATTR))

These are autosomally dominant transmitted diseases where the mutant protein forms amyloid fibrils, starting usually in middle age. The most common form is due to a mutant – transthyretin – which is a tetrameric protein with four identical subunits. It is a transport protein for thyroxine and retinol-binding protein and mainly synthesized in the liver. Over 80 amino acid substitutions have been described; for example, a common substitution is that of methionine for valine at position 30 (Met 30) in all racial groups, and alanine for threo-nine (Ala 60) in the English and Irish. These substitutions destabilize the protein, which precipitates following stimulation, and can cause disorders such as familial amyloidotic polyneuropathy (FAP), cardiomyopathy or the nephrotic syndrome. Major foci of FAP occur in Portugal, Japan and Sweden.

Other less common variants include mutations of apoprotein A-I, gelsolin, fibrinogen Ax and lysozyme.

Clinically, peripheral sensorimotor and autonomic neuropathy are common, with symptoms of autonomic dysfunction, diarrhoea and weight loss. Renal disease is less prevalent than with AL amyloidosis. Macroglossia does not occur. Cardiac problems are usually those of conduction. There may be a family history of unidentified neurological disease.

Other hereditary systemic amyloidoses include other familial amyloid polyneuropathies (e.g. Portuguese, Icelandic, Dutch). There is a familial Cretzfeldt–Jakob disease. In familial Mediterranean fever, renal amyloidosis is a common serious complication.

Reactive systemic (secondary AA) amyloidoses

These are due to amyloid formed from serum amyloid A (SAA), which is an acute phase protein. It is, therefore, related to chronic inflammatory disorders and chronic infection.

Clinical features depend on the nature of the underlying disorder. Chronic inflammatory disorders include rheumatoid arthritis, inflammatory bowel disease and untreated familial Mediterranean fever. In developing countries it is still associated with infectious diseases such as tuberculosis, bronchiectasis and osteomyelitis. AA amyloidosis often presents with chronic kidney disease, with hepatomegaly and splenomegaly. Macroglossia is not a feature and cardiac involvement is rare. The degree of renal failure correlates with the

**THE PORPHYRIAS**

This heterogeneous group of rare inborn errors of metabolism is caused by abnormalities of enzymes involved in the biosynthesis of haem, resulting in overproduction of the intermediate compounds called “porphyrins” (Fig. 19.22). The porphyrias show extreme genetic heterogeneity. For example, in acute intermittent porphyria more than 90 mutations have been identified in the porphobilinogen deaminase gene. One mutation has a high prevalence in patients in northern Sweden, suggesting a common ancestor.

Structurally, porphyrins consist of four pyrrole rings. These pyrrole rings are formed from the precursors glycine and succinyl-CoA, which are converted to δ-aminolaevulinic acid (δ-ALA) in a reaction catalysed by the enzyme δ-ALA synthase. Two molecules of δ-ALA condense to form a pyrrole ring.

Porphyrins can be divided into uroporphyrins, coproporphyrins or protoporphyrins depending on the structure of the side-chain. They are termed type I if the structure is symmetrical and type III if it is asymmetrical. Both uroporphyrins and coproporphyrins can be excreted in the urine.

The sequence of enzymatic changes in the production of haem is shown in Figure 19.22. The chief rate-limiting step is the enzyme δ-ALA synthase. This has two isoforms, ALA-N (non-erythroid) and ALA-E (erythroid). ALA-N is under negative feedback by haem but is upregulated by drugs and chemicals; there is no known inherited deficiency and the gene is on 3p21. Conversely ALA-E, encoded by Xp11.21, is unaffected by drugs or haem, and an inherited deficiency causes X-linked sideroblastic anaemia (Fig. 19.22).

Consequently:
- Haem (endogenous or exogenous) produces remission of hepatic porphyria.
- Chemicals and drugs can produce disease.
- Erythropoietic porphyria gives constant symptoms and is affected by sunlight.

**Clinical features**

All of the haem intermediates shown in Figure 19.22 are potentially toxic. Three patterns of symptoms occur in the various types of porphyria:
- neurovisceral (Table 19.20)
- photosensitive
- haemolytic anaemia.

The most common types of porphyria are acute intermittent (AIP), porphyria cutanea tarda (PCT) and erythropoietic porphyria (EPP).

The diagnosis of various types is based on urinary excretion levels of aminolaevulinic acid (ALA), porphobilinogen (PBG) and porphyrin in aliquots from a 24-hour collection. Erythrocyte PBG deaminase activity is measured for neurovisceral symptoms. Urinary and plasma porphyrin concentrations are helpful for those with photocutaneous manifestations. Faecal porphyrin analysis is helpful in confirmatory testing.

**Neurovisceral**

**Acute intermittent porphyria (AIP)** (Fig. 19.22)

This is an autosomal dominant disorder. Presentation is in early adult life, usually around the age of 30 years, and

---

**Other amyloidoses**

**Cerebral amyloidosis, Alzheimer’s disease and transmissible spongiform encephalopathy**

The brain is a common site of amyloid deposition, although it is not directly affected in any form of acquired systemic amyloidosis. Intracerebral and cerebrovascular amyloid deposits are seen in Alzheimer’s disease. Most cases are sporadic, but hereditary forms caused by mutations have been reported. In hereditary spongiform encephalopathies several amyloid plaques have been seen.

Amyloid deposits are frequently found in the elderly, particularly cerebral deposits of Aβ protein. This is also seen in Down’s syndrome. Apoprotein E (involved in LDL transport, see p. 1062) interacts directly with β-A4 protein in senile plaques and neurofibrillary tangles in the brain. The gene for apoprotein E is on chromosome 19 and may be a susceptibility factor in the aetiology of Alzheimer’s disease.

**Local amyloidosis**

Deposits of amyloid fibrils of various types can be localized to various organs or tissues (e.g. skin, heart and brain).

**Dialysis-related amyloidosis**

This is due to the β2-microglobulin producing amyloid fibrils in chronic dialysis patients (see p. 638). It frequently presents with the carpal tunnel syndrome.

**Diagnosis**

This is based on clinical suspicion and, if possible, on tissue histology. Amyloid in tissues appears as an amorphous, homogeneous substance that stains pink with haematoxylin and eosin and stains red with Congo red. It also has a green fluorescence in polarized light. Tissue can be obtained from the rectum, gums or abdominal fat. The bone marrow may show plasma cells in amyloidosis or a lymphoproliferative disorder. A paraproteinaemia and proteinuria with light chains in the urine may also be seen in AL amyloidosis. In secondary or reactive amyloidosis there will be an underlying disorder. Scintigraphy using 123I-labelled serum amyloid P component is useful for the assessment of AL, ATTR and AA amyloidosis, but it is not widely available and is expensive.

**Treatment**

This is symptomatic or the treatment of the associated disorder. The nephrotic syndrome and congestive cardiac failure require the relevant therapies. Treatment of any inflammatory source or infection should be instituted. Colchicine may help familial Mediterranean fever. Epoetin, which interferes with interactions between amyloid proteins and glycosaminoglycans inhibits polymerization of amyloid fibrils; it slows the fall in renal function in AA amyloidosis. Chemotherapy with naphthal plus dexamethasone is showing some efficacy in AL amyloidosis. In ATTR amyloidosis where transthyretin is predominantly synthesized in the liver, liver transplantation (when there would be a disappearance of the mutant protein from the blood) is considered as the definitive therapy.
Fig. 19.22 Porphyrin metabolism showing the various porphyrias. ALA synthase is the rate-limiting enzyme. Deficiencies of the other seven enzymes (crosses) cause the different porphyrias:

1. X-linked sideroblastic anaemia
2. ALA dehydrase porphyria (ADP)
3. Acute intermittent porphyria (AIP)
4. Congenital erythropoietic porphyria (CEP)
5. Porphyria cutanea tarda (PCT) and hepatoerythropoietic porphyria (HEP)
6. Hereditary coproporphyria (HCP)
7. Variegate porphyria (VP)
8. Erythropoietic protoporphyria (EPP).

Screening
Family members should be screened to detect latent cases. Urinalysis is not adequate but measurement of erythrocyte porphobilinogen deaminase and ALA synthase is extremely sensitive.

Mixed neurovisceral and photocutaneous
Variegate porphyria (VP) (Fig. 19.22)
This combines neurovisceral symptoms with those of a cutaneous photosensitive porphyria. A bullous eruption develops on exposure to sunlight owing to the activation of porphyrins deposited in the skin.

Investigations
The urine turns red-brown or red on standing.

- Blood count. This is usually normal, with occasional neutrophil leucocytosis.
- Liver biochemical tests. There is elevated bilirubin and aminotransferase.
- Serum urea is often raised.
- ALA and PBG are raised.
- Erythrocyte PBG deaminase is decreased.

Porphyria cutanea tarda (cutaneous hepatic porphyria) (PCT) (Fig. 19.22)
This condition, which has a genetic predisposition, presents with a bullous eruption on exposure to sunlight; the eruption heals with scarring. Alcohol is the most common aetiological agent but hepatitis C, iron overload or HIV can also precipi-
tate the disease. Evidence of biochemical or clinical liver disease may also be present. Polychlorinated hydrocarbons have been implicated and porphyria cutanea tarda has been seen in association with benign or malignant tumours of the liver.

Hepatoerythropoietic porphyria (HEP, Fig. 19.22) is a rare disease clinically very similar to congenital erythropoietic porphyria presenting in childhood; haemolytic anaemia occurs. The defect of HEP is similar to that of PCT.

The diagnosis depends on demonstration of increased levels of urinary uroporphyrin. Histology of the skin shows subepidermal blisters with perivascular deposition of periodic acid–Schiff-staining material. The serum iron and transferrin saturation are often raised. Liver biopsy shows mild iron overload as well as features of alcoholic liver disease.

**Congenital erythropoietic porphyria (CEP)** (Fig. 19.22)

This is extremely rare and is transmitted as an autosomal recessive trait. Its victims show extreme sensitivity to sunlight and develop disfiguring scars. Dystrophy of the nails, blindness due to lenticular scarring, and brownish discoloration of the teeth also occur.

**Erythropoietic protoporphyria (EPP)** (Fig. 19.22)

This is more common than congenital erythropoietic porphyria and is inherited as an autosomal dominant trait. It presents with irritation and a burning pain in the skin on exposure to sunlight. The liver is usually normal but protoporphyrin deposition can occur. Diagnosis is made by fluorescence of the peripheral red blood cells and by increased protoporphyrin in the red cells and stools.

**Management of porphyrias**

**Neurovisceral**

**Acute.** The management of acute episodes is largely supportive. Precipitating factors, e.g. drugs, should be stopped. Analgesics should be given (avoiding drugs that may aggravate an attack). Intravenous carbohydrates, e.g. glucose, inhibit ALA synthase activity. Intravenous haem arginate (human haemin) infusion reduces ALA and PBG excretion by having a negative effect on ALA synthase-N activity (Fig. 19.22) and decreases the duration of an attack; this is useful in a severe attack. Calorie and fluid intake should be maintained.

**Prevention in remission period.** This is by avoidance of possible precipitating factors, e.g. drugs and alcohol. Stopping smoking, treatment of infections and stress avoidance are helpful. Surgery can precipitate attacks. A high-carbohydrate diet should be maintained and haemin infusions may also help.

**Photocutaneous episodes**

**Acute attacks** following exposure to UV light can only be treated symptomatically. However, venesection, which reduces urinary porphyrin, can be used for PCT in both acute and remission phases. Chloroquine can also aid excretion by forming a water-soluble complex with uroporphyrins.

Liver transplantation is used for severe cases.

**Prevention** is with avoidance of sunlight, and use of sunscreens and protective clothing.

Oral β-carotene, which quenches free radicals, provides effective protection against solar sensitivity in EPP.

[http://www.eatlas.idf.org International Diabetes Federation](http://www.eatlas.idf.org International Diabetes Federation)

The ear can be divided into three parts: outer, middle and inner (Fig. 20.1).

The outer ear has a skin-lined tube 2.5 cm long leading down to the tympanic membrane (the ear drum). Its outer third is cartilaginous and contains hair, sebaceous and ceruminous glands, but the walls of the inner two-thirds are bony. The outer ear is self-cleaning as the skin is migratory and there are no indications to use cotton wool buds. Wax should only be seen in the outer third.

The middle ear is an air-containing cavity derived from the branchial clefts. It communicates with the mastoid air cells superiorly, and the Eustachian tube connects it to the nasopharynx medially. The Eustachian tube ventilates the middle ear and maintains equal air pressure across the tympanic membrane. It is normally closed but opens via the action of the palatal muscles to allow air entry when swallowing or yawning. A defect in this mechanism, such as with a cleft palate, will prevent air entering the middle ear cleft which may then fill with fluid. Lying within the middle ear cavity are the three ossicles (malleus, incus and stapes) that transmit sound from the tympanic membrane to the inner ear.

On the medial wall of the cavity is the horizontal segment of the facial nerve, which may be damaged during surgery or by direct extension of infection in the middle ear.

The inner ear contains the cochlea for hearing and the vestibule and semicircular canals for balance. There is a semicircular canal arranged in each body plane and these are stimulated by rotatory movement. The facial, cochlear and vestibular nerves emerge from the inner ear and run through the internal acoustic meatus to the brainstem (see Fig. 21.7, p. 1106).

**PHYSIOLOGY OF HEARING**

The ossicles, in the middle ear, transmit sound waves from the tympanic membrane to the cochlea. They amplify the waves by about 18-fold to compensate for the loss of sound waves moving from the air-filled middle ear to the fluid-filled cochlea. Hair cells in the basilar membrane of the cochlea detect the vibrations and transduce these into nerve impulses which pass to the cochlear nucleus and then eventually to the superior olivary nuclei of both sides; thus lesions central to the cochlear nucleus do not cause unilateral hearing loss.
If the ossicles are diseased, sound can also reach the cochlea by vibration of the temporal bone (bone conduction).

**EXAMINATION**

The pinna and postauricular region should first be examined for scars or swellings. An auriscope is used to examine the external ear canal whilst the pinna is retracted backwards and upwards to straighten the canal. Look for wax, discharge or foreign bodies. The tympanic membrane should always be seen with a light reflex anteroinferiorly. Previous repeated infections may cause a thickened, whitish drum but fluid in the middle ear may show as dullness of the drum. Perforations are marginal or central.

**COMMON DISORDERS**

**The discharging ear (otorrhoea)**

Discharge from the ear is usually due to infection of the outer or middle ear.

*Otitis externa* is a diffuse inflammation of the skin of the ear canal. The organism may be bacterial, viral or fungal and the patient usually complains of severe pain. Gentle pulling of the pinna is tender and there may be lymphadenopathy of the preauricular nodes.

*Examination* may reveal debris in the canal which needs to be removed either by gentle mopping or preferably by suction viewed directly under a microscope. In severe cases the canal may be swollen and a view of the tympanic membrane impossible. Any foreign body seen should be removed with great care by trained personnel.

*Treatment* is with regular cleansing and topical antibiotics combined with corticosteroids; it resolves in 3–4 days.

*Otitis media* can also present with discharge from the middle ear through a perforation of the tympanic membrane. There are no mucus glands in the external ear canal, however, and if the discharge is serous then middle ear pathology is unlikely.

*Treatment* is with systemic antibiotics.

**Cholesteatoma**

Cholesteatoma is defined as keratinizing squamous epithelium within the middle ear cleft and can present with foul-smelling otorrhoea. Examination may show a defect in the tympanic membrane full of white cheesy material. Mastoid surgery is required to remove this sac of squamous debris as it can erode local structures such as the facial nerve or even extend intracranially.

**Hearing loss**

Deafness can be conductive or sensorineural and these can be differentiated at the bedside by the Rinne and the Weber tests (Box 20.1) or with pure-tone audiometry.

**Rinne test**

Normally a tuning fork, 512 Hz, will be heard as louder if held next to the ear (air conduction) compared to being placed on the mastoid bone (*Rinne positive*). If the tuning fork is perceived louder when placed on the mastoid (bone conduction), then a defect in the conducting mechanism of the external or middle ear is present (true *Rinne negative*).

**Weber test**

A tuning fork placed on the forehead or vertex of a patient with normal hearing (or with symmetrical hearing loss) should be perceived centrally.

**Conductive hearing loss** may be due to many causes (Table 20.1) but wax is the commonest.

**Pure tone audiometry**

The patient is asked to respond to a series of pure tones presented to each ear, in turn, in a soundproof room. An audiogram is produced (Fig. 20.3).

**Perforated tympanic membrane**

This may arise from trauma or chronic middle ear disease where recurrent infection results in a permanent defect. Surgical repair is only indicated if the patient is symptomatic with hearing loss or recurrent discharge.

**Otitis media**

This is an acute inflammation of the middle ear, causing severe pain (otalgia) and conductive hearing loss. This occurs because fluid accumulation in the middle ear impairs sound conduction to the cochlea. It is often viral in origin, e.g. following a cold, and will settle within 72 hours without antibacterial treatment. In patients with systemic features or after 72 hours, a systemic antibiotic, e.g. amoxicillin, should be given, particularly in the under 2 year olds. Topical therapy is of no value. Complications include infection of the mastoid bone.
Acute otitis media may spread to the mastoid area and if there is tenderness and swelling over the mastoid then an urgent ENT opinion should be obtained.

**Secretary otitis media with effusion (also called serous otitis media or glue ear)** (Fig. 20.2)

This is common in children because of Eustachian tube dysfunction. The effusion resolves naturally in the majority of cases but can persist giving hearing loss, and it predisposes to recurrent attacks of acute otitis media. A grommet (tympanostomy tube) is a tube that is inserted into the tympanic membrane and ventilates the middle ear cavity, i.e. it takes over the Eustachian tube’s function. Grommets are extruded from the tympanic membrane as it heals (lasting from 6 months to 2 years). However, developmental outcomes are not improved by grommet insertions. In most children the middle third of the face grows around the age of 7–14 years and Eustachian tube dysfunction is rare after this.

**Otosclerosis**

This is usually a hereditary disorder where new bony deposits occur within the derivatives of the otic capsule, specifically the stapes footplate and in the cochlea. Characteristically seen in the second and third decades, it is commoner in females and can become worse during pregnancy. The hearing loss may be mixed, and treatment includes a hearing aid or replacement of the fixed stapes with a prosthesis (stapedectomy).

**Presbycusis**

This is the commonest cause of deafness. It is a degenerative disorder of the cochlea and is typically seen in old age. It can be due to the loss of outer hair cells (sensory), loss of the ganglion cells (neural), strial atrophy (metabolic) or it could be a mixed picture. Ageing itself does not cause outer hair cell loss but environmental noise toxicity over the years is a major factor. The onset is gradual and the higher frequencies are affected most (Fig. 20.3). Speech has two components: low frequencies (vowels) and high frequencies (consonants). When the consonants are lost, speech loses its intelligibility. Increasing the volume merely increases the low frequencies and the characteristic response of ‘Don’t shout. I’m not deaf!’ A high-frequency-specific hearing aid will do much to ease the frustrations of both the patients and their close contacts.

**Noise trauma**

Cochlear damage can occur, for example, when shooting without ear protectors or from industrial noise (see p. 959) and characteristically has a loss at 4 kHz.

---

**Fig. 20.2**

**Secretary otitis media (glue ear).** Auroscopic view of tympanic membrane which is dull with loss of light reflex.

---

**Fig. 20.3**

**Audiogram showing presbycusis (high frequency loss).**

---

**Acoustic neuroma**

This is a slow-growing benign schwannoma of the vestibular nerve (see p. 1160) which can present with progressive sensorineural hearing loss. Any patient with an asymmetric sensorineural hearing loss or sudden sensorineural hearing loss should be investigated, e.g. with an MRI scan.

**Vertigo**

Vertigo is usually rotatory when it arises from the ear. The presence of otalgia, otorrhoea, tinnitus or hearing loss suggests an otologic aetiology. Vestibular causes can be classified according to the duration of the vertigo:

- seconds to minutes – benign paroxysmal positional vertigo
- minutes to hours – Ménière’s disease
- hours to days – labyrinthine or central pathology.

**Benign paroxysmal positional vertigo (BPPV)**

BPPV is thought to be due to loose otoliths in the semicircular canals, commonly the posterior canal. Positional vertigo is precipitated by head movements, usually to a particular position, and may occur when turning in bed or on sitting up. The onset is typically sudden and distressing. The vertigo lasts seconds or minutes and the phenomenon becomes less severe on repeated movements (fatigue). There is no serious underlying cause but it sometimes follows vestibular neuritis (see p. 1109), head injury or ear infection.

**Diagnosis**

This is made not only on the history but by precipitating an attack by carrying out a positional test in the outpatient clinic. The **Hallpike manoeuvre** involves sitting the patient on a couch and then turning the patient’s head towards the affected ear. The patient’s head is supported by the examiner and the patient then lies down so that the head is just below the horizontal. Nystagmus (following a latent interval of a few seconds) is commonly noted, as is any subjective sensation of vertigo. A positive Hallpike test confirms BPPV, which can be cured in over 90% of cases by the Epley manoeuvre. This involves gentle but specific manipulation and rotation of the patient’s head to shift the loose otoliths from the semicircular canals.
A differential diagnosis is a cerebellar mass, but here positional nystagmus (and vertigo) is immediately apparent (no latent interval) and does not fatigue.

**Ménière’s disease**

This condition is characterized by recurring episodic rotatory vertigo lasting 30 minutes to a few hours; attacks are recurrent over months or years. Classically it is associated with a low frequency sensorineural hearing loss, feeling of fullness in the affected ear, loss of balance, tinnitus and vomiting. There is a build-up of endolymphatic fluid in the inner ear, although its precise aetiology is still unclear.

*Treatment* involves the use of vestibular sedatives, e.g. cinchocaine in the acute phase. Preventative measures, such as a low-salt diet, betahistine and avoidance of caffeine are useful. If the disease cannot be controlled in this way, then a chemical labyrinthectomy, which involves perfusing the round window orifice with ototoxic drugs such as gentamicin, is possible. Gentamicin destroys the vestibular epithelium; therefore the patient has severe vertigo for around 2 weeks until the body compensates for the lack of vestibular input on that side. The patient will happily trade occasional mild vertigo when the balance system is challenged to the unpredictable, severe and disabling attacks of vertigo of Ménière’s disease.

**Labyrinthine or central causes of vertigo** (see Table 21.10)

These are managed with vestibular sedatives in the acute phase. Most patients will settle over a few days but continuous true vertigo with nystagmus suggests a central lesion. A patient with a deficit of vestibular function due to viral labyrinthitis or neuritis should be able to come off the vestibular sedatives within 2 weeks, as long-term use can give parkinsonian side-effects, delay central compensation and thus prolong the vertigo. Vestibular rehabilitation by a physiotherapist or audiological scientist can speed up the compensation process, although most patients will be able to do this themselves with time.

**Tinnitus**

This is a sensation of a sound when there is no auditory stimulus. It can occur without hearing loss. Patients describe a hissing or ringing in their ears and this can cause much distress. It usually does not have a serious cause but vascular malformation, e.g. aneurysms, or vascular tumours may be associated. Tinnitus associated with deafness is described above.

*Treatment* This is difficult. A tinnitus masker (a mechanically produced continuous soft sound) can help. Specialist audiological services are of use and may rehabilitate patients well.

**FURTHER READING**

---

**THE NOSE**

**ANATOMY AND PHYSIOLOGY** (Fig. 20.4)

The function of the nose is to facilitate smell and respiration. Smell is a sensation conveyed by the olfactory epithelium in the roof of the nose. The olfactory epithelium is supplied by the first cranial nerve (see p. 1100). The nose also filters, moistens and warms inspired air and in doing so assists the normal process of respiration.

The external portion of the nose consists of two nasal bones attached to the rest of the facial skeleton and to the upper and lower lateral cartilages. The internal nose is divided by a midline septum that comprises both cartilage and bone. This separates the internal nose from the external nostril to the posterior choanae. The posterior choanae are in continuity with the nasopharynx posteriorly. The paranasal sinuses open into the lateral wall of the nose and are a system of aerated chambers within the facial skeleton.

The blood supply of the nose is derived from branches of both the internal and external carotid arteries. The internal carotid artery supplies the upper nose via the anterior and posterior ethmoidal arteries. The external carotid artery supplies the posterior and inferior portion of the nose via the superior labial artery, greater palatine artery and sphenopalatine artery. On the anterior nasal septum is an area of confluence of these vessels (Little’s area) (Fig. 20.5a).

**EXAMINATION**

The anterior part of the nose can be examined using a nasal speculum and light source. Endoscopes are required to examine the nasal cavity and postnasal space.

**COMMON DISORDERS**

**Epistaxis**

Nose bleeds vary in severity from minor to life-threatening. Little’s area (Fig. 20.5a) is a frequent site of nasal haemorrhage. First aid measures should be administered immediately, including external compression of the anterior lower portion of the external nose, ice packs and leaning forward. The patient should be asked to avoid swallowing any blood...
running posteriorly. If the bleeding continues profusely then resuscitation in the form of intravenous access, fluid replacement or blood, and oxygen can be administered. If further intervention is necessary, consideration should be given to intranasal cautery of the bleeding vessel, or intranasal packing may be undertaken using a variety of commercially available nasal packs (Fig. 20.5b). In addition to direct treatment of the epistaxis, a cause and appropriate treatment of a cause should be sought (Table 20.2).

Rhinitis

See page 831.

Nasal obstruction

Nasal obstruction is a symptom and not a diagnosis. It can significantly affect a patient’s quality of life. Causes include:

- **Rhinitis** (see p. 831). If an allergen is identified, then allergen avoidance is the mainstay of treatment. Topical steroids and/or antihistamines can be tried. If severe, then oral antihistamines or referral to an allergy clinic for immunotherapy may be warranted.
- **Septal deviation**. Correction of this deviation can be undertaken surgically.
- **Nasal polyps**. This condition occurs with inflammation and oedema of the sinus nasal mucosa. This oedematous mucosa prolapses into the nasal cavity and can cause significant nasal obstruction. In allergic rhinitis (see p. 831) the mucosa lining the nasal septum and inferior turbinate are swollen and a dark red or plum colour. Nasal polyps can be identified as glistening swellings which are not tender. Treatment with intranasal steroids may help but if polyps are large or unresponsive to medical treatment then surgery is necessary.

- **Foreign bodies**. These are usually seen in children who present with unilateral nasal discharge. Clinical examination of the nose with a light source often reveals the foreign body, which requires removal either in clinic or in theatre with a general anaesthetic.
- **Sinonasal malignancy**. This is extremely rare. The diagnosis must be considered if unusual unilateral symptoms are seen, including nasal obstruction, epistaxis, pain, epiphoria, cheek swelling, paraesthesia of the cheek and proptosis of the orbit.

**Sinusitis**

Sinusitis is an infection of the paranasal sinuses that may be bacterial (mainly *Streptococcus pneumoniae* and *Haemophilus influenzae*) or occasionally fungal. It is most commonly associated with an upper respiratory tract infection and can occur with asthma. Symptoms include frontal headache, purulent rhinorrhea, facial pain with tenderness and fever. It can be confused with a variety of other conditions such as migraine, trigeminal neuralgia and cranial arteritis.

**Treatment**

Treatment for a bacterial sinusitis includes nasal decongestants, e.g. xylometazoline, broad-spectrum antibiotics, e.g. co-amoxiclav because *H. influenzae* can be resistant to amoxicillin, anti-inflammatory therapy with topical corticosteroids such as fluticasone propionate nasal spray to reduce mucosal swelling, and steam inhalations.

If the symptoms of sinusitis are recurrent (Box 20.2) or complications such as orbital cellulitis arise, then an ENT opinion is appropriate and a CT scan of the paranasal sinuses is undertaken. Plain sinus X-rays are now rarely used to image the sinuses.

CT scan of the sinuses or an MRI scan can demonstrate bony landmarks and soft tissue planes (Fig. 20.6).

**Functional endoscopic sinus surgery** (FESS) is used for ventilation and drainage of the sinuses.

**Fig. 20.5** (a) Blood supply of Little’s area on the septum of the nose. (b) Nasal pack.
Anosmia

Olfaction is mainly under the control of cranial nerve I, although irritant, unpleasant nasal sensations are carried by cranial nerves V, IX and X. Anosmia is a complete loss of the sense of smell and hyposmia is a decreased sense of smell. If odorant molecules do not reach the olfactory epithelium high in the nose, a conductive deficit of smell occurs. If the neural transmission of smell is affected then a sensorineural loss of smell is incurred. Some conditions may predispose to a mixed (conductive and sensorineural) loss of smell. The main cause of a loss of smell is nasal obstruction due to upper respiratory infection or nasal polyps. Other causes include sinonasal disease, old age, drug therapy and head injury/trauma. It is difficult to predict the speed and extent of recovery in the latter causes.

Idiopathic cases will account for many patients but before this diagnosis is accepted an assessment of the patient for the possibility of an intranasal tumour or intracranial mass should be undertaken.

Fractured nose

Patients with a fractured nose present with epistaxis, bruising of the eyes and nasal bridge swelling. Initially, it is often difficult to assess if the bones are deviated, particularly if there is significant swelling. Reduction of the fracture should be undertaken in the first 2 weeks after injury and can be achieved by manipulation. However, if the fracture sets, a more formal rhinoplasty may have to be undertaken at a later stage. The patient should be examined for a head injury and the nose should also be checked for a septal haematoma.

This is painful, can cause nasal obstruction, is fluctuant to touch on the nasal septum and requires immediate drainage.

THE THROAT

ANATOMY AND PHYSIOLOGY

The throat can be considered as the oral cavity, the pharynx and the larynx. The oral cavity extends from the lips to the tonsils. The pharynx can be divided into three areas:

- nasopharynx – extending from the posterior nasal openings to the soft palate
- oropharynx – extending from the soft palate to the tip of the epiglottis
- hypopharynx – extending from the tip of the epiglottis to just below the level of the cricoid cartilage where it is continuous with the oesophagus.

Lying within the hypopharynx is the larynx. This consists of cartilaginous, ligamentous and muscular tissue with the primary function of protecting the distal airway. The pharynx is innervated from the pharyngeal plexus. In the larynx there are two vocal cords which abduct (open) during inspiration and adduct (close) to protect the airway and for voice production (phonation). The main nerve supply of the vocal cords comes from the recurrent laryngeal nerves (branches of the vagus nerve) which arise in the neck, but on the left side passes down around the aortic arch and then ascends in the tracheo-oesophageal groove to the larynx.

Normal vocal cords in phonation vibrate between 90 (male) and 180 (female) times per second, giving the voice its pitch or frequency. A healthy voice requires full closure of the vocal cords with a smooth, regular pattern of vibration, and any pathology that prevents full closure will result in air escaping between the vocal cords during phonation and a ‘breathy’ voice.

EXAMINATION

Good illumination is essential. Look at teeth, gums, tongue, floor of mouth and oral cavity. Tonsils, soft palate and uvula are easily seen, and a gag reflex (see p. 1110) is present. The remainder of the pharynx and larynx can be inspected with a laryngeal mirror or endoscope.

Examination of the neck for lymph nodes and other masses is also performed.

COMMON DISORDERS

Hoarseness (dysphonia)

There are three essential components for voice production: an air source (the lungs); a vibratory source (the vocal cords); and a resonating chamber (the pharynx, the nasal and oral cavities). Although chest and nasal disorders can affect the voice, the majority of hoarseness is due to laryngeal pathology.

Inflammation which increases the ‘mass’ of the vocal cords will cause the vocal cord frequency to fall, giving a much deeper voice. Thus listening to a patient’s voice can often give a diagnosis before the vocal cords are examined.

**Fig. 20.6** CT of the sinuses showing an inverting papilloma obstructing the right nostril and mucosal thickening of the right maxillary sinus.
**Nodules**

Nodules (always bilateral and commoner in females) and polyps (Fig. 20.7) are found on the free edge of the vocal cord preventing full closure and giving a ‘breathy, harsh’ voice. They are commonly found in professions that rely on their voice for their livelihood, such as teachers, singers and lawyers. They are usually related to poor technique of voice production and can usually be cured with speech therapy. If surgery is needed, great care must be taken to remain in the superficial layers of the vocal cord in order to prevent deep scarring which may leave the voice permanently hoarse.

**Reinke’s oedema** (Fig. 20.8)

This is due to a collection of tissue fluid in the subepithelial layer of the vocal cord. The vocal cord has poor lymphatic drainage, predisposing it to oedema. Reinke’s oedema is associated with irritation of the vocal cords: smoking, voice abuse, acid reflux and very rarely hypothyroidism. Treatment is to remove the irritation in most cases but surgery to thin the cords will also allow the voice to return to its normal pitch.

**Acute-onset hoarseness**

Hoarseness, in a smoker, is a danger sign. Any patient with a hoarse voice for over 6 weeks should be seen by an ENT surgeon. The voice may be deep, harsh and breathy indicating a mass on the vocal cord or it can be weak suggesting a paralysed left vocal cord secondary to mediatinal disease, e.g. bronchial carcinoma.

*Early squamous cell carcinoma of the larynx* (Fig. 20.9) has a good prognosis. Treatment is with carbon dioxide laser resection or radiotherapy. Spread of the tumour can lead to referred otalgia which may then require a laryngectomy with possible neck dissection. A patient with a paralysed left vocal cord must have a CT of the neck and chest. Medialization of the paralysed cord to allow contact with the opposite cord can return the voice and give a competent larynx. This can be done under local anaesthesia, giving an immediate result whatever the long-term prognosis of the chest pathology.

**Stridor**

Stridor or noisy breathing can be divided into inspiratory (source is glottic or above), expiratory (intrathoracic trachea or below) or mixed (subglottis or extrathoracic trachea). All patients with stridor, both paediatric and adult, are potentially at risk of asphyxiation and should be investigated fully. Severe stridor may be an indication for either intubation or a tracheostomy (Table 20.3).

Tracheostomy tubes may be:

- **Cuffed or uncuffed.** A high-volume, low-pressure cuff is used to prevent aspiration and to allow positive-pressure ventilation.
- **Fenestrated or unfenestrated.** This is a small hole on the greater curvature of the tube (both outer and inner) allowing air to escape upwards to the vocal cords and therefore the patient can speak. This tube often has a valve which allows air to enter from the stoma but closes on expiration, directing the air through the fenestration.

Most long-term tracheostomy tubes have an inner and outer tube. The inner tube fits inside the outer tube and projects beyond its lower end. A major problem with a tracheostomy tube is crusting of its distal end with dried secretions, and this arrangement allows the inner tube to be removed, cleaned and replaced as frequently as required, without disrupting the outer tube.

When to decannulate a patient is often a difficult issue if laryngeal competence is unclear. Movement of the vocal cords requires an ENT examination but owing to the risk of aspiration, a speech therapist’s opinion can also be useful. The tracheostomy tube itself can also give problems due to compression of the oesophagus with a cuffed tube and by preventing the larynx from rising during normal swallowing.

**Tonsillitis and pharyngitis**

Viral infections of the throat are common and, although many practitioners are under pressure from the patient to give antibiotics, the vast majority are usually self-limiting, settling with bed rest, analgesia and encouraging fluid intake. Fungal infections, usually candidiasis, are uncommon and may indicate an immunocompromised patient or undiagnosed diabetes.

**Tonsilitis**

Tonsilitis, with a good history of pyrexia, dysphagia, lymphadenopathy and severe malaise is usually bacterial with β-haemolytic streptococcus the commonest organism.

**Glandular fever** (see p. 107)

This can also present with tonsillitis, although clinically the tonsils have a white exudate, there is often a petechial rash on the soft palate and an accompanying lymphadenopathy.

**Table 20.3 Indications for tracheostomy**

| Upper airway obstruction (real or anticipated) |
| Long-term ventilation                          |
| Bronchial lavage                               |
| Incompetent larynx with aspiration            |
**Quinsy**

Quinsy is a collection of pus outside the capsule of the tonsil usually located adjacent to its superior pole. The patient often has trismus making examination difficult but the pus pushes the uvula across the midline to the opposite side. The area is usually hyperaemic and smooth but unilateral tonsillar ulceration is more likely to be a malignancy. In either case urgent referral to an ENT specialist is essential.

*Indications for a tonsillectomy* are shown in Table 20.4. This is carried out under a general anaesthetic and current surgical techniques include diathermy dissection, laser excision and coblation (using an ultrasonic dissecting probe). There are strong advocates for each technique and much will depend on the individual surgeon’s preference. Some departments now carry out tonsillectomy as a day case procedure as most reactionary bleeding will occur within the first 8 hours postoperatively.

**Snoring**

Snoring is due to vibration of soft tissue above the level of the larynx. It is a common condition (50% of 50-year-old males will snore to some extent) and can be considered to be related to obstruction of three potential areas: the nose, the palate or the hypopharynx (see Fig. 14.28). An Epworth questionnaire (Table 20.5) can also assist in the discrimination of sleep apnoea from simple snoring. Patients with a history of habitual, non-positional, heroic (can be heard through a wall) snoring require a full ENT examination and can be investigated by sleep nasendoscopy in which a sedated, snoring patient has a flexible nasendoscope inserted to identify the source of vibration. Nasal pathology such as polyps can be removed surgically with good results and most patients will benefit from lifestyle changes such as weight loss. Stiffening or shortening the soft palate via surgery, often using a laser, can help for palatal snorers but hypopharyngeal snorers require either a dental prosthesis at night to hold the mandible forward or continuous positive airway pressure (CPAP) via a mask (see p. 915).

**Dysphagia** (see p. 249)

Difficulty in swallowing is a common symptom but can be the presenting feature of carcinoma of the pharynx and therefore requires investigation.

A pharyngeal pouch is a herniation of mucosa through the fibres of the inferior pharyngeal constrictor muscle (criopharyngeus) (Fig. 20.10). An area of weakness known as Killian’s dehiscence allows a pulse diverticulum to form. This will collect food which may regurgitate into the mouth or even down to the lungs at night with secondary pneumonia. Diagnosis is made radiologically and treatment is surgical, either via an external approach through the neck where the pouch is excised or more commonly endoscopically with stapling of the party wall (Fig. 20.10c).

*Foreign bodies* in the pharynx can be divided into three general categories: soft food bolus, coins (smooth), bones (sharp). Soft food bolus can be initially treated conservatively with muscle relaxants for 24 hours. Impacted coins should be removed at the earliest opportunity but sharp objects require emergency removal to avoid perforation of the muscle wall. If the patient perceives the foreign body to be to one side, then it should be above the criopharyngeus and an ENT examination will locate it; common areas are the tonsillar fossae, base of tongue, posterior pharyngeal wall and valleculae. Radiology will identify coins, and it can be a clinical decision to see whether a coin will pass down to the stomach, in which case no further treatment is required as it will exit naturally. Some departments advocate the use of a metal detector to monitor the position of the coin in the patient, who is usually a child or has a mental disorder. Fish can be divided into those with a bony skeleton (teleosts) and those with a cartilaginous skeleton (elasmobranchs), and therefore radiology may only be useful in some cases. Radiology can also identify air in the cervical oesophagus indicating a radiolucent foreign body lying distally.

**Globus pharyngeus**

This is not a true dysphagia. It is a condition with classic symptoms of an intermittent sensation of a lump in the throat. This is perceived to be in the midline at the level of the cricoid cartilage and is worse when swallowing saliva; indeed it often disappears when ingesting food or liquids. ENT examination is clear and normal laryngeal mobility can be felt when gently rocking the larynx across the postcricoid tissues. A contrast swallow will show not only the structures below the pharynx but also assess the swallowing dynamically. Any suspicious area will require an endoscopy with biopsy.

**Further Reading**

DISORDERS OF THE EYE

A careful and detailed history gives most of the facts needed to make a working diagnosis. The eye has only a few mechanisms by which it can convey a diseased state. Common symptoms include alteration in visual acuity, redness, pain, discharge and photophobia. It is vital that an accurate Snellen visual acuity is recorded in all patients with an eye problem.

Diabetic eye disease (see p. 1050) and hypertensive eye disease (see p. 801) are discussed elsewhere.

APPLIED ANATOMY AND PHYSIOLOGY

The average diameter of the human eye is 24 mm. The cornea occupies the central aspect of the globe and is one of the most richly innervated tissues in the body. This clear, transparent and avascular structure, measuring 12 mm horizontally and 11 mm vertically, provides 78% of the focusing power of the eye. The endothelial cells lining the inner surface of the cornea are responsible for maintaining the clarity of the cornea by continuously pumping fluid out of the tissue. Any factor which alters the function of these cells will result in corneal edema and cause blurred vision. The anterior surface of the cornea is lined by epithelial cells which, together with the tear film, provide a smooth and regular surface for the refraction of light. The eyelids prevent the cornea from drying and becoming an irregular surface by distributing the tear film over the surface of the globe with each blink. In addition, the lids protect the globe and provide an outflow channel for excess tears via the puncta to the nose (Fig. 20.11).

The cornea and the sclera give mechanical strength and shape to the exposed surface of the globe. The sclera is a white opaque structure covering four-fifths of the globe and is continuous with the cornea at the limbus. The six extraocular muscles responsible for eye movements are attached to the sclera and the optic nerve perforates it posteriorly.

The conjunctiva covers the anterior surface of the sclera. This richly vascularized and innervated mucous membrane stretches from the limbus over the anterior sclera and is then reflected onto the undersurface of the upper and lower lids. The area of conjunctival reflection under the lids makes up the upper and lower fornix. The conjunctiva over the sclera is referred to as the bulbar conjunctiva whilst that over the lids makes up the tarsal conjunctiva.

The anterior chamber is the space between the cornea and the iris, and is filled with aqueous humour (Fig. 20.11). This fluid is produced by the ciliary body (2 µL/min) and provides nutrients and oxygen to the avascular cornea. The outflow of aqueous humour is through the trabecular...
meshwork and canal of Schlemm adjacent to the limbus. Any factor which impedes its outflow will increase the intraocular pressure. The upper range of normal for intraocular pressure is 21 mmHg.

The iris is the coloured part of the eye under the transparent cornea. The muscles of the iris diaphragm regulate the size of the pupil, thereby controlling the amount of light entering the eye. Immediately posterior to the pupil and anterior to the vitreous humour lies the lens of the eye. This is a transparent biconvex structure and is responsible for 22% of the refractive power of the eye. By changing its shape it can alter its refractive power and help to focus objects at different distances from the eye. In the fourth decade of life this ability to change shape starts to decline (presbyopia) and the need for reading glasses becomes inevitable. With age the lens starts to become less transparent and cataracts begin to develop.

The inner aspect of the sclera is lined by a highly vascular tissue, the choroid, and then the retina. The vitreous humour fills the cavity between the retina and the lens.

The retina is a multi-layered structure. The metabolically active region of the retina is represented in Figure 20.13. There are two types of photoreceptors in the retina, rods and cones. There are approximately 6 million cones mainly confined to the macula and are responsible for detailed central vision and colour vision. The peripheral retina has around 125 million rods that are responsible for peripheral vision. The axons of the ganglion cells form the optic nerve (or disc) of the eye (Fig. 20.14).

The blood supply to the eye is via the ophthalmic artery and, in particular, the central retinal artery is responsible for supplying the inner retinal layers. Venous return is through the central retinal and ophthalmic veins. Local lymphatic drainage is to the pre-auricular and submental nodes.

The sensory innervation of the eye (see p. 1106) is through the trigeminal (V) nerve. Of the six extraocular muscles the abducens (VI) nerve supplies the lateral rectus, the trochlear (IV) nerve supplies the superior oblique, whilst the rest are supplied by the oculomotor (III) nerve. The III nerve also sup-

**Fig. 20.13** Schematic diagram of the retina.

plies the upper lid and indirectly the pupil (parasympathetic fibres are attached to it). The facial (VI) nerve supplies the obicularis and other muscles of facial expression.

### REFRACTIVE ERRORS

The eye projects a sharp and focused image onto the retina. Refractive errors refer to any abnormality in the focusing mechanism of the eye and not to any opacity in the system such as a corneal or retinal scar.

The refraction of light in emmetropic (normal), myopic and hypermetropic eyes is shown in Figure 20.15.

Astigmatism occurs when the eye is not of the same radius of curvature for refraction. It may be myopic in one plane and hypermetropic or emmetropic in the other plane. In this situation the front surface of the eye is more rugby ball shaped than football shaped.

Presbyopia is the term used to describe the normal ageing of the lens and leads to a change in the refractive state of the eye. As the lens ages it becomes less able to alter its curvature and this causes difficulty with near vision, especially reading.

**Treatment**

Errors of refraction can be corrected by using spectacles or contact lenses. The latter result in better quality, but carry the risk of infection. They may be the only option in some refractive states such as keratoconus. There are a number
of surgical techniques available with varying degrees of accuracy. The most popular method is to use an excimer laser to re-profile the corneal curvature (PRK, LASIK, LASEK). Here the laser either removes corneal tissue centrally to flatten the cornea in myopia or it removes tissue from the peripheral cornea to steepen it in hypermetropia.

**DISORDERS OF THE LIDS**

The lids afford protection to the eyes and help to distribute the tear film over the front surface of the globe. Excess tears are drained via the punctae and lacrimal system. Malposition of the lids, factors which affect blinking or lacrimal drainage, can all cause problems.

**Entropion.** The lid margin rolls inwards so that the lashes are against the globe (Fig. 20.16a). The lashes act as a foreign body and cause irritation, leading to a red eye which can mimic conjunctivitis. Occasionally the constant rubbing of lashes against the cornea causes an abrasion. The commonest cause is ageing and surgery is usually required.

**Ectropion.** The lid margin is not apposed to the globe. As a result the lacrimal puncta is not in the correct anatomical position to drain tears and patients usually complain of a watery eye. Underlying factors include age, VII nerve palsy and cicatricial skin conditions. Surgery is usually required.

**Dacryocystitis.** This is inflammation of the lacrimal sac. Patients usually present with a painful lump at the side of the nose adjacent to the lower lid (Fig. 20.16b). This should be treated with oral broad-spectrum antibiotics such as cefalexin, and patients should be watched carefully for signs of cellulitis. These patients should be referred to the ophthalmologist as some may have an underlying mucocele or dilated sac, and will require surgery.

**Blepharitis.** This is inflammation of the lid margins. Inflammation may involve the lashes and lash follicles (Fig. 20.17a) resulting in styes, or inflammation and blockage of meibomian glands (Fig. 20.17b) leading to chalazion (Fig. 20.18). Treatment involves lid toilet and topical antibiotics such as chloramphenicol or fusidic acid. If there is associated cellulitis then broad-spectrum oral antibiotics are required. Some patients are left with a lump once the acute inflammatory phase of the chalazion has subsided. Most of these patients find the lump cosmetically unacceptable and require incision and curettage.

**CONJUNCTIVITIS**

This is the commonest cause of a red eye. Inflammation of the conjunctiva leading to a red eye can arise from a number of causes, with viral, bacterial and allergic being the commonest. Common features in all types of conjunctivitis include soreness, redness and discharge, and in general the visual acuity is good. History should include the speed of onset of the inflammation, the colour and consistency of the discharge, whether the eye is itchy, and if there has been a recent history of a cold or sore throat. In the neonate it is vital to ensure there has been no associated maternal sexually transmitted infection. The differential diagnosis of conjunctivitis is shown in Table 20.6.
Bacterial conjunctivitis

Bacterial conjunctivitis is uncommon, making up 5% of all cases of conjunctivitis. In the vast majority of patients it causes a sore or gritty eye in the presence of good vision. Bacterial conjunctivitis is invariably bilateral and should be suspected when conjunctival inflammation is associated with a purulent discharge. The rapidity of onset together with the severity of discharge is helpful in determining the underlying organism.

Clinical features

Gonococcal conjunctivitis should be suspected when the onset of symptoms is rapid, the discharge is copious, and ocular inflammation includes chemosis (conjunctival oedema) and lid oedema. Gonococci are a cause of conjunctivitis giving rise to a pre-auricular node.

Less acute or subacute purulent conjunctivitis with moderate discharge can be attributed to organisms such as Haemophilus influenzae and Streptococcus pneumoniae. Chronic conjunctivitis is usually associated with mild conjunctival injection and scant purulent discharge. Common organisms include Staphylococcus aureus and Moraxella lacunata.

Treatment

Prompt treatment with oral and topical penicillin is given in gonococcal conjunctivitis to ensure a reduced rate of corneal perforation. A Gram stain of the conjunctival swab can quickly confirm the presence of diplococci. Gonococcal conjunctivitis is a notifiable disease in the UK.

Empirical treatment for both subacute and chronic conjunctivitis involves a topical broad-spectrum antibiotic such as chloramphenicol. Swabs should be taken if these cases do not respond to this initial treatment.

Chlamydial conjunctivitis

This is a sexually transmitted infection and is most prevalent in sexually active adolescents and young adults. Direct or indirect contact with genital secretions is the usual route of infections but shared eye cosmetics can also be involved. It is caused by Chlamydia trachomatis (see p. 176). Neonatal chlamydial conjunctivitis is a notifiable disease in the UK and should be suspected in newborns with a red eye. Mothers should be asked about sexually transmitted infections. Trachoma caused by the same organism is found mainly in the tropics and the Middle East and is a very common cause of blindness in the world (see p. 143).

Clinical features

The onset of symptoms is slow, and patients may complain of mild discomfort for weeks. In these cases the red eye is associated with a scanty mucopurulent discharge and a palpable preauricular lymph node. In chronic cases it is not unusual to see superior corneal vascularization. In neonates the onset of the red eye is typically around 2 weeks after birth, whereas gonococcal conjunctivitis occurs within days of birth. Conjunctival swabs should be taken prior to commencement of treatment.

Treatment

Topical erythromycin twice daily is commenced and patients referred to the genitourinary physician. Neonates should be started on topical erythromycin and referred to the paediatrician as there may be associated otitis media or pneumonitis.

Viral conjunctivitis

Adenoviral conjunctivitis

This is highly contagious and can cause epidemics in communities. Transmission is through direct or indirect contact with infected individuals. The onset of symptoms may be preceded by a cold or flu-like symptoms. The eye becomes inflamed and this is commonly associated with chemosis, lid oedema and a palpable preauricular lymph node. Some patients may develop a membrane on the tarsal conjunctiva (Fig. 20.19a,b) and haemorrhage on the bulbar conjunctiva. Viral conjunctivitis can cause deterioration in visual acuity owing to corneal involvement (focal areas of inflammation). In 50% of the patients the conjunctivitis is unilateral.

Treatment

The condition is largely self-limiting in the majority of cases. Lubricants together with a cold compress can be soothing for patients. Strict hygiene and keeping towels separate from the rest of the household goes a long way towards reducing the spread of the infection. Clinicians also need to ensure good hygiene practice to reduce cross-infection and infecting themselves. In patients with conjunctival involvement or intense conjunctival inflammation, topical steroids are indicated.

Herpes simplex conjunctivitis

Primary ocular herpes simplex conjunctivitis is typically unilateral. It usually causes a palpable preauricular lymph node

![Fig. 20.19 (a and b) Viral conjunctivitis; (b) with pseudomembrane on lower lid.](image-url)
and cutaneous vesicles develop on the eyelids and the skin around the eyes in the majority of patients. Over 50% of these patients may develop a dendritic corneal ulcer (Fig. 20.20). The organism responsible for this condition is the herpes simplex virus (HSV), which is usually HSV-1 but HSV-2 can give rise to ocular infection.

**Molluscum contagiosum conjunctivitis**

This is typically unilateral and produces a red eye that generally goes unrecognized and comes to the forefront because patients fail to improve and the cornea starts to become involved. A closer look at the eyelids and the margin will reveal pearly umbilicated nodules and these are filled with the DNA poxvirus. A high index of suspicion is needed to make an early diagnosis.

**Treatment**

This includes curettage of the central portion of the lesion, freezing the centre or completely excising the lesion. If the corneal involvement is severe or the eye is very inflamed, a short course of topical steroids such as prednisolone 0.5% or dexamethasone 0.1% is helpful.

**Allergic conjunctivitis**

There are five main types of allergic conjunctivitis: seasonal, perennial, vernal, atopic and giant papillary. The last three are difficult to treat, chronic and can be sight-threatening. They should be referred to an ophthalmologist.

**Seasonal/perennial conjunctivitis**

Seasonal allergic conjunctivitis and perennial conjunctivitis affect 20% of the general population in the UK. Seasonal allergic conjunctivitis involves an allergic reaction to grass, pollen and fungal spores and occurs mainly in spring and summer. Perennial allergic conjunctivitis occurs all year round but peaks in the autumn and includes allergens such as house-dust mites.

The main symptoms include itching, redness, soreness, watering and a stringy discharge. Occasionally the conjunctiva may become so hyperaemic that chemosis results. This is usually associated with swollen lids.

**Treatment**

Reducing the allergen load (reducing dust, p. 832) is helpful. Medical treatment includes the use of antihistamine drops such as azelastine and emedastine together with topical mast cell-stabilizing agents such as sodium cromoglicate and nedocromil. Olopatadine (bd) has dual action and is very effective. Corticosteroid drops should be avoided. Oral antihistamines help the itching.

---

**CORNEAL DISORDERS**

**Trauma**

**Corneal abrasions**

Trauma resulting in the removal of a focal area of epithelium on the cornea is very common. Abrasions usually occur when the eye is accidentally poked with a finger, a foreign body (FB) flies into the eye or something brushes against the eye.

**Clinical features**

Symptoms include severe pain, due to exposure of the corneal nerve endings, lacrimation and inability to open the eye (blepharospasm). Blinking and eye movement can aggravate the pain and foreign body sensation. The visual acuity is usually reduced. Most cases will need topical anaesthetic drops such as oxybuprocaine or tetracaine to be administered before it is possible to examine the eye. The cornea should be inspected with a blue light after instillation of fluorescein drops. The orange dye will stain the area of the abrasion. Under blue light the abrasion lights up green. Occasionally FBs can lodge on the under surface of the upper lid and give rise to linear vertical abrasions. Eversion of the upper lid is necessary in all cases of abrasions (Fig. 20.21).

**Treatment**

This involves instillation of a broad-spectrum antibiotic such as chloramphenicol drops or ointment four times a day for 5 days. The role of padding is controversial but common practice is to pad the affected eye for 24 hours once chloramphenicol ointment has been applied to the eye.

**Corneal foreign body**

Occasionally when something flies into the eye it gets stuck on the cornea (Fig. 20.22a). It may be associated with lacrimation and photophobia. Examination is best attempted following instillation of a topical anaesthetic and should include evertting the upper lid (Fig. 20.22b). Corneal foreign bodies can usually be seen directly with a white light.

**Treatment**

The corneal FB should be removed and the patient given a topical antibiotic such as chloramphenicol four times a day for 5 days or fusidic acid twice a day for 5 days.

---

**Fig. 20.20** Dendritic ulcers on the cornea. (a) Stained with fluorescein. (b) Stained with fluorescein and viewed with blue light.

**Fig. 20.21** Linear corneal abrasion. (a) Stained with fluorescein. (b) Stained with fluorescein and viewed with blue light.
Trauma

In cases of high-velocity trauma corneal perforation or intra-ocular FB should be suspected. Examination may show a corneal laceration with or without the FB embedded in the cornea. The FB may be present on the iris or the lens. Other clues of a penetrating injury include a flat anterior chamber or the presence of blood in the anterior chamber (hyphaema) or a large subconjunctival haemorrhage. Urgent referral to the ophthalmologist is mandatory, ensuring that no drops are instilled into the eye and that a plastic shield has been placed over the eye to minimize further risk of trauma.

Blunt trauma usually results in periorbital bruising and gross lid oedema, which can make examination to exclude perforating injury difficult. These patients should be referred to the ophthalmologist for a detailed ocular examination to exclude a perforation retinal detachment or a traumatic hyphaema (Fig. 20.23).

Keratitis

This is a general term to describe corneal inflammation. Common causes include herpes simplex virus, contact lens-associated infection and blepharitis. Symptoms include the sensation of a foreign body or pain (depending on the size and depth of the ulcer), photophobia and lacrimation. Vision is reduced if the ulcer is in the visual axis.

Herpes simplex keratitis

Corneal epithelial cells infected with the virus eventually undergo lysis and form an ulcer which is typically dendritic in shape (Fig. 20.20). The ulcer stains with fluorescein and can be observed easily with a blue light. Topical immunosuppression, e.g. steroid drops, or systemic immunosuppression, e.g. AIDS, can lead to the centrifugal spread of the virus such that the ulcer increases in area and is referred to as a geographic ulcer. Recurrent attacks of HSV keratitis can be triggered by ultraviolet light, stress and menstruation. All these factors are responsible for activating the virus, which normally lies dormant in the ganglion of the V nerve.

Treatment

Aciclovir ointment five times a day for 2 weeks is usually very effective.

Contact lens-related keratitis

A small number of contact lens wearers develop infective corneal ulcers which are potentially sight-threatening (Fig. 20.24a,b). The organisms usually responsible include Gram-positive and Gram-negative bacteria. Patients should be referred to an ophthalmologist for scraping of the ulcer and commencement of antibiotic treatment.

Blepharitis

This is an extremely common condition where the lid margins are inflamed. Common underlying causes of blepharitis include meibomian gland dysfunction, seborrheoa and *Staphylococcus aureus* infection. Patients can be asymptomatic or complain of itchy, burning eyes because of tear film instability resulting from meibomian gland dysfunction. *Staphylococcus aureus* is frequently responsible for chronic blepharoconjunctivitis and some patients may develop keratitis (Fig. 20.25).

Treatment

Lid hygiene is the mainstay of treatment as it helps to reduce the bacterial load and unblock meibomian glands. A short course of topical chloramphenicol is useful in chronic cases but in severe cases or cases where acne rosacea is suspected, oral doxycycline may be required. Patients with keratitis should be referred to the ophthalmologist as they will require topical steroids.

Cataracts

Cataract (Fig. 20.26a,b) is by far the commonest cause of preventable blindness in the world with an effective surgical treatment. In the UK approximately 250,000 cataract operations are performed each year, making it the commonest surgical procedure.

Aetiology

Age-related opacification of the lens (cataract) is the commonest cause of visual impairment with 30% of people over 65 years having visual acuities below that required for driving (Snellen acuity less than 6/12). The common causes of cataracts are summarized in Table 20.7.
In young patients, familial or congenital causes should be excluded. Any history of ocular inflammation is noted. Cataracts diagnosed in infants demand urgent referral to the ophthalmologist in order to minimize the subsequent development of amblyopia.

Clinical features
Gradual painless deterioration of vision is the commonest symptom. Other symptoms are dependent upon the type of cataract, for example a posterior capsular type would lead to glare and problems with night driving. Early changes in the lens are correctable by spectacles but eventually the opacification needs surgical intervention.

Investigations
Blood glucose, serum calcium and liver biochemistry should be measured to diagnose metabolic disorders.

Treatment
Cataract extraction with the insertion of an intraocular lens is the treatment of choice (Fig. 20.26c). The aetiology and density of the cataracts usually determines the technique employed. Currently, small incision surgery called phacoemulsification is the most popular technique used for routine cases.

Fig. 20.26 Cataracts. (a) Early cataract. (b) White mature cataract. (c) Artificial intraocular lens following phacoemulsification.

Fig. 20.27 (a) Normal optic disc and (b) glaucomatous optic disc. The central cup is enlarged and deepened.

GLAUCOMA

This refers to a group of diseases where the pressure inside the eye is sufficiently elevated to cause optic nerve damage and result in visual field defects (Fig. 20.27). Normal intraocular pressure (IOP) is between 10 and 21 mmHg. Some types of glaucoma can result in an IOP exceeding 70 mmHg. Glaucoma as a disease entity is the second commonest cause of blindness world-wide and the third commonest cause of blind registration in the UK.

Primary open-angle glaucoma (POAG)

This is the commonest form of glaucoma. High intraocular pressures result from reduced outflow of aqueous humour through the trabecular meshwork. The cause of this increased resistance to aqueous outflow at the level of the meshwork is not fully understood. Common risk factors include age (0.02% of 40-year-olds vs 10% of 80-year-olds), race (black Africans are at five times greater risk than whites), positive family history and myopia.

POAG causes a gradual, insidious, painless loss of peripheral visual field. The central vision remains good until the end-stage of the disease. Diagnosis is only made if the IOP is measured. The optic disc is inspected and shows an enlarged cup with a thin neuroretinal rim. Visual fields are performed and show a normal blind spot with scotomas. Most patients are identified as having glaucoma whilst undergoing a routine ophthalmic examination.

Treatment
Treatment aims to reduce the IOP and this is achieved either by reducing aqueous production or increasing aqueous drainage. Beta-blockers such as timolol, carteoloi and levobunolol reduce aqueous production and are the commonest prescribed topical agents. These drugs are contraindicated in patients with COPD, asthma or heart block. Prostaglandin analogues such as latanoprost and travoprost, increase aqueous outflow and are also used (alone or in combination with beta-blockers) for POAG as they can reduce IOP by 30%. Patients should be monitored as the irises can become brown. Carbonic anhydrase inhibitors such as acetazolamide reduce aqueous production and are available in both topical and oral form. In its oral form acetazolamide is the most potent drug for reducing ocular pressure. It should not be used in patients with sulphonamide allergy.

Acute angle-closure glaucoma (AACG)

This is an ophthalmic emergency. In this type of glaucoma there is a sudden rise in intraocular pressure to levels greater
than 50 mmHg. This occurs due to reduced aqueous drainage as a result of the ageing lens pushing the iris forward against the trabecular meshwork. People most at risk of developing AACG are those with shallow anterior chambers such as hypermetropes and women. The attack is more likely to occur under reduced light conditions when the pupil is dilated.

AACG causes sudden onset of a red painful eye and blurred vision. Patients become unwell with nausea and vomiting and complain of headache and severe ocular pain. The eye is injected, tender and feels hard. The cornea is hazy and the pupil is semi-dilated (Fig. 20.28). Table 20.8 shows the differential diagnosis of the acute red eye. Emergency Box 20.1 shows features that require urgent referral to an ophthalmologist.

Prompt treatment is required to preserve sight and includes i.v. acetazolamide 500 mg (provided there are no contraindications) to reduce IOP, and instillation of pilocarpine 4% drops to constrict the pupil to improve aqueous outflow and prevent iris adhesion to the trabecular meshwork. Other topical drops such as beta-blockers and prostaglandin analogues can also be instilled if available, provided there are no contraindications. Analgesia and antiemetics are given as required.

These patients must be referred to an ophthalmologist immediately so that reduction in IOP can be monitored and other agents such as oral glycerol or i.v. mannitol can be administered to non-responding patients. Definitive treatment involves making a hole in the periphery of the iris of both eyes either by laser or surgically.

**UVEITIS**

Uveitis is inflammation of the uveal tract, which includes the iris, ciliary body and choroid. Inflammation confined to the anterior segment of the eye (in front of the iris) is referred to as iritis or anterior uveitis, that involving the ciliary body is referred to as intermediate uveitis whilst inflammation of the choroid is termed posterior uveitis. If all three regions are involved then the term pan-uveitis is used.

The most common symptoms of uveitis are blurred vision, pain, redness, photophobia and floaters. Each symptom is determined by the location of the inflammation such that photophobia and pain are common features of iritis whilst floaters are commonly seen with posterior uveitis.

Uveitis is commonly encountered with ankylosing spondylitis and positive HLA-B27 (see p. 533), arthritis, inflammatory bowel disease, sarcoid, tuberculosis, syphilis, toxoplasmosis, Behçet’s syndrome, lymphoma and viruses such as herpes, cytomegalovirus and HIV. In a number of patients no cause is found (idiopathic uveitis).

**Anterior uveitis (iritis)**

The classic presentation entails a triad of eye symptoms: redness, pain and photophobia. Vision can be normal or blurred depending on the degree of inflammation. The eye can be generally red or the injection can be localized to the limbus. The anterior chamber shows features consistent with inflammation including cells with keratic precipitates (KP) on the corneal endothelium, fibrin or hypopyon (pus), and the pupil may have adhered to the lens (posterior synechiae) (Fig. 20.29). The IOP may be normal or raised either due to cells

---

**Emergency Box 20.1**

**Red Flags for a red eye**

The following symptoms require urgent referral:
- severe pain
- photophobia
- reduced vision
- coloured halos around point of light in a patient’s vision
- proptosis
- smaller pupil in affected eye

On medical assessment:
- high intraocular pressure
- corneal epithelial disruption
- shallow anterior chamber depth
- ciliary flush

**Fig. 20.29 Anterior uveitis. (a) Acute with hypopyon. (b) Showing keratic precipitates on the corneal endothelium.**
clogging up the trabecular meshwork or posterior synechiae causing aqueous to build up behind the iris and force the iris against the trabecular meshwork and so reduce aqueous drainage.

**Treatment**

This consists of reducing inflammation with the use of topical steroids such as dexamethasone 0.1% and dilating the pupil with cyclopentolate 1% to prevent formation of posterior synechiae. Dilatation also allows fundoscopy to exclude posterior segment involvement. If the IOP is raised, this is treated with either topical beta-blockers, prostaglandin analogues, or oral or i.v. acetazolamide. These patients should be referred to the ophthalmologist.

**DISORDERS OF THE RETINA**

### Central retinal vein occlusion (CRVO)

This usually leads to profound sudden painless loss of vision with thrombosis of the central retinal vein at or posterior to the lamina cribrosa where the optic nerve exits the globe. The thrombus causes obstruction to the outflow of blood leading to a rise in intravascular pressure. This results in dilated veins, retinal haemorrhage, cotton wool spots, and abnormal leakage of fluid from vessels resulting in retinal oedema (Fig. 20.30). In severe cases an afferent papillary defect is usually present (see p. 1103).

Predisposing factors include increasing age, hypertension and cardiovascular disease, diabetes, glaucoma, blood dyscrasias and vasculitis.

**Treatment**

Treatment of any underlying medical condition is mandatory. Referral to an ophthalmologist is essential to monitor the eye, as some patients can develop retinal ischaemia with resulting neovascularization of the retina and iris. Patients who develop iris neovascularization, rubeosis, are at risk of developing rubeotic glaucoma.

### Central retinal artery occlusion (CRAO)

This results in sudden painless severe loss of vision. Retinal arterial occlusion results in infarction of the inner two-thirds of the retina. The arteries become narrow and the retina becomes opaque and oedematous. A cherry red spot is seen at the fovea because the choroid shows up through the thinnest part of the retina (Fig. 20.31). An afferent papillary defect is usually present (see p. 1103).

Arteriosclerosis-related thrombosis is the most common cause of CRAO. Emboli from atheromas and diseased heart valves are other causes. Giant cell arteritis (see p. 1138) must be excluded.

**Treatment**

CRAO is an ophthalmic emergency since studies have shown that irreversible retinal damage occurs after 90 minutes of onset. Ocular massage and 500 mg i.v. acetazolamide help to reduce ocular pressure and may help in dislodging the emboli. Breathing into a paper bag allows a build-up of carbon dioxide which acts as a vasodilator and so helps in dislodging the emboli. Other options include making a corneal paracentesis to drain off some aqueous humour, thereby reducing the intraocular pressure.

Patients with CRAO should have a thorough medical evaluation to determine the aetiology of the emboli or thrombus. Some patients may present with transient loss of vision or amaurosis fugax (see p. 1128). All patients with CRAO and amaurosis fugax should be started on oral aspirin if it is not medically contraindicated.

### Retinal detachment

This causes a painless progressive visual field loss. The shadow corresponds to the area of detached retina. Following a tear in the retina, fluid collects in the potential space between the sensory retina and the pigment epithelium (Fig. 20.32). Patients usually report a sudden onset of floaters often associated with flashes of light prior to the detachment. These patients should be referred to an ophthalmologist for a detailed fundal examination.

### Age-related macular degeneration (AMD)

This is the commonest cause of visual impairment in patients over 50 years in the western world, andblind registration in this age group. It affects 10% of people over 65 years and 30% over 80 years. Mutations in various genes have been reported; fubulin 5, complement factor 8, Arg 80 Gly variant of complement C3.

The cause is unknown but suggested risk factors include increasing age, smoking, hypertension, hypercholesterolaemia and ultraviolet exposure.

There are two types:

- **Non-exudative (dry) macular degeneration** describes a painless and progressive loss of vision. With age,
lipofuscin deposits (drusen) are found between the retinal pigment epithelium (RPE) and Bruch's membrane (see Fig. 20.13 and Fig. 20.33a). Drusen may be hard or soft and there may be focal RPE detachment. Not all patients with these changes will be affected visually but some develop distortion and blurring of their central vision. Extensive atrophy of RPE can occur (geographic atrophy).

- **Exudative (wet) AMD** (10% of cases) occurs with the development of abnormal subfoveal choroidal neovascularization in the region of the macula and causes severe central visual loss (Fig. 20.33b).

### Treatment

The Age-Related Eye Disease Study (AREDS) has shown that vitamins C and E, β-carotene, zinc and copper have been shown to slow progression of the disease. Anti-vascular endothelial growth factors (anti-VEGF) are being used in the treatment of wet AMD. Pegaptanib, ranibizumab and bevacizumab are given by intravitreal injections while verteporfin is given intravenously and activated by local eye irradiation using non-thermal red light.

Patients with central distortion or with frank macular pathology should be referred to the ophthalmologist for assessment of treatment. Only a few patients will fulfill the clinical requirement to receive laser treatment or photodynamic therapy (PDT). All patients should be assessed for low-vision aids such as magnifying glasses as this may help to improve their independence.

### CAUSES OF VISUAL LOSS

Box 20.3 summarizes the causes of visual loss. In developing countries the common causes of blindness are similar to those in the developed world and include trauma, cataract, diabetic retinopathy, glaucoma and macular degeneration. In addition, trachoma due to *Chlamydia trachomatis* (see p. 143) accounts for 10% of global blindness and onchocerciasis (river blindness) due to *Onchocerca volvulus* (see p. 165) accounts for blindness in about 1 million people, although this is decreasing with treatment. In leprosy, 70% of patients have ocular involvement, and blindness occurs in 5–10% of these. Ocular involvement is common in cerebral malaria (see p. 155), although loss of vision is rare. HIV infection can produce uveitis but the major problem is severe opportunistic infection of the eye when the CD4 count falls (see p. 202).

Vitamin A deficiency and xerophthalmia affects millions each year, and the WHO classification of xerophthalmia by ocular signs is shown in Table 5.10 (see p. 219).

### FURTHER READING

Neurology is a large and diverse subject which covers many conditions that require long-term coordinated care and have serious effects on the daily lives of patients and their families. Prevalence rates vary widely between countries, being dependent upon incidence (Table 21.1), prognosis and level of medical care provided.

- What is/are the site(s) of the lesion(s)?
- What is the likely pathology?
- Does a recognizable disease fit this pattern?

This is the essence of clinical diagnosis. Notes of symptoms should portray the story from the patient or relatives.

**Headaches**

*Headache* is an almost universal experience and one of the most common symptoms in medical practice. It varies from an infrequent and trivial nuisance to a pointer to serious disease.

**Mechanisms**

Pain receptors are located at the base of the brain in arteries and veins and throughout meninges, extracranial vessels, scalp, neck and facial muscles, paranasal sinuses, eyes and teeth. Curiously, brain substance is almost devoid of pain receptors.

Head pain is mediated by mechanical and chemical receptors (e.g. stretching of meninges, 5-HT and histamine stimulation). Nerve impulses travel centrally via the Vth and IXth cranial nerves and upper cervical sensory roots.

Most headaches are benign, but the diagnostic issue – and usual concern – is the question of serious disease. Here are some useful clinical pointers.

**Chronic (benign) and recurrent headaches**

Almost all recurring headaches lasting hours or days – band-like, generalized head pains, with a history for several years or months – are vaguely ascribed to muscle tension and/or migraine (p. 1136). Depression is a common accompaniment.

In localized pain of short duration (minutes to hours), sinusitis, glaucoma and migraineous neuralgia (p. 1137) should be considered. Headaches are not caused by essential hypertension; malignant hypertension, with arterial damage and brain swelling, occasionally causes headache (p. 1096).

Eye strain from refractive error does not cause headache, though new prescription lenses sometimes provoke pain.

**Pressure headaches**

Intracranial mass lesions displace and stretch meninges and basal vessels. Pain is provoked when these structures are shifted either by a mass or by changes in cerebrospinal fluid (CSF) pressure, e.g. coughing. Cerebral oedema around brain tumours causes further shift. These ‘pressure headaches’ typically become worse on lying down.

Any headache present on waking and made worse by coughing, straining or sneezing may be due to a mass lesion. Vomiting often accompanies pressure headaches. Such headaches are caused early, over days or weeks, by posterior fossa masses (see hydrocephalus, p. 1162), but over a longer time scale – months or years – by hemisphere tumours.

A rare cause of prostrating headache with lower limb weakness is an intraventricular tumour causing intermittent hydrocephalus.

**Headache of subacute onset**

The onset and progression of a headache over days or weeks with or without features of a pressure headache should always raise suspicion of an intracranial mass or serious intracranial disease. Encephalitis (p. 1156), viral meningitis (p. 1154) and chronic meningitis (p. 1155) should also be considered.

**Headaches with scalp tenderness**

Patches of exquisite tenderness overlying superficial scalp arteries are caused by giant cell arteritis (p. 1138) in patients over 50.

**Headache following head injury**

The majority of post-trauma headaches lasting days, weeks or months are not caused by any serious intracranial pathology. However, subdural haematoma (p. 1135) must be considered.

**A single episode of severe headache**

This common emergency is caused by one of the following:

- subarachnoid haemorrhage (SAH) and cerebral arterial dissection
- migraine, or other benign headaches
- meningitis (occasionally).

Particular attention should be paid to suddenness of onset (suggestive of SAH). The exact time of onset, time to peak, duration, associated symptoms and previous headache history should be documented. Neck stiffness, vomiting (meningeal irritation) and a rash and/or fever suggest bacterial meningitis.

**Difficulty walking and falls**

Change in walking pattern is a common complaint (Table 21.2). Arthritis and muscle pain make walking stiff and slow (antalgia). The pattern of gait is valuable diagnostically.
Spasticity and hemiparesis
Spasticity (p. 1112), more pronounced in extensor muscles, with or without weakness, causes stiff and jerky walking. Toes of shoes become scuffed, catching level ground. Pace shortens; a narrow base is maintained. Clonus – involuntary extensor rhythmic leg jerking – may occur.

In a hemiparesis when spasticity is unilateral and weakness marked, the stiff, weak leg is circumducted and drags.

Parkinson’s disease: shuffling gait
There is muscular rigidity (p. 1146) throughout extensors and flexors. Power is preserved; the pace shortens, and slows to a shuffle; its base remains narrow. A stoop and diminished arm swinging become apparent. Gait becomes festinant (hurried) with short rapid steps. There is difficulty turning quickly and initiating movement, sometimes with falls. Retropulsion means small backward steps, taken involuntarily when a patient is halted.

Cerebellar ataxia: broad-based gait
In lateral cerebellar lobe disease (p. 1114) stance becomes broad-based, unstable and tremulous. Ataxia describes this incoordination. When walking, the person tends to veer to the side of the affected cerebellar lobe.

In disease of midline structures (cerebellar vermis), the trunk becomes unsteady without limb ataxia, with a tendency to fall backwards or sideways – truncal ataxia.

Sensory ataxia: stamping gait
Peripheral sensory lesions (e.g. polyneuropathy, p. 1172) cause ataxia because of loss of proprioception (position sense). Broad-based, high-stepping, stamping gait develops. This form of ataxia is exacerbated by removal of sensory input (e.g. vision) and worse in the dark. Romberg’s test, first described in sensory ataxia of tabes dorsalis (p. 1157), becomes positive.

Lower limb weakness: slapping and waddling gaits
When weakness is distal, each foot must be lifted over obstacles. When ankle dorsiflexors are weak, e.g. in a common peroneal nerve palsy (p. 1172), the sole returns to the ground with an audible slap.

Weakness of proximal lower limb muscles (e.g. polymyositis, muscular dystrophy) causes difficulty rising from sitting. Walking becomes a waddle, the pelvis being poorly supported by each leg.

Gait apraxia
With frontal lobe disease (e.g. tumour, hydrocephalus, infarction), acquired walking skills become disorganized. Leg movement is normal when sitting or lying but initiation and organization of walking fail. Shuffling small steps (marche à petits pas), gait ignition failure or undue hesitancy may predominate. Urinary incontinence and dementia are often present.

Falls
Falls in the elderly are a major cause of hospital admission, e.g. following fractures. Often no precise cause can be found. A multidisciplinary approach is essential, e.g. reviewing risk factors such as rugs, stairs, footwear and home circumstances.

Dizziness, vertigo and blackouts
Dizziness covers many complaints, from a vague feeling of unsteadiness to severe, acute vertigo. It is frequently used to describe light-headedness, panic, anxiety, palpitations and chronic ill-health. The real nature of this symptom must be determined.

Vertigo (p. 1108) means the illusion of movement, a sensation of rotation or tipping. The patient feels the surroundings are spinning or moving. This is distressing and often accompanied by nausea or vomiting.

Blackout, like dizziness, is simply descriptive, implying either altered consciousness, visual disturbance or falling. Epilepsy (p. 1139) and syncope are mentioned in detail (p. 1144); hypoglycaemia and anaemia must be considered. Commonly no sinister cause is found. A careful history is essential.

Collapse is a vague term, but often used. Avoid it.

No serious disease is found in many patients (>20%) referred with symptoms suggestive of possible neurological conditions. y.

Fatigue is common: when it is an isolated symptom, neurological disease is rarely discovered. There is a borderland (sometimes contentious) between neurology and psychiatr

**EXAMINATION AND FORMULATION** (see Practical boxes 21.1 and 21.2 and Table 21.3)

Following a short or detailed examination, relevant findings are summarized in a brief formulation – the basis for investigation, transfer of information and management.

### Practical Box 21.1 Five-part short neurological examination

1. **Look at the patient**
   - General demeanour
   - Speech
   - Gait
   - Arm swinging

2. **Head**
   - Fundi
   - Pupils
   - Eye movements
   - Facial movements
   - Tongue

3. **Upper limbs**
   - Posture of outstretched arms
   - Wasting, fasciculation
   - Power, tone
   - Coordination
   - Reflexes

4. **Lower limbs**
   - Power
   - Tone
   - Reflexes
   - Plantar responses

5. **Sensation**
   - Ask the patient
Practical Box 21.2 Ten-part neurological examination

1. State of consciousness, arousal, appearance
2. Mental state, attitude, insight
3. Cognitive function
   - Orientation, recall, level of intellect, language, other cortical problems, e.g. apraxia
4. Gait and balance tests
5. Skull – contour, bruits
6. Neck – stiffness, palpation and auscultation of carotids
7. Cranial nerves (Table 21.5)
8. Motor system
   - Upper limbs:
     - Wasting and fasciculation
     - Posture of arms: drift, rebound, tremor
     - Tone: spasticity, clonus, extrapyramidal rigidity
     - Power: 0–5 scale (Table 21.3)
   - Thorax and abdomen:
     - Respiration
     - Thoracic and abdominal muscles
     - Abdominal reflexes
     - Cremasteric reflexes
   - Lower limbs:
     - Wasting and fasciculation
     - Tone, power and tendon reflexes
   - Plantar responses
9. Coordination and fine movements
10. Sensory system
    - First: is feeling in limbs, face and trunk normal?
    - Posterior columns:
      - Vibration (128 Hz tuning fork)
      - Joint position
      - Light touch
      - 2-point discrimination (normal: 0.5 cm finger tips, 2 cm soles)
    - Spinthalamic tracts:
      - Pain: use a split orange-stick or a sterile pin
      - Temperature: warm and cold objects
      - If sensation is abnormal, chart areas involved

FUNCTIONAL NEUROANATOMY

The neurone and synapse

The neurone is the functional unit of the entire nervous system (Fig. 21.1). Its cell body and axon terminate in a synapse. Size and type of each group of neurones vary. A thoracic spinal cord α-motor neurone has an axonal length of more than 1 metre and innervates between several hundred and 2000 muscle fibres in one leg – a motor unit. By contrast, some spinal or intracerebral interneurones have axons under 100 μm long, terminating on one neuronal cell body.

Neurotransmitters

Neurotransmitters are excitatory (acetylcholine, noradrenaline, adrenaline, 5-hydroxytryptamine, dopamine, glutamate and aspartate) or inhibitory (gamma-aminobutyric acid (GABA), histamine and glycine). Neuropeptides, e.g. vasopressin, ACTH, substance P and opioid peptides, as well as the purines (ATP and AMP) are both excitatory and inhibitory. Nitric oxide also has modulatory properties.

Synaptic transmission is mediated by neurotransmitters released by action potentials passing down an axon. Neurotransmitters react with postsynaptic receptors and are removed by transporter proteins. The neurotransmitter-receptor reaction increases ionic permeability and propagates a further action potential. Axonal electrical activity and synaptic chemical release is the basis of neurological function.

The role of neurotransmitters in pathogenesis continues to be evaluated; acute and chronic neuronal injury is mediated by a final common pathway involving excessive stimulation of glutamate receptors.

Clinical features of focal brain lesions: general mechanisms

The symptoms and signs suggest the area of the brain that is malfunctioning (for example, aphasia – the left frontal lobe, hemiparesis – internal capsule, or a Bell’s palsy – VIIth cranial (facial) nerve).
Principal features of destructive cortical lesions in a right-handed individual.

Focal lesions of the cortex, and lesions throughout the nervous system, cause symptoms and signs by two processes:
- Suppression or destruction of neurones and surrounding structures (Fig. 21.2). This is the commonest process – part of the system simply fails to work.
- Synchronous discharge of neurones by irritative lesions (Fig. 21.3), e.g. cortical lesions, causes epilepsy, either partial or generalized.

Localization within the cerebral cortex

This subject causes unnecessary difficulty. Work on neuronal networks, functional imaging and plasticity questions traditional views of highly specific localization of cortical function. The following paragraphs summarize areas of clinical relevance.

The dominant hemisphere (usually left)

The concept of cerebral dominance arose from a simple observation: right-handed stroke patients with acquired language disorders had destructive lesions within the left hemi-

Fig. 21.2 Principal features of destructive cortical lesions in a right-handed individual.

Fig. 21.3 Effects of irritative cortical lesions.

sphere. Right-handed (and 70% of left-handed) people have language function on the left. More specifically, destructive lesions within the left fronto-temporo-parietal region cause disorders of communication:
- spoken language – aphasia, also called dysphasia
- writing – agraphia
- reading – acquired alexia.

Developmental dyslexia describes delayed, disorganized reading and writing ability in children, usually with normal intelligence.

Aphasia

Aphasia is loss of or defective language from damage to the speech centres within the left hemisphere. Numerous varieties have been described.

Broca’s (expressive, anterior) aphasia

Damage in the left frontal lobe causes reduced speech fluency with relatively preserved comprehension. The patient makes great efforts to initiate language, which becomes reduced to a few disjointed words with failure to construct sentences. Patients who recover say they know what they wanted to say, but could not get the words out.

Wernicke’s (receptive, posterior) aphasia

Left temporo-parietal damage leaves fluency of language but words are muddled. This varies from insertion of a few incorrect or non-existent words into speech to a profuse outpouring of jargon (i.e. rubbish with wholly non-existent words). Severe jargon aphasia is bizarre and often mistaken for psychotic behaviour.

Patients who recover from Wernicke’s aphasia say that they found speech, both their own and others’, like an unintelligible foreign language, i.e. incomprehensible, but they could neither stop speaking nor understand speech.

Nominal (anomic, amnestic) aphasia

This means difficulty naming familiar objects. Naming difficulty is an early feature in all types of aphasia.
Global (central) aphasia
This means the combination of the expressive problems of Broca’s aphasia and the loss of comprehension of Wernicke’s with loss of both language production and understanding. This is due to widespread damage to speech areas and is the commonest aphasia after a severe left hemisphere infarct. Writing and reading are also affected.

Dysarthria
Dysarthria is disordered articulation – slurred speech. Language is intact. Paralysis, slowing or incoordination of muscles of articulation or local discomfort causes various patterns of dysarthria. Examples are the gravelly speech of pseudobulbar palsy (p. 1110), the jerky, ataxic speech of cerebellar lesions, the monotone of Parkinson’s, and speech in myasthenia that fatigues and dies away. Many aphasic patients are also dysarthric.

The non-dominant hemisphere
Disorders in right-handed patients with right hemisphere lesions are often difficult to recognize. There are abnormalities of perception of internal and external space. Examples are losing the way in familiar surroundings, failing to put on clothing correctly (dressing apraxia), or failure to draw simple shapes – constructional apraxia.

Memory and its disorders
Disorders of memory follow damage to the medial surfaces of both temporal lobes and their brainstem connections – the hippocampi, fornices and mammillary bodies. Bilateral lesions are necessary to cause amnesia. In all organic memory disorders recent events are recalled poorly, in contrast to the relative preservation of distant memories.

Memory loss (the amnestic syndrome) is part of dementia (p. 1167) but also occurs as an isolated entity (Table 21.4).

Neuroanatomy: essential elements
For clinical purposes the complexity of neuroanatomy must be reduced to its core elements:

- cranial nerves
- three systems of motor control:
  - corticospinal or pyramidal system
  - extrapyramidal system
  - cerebellum
- motor unit
- reflex arc
- sensory pathways and pain
- control of the bladder and sexual function.

Fig. 21.4 The visual pathway.
1 Paracentral scotoma – retinal lesion.
2 Mononuclear field loss – complete optic nerve lesion.
3 Bitemporal hemianopia – chiasmal lesion.
4 Homonymous hemianopia – optic tract lesion.
5 Homonymous quadrantanopia – temporal lesion.
6 Homonymous quadrantanopia – parietal lesion.
7 Homonymous hemianopia with macular sparing – occipital cortex or optic radiation.
8 Homonymous hemianopia (hemiscotoma) – occipital pole lesion.

(5 and 6) to reach the visual, or calcarine, cortex of the occipital lobe (7 and 8). Upper retinæ (lower visual fields) project in the optic radiation through the parietal lobes to the upper part of the visual cortex, and the lower retinæ (upper fields) through the temporal lobes, to the lower visual cortex.

Impulses reach the cortex in strictly vertical topographical order (i.e. upper field to lower retina, tract, radiation and cortex, and vice versa.). Within the visual cortex itself there are synaptic connections between groups of cells that detect lines, orientation, shapes, movement, colour and depth. These are processed by neighbouring visual association areas.

Visual field defects caused by lesions of each optic tract, radiation and cortex are called homonymous to indicate the different (i.e. bilateral) origins of each unilateral pathway. A homonym is one word used to denote different things.

Field defects are hemianopic when half the field is affected and quadrantanopic when a quadrant is affected. Congruous denotes symmetry, and incongruous, lack of symmetry. Bitemporal defects (damage to crossing nasal fibres) are caused by optic chiasm lesions.

Visual acuity
This is assessed with a Snellen chart and/or Near Vision Reading Types, corrected for refractive errors with lenses or a pinhole occluder. Normal acuity is 6/6 to 6/9; if less, an explanation is necessary.

Visual loss is discussed on page 1094. Causes include:
- ocular causes, e.g. glaucoma, macular degeneration, cataract, retinal detachment, diabetes, trachoma, leprosy, vitamin A deficiency, trauma, onchocerciasis (river blindness)
- lesions of the visual pathway (optic nerve, chiasm, tract, radiation or cortex).

Visual field defects (Fig. 21.4)
These are checked by confrontation with white- and red-headed pins and, if abnormal or in doubt, recorded with a Goldmann (or similar) screen.

Retinal and local eye lesions (1, Fig. 21.4)
These produce either scotomata (holes) or peripheral visual loss (tunnel vision). Common causes are diabetic retinal vascular disease, glaucoma and retinitis pigmentosa. Local lesions (e.g. cataract) also cause visual loss.

Optic nerve lesions (2, Fig. 21.4)
Unilateral visual loss, commencing with a central or paracentral (off-centre) scotoma, is the hallmark of an optic nerve lesion. A total optic nerve lesion causes unilateral blindness with loss of pupillary light reflex (direct and consensual) when the blind eye is illuminated (see afferent pupillary defect, p. 1103). Causes are listed in Table 21.6.

The principal pathological appearances of the nerve (optic disc) are:
- disc swelling and hyperaemia (papilloedema)
- disc pallor (optic atrophy).

Papilloedema and optic neuritis
Papilloedema simply means swelling of the papilla – the optic disc (Table 21.7). In all forms of disc oedema there is axonal swelling within the optic nerve and blockage of axonal transport, with capillary and venous congestion.

Optic neuritis means inflammation in the nerve with swelling of the disc.

The earliest ophthalmoscopic signs of swelling are disc pinkness, with blurring and heaping up of disc margins, nasal first. There is loss of normal, visible, spontaneous pulsation
of retinal veins within the disc. The physiological cup becomes obliterated, the disc engorged with dilated vessels. Small haemorrhages often surround the disc.

Various conditions simulate true disc oedema. Marked hypermetropic (long-sighted) refractive errors make a disc appear pink, distant and ill-defined. Opaque (myelinated) nerve fibres at disc margins and hyaline bodies (drusen, p. 1094) can be mistaken for disc swelling.

Disc infiltration also causes a swollen disc with raised margins (e.g. in leukaemia).

When there is doubt about disc oedema, i.v. fluorescein angiography is diagnostic; retinal leakage is seen with papilloedema.

Early papilloedema from causes other than optic neuritis (e.g. a brain tumour) often produces few if any visual problems – the underlying disease is the source of the patient’s symptoms. However, as disc oedema progresses, blind spot enlargement and visual blurring develop. The disc becomes further engorged, its arterial blood flow falls; eventually, optic nerve infarction occurs, with sudden severe and permanent visual loss.

**Optic neuritis**

*Multiple sclerosis* is the most common cause of inflammation within the optic nerve. Disc swelling and visual loss due to optic neuritis is usually accompanied by dull ocular pain. *Retrobulbar neuritis* means that the inflammation is within the optic nerve but behind the eye; no abnormality is seen at the disc despite visual impairment.

*Leber’s hereditary optic neuropathy (LHON)*

LHON is a cause of isolated blindness in otherwise healthy young men. Unilateral or bilateral optic nerve neuropathy develops over days or weeks. There is sometimes disc swelling and telangiectasia around the disc in the acute phase, followed by optic atrophy. Severe bilateral visual loss is usual by the age of 40. Genetic analysis points to mitochondrial DNA mutations (p. 37), in many cases at G11778A. Exceptional cases occur in women.

**Optic atrophy**

Optic atrophy means disc pallor, from loss of axons, glial proliferation and decreased vascularity. This follows many processes, e.g. nerve infarction from thromboembolism or following papilloedema, inflammation (demyelinating optic neuritis in MS, syphilis, LHON), optic nerve compression, previous trauma, and toxic and metabolic causes (vitamin B₁₂ deficiency, quinine and methyl alcohol). Optic atrophy is called consecutive or secondary when it follows papilloedema of any cause. The degree of visual loss depends upon underlying pathology.

**Optic chiasm (3, Fig. 21.4)**

*Bitemporal hemianopic* fields occur when a mass compresses the chiasm. Common causes are:

- pituitary neoplasm (p. 972)
- meningioma
- craniopharyngioma
- secondary neoplasm.

In *any* case of bilateral visual loss, chiasmal compression must always be considered; with unilateral visual loss consider an optic nerve compression.

**Optic tract and optic radiation (4, 5 and 6, Fig. 21.4)**

Optic tract lesions (rare) cause field defects that are homonymous, hemianopic and often incomplete and incongruous. Optic radiation lesions cause homonymous quadrantanopic defects. Temporal lobe lesions (e.g. tumour, infarction) cause upper quadrant defects, and parietal lobe, lower.

**Occipital cortex (7 and 8, Fig. 21.4)**

Homonymous hemianopic defects are produced by unilateral posterior cerebral artery infarction. The macular cortex (at each occipital pole) is spared; it has a separate blood supply via the middle cerebral artery. Infarction of one occipital pole causes a small, congruous, scotomatous, homonymous hemianopia (8).

Widespread bilateral occipital lobe damage by infarction, trauma or tumour causes *cortical blindness* (Anton’s syndrome). The patient cannot see but characteristically lacks insight into this; he or she may even deny it. Pupillary responses remain normal (p. 1130).

**Pupil dilatation**

Sympathetic impulses via fibres in the nasociliary nerve pass to dilator pupillae. Sympathetic preganglionic fibres to the eye (and face) originate in the hypothalamus, pass uncrossed through midbrain and lateral medulla, and emerge from the spinal cord at T₁ (close to the lung apex) to form the superior cervical ganglion at C₂. Postganglionic fibres form a plexus around the carotid bifurcation. Fibres pass to the pupil from part of this plexus surrounding the *internal* carotid. Those fibres to the face (sweating and piloerection) arise from the part of the plexus surrounding the *external* carotid. See Horner’s syndrome (p. 1103).
Pupil constriction

Parasympathetic impulses cause pupillary constriction. Fibres in the short ciliary nerves arise from the ciliary ganglion and pass to *sphincter pupillae*, causing constriction. Parasympathetic and light reflex pathways are shown in Figure 21.5.

Light reflex

Light constricts the pupil being illuminated (direct reflex) and, by the consensual reflex, the contralateral pupil (Fig. 21.5).

Convergence reflex

Fixation (voluntary or reflex) on a near object requires convergence of the ocular axes and is accompanied by pupillary constriction. Afferent fibres in each optic nerve, passing through each lateral geniculate body, also relay to the *convergence centre*. This centre receives 1a spindle afferents from extraocular muscles – principally medial recti, innervated by the IIIrd nerve.

The efferent autonomic route is convergence centre to Edinger–Westphal nucleus to ciliary ganglion and pupils.

Clinical abnormalities of the pupils

Pupillary abnormalities in coma are discussed on page 1124, and those in brainstem death on page 920. It is easier to see pupillary reactions in a darkened room and with a bright torch.

Physiological changes and old age

A slight difference between the size of each pupil is common (*physiological anisocoria*). The pupil tends to become small (3–3.5 mm) and irregular in old age (senile miosis); anisocoria is more pronounced. Convergence becomes sluggish with ageing.

Afferent pupillary defect. A blind left eye, for example following complete optic nerve section, has a pupil larger than the right. The features of a *left afferent pupillary defect* are:

- The left pupil is unreactive to light (i.e. the direct reflex is absent).
- The consensual reflex (constriction of the right pupil when the left is illuminated) is absent. Conversely, the left pupil constricts when light is shone in the intact right eye, i.e. the consensual reflex of the right eye remains intact.

Relative afferent pupillary defect (RAPD). This occurs with incomplete damage to one afferent pupillary pathway (i.e. of one optic nerve relative to the other). RAPD can provide evidence of a left optic nerve lesion, when, for example, left retrobulbar neuritis occurred previously with complete clinical recovery of vision (p. 1152):

- Light shone in the left eye causes both pupils to constrict.
- When light is shone into the intact right eye, both pupils again constrict (i.e. right direct and consensual reflexes are intact).
- When the light is swung back to the affected, left eye, its pupil dilates slightly, relative to its previous size.

A left RAPD by the swinging light test indicates residual damage in the afferent pupillary fibres of the left optic nerve – the consensual reflex is stronger than the direct.

Horner’s syndrome

Unilateral pupillary constriction with slight ptosis and enophthalmos (Horner’s) indicates a sympathetic pathway lesion on the same side. The conjunctival vessels become slightly injected (Table 21.8). There is diminution of sweating on the same side, the extent depending upon the level of the lesion:

- Central lesions affect sweating over the entire half of the head, arm and upper trunk.
- Neck lesions proximal to the superior cervical ganglion cause diminished facial sweating.
- Lesions distal to the superior cervical ganglion do not affect sweating at all.

Testing with adrenaline can help indicate the level of the lesion. When drops of 1 : 1000 adrenaline are placed into the conjunctiva, the pupil dilates when the Horner’s lesion is distal to the superior cervical ganglion pupil (denervation hypersensitivity). This has little effect on a Horner’s pupil from a proximal lesion or on a normal pupil.

Myotonic pupil (Holmes–Adie pupil)

This is a dilated, often irregular, pupil, more frequent in women; it is common and usually unilateral. There is no (or very slow) reaction to bright light and also incomplete constriction to convergence. This is due to denervation in the ciliary ganglion, of unknown cause, and has no

---

**Afferent pathway**

1. Light generates action potentials in optic nerve axons.
2. Axons (some decussating at the chiasm) pass through each lateral geniculate body, and
3. Synapse at each pretectal nucleus.

**Efferent pathway**

4. Action potentials pass to each Edinger–Westphal nucleus of III, then,
5. Via IIIrd nerve, ciliary ganglion and short ciliary nerves to cause pupil constriction.
other pathological significance. A myotonic pupil is sometimes associated with diminished or absent tendon reflexes.

**Argyll Robertson pupil**

This small, irregular (3 mm or less) pupil is fixed to light but constricts on convergence. The lesion is in the brainstem surrounding the aqueduct of Sylvius.

![Fig. 21.6](image-url)  

(a) Principal input to PPRF  
(b) Principal output from PPRF

An Argyll Robertson pupil is (almost) diagnostic of neurosyphilis, though it is occasionally seen in diabetes.

### III, IV, VI: OCULOMOTOR, TROCHLEAR AND ABDUCENS NERVES

Mechanisms controlling eye movement are:

- central upper motor neurone mechanisms driving yoked parallel eye movements (conjugate gaze)
- movements generated via each oculomotor, abducens and trochlear nerve to muscles they supply.

**Conjugate gaze: yoked eye movements**

Fast voluntary and reflex eye movements originate in each frontal lobe. Fibres pass in the anterior limb of the internal capsule and cross in the pons to end in the centre for lateral gaze (paramedian pontine reticular formation – PPRF, Fig. 21.6a), close to each VIth nerve nucleus. Each PPRF also receives fibres from:

- the ipsilateral occipital cortex – pathway concerned with tracking objects
- both vestibular nuclei – pathways linking eye movements with position of the head and neck (doll’s head reflexes, p. 920).

Conjugate lateral eye movements are coordinated from each PPRF via the medial longitudinal fasciculus (MLF, Fig. 21.6b). Fibres from the PPRF pass both to the ipsilateral VIth nerve nucleus and, having crossed the midline, to the opposite IIIrd nerve nucleus via the MLF. Each VIth nucleus (lateral rectus) and the opposite IIIrd nerve nucleus (medial rectus and other muscles) are thus linked, enabling the eyes to be driven laterally, with axes parallel at the same velocity.

![Fig. 21.6](image-url)  

(a) Paramedian pontine reticular formation (PPRF): principal input. Impulses from right frontal cortex, left occipital cortex and both vestibular nuclei (VN) drive left PPRF. (b) PPRF: principal output. Impulses from PPRF pass via ipsilateral VIth nerve nucleus to lateral rectus muscle (ADduction) and via medial longitudinal fasciculus to right IIIrd nerve nucleus and thus to opposite medial rectus muscle (ADduction) of the right eye. A lesion at X gives limited ADduction to the right eye and nystagmus of the left eye.
Abnormalities of conjugate lateral gaze

A destructive lesion on one side allows yoked lateral gaze to be driven by the intact opposite pathway. A left frontal destructive lesion (e.g. an infarct) leads to failure of conjugate lateral gaze to the right. In an acute lesion the eyes are often deviated to the side of the lesion, past the midline and therefore look towards the left (normal) limbs; there is usually a contralateral (i.e. right) hemiparesis.

An irritative left frontal lobe lesion (e.g. an epileptic focus), stimulates the opposite, right, PPRF and drives lateral gaze away from the side of the lesion (i.e. to the right) during an attack.

In the brainstem a unilateral destructive lesion involving the PPRF leads to failure of conjugate lateral gaze towards that side. There is usually a contralateral hemiparesis and lateral gaze is deviated towards the side of the paralysed limbs.

Internuclear ophthalmoplegia

Damage to one MLF causes internuclear ophthalmoplegia (INO), a common complex brainstem oculomotor sign seen frequently in MS. In a right INO there is a lesion of the right MLF (Fig. 21.6b). On attempted left lateral gaze the right eye fails to AD duct. The left eye develops coarse nystagmus in AD duction. The side of the lesion is on the side of impaired ADDuction, not on the side of the (obvious, unilateral) nystagmus. When present bilaterally, INO is also pathognomonic of MS. A unilateral INO can also be caused by a small brainstem infarct.

Doll’s head reflexes and skew deviation

These are of some diagnostic value in coma (p. 920).

Abnormalities of vertical gaze

Failure of up-gaze is caused by an upper brainstem lesion such as a supratentorial mass or a brainstem tumour (e.g. pinealoma). When the pupillary convergence reflex fails in addition, this is called Parinaud’s syndrome. Convergence/retraction nystagmus can occur. Defective up-gaze also develops in certain degenerative disorders (e.g. progressive supranuclear palsy). Some impairment of up-gaze occurs as part of normal ageing.

Weakness of extraocular muscles

Diplopia (double vision) indicates weakness of one or more extraocular muscles. Causes are:

- lesions of the IIIrd, IVth and/or VIth cranial nerves or nuclei
- disorders of the neuromuscular junction (e.g. myasthenia gravis)
- disease of the ocular muscles and trauma
- orbital lesions.

Squint (strabismus)

Squint describes crossed or divergent eyes – the visual axes fail to meet at fixation. Squint is convergent or divergent, non-paralytic or paralytic.

Non-paralytic squint. Non-paralytic or concomitant squint describes a squint dating from infancy in which the angle between the visual axes does not vary when the eyes are moved – the squint remains the same in all directions of gaze. Diplopia is almost never a symptom. The deviating eye (the one that does not fixate) usually has defective (amblyopic) vision; this is called ambylophia ex anopsia. Non-paralytic squint may be latent (e.g. only visible when tired).

The cover test. The cover test is used principally to recognize latent squint. The patient is asked to fix on a light. When there is no squint, a pinpoint reflection is seen in the exact centre of each pupil. One eye is covered quickly. If a latent squint is present, the other (uncovered) eye moves to take up central fixation. The test is repeated with the opposite eye. The dominant, fixing eye will not move when the other, squinting, amblyopic eye is covered and uncovered.

Paralytic squint. Paralytic or inomitant squint occurs when there is an acquired defect of movement of an eye – the usual situation in neurological disease. There is a squint (and hence diplopia) maximal in the direction of action of the weak muscle.

III: Oculomotor nerve

The nucleus of the IIIrd nerve lies ventral to the aqueduct in the midbrain. Efferent fibres to four external ocular muscles (superior, inferior and medial recti, and inferior oblique), levator palpebrae superiors and sphincter pupillae (parasympathetic) enter the orbit through the superior orbital fissure. Causes of a IIIrd nerve lesion are listed in Table 21.9.

Signs of a complete IIIrd nerve palsy are:

- unilateral complete ptosis
- the eye facing down and out
- a fixed and dilated pupil.

Sparing of the pupil means that parasympathetic fibres remain undamaged; these run in a discrete bundle on the superior surface of the nerve, thus the pupil is of normal size and reacts normally. In diabetes, IIIrd nerve infarction usually spares the pupil.

In a IIIrd nerve palsy the eye can still AB duct (VIth nerve) and rotate inwards (intort, IVth). Preservation of intorsion (inward rotation) means that the IVth (trochlear) nerve is intact. To test this in a patient with a right IIIrd nerve palsy, ask the patient to look down and converge: conjunctival vessels of the right eye are seen to twist clockwise, indicating intorsion and an intact IVth nerve.

IV: Trochlear nerve

This supplies the superior oblique muscle. The patient complains of torsional diplopia (two objects at an angle) when attempting to look down (e.g. descending stairs); the head is tilted away from that side.

VI: Abducens nerve

This supplies the lateral rectus muscle (ABduction). There is an evident convergent squint with diplopia maximal looking to the side of the lesion. The eye cannot be ADducted beyond the midline. The VIth nerve has a long intracranial course. It can be damaged in the brainstem (e.g. by MS or pontine glioma). In raised intracranial pressure it is compressed against the tip of the petrous temporal bone. The nerve sheath may be infiltrated by tumours, particularly nasopharyngeal carcinoma. An isolated VIth nerve palsy occurs in diabetes (infarction) and is a common sequel of head trauma.

Complete external ophthalmoplegia

Complete external ophthalmoplegia describes an immobile eye when IIIrd, IVth and VIth nerves are paralysed at the orbital apex (e.g. by metastasis) or within the cavernous sinus (e.g. by sinus thrombosis).

V: TRIGEMINAL NERVE

This nerve is large and mainly sensory but has motor fibres.

Sensory fibres (Fig. 21.7; see also Figs 21.11 and 21.12) of the three divisions – opthalmic (V1), maxillary (V2) and mandibular (V3) – pass to the trigeminal (Gasserian) ganglion within the cavernous sinus at the apex of the petrous temporal bone. Central fibres enter the brainstem. Ascending fibres transmitting light touch enter the Vth nucleus in the pons. Descending central fibres carrying pain and temperature form the spinal tract of V, to end in the spinal Vth nucleus that extends from the medulla into the cervical cord.

Motor fibres arise in the upper pons and join the mandibular branch (V3) to supply muscles of mastication.

Fig. 21.7 Sensory input of Vth nerve (red) and motor output of VIth nerve (blue). GG, Gasserian ganglion; SOF, superior orbital fissure; FR, foramen rotundum; FO, foramen ovale; SF, stylomastoid foramen.

Signs of a Vth nerve lesion

A complete Vth nerve lesion causes unilateral sensory loss on the face, tongue and buccal mucosa, and the jaw deviates to that side as the mouth opens (motor fibres). Diminution of the corneal reflex is an early and sometimes isolated sign of a Vth nerve lesion.

Central (brainstem) lesions of the lower trigeminal nuclei (e.g. in syringobulbia, p. 1164) produce a characteristic circumoral sensory loss.

When the spinal nucleus alone is involved, sensory loss is restricted to pain and temperature sensation, i.e. dissociated (p. 1117).

Causes

Within the brainstem, lesions involve Vth nuclei and central connections, e.g.:

- brainstem glioma
- multiple sclerosis
- infarction
- syringobulbia.

At the cerebellopontine angle (CPA), the nerve is compressed by:

- acoustic neuroma
- meningioma
- secondary neoplasm.

As a CPA lesion enlarges, the neighbouring Vllth and Vlllth nerves become involved, producing facial weakness, deafness and vertigo.

At the apex of the petrous temporal bone, spreading middle ear infection or a secondary tumour damages the nerve. The combination of a painful Vth with a Vllth nerve lesion is called Gradenigo’s syndrome.

Within the cavernous sinus, the trigeminal (Gasserian) ganglion is compressed by:

- aneurysm of the internal carotid artery
- lateral extension of a pituitary neoplasm or metastasis
- thrombosis of the cavernous sinus.

The trigeminal ganglion itself becomes infected in ophthalmic herpes zoster (p. 1157), the most common lesion of the ganglion. Postherpetic neuralgia commonly follows (p. 1157).

Peripheral branches of V are infiltrated by skull base neoplasms, for example the ‘numb chin’ seen with a breast cancer metastasis.

Trigeminal neuralgia

Trigeminal neuralgia (tic douloureux) develops most commonly in the over 50 years age group and is almost always unilateral. Compression, most commonly from aberrant branches of the superior cerebellar artery in the cerebellomedullary angle, causes demyelination. It is thought that this sends ephaptic (short circuited) signals to cause pain.

Features

Paroxysms of knife-like or electric shock-like pain, lasting seconds, occur in the distribution of the Vth nerve. Pain tends to commence in the mandibular division (V3) and spreads upwards to maxillary (V2) and opthalmic divisions (V1). Spasms occur many times a day, but rarely in sleep. Each paroxysm is stereotyped, brought on by stimulation of one
or more trigger zones in the face. Washing, shaving, a cold wind or eating are examples of trivial stimuli that provoke pain. The face may be screwed up in agony (hence tic). Spontaneous remissions last months or years before (almost invariably) recurrence. There are no signs of Vth nerve dysfunction; the corneal reflex is preserved.

**Treatment**

Carbamazepine 600–1200 mg daily reduces severity of attacks in the majority. Phenytoin, gabapentin and clonazepam are used, but are less effective. If drugs fail, surgery (radiofrequency extirpation of the ganglion, neurovascular decompression or sectioning of the sensory root) is useful. Alcohol injection into the trigeminal ganglion or peripheral Vth nerve branches can also be carried out.

**Secondary trigeminal neuralgia**

Trigeminal neuralgia occurs in MS (p. 1152), with tumours of the Vth nerve (e.g. neuroma) and with cerebellopontine angle lesions. There are often physical signs – initially a depressed corneal reflex, progressing to trigeminal sensory loss.

**Idiopathic trigeminal neuropathy**

Chronic isolated Vth nerve lesions sometimes occur without apparent cause. When sensory loss is severe, trophic changes (facial scarring and corneal ulceration) develop.

### VII: FACIAL NERVE

The Vth nerve is largely motor, supplying muscles of facial expression. VII carries sensory taste fibres from the anterior two-thirds of the tongue via the chorda tympani and supplies motor fibres to stapedius. The Vth nerve (Fig. 21.7) arises from its nucleus in the pons and leaves the skull through the stylomastoid foramen. Neurones in each Vth nucleus supplying the upper face (principally frontalis) receive supranuclear fibres from each hemisphere.

**Unilateral facial weakness**

*Upper motor neurone (UMN) lesions* cause weakness of the lower part of the face on the opposite side. Frontalis is spared: normal furrowing of the brow is preserved; eye closure and blinking are largely unaffected. The earliest sign is slowing of one side of the face, e.g. on barring teeth. There is sometimes relative preservation of spontaneous emotional movement (e.g. smiling) compared with voluntary movement.

*Lower motor neurone (LMN) lesions.* A complete unilateral LMN Vth lesion causes weakness (ipsilateral) of all facial expression muscles. The angle of the mouth falls; unilateral dribbling develops. Frowning (frontalis) and eye closure are weak. Corneal exposure and ulceration occur if the eye does not close during sleep. Platysma is weak.

**Causes of facial weakness**

A common cause of a UMN lesion is a stroke, e.g. internal capsule infarction with hemiparesis.

At lower levels, lesion sites are recognized by LMN weakness with additional signs.

**Pons.** Here the Vth (abducens) nucleus is encircled by the Vth nerve (Fig. 21.7, leading to a lateral rectus palsy (convergent squint) with unilateral LMN facial weakness. When the neighbouring PPRF and corticospinal tract are involved, there is the triple combination of:

- LMN facial weakness
- failure of conjugate lateral gaze (towards lesion)
- contralateral hemiparesis.

Causes include pontine tumours (e.g. glioma), MS and infarction.

The facial nucleus itself can be affected in bulbar poliomyelitis (p. 110) and in motor neurone disease (p. 1166).

**Cerebellopontine angle (CPA).** The neighbouring Vth, Vth and VIIth nerves are compressed with VII in the CPA, e.g. by acoustic neuroma, menigioma or metastasis.

**Petrus temporal bone.** The geniculate ganglion (sensory for taste) lies at the genu (knee) of Vth (Fig. 21.7). Fibres join VII from the chorda tympani – taste from the tongue (anterior two-thirds). (The motor nerve to stapedius leaves VII distal to the genu. Lesions in this region cause:

- loss of taste on the anterior two-thirds of the tongue
- hyperacusis (loud noise distortion – paralysis of stapedius).

Causes include:

- Bell’s palsy
- trauma
- middle ear infection
- herpes zoster (Ramsay Hunt syndrome, p. 1108)
- tumours (e.g. glomus tumour).

**Skull base, parotid gland and within the face.** Swelling of VII within the stylomastoid foramen develops in Bell’s palsy. VII can be compressed by skull base tumours and in Paget’s disease of bone. Branches of VII that pierce the parotid are damaged by parotid gland tumours, mumps (p. 118), sarcoidosis (p. 869) and trauma. Each VIIth nerve can be involved in polyneuritis (e.g. Guillain–Barré syndrome, p. 1172), usually symmetrically.

Facial weakness (usually symmetrical) is also seen in muscle and neuromuscular junction disease, e.g.:

- myotonic dystrophy (p. 1181)
- facioscapulohumeral dystrophy (p. 1181)
- myasthenia gravis (p. 1180).

**Bell’s palsy**

This common, acute, isolated facial palsy is usually due to viral infection (often herpes simplex) that causes swelling of VII within the petrous temporal bone or as it traverses the stylomastoid foramen. There is sudden unilateral facial weakness, sometimes with loss of taste on the tongue, and hyperacusis. Pain behind the ear is common at onset. Diagnosis is made on clinical grounds. Other cranial nerves are not involved. Bell’s palsy occasionally recurs and is very rarely bilateral. (Bell’s phenomenon is the upward conjugate eye movement that occurs when the eyes are closed.)

**Management and course**

Weakness progresses over hours or several days. Spontaneous improvement usually begins during the second week. Thereafter, recovery continues but may take 12 months.
Nerve stimulation (EMG, p. 1121) is of help in predicting outcome but seldom necessary. After the third week, absence of evoked potentials from facial muscles indicates that full recovery is unlikely.

Steroids (e.g. prednisolone 60 mg daily, reducing to nil over 10 days) should be given. Antivirals (valaciclovir) and prednisolone are given for severe palsy, starting within 3 days of onset only, although the evidence for giving antivirals is poor. To prevent corneal exposure, adhesive tape to keep the eyelids closed is invaluable; suturing the upper to the lower lid (tarsorrhaphy) is considered if the eye cannot be closed for more than a week. Residual, unsightly paralysis occurs in more than 10%; cosmetic surgery is sometimes helpful.

**Ramsay Hunt syndrome**

This is herpes zoster (shingles) of the geniculate ganglion. There is a facial palsy (identical to Bell’s) with herpetic vesicles around the external auditory meatus and/or the soft palate (sensory twigs from VII). Deafness and a Vth nerve lesion may occur. Complete recovery is less likely than in Bell’s. Treatment for shingles should be given (e.g. famciclovir, p. 101).

**Hemifacial spasm**

This is an irregular, painless clonic spasm of facial muscles, usually occurring after middle age, and more common in women. It varies from a mild inconvenience to a severe, disfiguring spasm.

Causes are:
- idiopathic
- following Bell’s palsy
- acoustic neuroma
- Paget’s disease within the skull base
- pressure from vessels in the cerebellopontine angle (postulated).

There are clonic spasms of facial muscles on one side. Mild LMN facial weakness is common.

**Management**

Mild cases require no treatment. Decompression of the VIIth nerve in the CPA is sometimes helpful. Local botulinum toxin injection into facial muscles reduces the spasm for some months, and can be repeated. Drugs (e.g. carbamazepine) are of little value.

**Myokymia**

Myokymia describes a rare, continuous, fine, sinusous or wave-like movement of the lower face seen in brainstem lesions (e.g. MS, brainstem glioma). Myokymia is also used to describe the common innocent twitching around the eye.

**VIII: VESTIBULO-COCHLEAR NERVE**

**Cochlear nerve**

Auditory fibres from the spiral organ of Corti within the cochlea pass to the cochlear nuclei in the pons. Fibres from these nuclei cross the midline and pass upwards via the medial lemnisci to the medial geniculate bodies and then to the temporal gyr.

Symptoms of a cochlear nerve lesion are deafness and tinnitus (p. 1080). The deafness is termed sensorineural (or perceptive). Clinical detection is by tuning fork tests (256 or 512 Hz, not 128 Hz, Rinne’s and Weber’s) that distinguish conductive from sensorineural deafness (p. 1078).

**Basic investigations of cochlear lesions**

- Pure tone audiometry and auditory thresholds.
- Auditory evoked potentials (recording responses from repetitive clicks via scalp electrodes; lesion levels determined from response pattern).

Causes of deafness are listed in Tables 21.10 and 20.1 (see p. 1078).

**Vestibular nerve**

Nerve impulses generated by movement of sensory epithelia within the three semicircular canals, saccule and utricle pass to vestibular nuclei in the pons. Vestibular nuclei are connected to the cerebellum, nuclei of the ocular muscles, PPRF, extrapyramidal system, reticular formation, temporal lobes and spinal cord. Balance and posture also depend upon the interaction of proprioceptive impulses from the neck, spinal muscles and limbs. The main symptoms of vestibular lesions are vertigo and loss of balance. Vomiting frequently accompanies any acute vertigo. Nystagmus is the principal sign.

**Vertigo**

Vertigo, the definite illusion of movement of the subject or surroundings, typically rotatory, indicates a disturbance of the vestibular nerve, brainstem or, very rarely cortical function (Table 21.10). Deafness and tinnitus accompanying vertigo indicate involvement of the ear or cochlear nerve (p. 1078).

**Nystagmus**

Nystagmus is rhythmic oscillation of eye movement, and a sign of disease in the retina, oculomotor and/or vestibular

V, Vertigo; D, hearing loss.
systems and their connections. Nystagmus is either jerk or pendular. Nystagmus must be sustained within binocular gaze to be of diagnostic value – a few beats at the extremes of gaze are normal.

**Jerk nystagmus**

Jerk nystagmus (usual in neurological disease) is a fast/slow oscillation. This is seen in vestibular end-organ, VIIIth nerve, brainstem, cerebellar and (very rarely) cortical lesions. Direction of nystagmus is decided by the fast component, a reflex attempt to correct the slower, primary movement. Nystagmus is both a common and valuable indication of abnormality as a whole but there are difficulties using the direction of jerk nystagmus as a localizing sign. The following are useful starting points:

- **Horizontal or rotary jerk nystagmus** may be either of peripheral (middle ear) or central origin (VIIIth nerve, brainstem, cerebellum and connections).
  - In peripheral lesions, nystagmus is usually acute and transient (minutes or hours) and associated with severe prostrating vertigo.
  - In central lesions nystagmus tends to be long-lasting (weeks, months or more). Vertigo caused by central lesions tends to wane after days or weeks, the nystagmus outlasting it.
- **Vertical jerk nystagmus** is caused typically by central lesions.
- **Down-beat jerk nystagmus** is a rarity caused by lesions around the foramen magnum (e.g. menigioma, cerebellar ectopia).

**Pendular nystagmus**

Pendular describes movements to and fro, similar in velocity and amplitude. Pendular nystagmus is almost always binocular, horizontal and present in all directions of gaze. The causes are usually ocular (e.g. poor visual fixation from longstanding, severe visual impairment), or congenital, sometimes associated with head-nodding. Fine pendular, jelly nystagmus is seen (rarely) in MS (brainstem plaques) and brainstem glioma.

Other ocular movement disorders include ocular bobbing and opsoclonus – disorganized dancing eye movements seen typically in children with neuroblastoma and as a postinfective phenomenon (p. 455).

**Basic investigation of vestibular problems**

High-definition MRI provides the best structural imaging. Hallpike’s test (thrusting the head quickly to one side, p. 1079) may provoke nystagmus. Caloric tests assess labyrinth function, recording duration of evoked nystagmus when ice-cold, then warm, water is run into the external meatus. In the normal caloric test:

- ice-cold water in the left ear causes nystagmus with the fast movement to the right
- warm water in the left ear causes nystagmus with the fast movement to the left.

Decreased or absent nystagmus indicates ipsilateral labyrinth, VIIIth nerve or central involvement. Caloric tests are also used in confirmation of brainstem death (p. 920). There are difficulties relating abnormalities in caloric tests to clinical symptoms of dizziness. Other specialized neuro-otological tests are available. Vestibular positioning techniques (e.g. the Epley manœuvre) and exercises involving neck movement (e.g. Cawthorne–Cooksey exercises) are sometimes useful treatments.

**Vestibular and auditory lesions – central, VIIIth nerve and end organ**

Drugs (e.g. anticonvulsant toxicity), alcohol intoxication, MS and brainstem vascular disease are common central causes of vertigo. It is possible to recognize lesions from clinical features at six levels.

**Cerebral cortex.** Vertigo can be part of the aura of a partial (temporal lobe) seizure. Vertigo is also a psychological and perceptual sensation at heights, in panic attacks and agoraphobia. Deafness is rare in acquired cortical disease; bilateral lesions are necessary.

**Pons and brainstem.** Vertigo is common when lesions (MS, vascular, tumour, syring) involve vestibular nuclei and their connections. A Vth or VIIIth nerve lesion, internuclear ophthalmoplegia, lower cranial nerve lesions or contralateral hemiparesis help localization. Nystagmus is frequently present, while deafness is rare. Transient vertigo occurs in basilar migraine (p. 1137), preceding syncope, and occasionally in hypoglycaemic attacks. Its site of origin is often difficult to ascertain.

**Cerebellum.** Nystagmus develops towards the side of a cerebellar mass (tumour, haemorrhage, infarct or abscess). Limb ataxia is usually present. Bilateral cerebellar, or cerebellar connection disease (e.g. MS) causes bilateral nystagmus. Deafness does not occur.

**Cerebellopontine angle.** Ipsilateral sensorineural deafness, tinnitus and vertigo occur, with emergence of Vth, VIIth and Vth nerve lesions, followed by cerebellar signs (ipsilateral) and later pyramidal signs (contralateral). Nystagmus is often present. Causes include acoustic neuroma (p. 1160), meningioma and metastases, carcinomatous meningitis and inflammatory lesions (Table 21.10).

**Petrous temporal bone.** Facial weakness often accompanies the Vth nerve lesion. Causes include trauma, middle ear infection, secondary neoplasm and Paget’s disease of bone (see Gradenigo’s syndrome, p. 1106).

**End organs – cochlea, semicircular canals, middle and external ear.**

**Vestibular neuritis**

Vestibular neuritis is a common, poorly understood problem. It is an acute attack of isolated vertigo with nystagmus, often with vomiting, believed to follow viral infections. The disturbance lasts for several days or weeks, is self-limiting and rarely recurs. Vestibular neuritis is sometimes followed by benign positional vertigo (p. 1079). Deafness is absent. Acute treatment is with vestibular sedatives. Similar symptoms can be caused by MS or brainstem vascular lesions. Other signs are usually apparent.

**Further reading**

LOWER CRANIAL NERVES IX, X, XI, XII

The glossopharyngeal (IX), vagus (X) and accessory (XI) nerves arise in the medulla and leave the skull through the jugular foramen. The hypoglossal (XII) arises in the medulla, to leave the skull base via the anterior condylar foramen. Outside the skull, the four cranial nerves lie together, close to the carotid artery and sympathetic trunk.

Glossopharyngeal (IX)

This nerve is largely sensory, supplying sensation from the tonsillar fossa and pharynx (afferent pathway of gag reflex), taste from the tongue (posterior third) and fibres from the carotid sinus. Motor fibres supply stylopharyngeus, and autonomic fibres the parotid.

Vagus (X)

The vagus is a mixed nerve, largely motor, which supplies striated muscle of the pharynx (afferent gag reflex pathway), larynx (including vocal cords via recurrent laryngeal nerves) and upper oesophagus. There are sensory fibres from the larynx. Parasympathetic fibres supply the heart and abdominal viscera.

Accessory (XI)

The accessory nerve, a complex motor nerve, supplies trapezius and sternomastoid.

Hypoglossal (XII)

The hypoglossal nerve is a motor nerve to tongue muscles.

IXth and Xth nerve lesions

Principal causes of IXth, Xth, XIth and XIIth nerve lesions are listed in Table 21.11.

Isolated lesions of IXth and Xth nerves are unusual, since disease at the jugular foramen affects both nerves and sometimes XI.

A unilateral IXth nerve lesion causes diminished sensation on the same side of the pharynx, hard to recognize in isolation. A Xth nerve palsy produces ipsilateral failure of voluntary and reflex elevation of the soft palate, which is drawn to the opposite side, and ipsilateral vocal cords.

Bilateral lesions of IXth and Xth nerves cause weakness of palatal elevation and depression of palatal sensation with depression of the gag reflex, dysphonia and choking. Bulbar palsy is a general term describing palatal, pharyngeal and tongue weakness of LMN or muscle origin.

Recurrent laryngeal nerve lesions. Paralysis of this branch of each vagus causes hoarseness (dysphonia) and failure of the forceful, explosive part of voluntary and reflex coughing. There is no visible palatal weakness; vocal cord paralysis is seen endoscopically. Bilateral acute lesions (e.g. postoperatively) cause respiratory obstruction – an emergency.

The left recurrent laryngeal nerve (looping beneath the aorta) is damaged more commonly than the right.

Causes of recurrent laryngeal nerve lesions include:

- mediastinal primary tumours (e.g. thymoma)
- secondary spread from bronchial carcinoma
- aortic aneurysm
- trauma or surgery of neck or thorax.

Glossopharyngeal neuralgia. This is intensely painful, paroxysmal neuralgic spasm within the pharynx triggered repeatedly by swallowing. There are no physical signs. Treatment of this rarity is with carbamazepine (p. 1107) or IXth nerve section.

XIth nerve lesions

XIth nerve lesions cause weakness of sternomastoid (rotation of the head and neck to the opposite side) and trapezius (shoulder shrugging). Nerve section (e.g. following lymph node biopsy in the neck posterior triangle) is followed by persistent neuralgic pain.

XIIth nerve lesions

LMN lesions of XII lead to unilateral tongue weakness, wasting and fasciculation. The protruded tongue deviates towards the weaker side. Bilateral supranuclear (UMN) lesions produce slow, limited tongue movements and a stiff tongue that cannot be protruded far. Fasciculation is absent.

BRAINSTEM LESIONS

Bulbar and pseudobulbar palsy

Bulbar palsy describes LMN weakness of muscles whose cranial nerve nuclei lie in the medulla (the bulb). Paralysis of bulbar muscles is caused by disease of lower cranial nerve nuclei, lesions of IXth, Xth and XIIth nerves (Table 21.11), malfunction of their neuromuscular junctions (e.g. myasthenia gravis, botulism) or disease of muscles themselves (e.g. dystrophies).

Pseudobulbar palsy describes bilateral supranuclear (UMN) lesions of lower cranial nerves producing weakness of the tongue and pharyngeal muscles. This resembles, superficially, a bulbar palsy, hence pseudobulbar. Findings are a stiff, slow, spastic tongue (not wasted), dysarthria with a stiff, slow voice sounding dry and gravelly, and dysphagia. Gag and palatal reflexes are preserved and the jaw jerk exag-
gerated. Emotional lability (inappropriate laughing or crying) often accompanies pseudobulbar palsy.

Principal causes are:

- motor neurone disease – often both UMN and LMN lesions (i.e. elements of both pseudobulbar and bulbar palsy)
- MS, mainly as a late event
- cerebrovascular disease, typically following multiple infarcts
- following severe brain injury.

Difficulty swallowing, dysarthria and a slow tongue also develop in late stages of Parkinson’s disease.

**MOTOR CONTROL SYSTEMS**

There are three systems, each of which interacts by feedback loops with the other two, with sensory input and the reticular formation:

- The corticospinal (or pyramidal) system enables purposive, skilled, intricate, strong and organized movements. Defective function is recognized by a distinct pattern of signs – loss of skilled voluntary movement, spasticity and reflex change – seen, for example in a hemiparesis, hemiplegia or paraparesis.
- The extrapyramidal system facilitates fast, fluid movements that the corticospinal system has generated. Defective function produces slowness (bradykinesia), stiffness (rigidity) and/or disorders of movement (rest tremor, chorea and other dyskinesias). One feature (e.g. stiffness, tremor or chorea) will often predominate.
- The cerebellum and its connections have a role coordinating smooth and learned movement, initiated by the pyramidal system, and in posture and balance control. Cerebellar disease leads to unsteady and jerky movements (ataxia), with characteristic limb signs of past pointing, action tremor and incoordination, gait ataxia and/or truncal ataxia.

**CORTICOSPINAL (PYRAMIDAL) SYSTEM**

The corticospinal tracts originate in neurones of the cortex and terminate at motor nuclei of cranial nerves and spinal cord anterior horn cells. The pathways of particular clinical significance (Fig. 21.8) congregate in the internal capsule and cross in the medulla (decussation of the pyramids), passing to the contralateral cord as the lateral corticospinal tracts. This is the pyramidal system, disease of which causes upper motor neurone (UMN) lesions. ‘Pyramidal’ is simply a descriptive term that draws together anatomy and characteristic physical signs, and is used interchangeably with the term UMN.

A proportion of the corticospinal outflow is uncrossed (anterior corticospinal tracts). This is of no relevance in practice.

**Characteristics of pyramidal lesions**

(Table 21.12)

Signs of an early pyramidal lesion may be minimal. Weakness, spasticity or changes in superficial reflexes can predominate, or be present in isolation.

![Fig. 21.8 The motor system.](image)

**Pyramidal drift of an upper limb**

Normally, the outstretched upper limbs are held symmetrically, when the eyes are closed. With a pyramidal lesion, when both upper limbs are held outstretched, palms uppermost, the affected limb drifts downwards and medially. The forearm tends to pronate and the fingers flex slightly. This sign is often first to emerge, sometimes before weakness and/or reflex changes become apparent.

**Weakness and loss of skilled movement**

A unilateral pyramidal lesion above the decussation in the medulla causes weakness of the opposite limbs. When acute and complete, this weakness will be immediate and total, e.g. a hemiplegia following an internal capsule infarct. With slowly
progressive lesions (e.g. a hemisphere glioma) a characteristic pattern of weakness emerges – a hemiparesis.

In the upper limb, flexors remain stronger than extensors, whereas in the lower limb, extensors remain stronger than flexors. In the upper arm, weaker movements are thus shoulder abduction and elbow extension; in the forearm and hand, wrist and finger extensors and abductors are weaker than their antagonists. In the lower limb, weaker movements are hip flexion and abduction, knee flexion, ankle dorsiflexion and eversion. There is also loss of skilled movement – fine finger and toe control diminishes. Wasting (except from disuse) is not a feature. Muscles remain normally excitable electrically.

When a UMN lesion is below the decussation of the pyramids, e.g. in the cervical cord, hemiparesis is on the same side as the lesion, an unusual situation.

**Changes in tone and tendon reflexes**
An acute lesion of one pyramidal tract (e.g. internal capsule stroke) causes initially flaccid paralysis with loss of tendon reflexes. Increase in tone follows, usually within several days due to loss of inhibitory effects of the corticospinal pathways and an increase in spinal reflex activity. This increase in tone (spasticity) is detectable most easily in stronger muscles. Spasticity is characterized by sudden changing resistance to passive movement – the clasp–knife effect. Relevant tendon reflexes become exaggerated; clonus may emerge.

**Changes in superficial reflexes**
The normal flexor plantar response becomes extensor (a positive Babinski). In a severe acute lesion, this extensor response can be elicited from a wide area of the foot. As recovery progresses, the receptive area diminishes until the lateral posterior third of the sole remains receptive to an orange-stick stimulus (an appropriate instrument). An extensor plantar is certain when great toe dorsiflexion is accompanied by abduction of adjacent toes. Abdominal (and cremasteric) reflexes are abolished on the side affected.

**Patterns of UMN disorders**
There are three main patterns:
- Hemiparesis means weakness of the limbs on one side; it is usually caused by a lesion in the brain and occasionally in the cord.
- Paraparesis means weakness of both lower limbs and is usually diagnostic of a cord lesion; bilateral brain lesions occasionally cause paraparesis.
- Tetraparesis (syn. quadriplegia) means weakness of four limbs.

Hemiplegia, paraplegia and tetraplegia indicate (strictly) total paralysis, but are often used to denote some degree of weakness.

**Hemiparesis**
The level within the corticospinal system is recognized by particular features.

*Motor cortex.* Weakness and/or loss of skilled movement confined to one contralateral limb (an arm or a leg – monoplegia) or part of a limb (e.g. a clumsy hand) is typical of an isolated motor cortex lesion (e.g. a secondary neoplasm). A defect in cognitive function (e.g. aphasia) and focal epilepsy may occur.

**Internal capsule.** Corticospinal fibres are tightly packed in the internal capsule (about 1 cm³), thus a small lesion causes a large deficit. A middle cerebral artery branch infarction (p. 1129) produces a sudden, dense, contralateral hemiplegia.

**Pons.** A pontine lesion (e.g. an MS plaque) is rarely confined to the corticospinal tract. Adjacent structures, e.g. VIth and VIIth nuclei, MLF and PPRF (p. 1104) are involved – diplopia, facial weakness, internuclear ophthalmoplegia (INO) and/or a lateral gaze palsy occur with contralateral hemiparesis.

**Spinal cord.** An isolated lesion of one lateral corticospinal tract (e.g. a cervical cord injury) causes a ipsilateral UMN lesion, the level indicated by changes in reflexes (e.g. absent biceps, C5/6), features of a Brown–Séquard syndrome (p. 1118) and muscle wasting at the level of the lesion (p. 1163).

**Paraparesis** (Table 21.13)
Paraparesis indicates bilateral damage to corticospinal pathways. Cord compression (p. 1163) or cord diseases are the usual causes; cerebral lesions occasionally produce paraparesis. Paraparesis is a feature of many neurological conditions; finding the cause is crucial (p. 1164).

**EXTRAPYRAMIDAL SYSTEM**
The extrapyramidal system is a general term for basal ganglia motor systems, i.e. corpus striatum (caudate nucleus + globus pallidus + putamen), subthalamic nucleus, substantia nigra and parts of the thalamus. In basal ganglia/extrapyramidal disorders, two features (either or both) become apparent, in limbs and axial muscles:

- reduction in speed (bradykinesia, meaning slow movement) or akinesia (no movement), with muscle rigidity
- involuntary movements (e.g. tremor, chorea, hemiballismus, athetosis, dystonia).

Extrapyramidal disorders are classified broadly into akinetic-rigid syndromes (p. 1145) where poverty of movement pre-
Fig. 21.19 Extrapyramidal system: connections and neurotransmitters. The inhibitory pathways are in blue (B, C, D, F, G) and excitatory in red. VAVL, ventral anterior and ventro-lateral thalamic nuclei. GPI, lateral globus pallidus. GPIm: medial globus pallidus. SNr, substantia nigra pars reticulata. GLU, glutamate; ENK, enkephalin; GABA, gamma-amino butyric acid.

dominates, and dyskinesias where there are involuntary movements (p. 1146).

The most common extrapyramidal disorder is Parkinson’s disease.

Essential anatomy

The corpus striatum lies close to the substantia nigra, thalami and subthalamic nuclei, lateral to the internal capsule (Figs 21.8 and 21.9).

Function and dysfunction

Overall function of this system is modulation of cortical motor activity by a series of servo loops between cortex and basal ganglia (Fig. 21.9). In involuntary movement disorders there are specific changes in neurotransmitters (Table 21.14) rather than focal lesions seen on imaging or at autopsy.

Proposed model of principal pathways

1. Direct pathway from striatum to medial globus pallidus (GPm) and substantia nigra pars reticulata (SNr). Inhibitory synapse F, GABA and substance P.
2. Indirect pathway from striatum to globus pallidus; via lateral globus pallidus (GPi, inhibitory synapse C, GABA, enkephalin) and subthalamic nucleus inhibitory synapse D, GABA). Terminates in GPm-SNr (in excitatory synapse E, glutamate).
3. Direct pathways, both inhibitory and excitatory from substantia nigra pars compacta (SNc) to striatum.
   Synapse A, dopamine, D1, excitatory; and synapse B, D2, inhibitory.
4. GPm and SNr to thalamus. Inhibitory synapse G, GABA.
5. Thalamus to cortex. Excitatory, synapse H, GABA.

The model helps explain how basal ganglia can either reduce excitatory thalamo-cortical activity at synapse H, i.e. movement – causing bradykinesia, or increase it, causing dyskinesias.

Parkinson’s disease (PD). This is characterized by slowness, stiffness and rest tremor (p. 1146). Degeneration in SNc causes loss of dopamine activity in the striatum. Dopamine is excitatory for synapse A and inhibitory for synapse B. Through the direct pathway there is reduced activity at synapse F, leading to increased inhibitory output (G) and decreased cortical activity (H).

Also in PD, in the indirect pathway, dopamine deficiency results in disinhibition of neurones synapsing at C. This leads to reduced activity at D, and to increased activity of neurones in the subthalamic nucleus. There is excess stimulation at synapse E, enhancing further inhibitory output of GPm-SNr.

The net effect via both pathways is to inhibit the ventral anterior (VA) and ventrolateral (VL) nuclei of the thalamus at synapse G. Cortical (motor) activity at H is thus reduced.

Levodopa helps slowness and tremor in PD (p. 1147) but induces unwanted dyskinesias by increasing dopamine activity at synapses A and B, it is thought by reversing sequences in both direct and indirect pathways.

Huntington’s disease (HD). HD is an inherited dementia (p. 1149) with progressive chorea. Chorea results from damage to neurones (GABA, enkephalin) in the indirect pathway from striatum to GPi, reducing activity at synapse C. In turn, there is increased inhibition of subthalamic neurones at D, reduced stimulation at E and decreased inhibition of VA/VL at G. Cortical activity at H increases.

Hemiballismus. Wild, flinging (ballistic) limb movements are caused by a lesion in the subthalamic nucleus, typically an infant. This reduces excitatory activity at synapse E, reduces inhibition at G, with increased thalamo-cortical neuronal activity, and increases activity at H.

CEREBELLUM

The third system of motor control modulates coordination and learned movement patterns, rather than speed. Ataxia, i.e. unsteadiness, is characteristic.
The cerebellum receives afferents from:
- proprioceptive receptors (joints and muscles)
- vestibular nuclei
- basal ganglia
- the corticospinal system
- olivary nuclei.

Efferents pass from the cerebellum to:
- each red nucleus
- vestibular nuclei
- basal ganglia
- corticospinal system.

Each lateral cerebellar lobe coordinates movement of the ipsilateral limbs. The vermis (a midline structure) is concerned with maintenance of axial (midline) posture and balance.

Cerebellar lesions (Table 21.15)

Expanding lesions obstruct the aqueduct to cause hydrocephalus, with severe pressure headaches, vomiting and papilloedema. Coning of the cerebellar tonsils (p. 1161) through the foramen magnum leads to respiratory arrest, sometimes within minutes/hours. Rarely, tonic seizures (attacks of limb stiffness) occur.

Lateral cerebellar lobes

A lesion within one cerebellar lobe (e.g. tumour or infarction) causes disruption of the normal sequence of movements (dyssynergia) on the same side.

Posture and gait. The outstretched arm is held still in the early stages of a cerebellar lobar lesion (cf. the drift of pyramidal lesions) but there is rebound upward overshoot when the limb is pressed downwards and released. Gait becomes broad and ataxic, faltering towards the side of the lesion.

Tremor and ataxia. Movement is imprecise in direction, force and distance (dysmetria). Rapid alternating movements (tapping, clapping or rotary hand movements) become disorganized (dysdiadochokinesis). Intention tremor (action tremor with past-pointing) is seen, but speed of fine movement is preserved, cf. extrapyramidal and pyramidal lesions.

Nystagmus. Coarse horizontal nystagmus (p. 1109) develops with a lateral cerebellar lobe lesion. The fast component is always towards the side of the lesion.

Dysarthria. Halting, jerking speech develops – scanning speech.

Other signs. Titubation – rhythmic head tremor as either forward and back (yes–yes) movements or rotary (no–no) movements – can occur, mainly when cerebellar connections are involved (e.g. in essential tremor and MS, pp. 1149 and 1151). Hypotonia (floppy limbs) and depression of reflexes (with slow, pendular reflexes) are also sometimes seen.

Midline cerebellar lesions

Cerebellar vermis lesions have dramatic effects on trunk and axial muscles. There is difficulty standing and sitting unsupported (truncal ataxia), with a rolling, broad, ataxic gait. Lesions of the flocculonodular region cause vertigo and vomiting with gait ataxia if they extend to the roof of the IVth ventricle. Table 21.15 summarizes the main causes of cerebellar disease.

Tremor means a regular and sinusoidal oscillation of the limbs, head or trunk.

Postural tremor

Everyone has a physiological tremor (often barely perceptible) of the outstretched hands at 8–12 Hz. This is increased with anxiety, caffeine, hyperthyroidism and drugs (e.g. sympathomimetics, sodium valproate, lithium) and occurs in mercury poisoning. A coarser, postural tremor is seen in benign essential tremor (usually at 5–8 Hz) and in chronic alcohol abuse.

Intention tremor

Tremor exacerbated by action, with past-pointing and accompanying incoordination of rapid alternating movement (dysdiadochokinesis), occurs in cerebellar lobe disease and with lesions of cerebellar connections. Titubation and nystagmus may be present.

Rest tremor

Seen typically in Parkinson’s disease, this tremor is noticeably worse at rest, usually 4–7 Hz (pill-rolling, between thumb and forefinger).

Other tremors

Coarse tremor is seen following lesions of the red nucleus (e.g. infarction, multiple sclerosis) and rarely with frontal lesions.
LOWER MOTOR NEURONE (LMN) LESIONS

The LMN is the pathway from anterior horn cell (or cranial nerve nucleus) via a peripheral nerve to muscle motor endplates. The motor unit consists of one anterior horn cell, its single fast-conducting axon that leaves the cord via the anterior root, and the group of muscle fibres (100–2000) supplied via the nerve. Anterior horn cell activity is modulated by impulses from:

- corticospinal tracts
- extrapyramidal system
- cerebellum
- afferents via posterior roots.

Signs of lower motor neurone lesions

These are seen in voluntary muscles that depend upon an intact nerve supply both for contraction and metabolic integrity. Signs follow rapidly if the LMN is interrupted (Table 21.16).

Causes

Examples of LMN lesions at various levels are:

- cranial nerve nuclei (Bell's palsy) and anterior horn cell (motor neurone disease)
- spinal root – cervical and lumbar disc protrusion, neuralgia amyotrophy (p. 1177)
- peripheral (or cranial) nerve – trauma, entrapment (p. 1171), polyneuropathy (p. 1172).

SPINAL REFLEX ARC

Components are illustrated in Figure 21.10. The stretch reflex is the physiological basis for all tendon reflexes. In the knee jerk, a tap on the patellar tendon activates stretch receptors in the quadriceps. Impulses in first-order sensory neurones pass directly to LMNs (L3 and L4) that contract quadriceps. Loss of a tendon reflex is caused by a lesion anywhere along the spinal reflex path. The reflex lost indicates its level (Table 21.17).

Reinforcement. Distraction of the patient’s attention, clenching teeth or pulling interlocked fingers enhances reflex activity. Such reinforcement manoeuvres should be done before a reflex is recorded as absent.

SENSORY PATHWAYS AND PAIN

Peripheral nerves and spinal roots

Peripheral nerves carry all modalities of sensation from either free or specialized nerve endings to dorsal roots and thence to the cord. Sensory distribution of spinal roots (dermatomes) is shown in Figure 21.11.

Spinal cord

Posterior columns

Axons in the posterior columns whose cell bodies are in the ipsilateral gracile and cuneate nuclei in the medulla carry sensory modalities of vibration, joint position (proprioception), light touch and two-point discrimination. Axons from second-order neurones then cross in the brainstem to form the medial lemniscus, passing to the thalamus (Fig. 21.12).

Spinothalamic tracts

Axons carrying pain and temperature sensation synapse in the dorsal horn of the cord, cross within the cord and pass in the spinothalamic tracts to the thalamus and reticular formation.

Sensory cortex

Fibres from the thalamus pass to the parietal region sensory cortex (Fig. 21.12). Connections exist between the thalamus, sensory cortex and motor cortex.

Fig. 21.10  Knee jerk: a spinal reflex arc. Sudden patellar tendon stretching generates sensory action potentials in 1α muscle spindle afferents that synapse with γ motor fibres to spindles and α motor fibres. Motor action potentials cause brisk extensor muscle contraction; there is also inhibition of knee flexors.
Fig. 21.11 Dermatomes of spinal roots and Vth nerve.

LESIONS OF THE SENSORY PATHWAYS

Altered sensation (paraesthesia), tingling, clumsiness, numbness and pain are the principal symptoms of sensory lesions. The pattern and distribution point to the site of pathology (Fig. 21.13).

Peripheral nerve lesions

Symptoms are felt within the distribution of a peripheral nerve (p. 1171). Section of a sensory nerve is followed by complete sensory loss. Nerve entrapment (p. 1171) causes numbness, pain and tingling. Tapping the site of compression sometimes causes a sharp, electric-shock-like pain in the distribution of the nerve, known as Tinel’s sign, e.g. in carpal tunnel syndrome (p. 508).

Neuralgia

Neuralgia refers to pain, usually of great severity, in the distribution of a damaged nerve. Examples are:

- trigeminal neuralgia (p. 1106)
- postherpetic neuralgia (p. 1157)
- complex regional pain syndrome type II (causalgia) – chronic burning pain that occasionally follows nerve section.

Spinal root lesions

Root pain

Pain of root compression is felt in the myotome supplied by the root, and there is also a tingling discomfort in the dermatome. The pain is worsened by manoeuvres that either stretch

Fig. 21.12 Principal sensory pathways. Posterior columns remain uncrossed until the medulla. Spinothalamic tracts cross close to their entry into the cord.

the root (e.g. straight leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining). Cervical and lumbar disc protrusions (p. 1177) are common causes of root lesions.

Dorsal spinal root lesions

Section of a dorsal root causes loss of all modalities of sensation within a dermatome (Fig. 21.11). However, overlap between adjacent dermatomes makes it difficult to detect anaesthesia when a single root is destroyed.

Lightning pains. Tabes dorsalis (rare in the UK) is a form of neurosyphilis that causes low-grade inflammation of dorsal roots and spinal cord root entry zones. Irregular, sharp, stabbing pains (like lightning) involve one or two spots, typically in a calf, thigh or ankle.

Spinal cord lesions

Posterior column lesions

These cause:

- tingling
- electric-shock-like sensations
- clumsiness
- numbness
- band-like sensations.

These symptoms, though lateraled, are often felt vaguely without a clear sensory level. Position sense, vibration sense, light touch and two-point discrimination are diminished below the lesion. Position sense loss produces a stamping gait (sensory ataxia, p. 1097).

Lhermitte’s phenomenon

Electric-shock-like sensations radiate down the trunk and limbs on neck flexion. This points to a cervical cord lesion.
Lhermitte’s is common in acute exacerbations of MS (p. 1152), and also occurs in cervical myelopathy (p. 1176), subacute combined degeneration of the cord (p. 1175), radiation myelopathy (p. 1165) and cord compression.

**Spinothalamic tract lesions**

Pure spinothalamic spinal lesions cause contralateral loss of pain and temperature sensation with a clear level below the lesion. This is called *dissociated* sensory loss – pain and temperature are dissociated from light touch, which remains preserved. This is seen typically in syringomyelia where a cavity occupies the central cord (p. 1164).

The spinal level is modified by lamination of fibres within the spinothalamic tracts. Fibres from lower spinal roots lie superficially and are damaged first by compressive lesions from outside the cord. As an external compressive lesion (e.g. a midthoracic extradural meningioma; Fig. 21.14) enlarges, the spinal sensory level ascends as deeper fibres become involved. Conversely, a central cord lesion (e.g. a syrinx, p. 1165) affects deeper fibres first. Spinothalamic tract lesions cause loss of pain and temperature perception (e.g. painless burns). Perforating ulcers and neuropathic (Charcot) joints develop.

**Spinal cord compression** (Fig. 21.14)

Cord compression causes progressive spastic paraparesis (or tetraparesis/quadruparesis) with sensory loss below the level of compression. Sphincter disturbance is common.

---

**Fig. 21.13 Principal patterns of loss of sensation.**

- (a) Thalamic
- (b) Mid-brainstem
- (c) Central cord
- (d) Unilateral cord lesion (Brown–Séquard)
- (e) Transverse thoracic spinal cord
- (f) Dorsal column
- (g) Sensory roots
- (h) Polyneuropathy

*Fig. 21.14 Spinal cord compression: features and anatomy.*

Root pain is frequent but not invariable, felt characteristically at the level of compression. With thoracic cord compression (e.g. an extradural meningioma), pain radiates around the chest, exacerbated by coughing and straining, as meningeal root sheaths are stretched.
Damage to one spinothalamic tract (contralateral loss of pain and temperature) with the ipsilateral corticospinal tract is known as the Brown–Séquard syndrome (originally, cord hemisection). The patient complains of numbness on one side and weakness on the other. Paraparesis/spinal cord lesions are discussed on page 1163.

Pontine lesions
Since lesions (e.g. an MS plaque) lie above the decussation of the posterior columns, and both medial lemniscus and spinothalamic tracts are close together, there is loss of all forms of sensation on the side opposite the lesion. Combinations of III, IV, V, VI and VII cranial nerve nuclei are seen, and may indicate a level (Fig. 21.12).

Thalamic lesions
Thalamic pain (also called central post-stroke pain or thalamic syndrome) follows a small thalamic infarct. The patient has a stroke (hemiparesis and sensory loss). Weakness improves, but deep-seated constant pain in the paretic limbs develops. Choreo-athetotic movements occur. Secondary depression may lead to self-harm. Thalamic lesions can also cause diminished sensation alone, on the opposite side; this is less usual.

Parietal cortex lesions
Sensory loss, neglect of one side, apraxia (p. 1097) and subtle disorders of sensation occur. Pain is not a feature of destructive cortical lesions. Irritative phenomena (e.g. partial sensory seizures from a parietal cortex glioma) cause tingling sensations in a limb, or elsewhere.

PAIN
Pain is an unpleasant, unique physical and psychological experience. Acute pain serves a biological purpose (e.g. withdrawal) and is typically self-limiting, ceasing as healing ensues. Some forms of chronic pain (e.g. causalgia, p. 1116) outlast the period required for healing, and may be permanent.

Essential physiology of pain
Pain perception is mediated by free nerve endings, terminations of finely myelinated A-delta and of non-myelinated C fibres. Chemicals released following injury produce pain either by direct stimulation or by sensitizing nerve endings. A-delta fibres give rise to perception of sharp, immediate pain, then slower-onset, more diffuse and prolonged pain is mediated by slower-conducting C fibres.

Sensory impulses enter the cord via dorsal spinal roots. Impulses ascend either in each dorsal (posterior) column or in each spinothalamic tract. Grey matter neurones in the cord are arranged in laminae labelled I to X (dorsal to ventral). A fibres terminate in laminae I and V and excite second-order neurones that project to the contralateral side via the anterior commissure and via the anterolateral column of the direct spinothalamic tract. C fibres mostly terminate in the substantia gelatinosa (laminae II and III); axons then pass through the anterior commissure to the contralateral side and rostrally, up the spino-reticulo-thalamic tract.

The spinothalamic tracts carry impulses that localize pain. Thalamic pathways to and from the cortex mediate emotional components. Sympathetic activity increases pain, e.g. hyperaemia in a painful limb.

Gate theory of pain
Gate theory, a useful way of thinking about pain, proposes that entry of afferent impulses is monitored first by the substantia gelatinosa. This gate determines whether or not sufficient activity penetrates to fire secondary neurones in the dorsal horn. This, and subsequent gates, are influenced by brain and cord regulators that alter how far a gate remains open.

Animal studies suggest that downstream regulators binding to calcium-regulated transcription factors control CNS endogenous opiate precursors (e.g. pro-dynorphin). These modulate pain.

Endogenous opiates
Endorphin peptides have opioid activity and probably account for placebo phenomena, effects of stress and acupuncture, and may explain in part why some patients develop chronic pain syndromes. Endorphins are CNS neurotransmitters acting at inhibitory synapses via δ, κ and μ receptors. Dynorphin (from the precursor, pro-dynorphin) is thought to modulate nociceptive (pain) impulses entering the cord.

Management of chronic pain
Chronic pain is gravely disabling, distressing, and taxing to treat (p. 494). Multidisciplinary pain-relief clinics provide specific and supportive therapy.

Management plans for intractable pain have seven components:

Diagnostic
Rigorous attention must be paid to the diagnosis, reviewing the entire history and investigations. A specific surgical approach may become apparent (e.g. spinal stenosis, trigeminal neuralgia, glossopharyngeal neuralgia, or syringomyelia).

Psychological
Chronic pain influences quality of life. Depression (p. 1198) is commonly associated with pain when the pathology is benign; antidepressants can help. Of patients suffering pain from secondary cancer about one-third are clinically depressed.

Analgesics
Perseverance and compliance with therapy is a common problem. The WHO analgesic ladder (p. 494) is useful.

Co-analgesics
Co-analgesics have a primary use other than for pain but help either alone or when added to analgesics. Examples are tricyclic antidepressants and anticonvulsants (p. 495). Calcium-channel blockers (nifedipine) improve sympathetically mediated pain in, for example, Raynaud’s disease. Muscle relaxants (spasmylics), antibiotics (infection) and steroids (inflammatory arthropathy) can each reduce pain.

Stimulation
Acupuncture, ice, heat, ultrasound, massage, transcutaneous electrical nerve stimulation (TENS) and spinal cord stimu-
lotion all achieve analgesia by gating effects on large myelinated nerve fibres.

**Nerve blocks**
Pain pathways can be blocked either temporarily by local anaesthetic or permanently with phenol, or radiofrequency lesions:
- somatic blocks:
  - (a) peripheral nerve and plexus injections
  - (b) epidural and spinal analgesia
- sympathetic blocks:
  - (a) sympathetic ganglia injections
  - (b) central epidural and spinal sympathetic blockade.

**Neurosurgery**
Highly specialized techniques have a place alongside drugs. Examples are dorsal rhizotomy, sympathectomy, cordotomy and neurostimulation.

**BLADDER CONTROL AND SEXUAL DYSFUNCTION**

Changes in micturition and failure of normal sexual activity due to neurological conditions are seen in sacral, spinal cord and cortical disease.

**Essential functions and anatomy**
The bladder has two functions – storage and voiding. Afferent pathways (T12–S4) respond to pressure within the bladder and sensation from the genitalia. As the bladder distends, continence is maintained by suppression of parasympathetic and reciprocal activation of sympathetic outflow. Both are under some voluntary control. Voiding takes place by parasympathetic activation of the detrusor, and relaxation of the internal sphincter (Table 21.18).

Cortical awareness of bladder fullness is located in the post-central gyrus, parasagittally, while initiation of micturition is in the pre-central gyrus. Voluntary control of micturition is located in the frontal cortex, parasagittally.

**Neurological disorders of micturition**
Urogenital tract disease is dealt with largely by urologists. Incontinence is common and easy to recognize; neurological causes are sometimes not obvious. These are:

**Cortical:**
- Post-central lesions cause loss of sense of bladder fullness.
- Pre-central lesions cause difficulty initiating micturition.
- Frontal lesions cause socially inappropriate micturition.

**Spinal cord.** Bilateral UMN lesions (pyramidal tracts) cause urinary frequency and incontinence. The bladder is small and hypertonic, i.e. sensitive to small changes in intravesical pressure. Frontal lesions can also cause a hypertonic bladder.

**LMN.** Sacral lesions (conus medullaris, sacral root and pelvic nerve – bilateral) cause a flaccid, atomic bladder that overflows (cauda equina, p. 1177), often unexpectedly.

**Management.** Assessment of both urological causes (e.g. calculi, prostatism, gynaecological problems) and potential neurological causes of incontinence is necessary. Intermittent self-catheterization is used by many patients, with for example spinal cord lesions.

**Male erectile dysfunction**
Failure of penile erection often has mixed organic and psychological causes. Depression is common. Endocrine aspects of sexual dysfunction are described on page 1000. Erectile dysfunction is sometimes helped by phosphodiesterase type 5 inhibitors, e.g. sildenafil.

**NEUROLOGICAL TESTS**

**NEURO-IMAGING**

**Skull and spinal X-rays**

These show:
- fractures of the vault or base
- vault and skull base disease (e.g. metastases, osteomyelitis, Paget’s disease, abnormal skull foramina, fibrous dysplasia)
- enlargement or destruction of the pituitary fossa – intrasellar tumour, raised intracranial pressure
- intracranial calcification – tuberculoma, oligodendroglioma, wall of an aneurysm, cysticercosis.

**Spinal X-rays** show fractures, congenital and destructive lesions (bone cysts, infection, metastases) and degenerative spondylosis.

**Imaging brain and spinal cord**

Brain CT and MRI are widely available world-wide. Myelography (contrast imaging of the cord and ventricles (ventriculography)) is obsolete.

**Brain computed tomography (CT)**

A collimated X-ray beam moves synchronously across a brain slice 2–13 mm thick. Transmitted X-irradiation from a pixel, an element <1 mm², is computer-processed to assign a Hounsfield number to its density (air = −1000 units; water = 0; bone = +1000 units). The digital data are converted to cross-sectional images to reconstruct brain anatomy. Helical

CT (spiral or volumetric CT) provides greater definition in a shorter time. It is used for two-dimensional reconstruction.

Differences in attenuation (density) between bone, brain and CSF enable recognition of normal and infarcted tissue, tumour, blood, intracerebral haemorrhage, free subarachnoid blood, subdural and extradural haematoma and oedema.

Enhancement with i.v. contrast delineates areas of altered blood supply (CT angiography).

**Safety.** The irradiation involved is relatively small. There are occasional reactions to contrast.

**Limitations of brain CT**
- Lesions under 1 cm in diameter may be missed.
- Lesions with attenuation close to bone may be missed, if near the skull.
- Lesions with attenuation similar to brain are poorly displayed (e.g. MS plaques, isodense subdural haematoma).
- CT is not good at detecting posterior fossa lesions because of surrounding bone.
- Patient cooperation: an anaesthetic is very occasionally needed.

**Magnetic resonance imaging: MRI**

A hydrogen nucleus is a proton whose electrical charge creates a local electrical field. Protons are aligned by sudden strong magnetic impulses and then imaged with radiofrequency waves at right angles to their alignment. The protons resonate and spin, then revert to their normal alignment. As they do so, images are made at different phases of relaxation, known as T1, T2, T2 STIR, FLAIR, diffusion-weighted imaging (DWI) and other sequences. From these sequences, often referred to as different weightings, recorded images are compared. Gadolinium is used as i.v. contrast to show areas of increased vascularity.

**Advantages of MRI**
- MR distinguishes between white and grey matter in the brain and cord.
- Cord and nerve roots are imaged directly.
- Pituitary imaging.
- MRI has resolution superior to CT (around 0.5 cm).
- No radiation is involved.
- MR angiography (MRA) images blood vessels without contrast.
- MR images soft tissues.
- Tumours, infarction, haemorrhage, MS plaques, posterior fossa, foramen magnum and cord are demonstrated well by MRI.

Limitations are principally time and cost. Patients need to keep still within a narrow tube: claustrophobia is an issue; open machines are available that are less claustrophobic. Patients with pacemakers or metallic fragments in the brain cannot be imaged. MR imaging for some days after lumbar puncture (p. 1121) frequently shows diffuse meningeal enhancement with gadolinium.

**Doppler studies**

B-mode and colour ultrasound are valuable in detection of carotid stenosis.

**Digital cerebral and spinal angiography**

Where advanced MRI and CT are available, these techniques are little used. Contrast is injected intra-arterially or intravenously. Angiography carries a mortality and stroke risk (<1%). Images of aorta, carotid, vertebral and brain arteries demonstrate occlusion, stenoses, atheroma, aneurysms and arteriovenous malformations (AVMs). Spinal angiography images cord AVMs.

**Positron emission tomography (PET), single proton emission computed tomography (SPECT), dopamine transporter imaging (DAT) and functional MRI (fMRI)**

These functional imaging techniques track uptake of radioisotopes and/or metabolites. PET is used principally in the detection of occult neoplasms, outside the CNS. SPECT is now little used in cerebrovascular disease and traumatic brain injury – there are issues of reliability. DAT is used in basal ganglia disease. fMRI is largely a research tool for mapping brain function, in health and disease.

**Isotope bone scanning**

The radioisotope [99mTc]-pertechnetate is given intravenously. The technique is used principally in detection of vertebral, skull and bone metastases.

**Electroencephalography (EEG)**

EEG (Fig. 21.15) recorded from scalp electrodes (16 channels simultaneously) is of value in epilepsy and diffuse brain diseases. Videotelemetry, combining EEG with video, is invaluable in attacks difficult to diagnose.

**Epilepsy**

Spikes, or spike-and-wave abnormalities, are hallmarks of epilepsy, but it should be emphasized that patients...
with epilepsy often have a normal EEG between seizures (p. 1141).

**Diffuse brain disorders**
Slow-wave EEG abnormalities appear in encephalitis, prion (Creutzfeldt–Jakob) diseases and metabolic states (e.g. hypoglycaemia, hepatic coma).

**Brain death**
The EEG is isoelectric (flat); EEG is no longer necessary to confirm brain death (p. 920).

**Electromyography and conduction studies**

**Electromyography**
A concentric needle electrode is inserted into voluntary muscle. Amplified recordings, on an oscilloscope, are also heard through a speaker. The main EMG features are:
- normal interference pattern
- denervation and reinnervation changes
- myopathic, myotonic and myasthenic changes (p. 1178).

**Peripheral nerve conduction** (Fig. 21.16)
Four measurements are of principal value in neuropathies and nerve entrapment:
- mean nerve (motor and sensory) conduction velocity
- distal motor latency
- sensory action potentials
- muscle action potentials.

Measurements differentiate between axonal and demyelinating damage and determine whether pathology is focal or diffuse.

**Cerebral-evoked potentials**
Visual-evoked potentials (VEPs) record the interval visual stimuli take to reach the occipital cortex, and the amplitude of response. VEPs are used to confirm previous retrobulbar neuritis (p. 1102); this leaves a delayed latency despite clinical recovery.

Similar techniques for auditory and somatosensory potentials (from a limb) are also used.

**Lumbar puncture and CSF examination** (Table 21.19 and Practical box 21.3)

Indications for lumbar puncture (LP) are:
- diagnosis of meningitis and encephalitis
- diagnosis of subarachnoid haemorrhage (sometimes)
- measurement of CSF pressure, e.g. idiopathic intracranial hypertension (p. 1162)
- removal of CSF therapeutically, e.g. idiopathic intracranial hypertension
- diagnosis of various conditions, e.g. MS, neurophilis, sarcoidosis, Behçet’s, neoplastic involvement, polyneuropathies
- intrathecal injection/drugs.

Meticulous attention should focus on microbiology in suspected CNS infection. Close liaison between clinician and microbiologist is essential. Specific techniques (e.g. polymerase chain reaction to identify bacteria) are invaluable. Repeated CSF examination is often necessary in chronic infection such as tuberculosis. Post-LP headaches, worse on standing, are a common complaint for several days (or more). Prolonged headaches can be treated by an ‘autologous intrathecal blood patch’ – injection of 20 mL of the patient’s venous blood into the CSF.

**Biopsy**
Interpretation of brain, tonsillar, muscle and nerve histology requires specialist neuropathology services.

**Brain and meninges**
Brain biopsy (e.g. of a non-dominant frontal lobe) is sometimes used to diagnose inflammatory and degenerative brain diseases. CT and MR stereotactic biopsies of intracranial lesions are standard procedures.

**Tonsillar biopsy**
This is used in the diagnosis of variant Creutzfeldt–Jakob disease.

Practical Box 21.3 Lumbar puncture

The procedure should be explained carefully to the patient, and consent obtained. LP should not be performed in the presence of raised intracranial pressure or when an intracranial mass lesion is a possibility.

Technique
- The patient is placed on the edge of the bed in the left lateral position with knees and chin as close together as possible.
- The third and fourth lumbar spines are marked. The fourth lumbar spine usually lies on a line joining the iliac crests.
- Using sterile precautions, 2% lidocaine is injected into the dermis by raising a bleb in either the third or fourth lumbar interspace.
- The LP needle is pushed through the skin in the midline, steadily forwards and slightly towards the head, with the head and spine bolstered horizontally with pillows.
- When the needle is felt to penetrate the dura, the stylet is withdrawn and a few drops of CSF allowed to escape.
- The CSF pressure can then be measured with a manometer connected to the needle. The patient’s head must be on the same level as the sacrum. Normal CSF pressure is 60–150 mm of CSF. The level rises and falls with respiration and heart beat, and rises on coughing.
- CSF specimens are collected in three sterile bottles and a sample for CSF glucose, together with a simultaneous blood glucose sample.
- Record CSF naked-eye appearance: clear, cloudy, yellow (xanthochromic), red.
- The patient is asked to lie flat after the procedure to avoid subsequent headaches, but this manoeuvre is probably of little value.
- Analgesics may be required for post-LP headaches.

Contraindications
- Suspicion of a mass lesion in the brain or cord. Caudal herniation of the cerebellar tonsils (coning) may occur if an intracranial mass is present and the pressure below is reduced by removal of CSF.
- Any cause of raised intracranial pressure.
- Local infection near the LP site.
- Congenital lesions in the lumbosacral region (e.g. meningomyelocele).
- Platelet count <40 × 10^9/L and other clotting abnormalities, including anticoagulant drugs.
- Unconscious patients and those with papilloedema must have a CT scan before lumbar puncture.

Notes
- Contraindications are relative; there are circumstances when LP is carried out despite them.
- Composition of normal CSF is shown in Table 21.19.

Psychometric assessment

Psychometric testing assesses cognitive function. Preservation of verbal IQ (a measure of past attainments) with deterioration of performance IQ (a measure of present abilities) indicates decline of cognitive function, seen for example following brain injury or in dementia. Low subtest scores (e.g. block design, various aspects of memory, visual, speech and constructional skills) indicate impaired function of specific brain regions.

Depression and lack of attention also reduce scores – a substantial problem. Opinions sometimes vary between psychologists about interpretation of tests, particularly after brain injury, limiting the value of the tests.

Routine tests

See Table 21.20.

Specialized tests in specific diseases

Various tests are employed to diagnose individual (sometimes rare) diseases. Examples are:
- anti-cardiolipin and lupus anticoagulant antibody and detailed clotting studies in stroke (p. 544)
- antibody to acetylcholine receptor protein and anti-Mu SK antibodies in myasthenia gravis (p. 1180)
- serum copper and caeruloplasmin in Wilson’s disease (p. 357)
- blood lactate studies (failure to rise on exercise) in McArdle’s syndrome (p. 1182)
- anti-neuronal antibodies (paraneoplastic syndromes)
- serum phytic acid (elevated) in Refsum’s disease (p. 1174)
- serum long-chain fatty acid (present) in adrenoleucodystrophy (p. 1152)
- genetic studies – e.g. Huntington’s disease, hereditary sensorimotor neuropathies and ataxias (p. 1149 and p. 1175).

UNCONSCIOUSNESS AND COMA

The ascending reticular formation, extending from lower brainstem to thalamus, influences the state of arousal. Our state of consciousness is the product of complex interactions between parts of the reticular formation, cortex and brainstem, and all sensory stimuli.

Disturbed consciousness: definitions

Each term simply describes a recognizable state:
- Consciousness means wakefulness with awareness of self and surroundings.

- **Clouding of consciousness** – used more in psychiatry than neurology – means reduced wakefulness and/or self-awareness, sometimes with confusion.
- **Confusion** means that the subject is bewidered and misinterprets his/her surroundings.
- **Delirium** is a state of confusion, sometimes with visual hallucination, and often high arousal (e.g. *delirium tremens*, p. 1213).
- **Sleep** is normal mental and physical inactivity; the subject can be roused.
- **Stupor** is abnormal; a sleepy state from which the subject can be aroused by vigorous or repeated stimuli. The term is also used for psychiatric states, e.g. catatonic and depressive stupor (p. 1216).
- **Coma** means unrousable unresponsiveness.

The Glasgow Coma Scale, designed for recording coma following head injuries, is shown in Table 21.21.

### Mechanisms of coma

Altered consciousness is produced by three mechanisms affecting brainstem, reticular formation and cortex.

- **Diffuse brain dysfunction.** Generalized severe metabolic or toxic disorders (e.g. alcohol, sedatives, uraemia, septicaemia) depress overall brain function.
- **Direct effect within the brainstem.** A brainstem lesion inhibits the reticular formation.
- **Pressure effect on the brainstem.** A mass lesion within the brain compresses the brainstem, inhibiting the reticular formation.

A single focal hemisphere (or cerebellar) lesion does not produce coma unless it compresses or damages the brainstem. Cerebral oedema frequently surrounds masses, increasing their effects.

Other states of unresponsiveness must be distinguished from coma; this sometimes causes difficulty. Features of these are listed in Table 21.24 and illustrated in Figure 21.17.

### Causes of coma and stupor

Principal causes of coma and stupor are shown in Table 21.22. A common cause of coma in the UK is self-poisoning; world-wide, cerebral malaria is a frequent cause.
THE UNCONSCIOUS PATIENT

Immediate assessment
Actions that take seconds save lives, see Table 21.23.

- Assess airway; resuscitate.
- Obtain a history – circumstances, witnesses, paramedics, police. Many people carry drug details and identification data.

General and neurological examination
- Record depth of coma (Table 21.21).
- Examine the patient as fully as possible.
Many clues can point to the cause.

Temperature
Body temperature is raised in infection and hyperpyrexia, and is subnormal in hypothermia. Feel the abdomen and record the temperature.

Skin, skull, spine and injuries
Look for skull trauma/burr holes, neck stiffness, other injuries, cyanosis, jaundice, purpura, rashes, pigmentation and injection marks. In hypothyroidism, the skin is coarse/dry.

Breath
Sniff – for ketones, alcohol, hepatic and uraemic fetor.

Respiration
Depressed but regular respiration occurs in many states of stupor and coma. As coma deepens, respiration becomes irregular. Patterns of abnormal respiration are of significance:

- Cheyne–Stokes (periodic) respiration is alternating hyperpnoea and periods of apnoea. This may point to bilateral cerebral or upper brainstem dysfunction and may be a sign of incipient coning. A similar pattern can occur in normal people during deep sleep, in metabolic comas, with CO₂ retention, and chronic hypoxia at altitude.
- Acidotic (Kussmaul) respiration is sustained, deep, sighing hyperventilation seen in diabetic ketoacidosis and uraemia.
- Central neurogenic hyperventilation is sustained, rapid, respiration seen with pontine lesions. It may switch off and on abruptly.
- Ataxic respiration is shallow, halting, irregular respiration that frequently precedes death. The medullary respiratory centre is failing.
- Vomiting, hiccup and excessive yawning in stupor point to a lower brainstem lesion.

Pupils
Record size and reaction to light.

- Dilatation of one pupil that then becomes fixed to light indicates compression of the IIIrd nerve (coning of the temporal lobe uncus). This is a potential neurosurgical emergency (e.g. extradural haematoma).
- Horner’s syndrome (ipsilateral pupillary constriction and ptosis, p. 1103) occurs with hypothalamic damage and also, rarely, in coning.
- Bilateral mid-point reactive pupils (i.e. normal pupils) are characteristic of metabolic comas and follow coma due to sedative drugs except opiates.
- Bilateral light-fixed, dilated pupils are one cardinal sign of brain death. They can occur in deep coma of any cause, but particularly in barbiturate intoxication and hypothermia.
- Bilateral pinpoint, light-fixed pupils occur with pontine lesions (e.g. haemorrhage) and with opiates.
- Bilateral mid-position light-fixed or slightly dilated light-fixed pupils (4–6 mm), sometimes irregular, are seen in brainstem lesions.
- Mydriatic drugs and previous pupillary surgery can cause diagnostic difficulty.

Fundus
Look for papilloedema and retinal haemorrhage.

Ocular movements
In light coma, slow, roving, side-to-side eye movements are seen; oculan axes are often slightly divergent.

Vestibulo-ocular reflexes. Passive head turning produces conjugate ocular deviation away from the direction of rotation (doll’s head reflex). This reflex disappears in deep coma, in brainstem lesions and in brain death.

Calorics. Slow tonic ocular deviation towards the irrigated ear is seen when ice-cold water is run into the external auditory meatus – caloric/vestibulo-ocular reflexes, indicating an intact brainstem. Calorics are used in the confirmation of brain death (p. 920).

Abnormalities of conjugate gaze (p. 1105):

- Sustained conjugate lateral deviation towards a destructive frontal lesion – eyes look towards the normal limbs. An irritative lesion in one frontal lobe (e.g. an epileptic focus) drives the eyes away – deviation is away from the lesion. In the pons lesion, when one PPRF is damaged (p. 1104), sustained conjugate lateral deviation occurs away from the lesion, towards the weak limbs, because the opposite PPRF is active.
- Skew deviation (one eye up, the other down) indicates a brainstem or cerebellar lesion.
- Ocular bobbing, i.e. sudden, brisk, downward-diving eye movements, occur in pontine (or cerebellar) haemorrhage.

Other spontaneous eye movements (other than roving movements) are distinctly unusual in true coma.

Laterzelizing signs
Coma makes it difficult to recognize lateralizing signs. These are helpful:
Asymmetry of response to visual threat in a stuporous patient: suggests hemianopia.

Asymmetry of face: drooping or dribbling on one side, blowing in and out of mouth when the paralysed cheek does not move.

Asymmetry of tone. Unilateral flaccidity or spasticity may be the only sign of hemiparesis.

Asymmetry of decerebrate and decorticate posturing.

Asymmetrical response to painful stimuli.

Asymmetry of tendon reflexes and plantar responses. Both plantars are often extensor in deep coma.

Unresponsiveness of psychological origin is also a prominent cause of apparent coma.

**Investigations in coma**

Often, the cause is evident (e.g. head injury, cerebral haemorrhage, self-poisoning); if no cause is evident, further investigations are essential.

**Blood and urine**

- **Drugs screen** (e.g. salicylates, diazepam, narcotics, amphetamines).
- Routine biochemistry (urea, electrolytes, glucose, calcium, liver biochemistry).
- Metabolic and endocrine studies (TSH, cortisol).
- Blood cultures.
- Other, e.g. cerebral malaria (request thick blood film) and porphyria (p. 1073).

**Imaging**

CT or MR brain imaging may indicate an unsuspected mass lesion or intracranial haemorrhage.

**CSF examination**

Lumbar puncture should be performed in coma only after careful risk assessment. It is contraindicated when an intracranial mass lesion is a possibility: CT is essential to exclude this. CSF examination is likely to alter therapy only if undiagnosed meningoencephalitis or other infection is present.

**Electroencephalography**

EEG is of some value in the diagnosis of metabolic coma and encephalitis.

**Management**

Comatose and stuporose patients – at home or outside, on a trolley, in a ward or ITU – need immediate careful nursing, meticulous attention to the airway, and frequent monitoring of vital functions.

Longer-term essentials are:

- skin care – tuning (to avoid pressure sores and pressure palsies), removal of jewellery
- oral hygiene – mouthwashes, suction
- eye care – prevention of corneal damage (lid taping, irrigation)
- fluids – intragastric or i.v.
- calories – liquid diet through a fine intragastric tube, 1255 kJ (3000 kcal) daily
- sphincters – catheterization when essential (use Paul’s tubing if possible); rectal evacuation.

**Differential diagnosis of the vegetative state**

Prolonged coma and similar states require accurate diagnosis to assess the nature of the problem, prognosis and management (Table 21.24).

EEG, electroencephalography; PET, positron emission tomography; VS, vegetative state

EEG and PET are not required to confirm brain death

Vegetative state (VS) is a sequel of, for example, widespread cortical damage after brain injury. Brainstem function is normal. VS implies loss of sentient behaviour. The patient perceives little or nothing but lies apparently awake, breathing spontaneously.

Minimally conscious state (MCS) describes patients with some sentient behaviour, e.g. apparent, vague pain perception. A patient may emerge from VS into MCS.

Locked-in syndrome is a state of unresponsiveness due to massive brainstem damage below the level of the IIIrd nerve nuclei. The patient has a functioning cerebral cortex and is fully aware, unlike the VS/MCS patient. They cannot move or communicate except by vertical eye movement.

Brainstem death is discussed on page 920.

Distinction between these states is essential before addressing issues of prognosis and cessation of supportive care.

STROKE AND CEREBROVASCULAR DISEASE

Stroke is the second commonest cause of death (9%) and a major cause of disability world-wide. Although data are difficult to obtain, approximately two-thirds of the global burden of strokes is in middle- and low-income countries. WHO has introduced a strokes surveillance study in developing countries (STEPS surveillance). The age-adjusted annual death rate from strokes is about 200 per 100,000 in the UK (12% of all deaths). Rates are higher in Asian and black African populations than in Caucasians. Stroke is uncommon below the age of 40 and commoner in males. The death rate following stroke is 20–25%. Hypertension is the most treatable stroke risk factor; stroke is decreasing in the 40–60 age group because hypertension is treated. In the elderly, it remains a major cause of morbidity and mortality. Thromboembolic infarction (80%), cerebral and cerebellar haemorrhage (10%) and subarachnoid haemorrhage (SAH) (about 5%) are the main causes; arterial dissection and arteriovenous malformations also contribute.

Definitions

Stroke. To the public, stroke means weakness, usually permanent on one side, often with loss of speech. Stroke is defined as a syndrome of rapid onset of cerebral deficit (usually focal) lasting >24 hours or leading to death, with no cause apparent other than a vascular one. Hemiplegia following middle cerebral arterial thromboembolism is the typical example.

Completed stroke means the deficit has become maximal, usually within 6 hours.

Stroke-in-evolution describes progression during the first 24 hours.

Minor stroke. Patients recover without significant deficit, usually within a week.

Transient ischaemic attack (TIA) means a sudden focal deficit, e.g. a weak limb, aphasia or loss of vision lasting from seconds to 24 hours with complete recovery. This definition is unsatisfactory as after 1 hour ischaemic damage has already occurred (see below). TIAs have a tendency to recur, and may herald thromboembolic stroke.

Avoid the vague term ‘cerebrovascular accident’.

Pathophysiology

Different pathological processes cause similar clinical events in cerebrovascular disease.

Completed stroke

This is caused by:

- arterial embolism from a distant site (usually heart, carotid, vertebral or basilar arteries) and subsequent brain infarction
- arterial thrombosis in atheromatous carotid, vertebral or cerebral arteries with subsequent infarction
- haemorrhage (intracranial or SAH).

Less commonly, other processes cause stroke:

- venous infarction
- carotid or vertebral artery dissection
- polycythaemia and hyperviscosity syndromes
- fat and air embolism (see diving, p. 956)
- multiple sclerosis – demyelinating plaque(s)
- mass lesions (e.g. brain tumour, abscess, subdural haemorrhage).

Transient ischaemic attacks

TIAs are usually the result of microemboli, but different mechanisms produce similar clinical events. For example, TIAs may be caused by a fall in cerebral perfusion (e.g. a cardiac dysrhythmia, postural hypotension or decreased flow through atheromatous arteries). Infarction is usually averted by autoregulation (p. 1127). Small areas of infarction following thrombosis or haemorrhage may occasionally cause a clinical TIA, and 25% of TIAs have MRI changes showing small infarcts. Rarely, tumours and subdural haematomas cause episodes indistinguishable from thromboembolic TIAs: a clinical TIA is thus not a reliable indicator of thromboembolism. Principal sources of emboli to the brain are cardiac thrombi and atheromatous plaques/thrombi within the great vessels, carotid and vertebral systems. Cardiac thrombi (mural and valvular) follow atrial fibrillation, often secondary to valvular disease, or myocardial infarction. Polycythaemia is also a cause. Thromboembolism from sources outside the brain generates 80% of TIAs and also 70% of strokes.

Carotid and vertebral artery dissection

Dissection accounts for around 1 in 5 strokes below age 40 and is sometimes a sequel of head or neck trauma. Stroke, TIA or sudden headache/migraine-like symptoms occur, sometimes with neck pain at the site of dissection.

Risk factors and prevention

The principal risk factors and effects of altering these are shown in Table 21.25.

Low-dose aspirin is used in primary prevention in men and women with a 10-year risk of coronary heart disease greater than 10%; its effect on stroke prevention is unclear.

For brain haemorrhage, hypertension, bleeding disorders, anticoagulants and antiplatelet drugs, pre-existing cerebral aneurysms and AVMS are risk factors.
Rarer risk factors and other causes of stroke

- Thrombocytopenia and thrombophilia (protein C deficiency, factor V Leiden) are weakly associated with arterial stroke but predispose to cerebral venous thrombosis.
- Anti-cardiolipin and lupus anticoagulant antibodies (antiphospholipid syndrome, p. 544) predispose to arterial thrombotic strokes in young patients.
- Endocarditis (p. 769) – thromboembolic stroke may be the presenting feature.
- Low-dose oestrogen-containing oral contraceptives do not increase stroke risk significantly in healthy women but probably do so with other risk factors, e.g. uncontrolled hypertension or smoking.
- Migraine is a rare cause of cerebral infarction (p. 1136).
- Vasculitis (systemic lupus erythematosus (SLE), polyarteritis, giant cell arteritis, granulomatous CNS angiitis) is a rare cause of stroke.
- Amyloidosis can present as recurrent cerebral haemorrhage (p. 1072).
- Hyperhomocysteinaemia predisposes to thrombotic strokes. Folic acid therapy does not reduce the incidence.
- Neurosyphilis, SLE, mitochondrial disease.
- Drugs of abuse e.g. cocaine, and possibly over-the-counter cold remedies containing vasoconstrictors.
- Cox-2 inhibitors are associated with a slightly increased incidence of stroke (p. 517).

CADASIL (cerebral dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is a rare inherited cause of stroke/vascular dementia. There is a mutation in the NOTCH3 gene on chromosome 19. Characteristic damage to small brain arterioles follows with multiple infarcts, which can be seen on MRI in the subcortical white matter. A skin biopsy shows granular osmophilic material (GOM). Familial migraine and depression occur in youth, progressing to TIA and stroke in the third and fourth decades, and dementia in the sixth.

Vascular anatomy

Knowledge of normal arterial anatomy and likely sites of atheromatous plaques and stenoses helps understanding of the main stroke syndromes.

The circle of Willis is supplied by the two internal carotid arteries and by the basilar. The distribution of the anterior, middle and posterior cerebral arteries that supply the cerebrum is shown in Figures 21.18–21.20.

Stenoses and plaques proximal to the circle of Willis are seen typically at four extracranial sites (1–4: see Fig. 21.20):

- origin of common carotid artery (1)
- origin of internal carotid artery (2)
- origin of vertebral artery (3)
- subclavian artery (4) and carotid artery syphon – within the cavernous sinus.

Autoregulation

Usually, constant cerebral blood flow (CBF) is maintained at mean arterial blood pressures between 60 and 120 mmHg. Smooth muscle in small arteries responding directly to changes in pressure. CBF is normally independent of perfusion pressure, i.e. there is autoregulation.

In disease, CBF autoregulation can fail. Contributory causes are:

Differential diagnosis

TIAs can be distinguished, usually on clinical grounds, from other transient episodes (p. 1144). Occasionally, events identical to TIAs are produced by mass lesions. Focal epilepsy is usually recognized by its positive features (e.g. limb jerking and loss of consciousness) and progression over minutes. In a TIA, involuntary limb movements do occur occasionally; deficit is usually instantaneous. A focal prodrome in migraine sometimes causes diagnostic difficulty. Headache, common but not invariable in migraine, is rare in TIA. Typical migrainous visual disturbances are not seen in TIA. Investigations and management are discussed with stroke (p. 1131).

Prognosis

Prospective studies show that 5 years after a single thromboembolic TIA:

- 30% have had a stroke, a third of these in the first year
- 15% have suffered a myocardial infarct.

TIAs in the anterior cerebral circulation carry a more serious prognosis than those in the posterior circulation (see Table 21.26).

Cerebral infarction

Major thromboembolic cerebral infarction usually causes an obvious stroke. Some small infarcts cause TIAs; others are silent. The clinical picture is thus very variable, depending on the infarct site and extent. Whilst the general site can be deduced from physical patterns (e.g. cortex, internal capsule, brainstem), clinical estimations of precise vascular territories are often inaccurate, when compared to imaging.

Following vessel occlusion brain ischaemia occurs, followed by infarction. The infarcted region is surrounded by a swollen area which does not function but is structurally intact. This is the ischaemic penumbra, which is detected on MRI and can regain function with neurological recovery.

Within the ischaemic area, hypoxia leads to neuronal damage. There is a fall in ATP with release of glutamate, which opens calcium channels with release of free radicals. These alterations lead to inflammatory damage, necrosis and apoptotic cell death.

Clinical features

The stroke most typically seen is caused by infarction in the internal capsule following thromboembolism in a middle cerebral artery branch (Fig. 21.21). A similar picture is caused by internal carotid occlusion (see Fig. 21.20). Limb weakness on the opposite side to the infarct develops over seconds, minutes or hours (occasionally longer). There is a contralateral hemiplegia or hemiparesis with facial weakness. Aphasia is usual when the dominant hemisphere is affected. Weak limbs are at first flaccid and areflexic. Headache is unusual. Consciousness is usually preserved. Exceptionally, an epileptic seizure occurs at the onset. After a variable interval, usually several days, reflexes return, becoming exaggerated. An extensor plantar response appears. Weakness is maximal at first; recovery occurs gradually over days, weeks or many months.

Brainstem infarction

This causes complex signs depending on the relationship of the infarct to cranial nerve nuclei, long tracts and brainstem connections (Table 21.27).

- The lateral medullary syndrome (posterior inferior cerebellar artery (PICA) thrombosis and Wallenberg’s syndrome) is a common example of brainstem infarction presenting as acute vertigo with cerebellar and other signs (Table 21.28 and Fig. 21.22). It follows thromboembolism in the PICA or its branches, vertebral artery thromboembolism or dissection. Features depend on the precise structures damaged.
- Coma follows damage to the brainstem reticular activating system.
- The locked-in syndrome is caused by upper brainstem infarction (p. 1126).
- Pseudobulbar palsy (p. 1110) can follow lower brainstem infarction.

Other patterns of infarction

Lacunar infarction
Lacunes are small (<1.5 cm³) infarcts seen on MRI or at autopsy. Hypertension is commonly present. Minor strokes (e.g. pure motor stroke, pure sensory stroke, sudden unilat- eral ataxia and sudden dysarthria with a clumsy hand) are syndromes caused typically by single lacunar infarcts. Lacunar infarction is often symptomless.

Hypertensive encephalopathy (p. 800)
This is due to cerebral oedema, causing severe headaches, nausea and vomiting. Agitation, confusion, fits and coma occur if the hypertension is not treated. Papilloedema develops, either due to ischaemic optic neuropathy or following the brain swelling due to multiple acute infarcts. MRI shows oedematous white matter in the parieto-occipital regions.

Multi-infarct dementia (vascular dementia)
Multiple lacunes or larger infarcts cause generalized intel- llectual loss seen with advanced cerebrovascular disease. In the late stages, there is dementia, pseudobulbar palsy and a shuffling gait – the marche à petits pas (small steps), sometimes called atherosclerotic parkinsonism. Binswanger's disease is a term for widespread low attenuation in cerebral white matter, usually with dementia, TIA and stroke epi- sodes in hypertensive patients (the changes being seen on imaging/autopsy).

Visual cortex infarction
Posterior cerebral artery infarction or infarction of the middle cerebral artery macular branch causes combinations of hemianopic visual loss and cortical blindness (Anton's syndrome, Fig. 21.19 and p. 1128).

Weber's syndrome
Ipsilateral Illrd nerve palsy with contralateral hemiplegia is due to a unilateral infarct in the midbrain. Paralysis of upward gaze is usually present.

Watershed (borderzone) infarction
Cortical infarcts, often multiple, follow prolonged periods of low perfusion (e.g. hypotension after massive myocardial infarction or cardiac bypass surgery). Infarcts occur in the borderzones, between areas supplied by the anterior, middle and posterior cerebral arteries. Cortical visual loss, memory loss and intellectual impairment are typical. In some cases a vegetative state or minimal conscious state follows (p. 1125).

Acute stroke: immediate care, and thrombolysis
Paramedics and members of the public are encouraged to make the diagnosis of stroke on a simple history and exami- nation – FAST:
- Face – sudden weakness of the face
- Arm – sudden weakness of one or both arms
- Speech – difficulty speaking, slurred speech
- Time – the sooner treatment can be started, the better.

Dedicated units with multidisciplinary, organized teams deliver higher standards of care than a general hospital ward, reducing stroke mortality and long-term disability. Evidence- based guidelines have contributed to clear protocols. Admission to hospital should proceed without delay, for imaging, care and investigation.

Following a stroke, immediate, continued and meticulous attention to the airway and to swallowing is essential. Manage- ment of unconscious or stuporose patients is outlined on page 1125.

In cerebral infarction, the issue is thrombolysis. Table 21.29 outlines the current proposals for stroke thrombolysis. The benefit of thrombolysis is shown on CT perfusion scans (Fig. 21.23 a and b) and decreases with time, even within the time window of 4.5 hours. Every minute counts. If thrombolysis is not given, aspirin 300 mg daily should be given as soon as a diagnosis of ischaemic stroke or thromboembolic TIA is confirmed, reducing to 75 mg after several days. Following thrombolysis aspirin should not be started until 24–48 hours later.

Investigations
The purpose of investigations in stroke is:
- to confirm the clinical diagnosis and distinguish between haemorrhage and thromboembolic infarction
- to look for underlying causes and to direct therapy
- to exclude other causes, e.g. tumour.

Sources of embolus should be sought (e.g. carotid bruit, atrial fibrillation, valve lesion, evidence of endocarditis, previ- ous emboli or TIA) and hypertension/postural hypotension assessed. Brachial BP should be measured on each side; >20 mmHg difference is suggestive of subclavian artery stenosis.

![Fig. 21.22 Medulla (cross-section): structures at risk after brainstem infarction.](image)

![Fig. 21.23 CT perfusion scans: (a) pre-thrombolysis; (b) post-thrombolysis showing reperfusion of the ischaemic site. (Courtesy of Professor Adrian Dixon, Cambridge Radiology Department, UK.)](image)
Routine investigations in thromboembolic stroke and TIA with their potential yields are listed in Box 21.1.

**Imaging in acute stroke**

**CT and MRI:**

- **Non-contrast CT** will demonstrate haemorrhage immediately but cerebral infarction is often not detected or only subtle changes are seen initially (Fig. 21.24a).
- MRI shows changes early in infarction (Fig. 21.25a) and a later MRI shows the full extent of the damaged area or penumbra (Fig. 21.25b).
- **Diffusion-weighted MRI (DWI)** can detect cerebral infarction immediately (see Fig. 21.24b) but is as accurate as CT for the detection of haemorrhage.

**Further investigations**

- Routine bloods (for ESR, polycythaemia, infection, vasculitis, thrombophilia, syphilitic serology, clotting studies, autoantibodies, lipids)
- Chest X-ray
- ECG
- Carotid Doppler studies
- MR angiography, if appropriate

**Further management**

- Drugs for hypertension, heart disease, diabetes, other medical conditions
- Other antiplatelet agents, e.g. dipyridamole
- Question of endarterectomy
- Question of anticoagulation – Table 21.30
- Speech therapy, dysphagia care, physiotherapy, occupational therapy
- Specific issues, e.g. epilepsy, pain, incontinence
- Preparations for future care

**Fig. 21.24 Middle cerebral artery infarction.** (a) CT performed initially shows only very subtle low density changes in right MCA territory. (b) Diffusion-weighted MRI done at the same time shows full extent of the area of ischaemia. (Courtesy of Dr Paul Jarman.)

CT is still more widely available than MRI and should be performed if MRI is unavailable so that there is no delay in giving thrombolysis for cerebral infarction.

More detailed studies involving perfusion-weighted images and diffusion-weighted MRI will differentiate the infarct core and the penumbral area which is potentially recoverable.

**Treatment of acute stroke**

This is shown in Box 21.2. Thrombolysis has been shown to improve outcome and should be used immediately if there are no contraindications. In a massive middle cerebral artery infarct, hemispheric swelling occurs with oedema (Fig. 21.26). Decompressive hemicraniectomy reduces the intracranial pressure and the mortality but extensive neurological deficits remain.

**Later investigations**

MR angiography (MRA) or CT angiography is valuable in anterior circulation TIAs to confirm surgically accessible arterial stenoses, mainly internal carotid stenosis (Fig. 21.25c). If ultrasound suggests carotid stenosis, normotensive patients with TIA or stroke in the anterior circulation should have vascular imaging.
Carotid Doppler and duplex scanning. These screen for carotid (and vertebral) stenosis and occlusion: in skilled hands they demonstrate accurately the degree of internal carotid stenosis.

**Long-term management**

**Medical therapy**

Risk factors (Table 21.25) should be identified and addressed.

**Antihypertensive therapy**

Recognition and good control of high blood pressure is the major factor in primary and secondary stroke prevention.

Transient hypertension, often seen following stroke, usually does not require treatment provided diastolic pressure does not rise >100 mmHg. Sustained severe hypertension needs treatment (p. 1805); BP should be lowered slowly to avoid any sudden fall in perfusion.

**Antiplatelet therapy** (see also p. 443)

Long-term soluble aspirin (75 mg daily) reduces substantially the incidence of further infarction following thromboembolic TIA or stroke. Aspirin inhibits cyclo-oxygenase, which converts arachidonic acid to prostaglandins and thromboxanes; predominant therapeutic effects are reduction of platelet aggregation. Clopidogrel and dipyridamole are also used (p. 443). Combined aspirin 75 mg daily and dipyridamole 200 mg twice daily possibly provide optimal prophylaxis against further thromboembolic stroke or TIA.
**Anticoagulants**

Heparin and warfarin should be given when there is atrial fibrillation, other paroxysmal dysrhythmias or when there are cardiac valve lesions (uninfected) or cardiomyopathies. Brain haemorrhage must be excluded by CT/MRI. Patients must be aware of the small risk of cerebral (and other) haemorrhage. Anticoagulants are potentially dangerous in the two weeks following infarction because of the risk of provoking cerebral haemorrhage; there are wide differences in clinical practice. Table 21.30 outlines the issues in secondary stroke prevention.

**Other measures**

Polycythaemia and any clotting abnormalities should be treated (p. 419). Statin therapy should be given for all.

**Surgical approaches**

**Internal carotid endarterectomy**

Surgery is usually recommended in TIA or stroke patients with internal carotid artery stenosis >70%. Successful surgery reduces the risk of further TIA/stroke by around 75%. Endarterectomy has a mortality around 3%, and a similar risk of stroke. Percutaneous transluminal angioplasty (stenting) is an alternative. The value of surgery for asymptomatic carotid stenosis is debatable.

**Stroke in the elderly**

Whilst in the elderly the yield of investigation in stroke diminishes, age is no barrier to recovery; elderly patients benefit the most from good rehabilitation. Consider social isolation, pre-existing cognitive impairment, nutrition, skin and sphincter care, and reassess swallowing. Carotid endarterectomy over 75 years carries little more risk than in younger cases.

**Rehabilitation: multidisciplinary approach**

Skilled physiotherapy has particular value in the first few weeks after stroke to relieve spasticity, prevent contractures and teach patients to use walking aids. The benefits of physiotherapy for longer-term outcome are still inadequately researched. Baclofen and/or botulinum toxin are sometimes helpful in the management of severe spasticity.

Speech therapists have a vital understanding of aphasics' problems and frustration. Return of speech is hastened by conversation generally. If swallowing is unsafe because of the risk of aspiration, either nasogastric feeding or percutaneous gastrostomy will be needed. Video-fluoroscopy while attempting to swallow is helpful.

Physiotherapy, occupational and speech therapy have a vital role in assessing and facilitating the future care pathway. Stroke is frequently devastating and, particularly during working life, alters radically the patient’s remaining years. Many become unemployable, lose independence and are financially embarrassed. Loss of self-esteem makes depression common.

At home, aids and alterations may be needed: stair and rail rails, portable lavatories, hoists, sliding boards, wheelchairs, tripods, stair lifts, electric blinds and modified sleeping arrangements, kitchen, steps, flooring and doorways. Liaison between hospital-based and community care teams, and primary care physician is essential.

Modified from Brown M. Medicine 2000; 28(7): 64.

**Intracranial haemorrhage**

This comprises:
- intracerebral and cerebellar haemorrhage
- subarachnoid haemorrhage
- subdural and extradural haemorrhage/haematoma.

**Intracerebral haemorrhage**

**Aetiology**

Intracerebral haemorrhage causes approximately 10% of strokes. Rupture of microaneurysms (Charcot–Bouchard
aneurysms, 0.8–1.0 mm diameter) and degeneration of small deep penetrating arteries are the principal pathology. Such haemorrhage is usually massive, often fatal, and occurs in chronic hypertension and at well-defined sites — basal ganglia, pons, cerebellum and subcortical white matter.

In normotensive patients, particularly over 60 years, lobar intracerebral haemorrhage occurs in the frontal, temporal, parietal or occipital cortex. Cerebral amyloid angiopathy (rare) is the cause in some of these haemorrhages, and the tendency to rebleed is associated with particular apolipoprotein E genotypes.

**Recognition**

At the bedside, there is no entirely reliable way of distinguishing between haemorrhage and thromboembolic infarction. Both produce stroke. Intracerebral haemorrhage tends to be dramatic with severe headache. It is more likely to lead to coma than thromboembolism.

Brain haemorrhage is seen on CT imaging immediately (cf. infarction, p. 1132) as intraparenchymal, intraventricular or subarachnoid blood. Routine MRI may not identify an acute small haemorrhage correctly in the first few hours but MRI diffusion weighted (MRI DW) is as good as CT.

**Management: haemorrhagic stroke**

The principles are those for cerebral infarction. The immediate prognosis is less good. Antplatelet drugs and, of course, anticoagulants are contraindicated. Control of hypertension is vital. Urgent neurosurgical clot evacuation is occasionally necessary when there is deepening coma and coning (particularly in cerebellar haemorrhage).

**Cerebellar haemorrhage** (Fig. 21.27)

There is headache, often followed by stupor/coma and signs of cerebellar/brainstem origin (e.g. nystagmus, ocular palsies). Gaze deviates towards the haemorrhage. Skew deviation (p. 1105) may develop. Cerebellar haemorrhage sometimes causes acute hydrocephalus, a potential surgical emergency.

**Subarachnoid haemorrhage (SAH)**

SAH means spontaneous arterial bleeding into the subarachnoid space, and is usually clearly recognizable clinically from its dramatic onset. SAH accounts for some 5% of strokes and has an annual incidence of 6 per 100,000.

**Causes**

The causes of SAH are shown in Table 21.31; it is unusual to find any contributing disease.

**Saccular (berry) aneurysms** (Fig. 21.28)

Saccular aneurysms develop within the circle of Willis and adjacent arteries. Common sites are at arterial junctions:

- between posterior communicating and internal carotid artery – posterior communicating artery aneurysm
- between anterior communicating and anterior cerebral artery – anterior communicating and anterior cerebral artery aneurysm
- at the trifurcation or a bifurcation of the middle cerebral artery – middle cerebral artery aneurysm.

Other aneurysm sites are on the basilar, posterior inferior cerebellar, intracavernous internal carotid and opthalmic arteries. Saccular aneurysms are an incidental finding in 1% of autopsies and can be multiple.

Aneurysms cause symptoms either by spontaneous rupture, when there is usually no preceding history, or by direct pressure on surrounding structures; for example, an enlarging unruptured posterior communicating artery aneurysm is the commonest cause of a painful IIIrd nerve palsy (p. 1105).

**Arteriovenous malformation (AVM)**

AVMs are collections of arteries and veins of developmental origin. An AVM may also cause epilepsy, often focal. Once an AVM has ruptured, the tendency is to rebleed – 10% will then do so annually.

Cavernous haemangiomas (cavernomas) are common (<0.5% of population) and consist of collections of capillary vessels; they are frequently symptomless (Fig. 21.29) and seen incidentally on imaging. Cavernomas occasionally have a genetic basis, with linkage to two loci on chromosome 7q. Rarely cavernomas cause seizures or bleed; exceptionally they cause sudden death from massive haemorrhage. Surgery is rarely appropriate.

*Fig. 21.27* CT: Cerebellar haemorrhage.

*Fig. 21.28* Digital subtraction angiogram: posterior communicating artery aneurysm.

*Fig. 21.29* MR T2: Symptomless frontal cavernoma (arrow).
Clinical features of subarachnoid haemorrhage

There is a sudden devastating headache, often occipital. Headache is usually followed by vomiting and often by coma and death. Survivors may remain comatose or drowsy for hours, days, or longer. Less severe headaches, without loss of consciousness, can cause difficulty (p. 1096); SAH is a possible diagnosis in any sudden headache.

Following major SAH there is neck stiffness and a positive Kernig’s sign. Papilloedema is sometimes present, with retinal and/or subhyaloid haemorrhage (tracking beneath the retinal hyaloid membrane). Minor bleeds cause few signs, but almost invariably headache.

Investigations

CT imaging is the immediate investigation needed (Fig. 21.30). Subarachnoid and/or intraventricular blood is usually seen. Lumbar puncture is not necessary if SAH is confirmed by CT, but should be performed if doubt remains. CSF becomes yellow (xanthochromic) several hours after SAH. Visual inspection of supernatant CSF is usually sufficiently reliable for diagnosis. Spectrophotometry to estimate bilirubin in the CSF released from lysed cells is used to define SAH with certainty. MR angiography is usually performed in all potentially fit for surgery, i.e. generally below 65 years and awake. In some, no aneurysm or source of bleeding is found, despite a definite SAH.

Differential diagnosis

SAH must be differentiated from migraine. This is sometimes difficult. Thunderclap headache is used (confusingly) to describe either SAH or a sudden (benign) headache for which no cause is ever found. Acute bacterial meningitis occasionally causes a very abrupt headache, when a meningeal microabscess ruptures; SAH also occasionally occurs at the onset of acute bacterial meningitis. Cervical arterial dissection can present with a sudden headache.

Complications

Blood in the subarachnoid space can lead to obstructive hydrocephalus, seen on CT. Hydrocephalus can be asymptomatic but may cause deteriorating consciousness following after SAH. Shunting may be necessary. Arterial spasm (visible on angiography and a cause of coma or hemiparesis) is a serious complication of SAH and a poor prognostic feature.

Management

Immediate treatment of SAH is bed rest and supportive measures. Hypertension should be controlled. Dexamethasone is often prescribed to reduce cerebral oedema; it also is believed to stabilize the blood-brain barrier. Nimodipine, a calcium-channel blocker, reduces mortality.

Subdural and extradural bleeding

These conditions can cause death following head injuries unless treated promptly.

Subdural haematoma (SDH)

SDH means accumulation of blood in the subdural space following rupture of a vein. This usually follows a head injury, sometimes trivial. The interval between injury and symptoms can be days, or extend to weeks or months. Chronic, apparently spontaneous SDH is common in the elderly, and also occurs with anticoagulants.

Headache, drowsiness and confusion are common; symptoms are indolent and can fluctuate. Focal deficits, e.g. hemiparesis or sensory loss, develop. Epilepsy occasionally occurs. Stupor, coma and coning may follow.

Extradural haemorrhage (EDH)

EDH typically follows a linear skull vault fracture tearing a branch of the middle meningeal artery. Extradural blood accumulates rapidly over minutes or hours. A characteristic picture is of a head injury with a brief duration of unconsciousness, followed by improvement (the lucid interval). The patient then becomes stuporose, with an ipsilateral dilated pupil and contralateral hemiparesis, with rapid transtentorial coning. Bilateral fixed dilated pupils, tetraplegia and respiratory arrest follow. An acute progressive SDH presents similarly.

Management

Possible extradural or subdural bleeding needs immediate imaging. CT (Fig. 21.31a) is the most widely used investigation because of its immediate availability. MRI is more sensi-
tive for the detection of small haematomas. T1 weighted MRI (Fig. 21.31b) shows bright images due to the presence of methaemoglobin.

EDHs require urgent neurosurgery; if it is performed early, the outlook is excellent. When far from a neurosurgeon, e.g. in wartime or at sea, drainage through skull burr-holes has been lifesaving when an EDH has been diagnosed clinically.

Subdural bleeding usually needs less immediate attention but close neurosurgical liaison is necessary. Even large collections can resolve spontaneously without drainage. Serial imaging is needed to assess progress.

CORTICAL VENOUS THROMBOSIS AND DURAL VENOUS SINUS THROMBOSIS

Intracranial venous thromboses are usually (>50%) associated with a pro-thrombotic risk factor, e.g. oral contraceptives, pregnancy, genetic or acquired pro-thrombotic states and dehydration. Head injury is also a cause. Infection, e.g. from a paranasal sinus, may be present. Venous thromboses can also arise spontaneously.

Cortical venous thrombosis

The venous infarct leads to headache, focal signs (e.g. hemiparesis) and/or epilepsy, often with fever.

Dural venous sinus thromboses

Cavernous sinus thrombosis causes ocular pain, fever, proptosis and chemosis. External and internal ophthalmoplegia with papilloedema develops.

Sagittal and lateral sinus thrombosis cause raised intracranial pressure with headache, fever, papilloedema and often epilepsy.

Management

MRI, MRA and MR venography (MRV) show occluded sinuses and/or veins. Treatment is with heparin initially, though its value is questioned, followed by warfarin for 6 months. Anti-convulsants are given if necessary.

HEADACHE, MIGRAINE AND FACIAL PAIN

Headache is one of the commonest symptoms in primary care and a frequent reason for hospital referral. Most headaches are innocent, reflecting no sinister intracranial disease. Headache symptoms are unpleasant, disabling, common world-wide and have a substantial economic impact because of time lost from work (p. 1096 and Table 21.1). There is an internationally agreed classification for headaches that defines all headache patterns in detail.

Tension headache

The vast majority of chronic daily headaches and recurrent headaches are thought to be generated by neurovascular irritation and referred to scalp muscles and soft tissues, although the exact pathogenesis remains unclear. Tight band sensations, pressure behind the eyes, throbbing and bursting sensations are common. What is clear is that almost all headaches with these features are benign.

There may be obvious precipitating factors such as worry, noise, concentrated visual effort or fumes. Depression is also a frequent co-morbid feature. Tension headaches are often attributed to cervical spondylosis, refractive errors or high blood pressure: evidence for such associations is poor. Headaches also follow even minor head injuries. Tenderness and tension in neck and scalp muscles are the only physical signs. Analgesic overuse is a prominent cause of headache.

Management

Headache management involves:

- explanation (imaging is often needed)
- avoiding evident causes, e.g. bright lights
- analgesic withdrawal
- physical treatments – massage, ice packs, relaxation
- antidepressants – when indicated
- drugs for recurrent headache/migraine.

Migraine

Migraine is recurrent headache associated with visual and gastrointestinal disturbance. The borderland between migraine and tension headaches can be indistinct. Over 20% of any population world-wide report migrainous symptoms; in 90%, these began before 40 years of age.

Mechanisms

Precise mechanisms remain unclear. Genetic factors play some part – a rare form of familial migraine is associated with mutation in the alpha-1 subunit of the P/Q-type voltage-gated calcium channel on chromosome 19.

The pathophysiology of migraine is now thought to involve changes in the brainstem blood flow which have been found on PET scanning during migraine attacks. This leads to an unstable trigeminal nerve nucleus and nuclei in the basal thalamus. This results in release of calcitonin-related peptide (CGRP), substance P and other vasoactive peptides, leading to neurogenic inflammation, which gives rise to pain, and vasodilatation of cerebral and dural vessels which also contribute towards the headache.
Cortical spreading depression is also proposed as a mechanism for the aura.

Some patients recognize precipitating factors:

- weekend migraine (a time of relaxation)
- chocolate (high in phenylethylamine)
- cheese (high in tyramine)
- noise and irritating lights
- association with premenstrual symptoms.

Migraine is common around puberty and at the menopause and sometimes increases in severity or frequency with hormonal contraceptives, in pregnancy and occasionally with the onset of hypertension or following minor head trauma. Migraine is not suggestive of any serious intracranial lesion. However, since migraine is so common, an intracranial mass and migraine sometimes occur together by coincidence.

Clinical patterns
Migraine attacks vary from intermittent headaches indistinguishable from tension headaches to discrete episodes that mimic thromboembolic cerebral ischaemia. Distinction between variants is somewhat artificial. Migraine can be separated into phases:

- well-being before an attack (occasional)
- prodromal symptoms
- the main attack – headache, nausea, vomiting
- sleep and feeling drained afterwards.

Migraine with aura (classical migraine)
Prodromal symptoms are usually visual and related to depression of visual cortical function or retinal function. Unilateral patchy scotomata (retina), hemianopic symptoms (cortex), teichopsia (flashes) and fortification spectra (jagged lines like battlements) are common. Transient aphasia sometimes occurs, with tingling, numbness, vague weakness of one side and nausea. The prodrome persists for a few minutes to about an hour. Headache then follows. This is occasionally hemicranial (i.e. splitting the head) but often begins locally and becomes generalized. Nausea increases and vomiting follows. The patient is irritable and prefers the dark. Superficial scalp arteries are engorged and pulsating. After several hours the migraine settles, sometimes with a diuresis. Deep sleep often ensues.

Migraine without aura (common migraine)
This is the usual variety. Prodromal visual symptoms are vague. There is a similar headache often accompanied by nausea and malaise.

Basilar migraine
Prodromal symptoms include circumoral and tongue tingling, vertigo, diplopia, transient visual disturbance (even blindness), syncope, dysarthria and ataxia. These occur alone or progress to a typical migraine.

Hemiparetic migraine
This rarity is classical migraine with hemiparetic features, i.e. resembling a stroke, but with recovery within 24 hours. Exceptionally, cerebral infarction occurs.

Ophthalmoplegic and facioplegic migraine
These rarities are a IIIrd, VIth or VIIth nerve palsy with a migraine, and they are difficult to diagnose without investigation to exclude other conditions.

Differential diagnosis
A sudden migraine headache may resemble SAH or the onset of meningitis. Hemiplegic, visual and hemisensory symptoms must be distinguished from thromboembolic TIAs (p. 1128). In TIAs maximum deficit is present immediately and headache is unusual. Unilateral tingling or numbness may resemble sensory epilepsy (partial seizures). In epilepsy, distinct march (progression) of symptoms is usual.

Management
General measures include:

- explanation
- avoidance of dietary factors – rarely helpful.

Patients taking hormonal contraceptives may benefit from a brand change, or trying without. Depot oestrogens are sometimes used. Severe hemiparetic symptoms are a potential reason to stop hormonal contraceptives. Premenstrual migraine sometimes responds to diuretics.

At the start of an attack. Paracetamol or other analgesics should be taken, with an antiemetic such as metoclopramide if necessary. Repeated use of analgesics leads to further headaches. Triptans (SHT, agonists) are also widely used, sometimes aborting an attack effectively. Sumatriptan was the first marketed; almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan and zolmitriptan are now available, with various routes of administration. Triptans should be avoided when there is vascular disease, and not overused.

Prophylaxis. The following are used continuously when attacks are frequent:

- pizotifen (SHT antagonist) 0.5 mg at night for several days, increasing to 1.5 mg (common side-effects are weight gain and drowsiness)
- propranolol 10 mg three times daily, increasing to 40–80 mg three times daily
- amitriptyline 10 mg (or more) at night.

Sodium valproate, methysergide, SSRIs, verapamil, topiramate, nifedipine and naproxen are also used. Gap junction blockers are being used in trials.

Other benign headaches
- Ice-cream headache. Sufferers describe intense, retropharyngeal head pain lasting for a few seconds or minutes following ice-cream or very cold foods.
- Primary cough headache is a sudden sharp head pain on coughing. No underlying cause is found but intracranial pathology should be excluded. The problem often resolves spontaneously. Very rarely, for severe headache, a lumbar puncture with removal of CSF can help.
- Primary low CSF volume headaches, seen typically on standing up, are also well recognized. The patient may give a history of some event, such as a vigorous Valsalva, straining or orgasm, but these headaches sometimes arise spontaneously. Treatment with an autologous intrathecal blood patch can be helpful. Secondary low CSF volume can follow lumbar puncture (p. 1121).
Primary sex headache describes varieties of headache that typically rise to a crescendo at orgasm, largely in males. Treatment with propranolol or diltiazem is said to be helpful, but these pains often resolve spontaneously after several attacks. Exceptionally, sex headaches occur with an unruptured intracranial aneurysm.

Many other varieties of primary headache are listed in the international classification, e.g. hemicrania continua, primary stabbing headache, primary exertional headache, hypnic headache, and primary thunderclap headache.

Post-traumatic headache is also a common problem. Headaches do sometimes follow a minor blow to the head; they tend to resolve, typically within 6–8 weeks. However, when there is third party involvement, and especially with litigation, these headaches can persist for long periods. Opinions vary about their cause.

Facial pain
The face has many pain-sensitive structures: teeth, gums, sinuses, temporomandibular joints, jaw and eyes. Facial pain is also caused by specific neurological conditions.

Trigeminal neuralgia (p. 1106), trigeminal nerve lesions (p. 1106) and postherpetic neuralgia (p. 1157) are described elsewhere.

Cluster headache
Cluster headache (migrainous neuralgia and trigeminal autonomic cephalgia type I), is distinct from migraine. It describes recurrent bouts of excruciating unilateral pain that typically wake the patient. Attacks cluster around one eye. Cluster headache affects adults, mostly males aged between 30 and 40. Alcohol sometimes provokes an attack, and experimentally, glyceryl trinitrate. During an attack, changes in the hypothalamus appear on MRI and PET. PET, presumed to be due to activation of the trigeminal-vascular and autonomic systems. Severe pain rises to an even worse crescendo over some minutes, lasting for several hours. Vomiting can occur. One cheek and nostril become congested. Transient ipsilateral Horner’s syndrome is common. One bout of cluster attacks, with pain every few nights, usually lasts one to two months. Despite excruciating pain there are no sequelae. Bouts recur at intervals over several years but tend to disappear after the age of 55.

Management. Analgesics are unhelpful. Subcutaneous sumatriptan is the drug of choice. Oxygen inhalation sometimes aborts an attack. Most prophylactic migraine drugs are unhelpful. Verapamil, topiramate, lithium carbonate and/or a short course of steroids sometimes help bring to an end a bout of cluster headaches.

Paroxysmal hemicrania
Episodic paroxysmal hemicrania (trigeminal autonomic cephalgia type II) is a rare condition describing unilateral sudden, brief (<20 min) pains with some characteristics of cluster headache. Paroxysms can occur many times each day; typically they respond to indomethacin.

SUNCT and SUNA (trigeminal autonomic cephalgia type III) are eponyms for other, rare and exceedingly painful sudden headaches.

In SUNCT (short-lasting unilateral neuralgiform headache with conjunctival injection and tearing) attacks last from 5 seconds to 2 minutes.

In SUNA (short-lasting unilateral neuralgiform headache with cranial autonomic symptoms) the pain is similar to SUNCT but there is no tearing or conjunctival injection.

Diagnosis is made from the clinical features. Preventative treatment with lamotrigine, topiramate or carbamazepine is sometimes helpful. In hospital, immediate i.v. lidocaine often aborts an attack.

Exceptionally, SUNCT-like symptoms have been described with pituitary tumours, and with posterior fossa tumours.

Atypical facial pain
Facial pain for which no cause can be found is seen in the elderly, mainly in women, and is believed (on little evidence) to be a somatic equivalent of depression. Tricyclic antidepressants are sometimes helpful.

Other causes of facial pain
Facial pain occurs in variants of migraine and in giant cell arteritis (see below).

Giant cell arteritis (temporal arteritis; cranial arteritis)
These are granulomatous arteritides seen almost exclusively in people over 50 (p. 550).

Clinical features

Heads are almost invariable in giant cell arteritis (GCA). Pain develops over inflamed superficial temporal and/or occipital arteries. Touching the skin over an inflamed vessel (e.g. combing hair) causes pain. Arterial pulsation is soon lost; the artery becomes hard, tortuous and thickened. The scalp over inflamed vessels may become red. Rarely, gangrenous patches appear.

Facial pain. Pain in the face, jaw and mouth is caused by inflammation of facial, maxillary and lingual branches of the external carotid artery in GCA. Pain is characteristically worse on eating (jaw claudication). Mouth opening and protruding the tongue become difficult. A painful, ischaemic tongue occurs rarely.

Visual problems. Visual loss from arterial inflammation and occlusion occurs in 25% of untreated GCA cases. Posterior ciliary artery occlusion causes anterior ischaemic optic neuropathy in three-quarters of these. Other mechanisms are central retinal artery occlusion, cilioretinal artery occlusion and posterior ischaemic optic neuropathy. There is sudden monocular visual loss (partial or complete), usually painless. Amaurosis fugax (p. 1128) may precede permanent blindness.

When the posterior ciliary vessels are affected, ischaemic optic neuropathy causes the disc to become swollen and pale; retinal branch vessels usually remain normal. When the central retinal artery is occluded, there is sudden permanent unilateral blindness, disc pallor and visible retinal ischaemia. Bilateral blindness may develop, with the second eye being affected in 1–2 weeks.
Rare complications. Brainstem ischaemia, cortical blindness, ischaemic microangiopathic neuropathy of peripheral or cranial nerves, and involvement of the aorta, coronary, renal and mesenteric arteries sometimes occurs.

Management
The ESR is greatly elevated. The diagnosis should be established immediately by superficial temporal artery biopsy, because of the risk of blindness. Immediate high doses of steroids (prednisolone, initially 60–100 mg daily) should be started in a patient with typical features, even before biopsy (p. 550). Since the risk of visual loss persists, long-term treatment is recommended, for some years at least.

FURTHER READING

Epilepsy and loss of consciousness
Epilepsy

‘Seizure’ means a convulsion or other transient event caused by a paroxysmal discharge of cerebral neurones. Epilepsy is the continuing tendency to have seizures, even if a long interval separates attacks. A generalized convulsion (grand mal fit) is the most common recognized event.

Epilepsy is common. Its prevalence is 5 times higher in developing than developed (0.5%) countries, and the incidence is doubled. Over 2% of the population in developed countries have two or more seizures during their lives; in 0.5% epilepsy is an active problem and common in primary care. In the UK approximately 65 people suffer a probable first seizure each day; the lifetime risk of having a single seizure is 5%. Often no clear cause is found for seizures, although rarely epilepsy is caused by a brain tumour or follows a stroke. Approximately 250,000 people in the UK take anticonvulsant drugs, the mainstay of treatment. Neurosurgery (e.g. temporal lobectomy) is highly effective in carefully selected cases.

Mechanisms and definitions
Spread of electrical activity between neurones is normally restricted and synchronous discharge of neurones takes place in confined groups, producing normal EEG rhythms. During a seizure, large groups of neurones are activated repetitively, unrestrictedly and hypersynchronously; synaptic inhibition between them fails. High-voltage spike-and-wave activity is the result, epilepsy’s EEG hallmark.

A partial seizure is epileptic activity confined to one area of cortex with a recognizable clinical pattern (Fig. 21.32). This activity either remains focal or spreads to generate epileptic activity in both hemispheres and thus a generalized seizure. This spread is called secondary generalization. The focal nature of a seizure may not be apparent clinically because of rapid secondary generalization – an apparent generalized tonic–clonic seizure may either have started as a focal seizure or be a primary generalized convolution. Brain becomes epileptogenic either because neurones are predisposed to be hyperexcitable, for example following abnormal neuronal migration in utero, or because they acquire this tendency. Trauma and brain neoplasms are examples of acquired conditions that alter neuronal seizure threshold.

Aura means a stereotyped perception caused by initial focal electrical events before a partial seizure, such as a smell, tingling in one limb, or strange recognizable inner feelings.

Seizure threshold
Each person has a seizure threshold. Experimentally some chemicals (e.g. pentylenetetrazol, a toxic gas) induce seizures in everyone. A low seizure threshold describes the tendency, for example, to have seizures provoked by flashing lights; it is a concept, not a measurement.

Classification
Various terms are used to classify epilepsy, e.g. idiopathic, symptomatic, cryptogenic, primary, focal or generalized. Here attacks are described by clinical pattern (Table 21.32).

- Generalized means bilateral abnormal electrical activity, with bilateral motor manifestations and impaired consciousness.
- A partial (focal) seizure means the electrical abnormality is localized to one part of the brain:
  (a) simple – without loss of awareness, e.g. one limb jerking (Jacksonian seizure)
  (b) complex – with loss of awareness, e.g. a temporal lobe attack.

![](image1)

**Fig. 21.32** Seizure types.
**Table 21.32** The commoner types of seizure

Abridged from International League against Epilepsy

1. **Generalized seizure types**
   - **Absence seizures**
     - Typical absences with 3 Hz spike-and-wave discharge (petit mal)
     - Atypical absences with other EEG changes
   - **Generalized tonic–clonic seizures** (grand mal)
   - **Myoclonic seizures**
   - **Tonic seizures**
   - **Akinetic seizures**
   - **Partial seizure types**
     - Simple partial seizures (without impaired awareness, e.g. Jacksonian seizures)
     - Complex partial seizures (with impaired awareness)
     - Partial seizures evolving to tonic–clonic seizures
     - Apparent generalized tonic–clonic seizures, with EEG but not clinical evidence of focal onset
   - **Unclassifiable seizures**
     - Seizures that do not fit a category above

**Generalized seizure types**

**Typical absence seizures (petit mal)**

This generalized epilepsy almost invariably begins in childhood. Each attack is accompanied by 3 Hz spike-and-wave EEG activity (Fig. 21.15, p. 1120). Activity ceases, the patient stares and pales slightly for a few seconds. The eyelids twitch; a few muscle jerks may occur. After an attack, normal activity is resumed. Typical absence attacks are never due to acquired lesions such as tumours. They are a developmental abnormality of neuronal control. Children with petit mal attacks tend to develop generalized tonic–clonic seizures in adult life (known as primary generalized epilepsy). Petit mal describes these 3 Hz absence seizures only; clinically similar episodes may also be produced by temporal lobe foci (partial seizures), a source of confusion.

**Generalized tonic–clonic seizures (GTCS, grand mal seizures)**

Following a vague warning, the tonic phase commences. The body becomes rigid, for up to a minute. The patient utters a cry and falls, sometimes suffering serious injury. The tongue is usually bitten. There may be incontinence of urine or faeces.

The clonic phase then begins, with generalized convulsing, frothing at the mouth and bilateral, rhythmic jerking of muscles. This lasts from a few seconds to several minutes. Seizures are usually self-limiting, followed by drowsiness, confusion or coma for several hours.

**Myoclonic, tonic and akinetic seizures**

Myoclonic seizures describe isolated muscle jerking. Juvenile myoclonic epilepsy is one variety, seen in adolescence. Tonic means intense stiffening of the body, not followed by jerking. Akinetic means cessation of movement, falling and loss of consciousness.

**Partial seizure types**

**Simple partial seizures**

One example is a focal motor seizure (Jacksonian). These simple partial seizures originate within the motor cortex. Jerking typically begins on one side of the mouth or in one hand, sometimes spreading to involve the entire side. This visible spread of activity is called the march of a seizure. With a frontal lesion, conjugate gaze (p. 1105) deviates away from the epileptic focus and the head turns; this is known as an adversive seizure. Local temporary paralysis of the limbs affected sometimes follows – Todd’s paralysis.

**Temporal lobe seizures**

These partial seizures, either simple or complex, can produce feelings of unreality (jamas vu) or undue familiarity (déjà vu) with the surroundings. Blank episodes of staring, vertigo, visual hallucinations (i.e. visions or faces) are other examples of temporal lobe seizures.

Many other types of partial seizure occur: panic attacks with overbreathing (temporal), strange smells (frontal), sensory disturbances (parietal) and crude visual shapes (occipital).

**Aetiology and precipitants** (Table 21.33)

A cause for epilepsy is found in less than one-third of cases in UK surveys: cerebrovascular disease accounts for less than 15%, tumours for 6%, alcohol-related seizures for 6% and post-traumatic epilepsy 2%. Hippocampal sclerosis is a cause of symptomatic epilepsy (resection may be possible); others are malformations of cortical development, AVMs, hamartomas, brain abscesses and tuberculosis. Neurocysticercosis is a major cause of epilepsy where cysticercosis is endemic (p. 170).

**Genetic predisposition and developmental anomalies**

Over 200 genetic disorders list epilepsy among their features, with complex syndromic classifications. These account for less than 2% of epilepsy. About 30% of epilepsy patients have first-degree relatives with seizures. Usually the mode of inheritance is uncertain. A low seizure threshold seems to run in some families. Petit mal and other primary generalized epilepsies are often inherited as autosomal dominant trait with variable penetrance. Primary epilepsies are due to complex developmental abnormalities of neuronal control; there are abnormalities in synaptic connections, and anom-
lies in neurotransmitter distribution and release. Neuronal migration defects in utero, dysplastic areas of cerebral cortex and hamartomas contribute to seizures both in infancy and adult life.

**Trauma, hypoxia and surgery**
Perinatal trauma (cerebral contusion and haemorrhage) and fetal anoxia are causes of childhood seizures. Hypoxic damage in childhood to the hippocampi leads to hippocampal sclerosis, another prominent cause. Brain injury is sometimes followed by seizures within the first week (early epilepsy) or many months or years later (late epilepsy). To cause epilepsy, the injury must (usually) be sufficient to cause coma. Early epilepsy, a depressed skull fracture, penetrating brain injury, cerebral contusion, dural tear or intracranial haematoma increase the incidence of late post-traumatic epilepsy.

Brain surgery is followed by seizures in 3–5%.

**Brain tumours (and abscesses)**
Mass lesions in the cortex cause epilepsy – either partial or secondary generalized seizures. If epilepsy develops in adult life, the chance of finding an unsuspected tumour is around 3%.

Hydrocephalus (p. 1162) also lowers seizure threshold.

**Vascular and degenerative brain disorders**
Seizures sometimes follow cerebral infarction; there is a peak in incidence late in life. A brain AVM can present with seizures, as occasionally can SAH. Seizures can occur in Alzheimer’s disease and in many degenerative diseases. Epilepsy is three times commoner in MS patients than in the general population.

**Encephalitis and inflammatory conditions**
Seizures are frequent features of encephalitis, cerebral abscess, tuberculoma, cortical venous thrombosis and neurosyphillis. They also occur in chronic meningitis (e.g. TB) and may rarely be the first sign of acute bacterial meningitis. Neurocysticercosis is a prominent cause of seizures in countries where the pork tapeworm is endemic, e.g. India, South America, and is a major public health problem.

**Alcohol and drugs**
Chronic alcohol abuse is a common cause of seizures. These occur either while drinking heavily or during periods of withdrawal. Alcohol-induced hypoglycaemia also provokes attacks (p. 1060).

Phenothiazines, monoamine oxidase inhibitors, tricyclic antidepressants, SSRIs, amfetamines, lidocaine, propofol and nalidix acid sometimes provoke fits, either in overdose or at therapeutic doses in individuals with a low seizure threshold.

Withdrawal of antiepileptic drugs (especially phenobarbital) and benzodiazepines may provoke seizures.

**Metabolic abnormalities**
Seizures can follow:
- hypocalcaemia, hypoglycaemia, hyponatraemia
- acute hypoxia
- uraemia, hepatocellular failure
- mitochondrial disease, porphyria.

**Provoked seizures: photosensitivity, pyrexia**
Seizures are occasionally precipitated by flashing lights or a flickering television screen. Photosensitivity may be recorded on occipital EEG electrodes. Rarely other stimuli (e.g. music) provoke attacks. High pyrexia can provoke convulsions in children under 5 years (febrile convulsions). In most, there is no recurrence; febrile convulsions are not labelled as epilepsy.

**Sleep deprivation**
A convulsion sometimes follows missing a night’s sleep in a susceptible person.

**Diagnosis**
The history from a witness is crucial, and usually enables one to distinguish other causes of disturbed consciousness (p. 1144). The onset, setting and stages of attacks are of importance. Neurological examination may be normal or point to a clinical diagnosis. General screening, including serum calcium, and an ECG (rhythm, conduction abnormalities, QT interval) should be done.

**Electroencephalography**
EEG is a useful test, despite limitations. It is usually performed following a first fit, though the therapeutic yield is low.

- *During a seizure* the EEG is almost invariably abnormal, because spikes reach electrodes overlying brain.
- *EEG evidence of seizure activity* is shown typically by focal cortical spikes (e.g. over a temporal lobe) or by generalized spike-and-wave activity. Epileptic activity is continuous in status epilepticus.
- *3 Hz spike-and-wave* occurs specifically in petit mal (Fig. 21.15, p. 1120), always during an attack and frequently in between them.
- *A normal EEG between attacks* (interictal) does not exclude epilepsy; many people with epilepsy have normal interictal EEGs.
- *An abnormal interictal EEG* does not prove that a particular attack was epileptic.
- *EEG videotelemetry* is vital for studying attacks of uncertain nature (e.g. non-epileptic attacks, p. 1144).

**CT and/or MR imaging**
Imaging is indicated in all new cases. CT is a reasonable urgent screening test for tumours in adults. MR, with imaging of the hippocampi, is used routinely to study epilepsy.

**Treatment**

**Emergency measures**
When faced with a seizure it is best simply to ensure that the patient comes to as little harm as possible and that the airway is maintained both during a prolonged seizure and in postictal coma. Wooden mouth gags, tongue forceps and physical restraint cause injury.

Most seizures last only minutes and end spontaneously. A prolonged seizure (longer than 3 minutes) or repeated seizures are treated with rectal (10 mg) or i.v. diazepam or midazolam. If there is any suspicion of hypoglycaemia, take blood for glucose and give i.v. glucose. Serial epilepsy describes repeated seizures with brief periods of recovery. These may lead to status epilepticus. Sudden death in a seizure is unusual but does occur.
Status epilepticus
This medical emergency (Practical box 21.4) means continuous seizures without recovery of consciousness. It consists of prolonged serial seizures (two or more) occurring with incomplete recovery of consciousness. Status epilepticus has a mortality of 10–15%. Over 50% of cases occur without a previous history of epilepsy. Some 25% with apparent refractory status have pseudostatus (non-epileptic attack disorder); iatrogenic errors and morbidity are significant.

Not all status is convulsive. In absence status, for example, status is non-convulsive – the patient is in a continuous, distant, stuporose state. Focal status also occurs. Epilepsia partialis continua is continuous seizure activity in one part of the body, such as a finger or a limb, without loss of consciousness. This is often due to a cortical neoplasm or, in the elderly, a cortical infarct.

Practical Box 21.4 Status epilepticus – management

- Of prime importance:
  - Treat convulsions quickly
  - Accuracy of diagnosis
  - Continued ITU monitoring and cardiorespiratory support

- Several treatment schedules exist:
  - At home, give immediate diazepam 10-20 mg i.v. at 5 mg/min and repeat once. If i.v. access is impossible, give rectal diazepam or paraldehyde
  - Arrange immediate admission
  - Administer oxygen, monitor ECG, BP, routine bloods (include alcohol, sugar, calcium, magnesium, drug screen, anticonvulsant levels)
  - Give thiamin i.v. (250 mg) if nutrition is poor or alcohol abuse suspected. (In the UK, give vitamin B and C, high-potency ampoules, one pair i.v. over 10 mins)
  - Antiepileptic drugs (AEDs):
    1. Give lorazepam i.v. 4 mg at 2 mg/min
    2. Reinstate previous AEDs. Measure levels urgently. Has the patient had phenytoin recently?
    3. If status continues, i.v. phenytoin or fosphenytoin is used
       - Phenyoitoin: give 15 mg/kg i.v. diluted to 10 mg/mL in 0.9% saline into a large vein at <50 mg/min (Phenytoin 250 mg 5 mL ampoule)
       - Fosphenytoin: this is a pro-drug of phenytoin and can be given faster than phenytoin. Doses are expressed in phenytoin equivalents (PE): fosphenytoin 1.5 mg = 1 mg phenytoin
       - Give 15 mg/kg (PE) fosphenytoin (15 mg × 1.5 = 22.5 mg) diluted to 10 mg/mL in 0.9% saline at 50–100 mg/PE/min (Fosphenytoin sodium 750 mg 10 mL ampoule)
  4. If status continues, give phenobarbital 10 mg/kg diluted 1 in 10 in water for injection at <100 mg/min. (Phenobarbital 200 mg/mL 1 mL vial in propylene glycol 90% with water for injection 10%) Intravenous clonazepam, paraldehyde and clomethiazole are also used
  5. If status persists >90 minutes, use thiopental or propofol anaesthesia with assisted ventilation
  - EEG monitoring is valuable if there is doubt about the nature of status
  - CT may reveal an underlying cause
  - Remember: 25% of apparent status turns out to be pseudostatus
  - Remember: potential unwanted effects of drugs, e.g. hypotension, cardiorespiratory arrest, and the need for continuous monitoring

Antiepileptic drugs (AEDs)
AEDs are indicated when there is a firm clinical diagnosis of epilepsy and a substantial risk of recurrent seizures. AED use carries the stigma of epilepsy. Concordance between doctor and patient in taking the drugs is essential, as is understanding of potential unwanted effects. For both partial and generalized seizures, monotherapy with an established first-line AED is the initial choice (Table 21.34). Doses should start low and be increased until control is achieved or tolerance exceeded. If control is not achieved, a second drug is added. There remain different views about the most appropriate drugs for each seizure type.

Drug levels. Serum levels of all AEDs can be measured. With phenytoin the therapeutic range is well defined and the level should usually be monitored every few months (Table 21.35). Monitoring serum levels of other AEDs is less useful. Levels are not usually measured routinely unless compliance or toxicity is an issue.

Unwanted effects of drugs. Intoxication with all AEDs causes ataxia, nystagmus and dysarthria. Chronic phenytoin causes gum hypertrophy, hypertrichosis, osteomalacia, folate deficiency, polyneuropathy and encephalopathy. A wide range of potential unwanted effects are known. See Table 21.36 for some serious idiosyncratic (i.e. non-dose-related) side-effects. The majority of severe skin reactions (e.g. toxic epidermal necrolysis) following phenytoin, carbamazepine, valproate (and phenobarbital) occur within the first 8 weeks of treatment.

Two drugs rarely commenced outside a specialist centre are phenobarbital and its derivative primidone (drowsiness, cognitive impairment), though phenobarbital still has a place in status. Vigabatrin can cause irreversible visual field defects and is no longer advocated.

Refractory epilepsy
Despite therapy, seizures persist in some 20–35% of cases. Rigorous attention to diagnosis, to concordance (compliance) and to trials of different drugs can sometimes reduce seizure frequency. Many cases of refractory seizures are treated in specialist units: the question of surgery can be reviewed.

Epilepsy in the elderly
Some 25% of new cases of epilepsy develop over the age of 65. Many patients have cerebrovascular disease, neurodegenerative conditions or brain tumours. The onset of seizures commonly leads to loss of independence and to physical injuries with their complications (e.g. fractures, subdural haematoma). With appropriate AEDs, seizure control can be achieved in some 70% of this vulnerable population.

Women, epilepsy, pregnancy and AEDs
Fertility. There is some reduction of fertility in women with epilepsy. This is multifactorial. One-third of women with epilepsy have some ovarian abnormality: irregular menstrual cycles, anovulatory cycles and polycystic ovaries. These are possibly more frequent in patients taking valproate.

Birth defects. The overall risk of birth defects in babies of mothers who take one AED is around 7%, higher than the 3% in the population. Counselling before conception is essential. Some women choose to stop AEDs before becom-
when such contraception as alone.Carbamazepine with suffering. 300–450 temporal Myoclonic Atypical absence, are considerable remain 40–80 imaging controlled, phenobarbital)) an anterior must be is be taken into account by in unrestricted and Carbamazepine with a reluctant AEDs dangerous lobe may be infrequent taken a. Anorexia simple, Toxic epidermal necrolysis by patients. In these highly selected cases (under 1% of epilepsy patients) in specialist centres this surgical treatment is very effective, with cure rates (complete seizure cessation) over 50%. Section of the corpus callosum and hemispherectomy are also used.

**Social consequences**

The majority of patients with epilepsy are managed in primary care or as outpatients, and suffer infrequent seizures. In a small minority who have exceedingly frequent seizures, treatment in hospital or even residential care is necessary. There remains a considerable stigma attached to the word epilepsy; this must be taken into account when the nature of attacks is uncertain. Employers are reluctant to accept people labelled with epilepsy.

Both adults and children with epilepsy should be encouraged to lead lives as unrestricted as reasonably possible, though with simple, sensible provisos such as avoiding swimming alone and dangerous sports such as rock-climbing or solo canoeing. Bicycling is felt to be reasonable by some but not by others. Advice at home includes leaving bathroom and lavatory doors unlocked. Support groups and information services are valuable.
Driving and epilepsy
Patients with epilepsy are not legally permitted to drive motor vehicles unless they have been seizure-free for 12 months in the UK and European Union, or as little as 3 months in parts of the USA. Rules for commercial vehicles are more strict. If attacks occur solely in sleep, driving may be permitted by the licensing authorities.

Stringent regulations also exist for potential aircraft pilots, sea captains, divers and other defined activities. The correct diagnosis of an attack at any age is therefore of particular social and legal importance.

It is an essential medical requirement to inform patients of the law. The patient should then inform the licensing authorities.

OTHER FORMS OF DISTURBED CONSCIOUSNESS (Table 21.37)
Transient disturbance of awareness, loss of consciousness and falls are common clinical problems. It is usually possible to distinguish between a fit (i.e. a seizure), a faint (i.e. syncope) and other types of attack from descriptions and an eyewitness account. Falls must be distinguished from episodes of disturbed consciousness. The precise cause of falls often remains ill-defined.

Syncope, postural hypotension and drop attacks
The simple faint that over half the population experiences at some time (particularly in childhood, in youth or in pregnancy) is due to sudden reflex bradycardia with vasodilatation of both peripheral and splanchnic vasculature. This simple syncope (neurocardiogenic syncope) is a common response to prolonged standing, fear, venesection or pain. Syncope almost never occurs in the recumbent posture. The subject falls to the ground and is unconscious for less than 2 minutes. Recovery is rapid. Jerking movements can occur. Incontinence of urine can occur.

Cardiac syncope (p. 689) is potentially serious and often treatable.

Syncope occurs after micturition in men, particularly at night, and in either sex when the venous return to the heart is obstructed by breath-holding and severe coughing. Effort syncope (on exertion) is of cardiac origin.

Postural hypotension (p. 689) can cause syncope and occurs in the elderly, in autonomic neuropathy, with phenothiazines, levodopa or tricyclic antidepressants. Carotid sinus problems (p. 689) can cause syncope. Syncope can occur with severe anaemia.

Drop attacks are instant, unexpected episodes of lower limb weakness with falling, largely in women over 60 years. Awareness is preserved. They are due to sudden change in lower limb tone, presumably of brainstem origin, rather than thromboembolism. Sudden attacks of leg weakness also occur in hydrocephalus.

Transient cerebral (posterior circulation) ischaemia rarely leads to loss of consciousness; patients sometimes faint during a severe basilar migraine.

Syncope: investigation and management
Syncope and related conditions can usually be distinguished from epilepsy on clinical grounds. Witnessed accounts are invaluable: persistent jerking movements and post-episode confusion with amnesia are suggestive of a fit, and unusual in a faint. Cardiac monitoring is used to detect dysrhythmia. Tilt testing (p. 697) is sometimes diagnostic, but has low sensitivity.

The immediate management of syncope, or impending syncope, is to lay the patient down, lift the legs and record the pulse. In rare circumstances where brain blood flow cannot be restored (e.g. propped upright in a dentist’s chair), brain infarction can follow syncope.

Other conditions
Non-epileptic attacks (pseudoseizures) regularly cause difficulty in diagnosis. Attacks are often labelled grand mal fits. Usually there are bizarre limb movements, but there can be extreme difficulty in separating these attacks from seizures. EEG videotelemetry is valuable. Apparent status epilepticus
can occur. The serum prolactin level is of some value: this rises during a grand mal seizure but not during a pseudoseizure (or a partial seizure).

**Panic attacks** are usually associated with autonomic disturbances such as tachycardia, sweating and piloerection. Consciousness is usually preserved and attacks easily recognized.

**Hyperventilation** is common (see Box 22.12, p. 1208) and overbreathing causes alkalosis. This leads to dizziness, anxiety and sometimes circumoral/ peripheral tingling and tetany, e.g. carpopedal spasm (p. 1022). Occasionally there is loss of consciousness.

**Breath-holding attacks** occur in children.

**Hypoglycaemia** (p. 1043) causes attacks of loss of consciousness, sometimes with a convulsion. There is often warning, with hunger, malaise, shaking and sweating. Prompt recovery occurs with i.v. (or oral) glucose, or household sugar. Prolonged hypoglycaemia causes widespread cerebral damage. Hypoglycaemic attacks unrelated to diabetes are rare (p. 1059). Feeling faint after fasting does not indicate anything serious.

**Hypocalcaemia** (see also p. 1021) may be accompanied by a grand mal fit as seizure threshold is lowered.

**Vertigo**. When acute, vertigo can be sufficiently severe as to cause prostration: a few seconds’ unconsciousness sometimes follows.

**Choking** causes intense coughing and laryngeal spasm when obstruction is partial. When a large food bolus (e.g. meat) blocks the larynx, the person becomes blue and silent. Death may follow if the blockage is not relieved promptly, e.g. by the Heimlich manoeuvre (p. 834) or gravity. Apnoeic episodes (p. 842).

**Drug reactions**. Acute dystonic reactions (oculogyric crises) are sometimes mistaken for epilepsy. Consciousness is preserved.

**Carcinoid syndrome, phaeochromocytoma and scombroid poisoning** (p. 284, p. 1025 and p. 950). Flushing and palpitation is sometimes mistaken for anxiety, allergy or possibly a partial seizure.

**Paroxysmal dyskinesias**. These are rare causes of attacks of abnormal limb movement.

**SLEEP AND ITS DISTURBANCES**

Sleep is required to preserve recent memory, refresh emotional equilibrium, and avoid neurotransmitter depletion. Poorly understood pathways – e.g. hypothalamic hypocretin (orexin) neuropeptides – between cortex and reticular formation are involved in sleep–waking cycles.

In **insomnia**, sleep is fitful (p. 1197). Less time than usual is spent in REM sleep. In old age, sleep requirement falls, sometimes to 4 hours a night. Insomnia is rarely a feature of neurological disease.

Seizures may occur predominantly or solely during sleep. Sleepwalking, jerking episodes and movements in sleep are events seen in the normal population and are not suggestive of brain pathology.

**Narcolepsy and cataplexy**

Narcoleptic attacks are periods of irresistible sleep, i.e. excessive daytime drowsiness, in inappropriate circumstances. Episodes occur when there is little distraction, after meals, while travelling in a vehicle, or sometimes without obvious cause (see Table 20.5, p. 1084). Narcolepsy is strongly associated with HLA-DR2 and HLA-DQBl*0602 antigens. Narcolepsy patients positive for these antigens may have subnormal CSF hypocretin 1 (orexin) levels, possibly on an autoimmune basis.

Cataplexy is sudden loss of lower limb tone – falling with intact awareness. Attacks are often set off by sudden surprise or emotion.

Narcolepsy and cataplexy sometimes coexist and are accompanied by vivid hypnagogic hallucinations (on falling asleep), hypnopompic hallucinations (on waking), and sleep paralysis – a frightening inability to move.

**Treatment**

Methylphenidate, dexamfetamine, modafinil, or small doses of tricylic antidepressants, particularly clomipramine, are used, rarely with great success. Siberian ginseng (Eluthro- coccus serticosus) and St John’s Wort (Hypericum perforatum) are also used.

**Central sleep apnoea** (p. 842)

This rarity is due to impairment of central ventilatory control due to brainstem pathology. Apnoea occurs typically at the onset of sleep. It is seen in non-obese people without the typical history of snoring seen in the more usual obstructive sleep apnoea (p. 842).

**Familial fatal insomnia**

This is a very rare, prion-related disease (p. 122).

**MOVEMENT DISORDERS**

Disorders of movement divide broadly into two:

- akinetic–rigid syndromes, i.e. slowed movement with increased tone
- dyskinesias – added, uncontrollable movements.

Both akinésia/rigidity and dyskinesia may coexist, leading to complex classifications. Table 21.38 outlines the principal clinical varieties: idiopathic Parkinson’s disease and essential tremor are much the commonest.

**AKINETIC–RIGID SYNDROMES**

**Idiopathic Parkinson’s disease**

In 1817, James Parkinson, a physician in Hoxton, London, published *The Shaking Palsy*, describing this common world-wide condition that has a prevalence of 150/100 000 increasing sharply in those over 70 years. Parkinson’s disease is clinically and pathologically distinct from other parkinsonian syndromes.

There are few real clues to the cause of idiopathic Parkinson’s disease (PD). The relatively uniform world-wide

The prevalence suggests that an environmental agent is not responsible. Some factors possibly involved are:

**Nicotine.** Several epidemiological studies confirm the curious fact that PD is less prevalent in tobacco smokers than in lifelong abstainers.

**MPTP.** Minute doses of a pyridine compound, methylphenyltetrahydropyridine (MPTP), a byproduct of illicit stimulant drug production, cause severe parkinsonism. Any link with idiopathic PD is tenuous. Suggestions that environmental MPTP-like herbicides are unsubstantiated.

**Encephalitis lethargica.** Survivors of an epidemic of encephalitis lethargica in the early 20th century sometimes developed severe parkinsonism. It is not thought that idiopathic PD is related to any infective agent.

**Genetic factors.** Idiopathic PD is not usually familial, but there is clustering of early-onset PD in some families. Mutations in the parkin gene on chromosome 6 have been found in families with autosomal recessive cases of PD and some young apparently sporadic cases. *Parkin* mutations probably account for most PD cases with onset below the age of 40. Mutations of the α-synuclein gene and ubiquitin carboxy-terminal hydrolase L1 (UCHL1), on chromosomes 2p13 and 4p14–16.3 respectively, also account for some of these cases. Relevance to the common sporadic older PD cases remains unclear.

**Pathology**

In idiopathic PD, the pars compacta of the substantia nigra undergoes progressive neuronal degeneration; eosinophilic inclusion bodies (Lewy bodies) develop. These contain protein filaments of ubiquitin and α-synuclein. Degeneration also occurs in other basal ganglia nuclei. There is loss of dopamine (and melanin) in the striatum. This correlates with cell loss and the degree of akinesia.

**Symptoms and signs**

The combination of tremor, rigidity and akinesia develops slowly, over months or several years, together with changes in posture. Common initial symptoms are tremor and slowness. Limbs and joints feel stiff; they ache. Fine movements become difficult. Slowness causes difficulty rising from a chair or getting into or out of bed. Writing becomes small (micrographia) and spidery, tending to tail off. Relatives often notice other features—slowness and an impassive face. Idiopathic PD is almost always initially more prominent on one side. The diagnosis is usually evident from the overall appearance.

**Tremor**

The characteristic 4–7 Hz pill-rolling tremor at rest (movements between thumb and forefinger) typically decreases with action. Tremor is often asymmetrical at first.

**Rigidity**

Stiffness develops throughout movements and is equal in opposing muscle groups, in contrast to the selective increase in limb tone found in spasticity. This lead pipe-like increase in tone (plastic rigidity) is usually more marked on one side and present in the neck and axial muscles. Plastic rigidity is more easily felt when a joint is moved slowly and gently; tone increases when the opposite arm moves actively. When stiffness occurs with tremor, smooth lead pipe rigidity is broken up into a jerky resistance to passive movement—cogwheeling (cogging).

**Akinesia**

Poverty/slowing of movement (bradykinesia) is an additional handicap, distinct from rigidity. There is difficulty initiating movement. Rapid fine finger movements, such as piano-playing, become indistinct, slow and tremulous. Facial immobility gives a mask-like semblance of depression. Frequency of spontaneous blinking diminishes, producing a serpentine stare.

**Postural and gait changes**

Stooping is characteristic. Gait becomes hurrying (festinant) and shuffling with poor arm swinging. The posture is sometimes called simian to describe the ape-like forward flexion, immobility and lack of animation. Balance deteriorates, but despite this the gait retains a narrow base. Falls, toppling like a falling tree, are common in later stages.

**Speech**

Pronunciation is initially a monotone and progresses to tremulous slurring dysarthria, the result of akinesia, tremor and rigidity. Eventually, speech may be lost (anarthria).

**Cognitive changes**

Cognitive decline may occur early in the condition and is rarely absent in advanced disease. Depression is common.

**Gastrointestinal and other symptoms**

These include constipation, sometimes an early symptom, heartburn, dribbling, dysphagia and weight loss. Urinary difficulties are common, especially in men. Skin is greasy and sweating excessive.

**Natural history and other features**

PD worsens over the years, beginning as a mild inconvenience but slowly progressing. Remissions are unknown except for rare, remarkable short-lived periods of release. These can occur at times of emotion, fear or excitement, when the sufferer is released for seconds or minutes and able to move quickly.
While bradykinesia and tremor worsen, power remains normal until immobility makes its assessment difficult. Patients often complain bitterly of limb and joint discomfort. There is no sensory loss. The reflexes are brisk; their asymmetry follows the increase in tone. The plantar responses remain flexor. The rate of progression is very variable, with a benign form running over several decades. Usually the course is over 10–15 years, with death resulting from bronchopneumonia with immobility and cognitive impairment.

**Diagnosis**

There is no laboratory test; diagnosis is made by recognizing physical signs and distinguishing idiopathic PD from other parkinsonian syndromes. Conventional imaging (MR) is normal initially; atrophy develops. Dopamine transporter (DAT) imaging is abnormal but discriminates poorly between PD and other akinetic–rigid syndromes.

Other diffuse and multifocal brain diseases can cause features of parkinsonism, i.e. slowing, rigidity and tremor seen in idiopathic PD. Examples are Alzheimer’s disease, multi-infarct dementia, sequelae of repeated head injury (p. 1163), and late effects of severe hypoxia or CO poisoning. Slowing also occurs in hypothyroidism, and in depression.

**Treatment**

While drugs alter little, if at all, the natural history of PD, levodopa and/or dopaminergic agonists produce striking initial improvement. Drugs are avoided until clinically necessary because of delayed unwanted effects. Older treatments such as antimuscarinics, e.g. trihexyphenidyl (benzhexol), helped little and frequently caused confusion; they remain of some value in severe tremor. The mechanism of action of drugs in PD is shown in Figure 21.33.

**Levodopa**

Levodopa is combined with an aromatic amino acid decarboxylase inhibitor – benserazide (co-benzeldopa, as Madopar) or carbidopa (co-careldopa, as Sinemet). The decarboxylase inhibitor reduces peripheral side-effects, principally nausea, of levodopa and its metabolites. Levodopa treatment is commenced (co-benzeldopa 62.5 mg or co-careldopa 110 mg, one tablet three times daily) and gradually increased.

The majority of idiopathic PD cases (but not other parkinsonian syndromes) improve initially with levodopa. Response in a severe, previously untreated case is sometimes dramatic.

**Unwanted effects of levodopa therapy**

Nausea and vomiting are the most common immediate symptoms of excess levodopa. Confusion, formed visual pseudo-hallucinations and chorea also occur. There are difficult issues with long-term therapy (e.g. levodopa-induced involuntary movements). After several years levodopa gradually becomes ineffective, even with increasing doses. As treatment continues, episodes of immobility develop (freezing). Falls are common. Fluctuation in response to levodopa also emerges, its effect turning on and off, to cause freezing alternating with dopa-induced dyskinesias, chorea and dystonic movements. Levodopa’s duration of action shrinks, with dyskinesias becoming prominent several hours after a dose (end-of-dose dyskinesia). The patient begins to suffer from a chronic levodopa-induced movement disorder.

Levodopa does not alter the natural progression of PD. After 5 years’ treatment, around half of PD cases suffer from minor or major unwanted effects of levodopa. The more distressing problems are often largely insoluble. Approaches to treatment of these complications include:

- Shortening the interval between levodopa doses and increasing each dose.
- Monoamine oxidase B inhibitors inhibit catabolism of dopamine in the brain. They are used to smooth out the end-of-dose fluctuations with levodopa.
- Dopaminergic agonists (see below) are added, or replace levodopa.
- Catechol-O-methyl transferase (COMT) inhibitors (entacapone and tolcapone) prevent the peripheral breakdown of levodopa, allowing lower doses to be used.
- Amorphine by subcutaneous pump.

**Dopamine receptor agonists**

Bromocriptine, pergolide, cabergoline (all ergot derivatives), pramipexole, ropinirole and rotigotine are oral, directly acting dopamine receptor agonists, acting principally on D1 and D2 receptors, and also on receptors D3-5. Of these, ropinirole is the usual drug of choice, as an alternative or an addition to levodopa therapy. The ergot derivatives are associated with pulmonary, retroperitoneal and pericardial fibrotic reactions and are little used.

Dopamine receptor agonists are in general less effective than levodopa in treating symptoms, but cause fewer late unwanted dyskinesias.

There is variation in clinical practice between the use of levodopa and dopamine receptor agonists. The trend is towards the use of receptor agonists as primary treatment (before levodopa) in cases below 65, and levodopa initially for older cases.
Apopomorphine, a potent D₁ and D₂ agonist, given by subcutaneous metered infusion, is one method of attempting to smooth out fluctuations in response to levodopa. Skilled nursing is required to train patients and relatives to deal with the pump. Vomiting is common. Haemolytic anaemia is an unusual side-effect.

Other agents
Antioxidant compounds such as vitamins C and E as possible neuroprotective agents are sometimes suggested; their role is uncertain and evidence of benefit is poor. Amantadine, originally marketed as an antiviral drug, occasionally has a modest effect in PD. Rasagiline and rivastigmine (p. 1168) may help cognitive changes and possibly the movement disorder.

Stereotactic neurosurgery
Stereotactic lesions, usually unilateral in the ventrolateral nucleus of the thalamus or in the globus pallidus (pallidotomy), were used widely before levodopa. Surgery still provides effective, if temporary improvement in tremor and dyskinesia with minor relief of bradykinesia. Thalamic stimulation is used increasingly, sometimes with dramatic improvement.

Tissue transplantation
Despite early promise and suggestive laboratory studies in rats with MPTP-induced parkinsonism, tissue transplantation is little used. Experimental transplantation of fetal or autologous dopamine-containing adrenal medulla and glial cell-line neurotrophic releasing factor (GDNF) into the cerebral ventricles or basal ganglia does not produce any sustained improvement. Stem cell research has produced no promising results in PD to date.

Physiotherapy and physical aids
Skilled therapy can help overcome particular problems. Practical guidance can be given on:

- clothing – avoid zips, fiddly buttons and lace-up shoes
- cutlery – use built-up handles
- chairs – high upright rather than deep, low chairs
- rails – near lavatory and bath
- shoes – easy to wear, with smooth soles
- flooring – vinyl is safer than loose rugs.

Walking aids are often a hindrance early on, but later a frame or a tripod may help. Falls must be avoided.

Neuropsychiatric aspects
Cognitive impairment and depression are common as PD progresses. SSRIs are the drugs of choice for depression. Tricyclic antidepressants (e.g. amitriptyline) have extrapyramidal side-effects. Type A MAO inhibitors (e.g. phenelzine) are contraindicated with levodopa.

All antiparkinsonian drugs can provoke visual hallucinations, especially at night, and exacerbate cognitive impairment.

OTHER AKINETIC–RIGID SYNDROMES

Drug-induced parkinsonism
Phenothiazines and butyrophenones (also reserpine and methyldopa, once used to treat hypertension) induce parkinsonism, usually with little tremor. Tricyclic antidepressants also cause some slowing. These unwanted effects tend not to progress and settle when drugs are stopped.

Neuroleptics and movement disorders

Neuroleptics (i.e. phenothiazines and butyrophenones) also produce other movement disorders.

- Akathisia. This is a restless, repetitive and irresistible need to move.
- Acute dystonic reactions. Spasmodic torticollis, trismus and oculogyric crises (episodes of sustained upward gaze) develop, dramatically and unpredictably, after single doses of neuroleptics and related drugs used widely as antiemetics and vestibular sedatives (e.g. metoclopramide and prochlorperazine). These acute dystonias respond promptly to i.v. antimuscarinics, e.g. benztropine 1–2 mg or procyclidine 5–10 mg. The offending drug (and all similar drugs) should be avoided, forever.
- Chronic tardive dyskinesias. These mouthing and lip-smacking grimaces occur several years after commencing neuroleptics. They often become temporarily worse when the drug is stopped or the dose reduced. Even if treatment ceases, resolution seldom follows.

Parkinsonism-plus
This term describes disorders in which there is parkinsonism with additional features and specific pathology. Progressive supranuclear palsy (Steele–Richardson–Olszewski syndrome) is the commonest. It consists of parkinsonism, axial rigidity, falls, dementia and inability to move the eyes vertically or laterally. Other examples are multiple system atrophies (MSA), such as olivo-ponto-cerebellar degeneration, striatoniogral degeneration and primary autonomic failure (Shy–Drager syndrome). Pathologically MSA shows α-synuclein positive glial cytoplasmic inclusions.

These disorders are progressive, although they sometimes respond to levodopa, and usually cause death within a decade.

Post-encephalitic parkinsonism and MPTP
See page 1146.

Akinetic–rigid syndromes in children
Some rare disorders cause akinetic–rigid syndromes usually with onset under 20 years; features may arise during adult life.

Wilson’s disease
This rare and treatable disorder of copper metabolism is inherited as an autosomal recessive. Copper deposition occurs in the basal ganglia, the cornea and liver (p. 357), where it can cause cirrhosis. All young patients with an akinetic–rigid syndrome with or without dyskinesia, or with liver cirrhosis should be screened for Wilson’s disease. Intellectual impairment develops. Neurological damage is reversible with early treatment. Diagnosis, and treatment with the chelating agent penicillamine, is discussed on page 357.
Athetoid cerebral palsy
Writhing movements, sometimes with progressive dystonia, occur in cerebral palsy following kernicterus. This is now rare following prophylactic eradication of rhesus haemolytic disease with anti-D immunoglobulin.

**DYSKINESIAS**

**Benign essential tremor**
This common condition, often inherited as an autosomal dominant trait, causes 5–8 Hz tremor, usually worse in the upper limbs. The head is often tremulous (titubation) and sometimes the trunk. Pathologically there is patchy neuronal loss in the cerebellum and its connections. Tremor develops when the hands adopt a posture, such as holding a glass or a spoon. Essential tremor occurs at any age but occurs most frequently in later life. Tremor is slowly progressive but rarely produces severe disability. Writing is shaky and undyed; micrographia is absent. Anxiety exacerbates the tremor, sometimes dramatically. In essential tremor, shaking occasionally occurs at rest, as in PD, or on action, as in cerebellar disease.

Treatment is often unnecessary, and unsatisfactory. Many patients are reassured to find they do not have PD, with which essential tremor is often confused. Small amounts of alcohol, beta-blockers (propranolol), primidone or the antidepressant mirtazapine may help. Symptohimetics (e.g. salsalbutamol) make all tremors worse. Stereotactic thalamotomy and thalamic stimulation are used in severe cases.

**Chorea**
Chorea means jerky, quasi-purposive, explosive, fidgety movements, flitting around the body. See Table 21.39 for causes.

**Huntington’s disease**
Relentlessly progressive chorea and dementia, usually in middle life but sometimes in childhood, are hallmarks of this inherited disease. Prevalence world-wide is about 5 in 100,000. Inheritance is as an autosomal dominant trait with full penetrance: children of an affected parent have a 50% chance of developing Huntington’s disease. Previous family history is often obscure. A mutation occurs in the distal short arm of chromosome 4 (4p16.3) with a variable expansion of a CAG-repeat sequence located in exon 1 of a large gene containing 67 exons. This results in translation of an extended glutamine sequence in *huntingtin*, the protein gene product; its function is unclear. Huntingtin is expressed throughout the body. Most adult-onset HD cases have CAG expansions of 40–55 repeats, while greater expansions (>70 repeats) are seen in childhood-onset HD.

**Pathology**
Cerebral atrophy progresses, with marked loss of neurones in the caudate nucleus and putamen.

- Changes in neurotransmitters (Fig. 21.9) occur:
  - reduced acetylcholine synthesis (due to reduced choline acetyl transferase) and GABA in the striatum
  - increased transglutaminase (catalyses aggregates of *huntingtin*) in cortex, cerebellum and corpus striatum
  - depleted GABA, angiotensin-converting enzyme and met-enkephalin in substantia nigra
  - high somatostatin levels in the corpus striatum.

In contrast to PD, dopamine and tyrosine hydroxylase remain normal.

**Management and course**
Other causes of chorea should be looked for. Imaging in Huntington’s, if practical with the chorea, shows caudate nucleus atrophy. There is steady progression of both dementia and chorea. While nothing arrests this, phenothiazines (e.g. sulpiride) and tetrabenazine reduce chorea. Death usually occurs 10–20 years from the onset.

Mutation analysis is used for presymptomatic testing. Test centres have protocols for counselling families and addressing ethical issues.

**Sydenham’s chorea (St Vitus’s dance)**
This transient postinfective chorea occurs largely in children and young adults. Streptococcal infection is one cause: about half the cases follow rheumatic fever, typically within 3 months (p. 136). Sydenham’s may recur, or present in adult life, during pregnancy as chorea gravidarum, and with hormonal contraceptives. There is a diffuse mild encephalitis.

The onset is gradual over a few weeks. There is irritability, emotional lability and inattentiveness with fidgetiness, sometimes mainly unilateral. A minority of patients become confused. Rheumatic heart disease is sometimes found. Fever is unusual. Antistreptolysin-O (ASO) titre and ESR are typically normal. Sedation may be needed. Recovery occurs spontaneously within weeks or months. Phenoxy-methylpenicillin should continue to the age of 20 to prevent recurrence.

**Hemiballismus** (see p. 1113 and Fig. 21.9)
Hemiballism describes violent swinging movements of one side caused usually by infarction or haemorrhage in the contralateral subthalamic nucleus.

**Myoclonus**
Myoclonus is sudden, involuntary jerking of a single muscle or a group of muscles. This occurs in a wide range of
disorders and is sometimes provoked by sudden stimuli such as loud noise.

**Benign essential myoclonus**

*Nocturnal myoclonus*—sudden jerking (often with a feeling of falling) on dropping off to sleep— is common and not pathological. Periodic limb jerks (repetitive dorsiflexion of the great toe or plantar flexion of the foot during Stage I or II sleep) are brief and also occur in restless leg syndrome (p. 626).

*Paramyoclonus multiplex* describes widespread, random muscle jerking usually occurring in adolescence. Fits do not occur.

**Myoclonus in epilepsy**

Muscle jerking occurs in many different forms of epilepsy (p. 1140). An antiepileptic drug, e.g. valproate, may be helpful.

**Progressive myoclonic epilepsies**

These rare conditions include familial and metabolic disorders where myoclonus accompanies progressive encephalopathy. *Lataera body disease* is one example, consisting of myoclonus, epilepsy and dementia, with mucopolysaccharide inclusions in neurones, liver cells and intestinal mucosa.

**Static myoclonic encephalopathy**

Non-progressive myoclonus sometimes can follow recovery from severe cerebral anoxia.

**Non-organic muscle jerking**

Sometimes volitional, this can be seen in somatization, non-epileptic attacks and malingering.

**Tics**

Some idiosyncratic movement of the face, neck or hand is part of our normal motor gestures. Patients or relatives seek advice when movements become frequent or irritating. Simple transient tics (e.g. sniffing or facial grimacing) are common in childhood, but may persist. The borderland between normal and pathological is vague.

**Gilles de la Tourette syndrome**

This describes multiple tics (motor and speech) with behavioural problems including attention deficit hyperactivity disorder (ADHD) and obsessive-compulsive disorder (OCD). It develops in childhood or adolescence, more commonly in males, and is lifelong. There is sometimes explosive barking and grunting of obscenities and gestures. The cause is believed to be an inherited disorder of synaptic transmission. Haloperidol is sometimes helpful.

**Dystonias**

Dystonia means movement caused by prolonged muscular contraction—part of the body is thrown into spasm. A brief explanatory classification of these unusual basal ganglia conditions is given in Table 21.40. Their causes are largely unknown.

**Primary torsion dystonia (PTD)**

Dystonia affecting gait and posture in childhood progresses, spreading to all parts of the body over one to four decades. Cognitive function remains normal. Spontaneous remissions occur occasionally. This rare disease is usually inherited as an autosomal dominant. A PTD gene is on chromosome 9 (9q34), a deletion of three base pairs encoding an ATP-binding protein, torsin A.

**Dopamine-responsive dystonia (DRD)**

This lower limb dystonia is almost completely abolished by small doses of levodopa. Typically dystonic walking begins in childhood and may resemble a spastic paraparesis. The usual form is autosomal dominant DRD with a point mutation of the GTP cyclohydrolase 1 gene on chromosome 14q 22.3. Patients with dystonic gaits are sometimes given test doses of levodopa.

**Spasmodic torticollis**

Dystonic spasms gradually develop around the neck, usually in the third to fifth decade. These cause the head to turn (torticollis) or to be drawn backwards (retrotorticollis) or forwards (antecollis). Minor dystonic movements often also affect the trunk and limbs. A curious feature in some patients is a single trigger area, often on the jaw. A gentle touch with a finger tip at a specific site relieves the spasm temporarily. Torticollis may remit but often persists indefinitely. Similar features can be seen when no organic disease is present, for example people malingering following minor neck trauma.

**Writer’s cramp**

This is a specific inability to perform a previously highly developed repetitive skilled movement, e.g. writing. The movement provokes dystonic posturing. Writer’s cramp occurs in those who spend many hours each day writing, and is thus seen less frequently than in years past. Other functions of the hand remain normal. There are no other neurological signs. Prolonged rest sometimes helps but the dystonia can cause substantial disability. Similar dystonias occur in other occupations.

**Blepharospasm and oromandibular dystonia**

These consist of spasms of forced blinking or involuntary movement of the mouth and tongue (e.g. lip-smacking and protrusion of the tongue and jaw). Speech may be affected.

**Treatment**

All dystonic movement disorders are particularly difficult to alleviate. Butyrophenones (e.g. haloperidol and sulpiride) and

---

antimuscarinics (e.g. trihexyphenidyl (benzhexol)) are sometimes helpful. Carefully sited botulinum toxin injections can help, temporarily, blepharospasm, torticollis and writer’s cramp. Neurosurgical treatment, principally stereotactic thalamotomy for torticollis, or neurostimulation offers some respite in selected cases.

**FURTHER READING**

**MULTIPLE SCLEROSIS (MS)**

MS is a chronic inflammatory disorder of the CNS. There are multiple plaques of demyelination within the brain and spinal cord. Plaques are disseminated both in time and place, hence the earlier name ‘disseminated sclerosis’.

**Prevalence**

MS prevalence varies widely, being directly proportional to distance of residence from the equator. At latitudes of 50°–65° N (roughly from southern England to Iceland) prevalence is 60–100 per 100 000; at latitudes less than 30° N prevalence is below 10 per 100000. At the equator MS is a rarity. Dietary factors, e.g. high animal fat consumption, have been suggested for this geographical distribution but there is little evidence for this. In the southern hemisphere this trend is similar – increasing prevalence with distance from the equator. In Europe and North America MS is a common neurological disease of young adults.

**Aetiology and pathogenesis**

Although the precise mechanism is unknown, there is an inflammatory process in the white matter of the brain and cord mediated by CD4 T cells. In active lesions (plaques) there is an increase in inflammatory cells, active myelin degradation and phagocytosis. Lymphocytes and monocytes gain access to the brain parenchyma from the circulation by adhering to vascular endothelial cells via the glycoprotein α4β1 integrin expressed on their surface. This integrin (very late antigen VLA4) is also a regulator of immune cell activation.

An initial inflammatory demyelinating event may prime autoreactive cellular and humoral immune responses against myelin. Antibody-mediated demyelination, e.g. against myelin basic protein, probably develops early in MS. Antibodies against myelin oligodendrocyte glycoprotein (MOG), a protein specific to the CNS, have also been found in vitro.

**Familial incidence, HLA linkage and migration**

First-degree relatives of a patient have an increased chance of developing MS, without a clear-cut pattern of inheritance. The concordance rate is 31% in monozygotic twins.

In Caucasians in northern Europe and the USA, there is a weak association between MS and antigens HLA-A3, B7, D2 and DR2.

Immigrants from low to high prevalence zones (e.g. from the equator to northern Europe) acquire the prevalence of their destination, provided they arrive before the age of 10, irrespective of racial origin.

**Infection**

Efforts to transmit MS experimentally have been uniformly unsuccessful. However, an abnormal immune response in many MS patients produces increased titres of serum and CSF antibodies to many common viruses, particularly measles. Some epidemic transmissible zoonoses, such as scrapie (demyelinating disease in sheep), have some similarities to MS. In man, human T-cell leukaemia virus 1 (HTLV-1) causes tropical spastic paraparesis, but no other features seen in MS. Chlamydia has been questioned as a cause. No known links exist between MS and any infection.

**Pathology** (Fig. 21.34)

Plaques of demyelination, initially 2–10 mm in size, are the cardinal features. Plaques are perivenular with a predilection for distinct CNS sites: optic nerves, the periventricular region, the brainstem and its cerebellar connections and the cervical cord (corticospinal tracts and posterior columns).

Acute relapses are caused by focal inflammatory demyelination, which causes conduction block. Remission follows as inflammation subsides and remyelination occurs, helping recovery. When damage is severe, secondary permanent axonal destruction occurs. In the cord, plaques rarely destroy large groups of anterior horn cells, thus focal muscle wasting (e.g. small hand muscles) is unusual. Plaques are not seen in myelin sheaths of peripheral nerves.

**Clinical features**

The commonest age of onset is between 20 and 45 years; diagnosis before puberty or after 60 is rare. MS is more common in women. No single group of signs or symptoms is diagnostic. The Macdonald criteria (revised in 2005) provide

![Fig. 21.34 Multiple sclerosis. Cross-section of spinal cord showing MS plaques in posterior column and lateral corticospinal tracts. (Courtesy of the late Prof. Ian Macdonald.)](image-url)
a fairly sensitive method which can be used for the diagnosis and use the clinical presentation along with radiological findings.

MS is often recognizable clinically by different patterns:

- relapsing and remitting MS (80–90%)
- primary progressive MS (10–20%)
- secondary progressive MS – this follows on from relapsing/remitting disease
- occasionally (<10%) MS runs a fulminating course over some months (fulminant MS).

Three characteristic common presentations of relapsing and remitting MS are optic neuropathy, brainstem demyelination and spinal cord lesions, described below.

Optic neuropathy (ON)

**Symptoms**
Blurring of vision in one eye develops over hours or days, varying from a frosted glass effect to severe unilateral visual loss, but rarely complete blindness. Mild ocular pain is usual. Recovery occurs, typically within 2 months. Bilateral ON can occur.

**Signs**
The optic disc appearance depends upon the site of the plaque within the optic nerve. When the lesion is in the nerve head there is disc swelling (optic neuritis, p. 1102). If the lesion is several millimetres behind the disc there are no ophthalmoscopic abnormalities – the doctor sees nothing and the patient sees nothing. This is *retrobulbar neuritis* (p. 1102).

Worsening of vision in ON during a fever, hot weather or after exercise is known as Uthoff’s phenomenon – central conduction is slowed by an increase in body temperature.

Disc swelling from optic neuritis causes early visual acuity loss, thus distinguishing it from disc swelling from raised intracranial pressure.

A *relative afferent pupillary defect* (p. 1103) is often found, and persists after recovery.

**Late sequelae of optic neuropathy**
There is often no residual loss of vision, but small scotomata and defects in colour vision can be found. Following optic neuropathy, disc pallor can develop (optic atrophy), first on the temporal side. Visual evoked responses (VER) remain abnormal (see below and p. 1121).

Brainstem demyelination
Acute MS in the brainstem causes combinations of diplopia, vertigo, facial numbness/weakness, dysarthria or dysphagia. Pyramidal signs in the limbs occur when the corticospinal tracts are involved. A typical picture is sudden diplopia, and vertigo with nystagmus, but without tinnitus or deafness. This lasts for some weeks before recovery. Diplopia is produced by many lesions – a VIth nerve lesion and internuclear ophthalmoplegia (INO, p. 1105) are examples.

Spinal cord lesions
Spastic paraparesis developing over days or weeks (p. 1164) is a typical result of a plaque in the cervical or thoracic cord, causing difficulty in walking and lower limb numbness. Lhermitte’s sign may be present (p. 1116). Urinary symptoms are common.

Unusual presentations
Epilepsy and trigeminal neuralgia (p. 1106) occur more commonly in MS patients than in the general population. Tonic spasms (brief spasms of one limb) are other unusual presentations. Organic psychosis is occasionally seen in early MS.

End-stage multiple sclerosis
Late MS causes severe disability with spastic tetraparesis, ataxia, optic atrophy, nystagmus, brainstem signs (e.g. bilateral INO), pseudobulbar palsy and urinary incontinence. Dementia is common. Death follows from uraemia and/or bronchopneumonia.

**Differential diagnosis and course**
Few other neurological diseases have a similar relapsing and remitting course. Thromboembolism typically causes events with more sudden onset. Other degenerative conditions, such as Friedreich’s ataxia, are gradually progressive.

Following an isolated neurological event that is *possible* MS, it is often unclear, even with MR imaging, whether or not MS is the cause. The pattern and imaging appearance of subsequent lesions establishes the diagnosis. Remissions may last for several or more years; their length is unpredictable and the mechanism of relapse and remission unknown. Infection sometimes appears to provoke a relapse. Claims are made for trauma to cause relapses: evidence for this is negligible.

Individual plaques (e.g. in optic nerve, brainstem or cord) must be distinguished from mass, vascular or other inflammatory lesions. Of the latter, CNS sarcoidosis, SLE and Behçet’s syndrome may mimic relapsing MS. Adrenoleucodystrophy can cause a progressive paraparesis identical to chronic progressive MS (p. 1122).

**Investigations**

- **MRI** of brain and cord is the definitive structural investigation. Multiple plaques are seen (Fig. 21.35), principally in the periventricular region, corpus callosum, cerebellar peduncles, juxtacortical posterior fossa, brainstem and cervical cord. Head MRI scans show lesions (elliptical in shape with discrete borders and lack of a mass effect) in 85% of patients with clinical MS. Typical lesions are multifocal (2 mm to 2 cm), with 10 or more lesions. Gadolinium can enhance active lesions. Plaques are rarely visible on CT.

- **CSF examination** is often unnecessary with suggestive MR imaging and a compatible clinical picture. CSF analysis shows oligoclonal IgG bands in 80% of cases but these are not specific. The CSF cell count may be raised (5–60 mononuclear cells/mm³).

- **Evoked responses**. Delay in visual evoked responses (VER) is seen in optic neuropathy. Some ON attacks are

![Fig. 21.35 Multiple sclerosis: MR T2. Arrows indicate brain plaques.](https://example.com/key-image-url)
subclinical: a delayed VER provides evidence of a previous, silent optic nerve lesion. This is helpful for diagnosis if there had been, for example, a previous apparently solitary cord lesion. Brainstem and somatosensory evoked potentials become delayed when these pathways have been damaged.

Peripheral nerve studies are normal and EEGs unhelpful.

- Blood/urine tests are unhelpful.

**Management and prognosis**

Once diagnosed, practical decisions need to be taken about employment, home and plans for the future in the face of a potentially disabling disease for which there is no curative treatment.

The course of MS is unpredictable: a florid MR lesion load at initial presentation is a strong predictor towards serious disability. There is wide variation in severity. Many patients continue to live self-sufficient, productive lives; others become gravely disabled.

Straightforward information and advice, with emphasis on the benign course of many MS cases, is required. The MS Society and other charities have helpful literature.

**MS therapies**

Many forms of treatment have been marketed, among them cryotherapy, pyrotherapy, radiotherapy, various vaccines, purified TB protein derivative (PPD), transfer factor, electrical stimulation, gluten-free diets, sunflower seed oil, arsenicals, vitamins and hyperbaric oxygen. None has been shown to improve outcome.

- **Acute relapses.** Short courses of steroids, such as i.v. methylprednisolone 1 g/day for 3 days or high-dose oral steroids, are used widely in relapses and do sometimes reduce severity. They do not influence long-term outcome.

- **Preventing relapse and disability.** Beta-interferon (both IFN-β1b and 1a) by self-administered injection is used in relapsing and remitting disease. This is defined as at least two attacks of neurological dysfunction over the previous 2 or 3 years followed by a reasonable recovery. IFN-β1b is also now licensed for secondary progressive MS. Interferon certainly reduces relapse rate in some patients and prevents an increase in lesions seen on MRI. Unwanted effects are flu-like symptoms and irritation at injection sites. Cost-benefit analyses are serious issues: beta-interferons are expensive.

- **Immunosuppressants** and antineoplastic drugs (azathioprine, cyclophosphamide, mitoxantrone and others) are also used; trials have sometimes shown slight benefits.

- **Glatiramer acetate,** an immunomodulator, has been shown to reduce relapse frequency in ambulatory patients with relapsing remitting MS – similar to beta-interferon.

- **Natalizumab** is a monoclonal antibody which inhibits migration of leucocytes into the central nervous system by inhibitory α4 integrins found on the surface of lymphocytes and monocytes. It is useful in severe, relapsing remitting MS that is unresponsive to other treatments. It is associated with a risk of progressive multifocal leucoencephalopathy (PML) and all patients need close surveillance for this and hypersensitivity reactions.

**The rehabilitative approach in MS**

Much can be done for patients with chronic disabling diseases. Practical advice at work, on walking aids, wheelchairs, car conversions and alterations to houses and gardens is needed, from professionals with experience. Wide-ranging support – for fear, reactive depression and sexual difficulties – is also helpful. Multidisciplinary team liaison between patient, carers, doctors and therapists is essential.

All infections should be treated. Urinary infection frequently exacerbates symptoms. Urinary incontinence may be helped by oxybutinin and/or intermittent self-catheterization.

Physiotherapy is of particular value in reducing pain and discomfort of spasticity, particularly lower limb flexor spasms. Muscle relaxants (e.g. baclofen, benzodiazepines, dantrolene and tizanidine) are sometimes helpful. Injected botulinum toxin is used for severe spasticity. Cannabis is used by many patients for painful spasms. Cannabis extracts and synthetic cannabinoids are also used. Prevention of pressure sores is vital. Amantadine is sometimes used for general fatigue.

**FURTHER READING**

**NERVOUS SYSTEM INFECTION AND INFLAMMATION**

**MENINGITIS**

Meningitis usually implies serious infection of the meninges (Table 21.41). Bacterial meningitis is fatal unless treated. Microorganisms reach the meninges either by direct extension from the ears, nasopharynx, cranial injury or congenital meningeal defect, or by bloodstream spread. Immunocompromised patients (e.g. HIV, cytotoxic drug therapy) are at risk of infection by unusual organisms. Non-infective causes of meningeal inflammation include malignant cells, intrathecal drugs and blood following subarachnoid haemorrhage.

**Pathology**

In acute bacterial meningitis, the pia–arachnoid is congested with polymorphs. A layer of pus forms. This may organize to form adhesions, causing cranial nerve palsies and hydrocephalus.

In chronic infection (e.g. TB), the brain is covered in a viscous grey-green exudate with numerous meningeal tubercles. Adhesions are invariable. Cerebral oedema occurs in any bacterial meningitis.

Emergency Box 21.1

**Meningococcal meningitis and meningococcaemia: emergency treatment**

Suspicion of meningococcal infection is a medical emergency requiring treatment immediately.

Clinical features:
- petechial or non-specific blotchy red rash
- fever, headache, neck stiffness.

All these features may not be present – and meningococcal infection may sometimes begin like any apparently non-serious infection.

**Immediate treatment for suspected meningococcal meningitis at first contact before transfer to hospital or investigation:**
- benzylpenicillin 1200 mg (adult dose) slow i.v. injection or intramuscularly
- alternative if penicillin allergy – cefotaxime 1 g i.v.

**In meningitis, minutes count: delay is unacceptable.**

**On arrival in hospital:**
- routine tests including blood cultures immediately
- watch out for septicaemic shock.

For further tests including blood cultures immediately

**Acute bacterial meningitis**

Onset is typically sudden, with rigors and high fever. Meningococcal meningitis is often heralded by a petechial or other rash, sometimes sparse (see Emergency box 21.1). The meningitis may be part of a generalized meningococcal septicaemia (p. 136). Acute septicaemic shock may develop in any bacterial meningitis.

**Viral meningitis**

This is almost always a benign, self-limiting condition lasting 4–10 days. Headache may follow for some months. There are no serious sequelae, unless an encephalitis is present (p. 1156).

**Chronic meningitis (see below)**

**Differential diagnosis**

It may be difficult to distinguish between the sudden headache of subarachnoid haemorrhage, migraine and acute meningitis. Meningitis should be considered seriously in

In viral meningitis there is a predominantly lymphocytic inflammatory CSF reaction without pus formation, polymorphs or adhesions; there is little or no cerebral oedema unless encephalitis develops.

**Clinical features**

**The meningitic syndrome**

This is a simple triad: headache, neck stiffness and fever. Photophobia and vomiting are often present. In acute bacterial infection there is usually intense malaise, fever, rigors, severe headache, photophobia and vomiting, developing within hours or minutes. The patient is irritable and often prefers to lie still. Neck stiffness and positive Kernig’s sign usually appear within hours.

In less severe cases (e.g. many viral meningitides) there are less prominent meningitic signs. However, bacterial infection may also be indolent, with a deceptively mild onset. Clinical pictures of apparently mild meningitis are highly unreliable.

In uncomplicated meningitis, consciousness remains intact, although anyone with high fever may be delirious. Progressive drowsiness, lateralizing signs and cranial nerve lesions indicate complications such as venous sinus thrombosis (p. 1136), severe cerebral oedema, hydrocephalus, or an alternative diagnosis such as cerebral abscess (p. 1159) or encephalitis (p. 1156). Papilloedema may develop.

**Specific varieties of meningitis**

Clinical clues point to the diagnosis (Table 21.42). If there is access to the subarachnoid space via skull fracture (recent or old) or occult spina bifida, bacterial meningitis can be recurrent, and the infecting organism is usually pneumococcus.
anyone with headache and fever and in any sudden headache. Neck stiffness should be assessed carefully – it may not be obvious. Chronic meningitis sometimes resembles an intracranial mass lesion, with headache, epilepsy and focal signs. Cerebral malaria can mimic bacterial meningitis.

**Management** (Emergency Box 21.1)

Recognition and immediate treatment of acute bacterial meningitis is vital. Minutes save lives. Bacterial meningitis is lethal. Even with optimal care, mortality is around 15%. The following applies to adult patients; management is similar in children.

When meningococcal meningitis is diagnosed clinically by the petechial rash, immediate i.v. antibiotics should be given and blood cultures taken; lumbar puncture is unnecessary. In other causes of meningitis a lumbar puncture is performed if there is no clinical suspicion of a mass lesion (p. 1121). If the latter is suspected an immediate CT scan must be performed because coning of the cerebellar tonsils may follow. Typical CSF changes are shown in Table 21.43. CSF pressure is characteristically elevated. If a presumptive diagnosis of the organism can be made (e.g. pneumococcus is likely with skull fracture or sinus infection), targeted treatment should be started immediately. Immediate antibiotic treatment in acute bacterial meningitis is shown in Table 21.44.

Blood should be taken for cultures, glucose and routine tests. Chest and skull films should be obtained if appropriate.

CSF stains demonstrate organisms (e.g. Gram-positive intracellular diplococci – pneumococcus; Gram-negative cocci – meningococcus). Ziehl–Neelsen stain demonstrates acid-fast bacilli (TB), though TB organisms are rarely numerous. Indian ink stains fungi.

It cannot be emphasized enough that meticulous attention should focus on microbiological studies in suspected CNS infection with close liaison between clinician and microbiologist. Specific techniques (e.g. polymerase chain reaction for meningococci and other bacteria) are invaluable. Syphilitic serology should always be carried out.

The clinical picture and CSF examination should thus yield a presumptive cause for acute meningitis within hours. Antibiotics, however, must be started before the actual organism is identified.

If bacterial meningitis is diagnosed, further discussion with the microbiologist should include antibiotics, drug resistance, recent infections in the locality, barrier nursing and prophylaxis.

In adults with pneumococcal meningitis, there is some evidence to support the use of dexamethasone, given first with the initial antibiotics.

</tr>
</tbody>
</table>

Intrathecal antibiotics are no longer used.

Local infection (e.g. paranasal sinus) should be treated surgically if necessary. Repair of a depressed skull fracture or meningeal tear may be required.

**Prophylaxis**

Meningococcal infection should be notified to public health authorities, and advice sought about immunization and prophylaxis of contacts, e.g. with rifampicin or ciprofloxacin. MenC, a meningococcal C conjugate vaccine, is part of childhood UK immunization and often given to case contacts. A combined A and C meningococcal vaccine is sometimes used prior to travel to endemic regions, e.g. Africa, Asia; and a quadrivalent ACYW vaccine for specific events, e.g. the Haj and Umrah in Mecca. There is no vaccine for Group B.

A polyvalent pneumococcal vaccine is used after recurrent meningitis, e.g. after a CSF leak following skull fracture.

Hib (*Haemophilus influenzae*) vaccine is given routinely in childhood in the UK and other countries, e.g. Gambia, virtually eliminating a common cause of fatal meningitis.

**Chronic meningitis**

Tuberculous meningitis (TBM) and cryptococcal meningitis commence typically with vague headache, lassitude, anorexia and vomiting. Acute meningitis can occur but is unusual. Meningitic signs often take some weeks to develop. Drowsiness, focal signs (e.g. diplopia, papilloedema, hemiparesis) and seizures are common. Syphilis, sarcoidosis and Behçet’s also cause chronic meningitis. In some cases of chronic meningitis an organism is never identified.

**Management of tuberculous meningitis**

TBM is a common and serious disease world-wide. Brain imaging, usually with MRI, may show meningeal enhancement, hydrocephalus and tuberculomas (p. 1159), though it may remain normal (see Table 21.43 for CSF changes). In many cases the sparse TB organisms cannot be seen on
staining and PCR testing should be performed, although results may be negative. Repeated CSF examination is often necessary and it will be some weeks before cultures are confirmatory. Treatment with antituberculosis drugs (p. 866) – rifampicin, isoniazid and pyrazinamide – must commence on a presumptive basis and continue for at least 9 months. Ethambutol should be avoided because of its eye complications. Adjutent corticosteroids, e.g. prednisolone 60 mg for 3 weeks, are now recommended (often tapered off). Relapses and complications (e.g. seizures, hydrocephalus) are common in TBM. The mortality remains over 60% even with early treatment.

Malignant meningitis
Malignant cells can cause a subacute or chronic non-infective meningitic process. A meningitic syndrome, cranial nerve lesions, paraparesis and root lesions are seen, often in confusing and fluctuating patterns. The CSF cell count is raised, with high protein and low glucose. Treatment with intrathecal cytotoxic agents is rarely helpful.

Cells in a sterile CSF (pleocytosis)
A raised CSF cell count is present without an evident infecting organism. CSF pleocytosis, i.e. a mixture of lymphocytes and polymorphs, is the usual situation (Table 21.45).

**Further reading**
Department of Health. Immunisation Against Infectious Disease, 1999. PL CMO (99) 4, PL CNO (99) 8, PL CPHO (99) 3.

**Encephalitis**
Encephalitis means inflammation of brain parenchyma, usually viral.

**Acute viral encephalitis**
The viruses cultured from adult UK cases are usually herpes simplex, ECHO, Coxackie, mumps and Epstein–Barr viruses. Adenovirus, varicella zoster, influenza, measles and other viral encephalitides are less common. Often, the virus is never identified.

Epidemic and endemic viral encephalitides occur world-wide:
- Japanese encephalitis in South East Asia
- Tick-borne flavivirus encephalitis over a large area from Western Europe to Japan (p. 116)
- Ross River fever in Australia
- California encephalitis in the USA
- Omsk haemorrhagic fever in Russia
- West Nile encephalitis in Egypt and Sudan.

Local epidemics occur. For example, encephalitis caused by Nipah virus, a virus hitherto not known to cause human disease, occurred in Malaysian abattoir workers in the 1990s. In New York in the 1990s, West Nile virus caused an epidemic. Chandipura virus caused an outbreak in children in Southern India in 2003. In 2007/8, St Louis encephalitis was epidemic in Florida, and a new epidemic/epizootic Venezuelan equine virus was isolated from encephalitis cases in South America.

**Clinical features**
Many encephalitides are mild; recovery occurs. In the minority, serious illness develops with high fever, headache, mood change and drowsiness over hours or days. Focal signs, seizures and coma ensue. Death, or brain injury follows; herpes simplex (HSV-1) accounts for many of these in the UK. In South East Asia, Japanese encephalitis (arbovirus) is a more usual cause.

**Differential diagnosis**
This includes:
- bacterial meningitis with cerebral oedema
- cerebral venous thrombosis
- brain abscess
- endocarditis
- acute disseminated encephalomyelitis
- cerebral malaria
- septicaemia, vasculitis
- toxic confusional states.

**Investigations**
CT and MR imaging show areas of oedema, often in the temporal lobes. EEG shows slow wave changes; a normal EEG is exceptional. CSF cell count is raised. Viral serology (blood and CSF) is helpful. Brain biopsy is occasionally performed.

**Treatment**
Suspected HSV encephalitis is treated immediately with i.v. aciclovir (10 mg/kg 3 times a day for 14–21 days), the active form of which inhibits DNA synthesis. Phosphorylation of aciclovir is dependent upon viral thymidine kinase; the drug is specific for herpesvirus infections. Coma is usually followed by a poor outlook, with or without aciclovir. Seizures are treated with anticonvulsants.

Prophylactic immunization against Japanese encephalitis is available for travellers to endemic areas in Asia. Tick-borne
encephalitis vaccine is also available. Both vaccines are
given routinely to children in endemic areas.

**Acute disseminated encephalomyelitis (ADEM)**

ADEM follows many viral infections (e.g. measles, varicella
zoster, mumps and rubella) and rarely immunization against
rabies, influenza or pertussis. The syndrome is often similar
to acute viral encephalitis, with additional focal brainstem
and/or spinal cord lesions due to demyelination (see also MS,
p. 1152). Viral particles are not present in the lesions, which
are well seen on T2 weighted MRI. Prognosis is variable. Mild
cases recover completely. When there is coma, mortality
remains approximately 25%. Survivors often have permanent
brain damage. Treatment is supportive, with steroids and
anticonvulsants.

**MYELITIS**

Myelitis means spinal cord inflammation causing paraparesis
or tetraparesis. This occurs with varicella zoster or ADEM.
Poliomyelitis is a specific spinal cord anterior horn cell
together with infection having been chick-
enpox many years previously. Chickenpox and shingles
viruses are identical.

**HERPES ZOSTER (SHINGLES)**

This is the recurrence of varicella zoster infection within
dorsal root ganglia, the original infection having been chick-
enpox many years previously. Chickenpox and shingles
viruses are identical.

**Clinical features**

For shingles pain, see page 106.

In the cranial nerves, herpes zoster has a predilection for
the Vth and VIIth nerves. Ophthalmic herpes is infection of
V1, This can lead to corneal scarring and gradual panop-
thalmitis. Geniculate herpes (geniculate ganglion of VIIth
nerve) is also called Ramsay Hunt syndrome (p. 1108). Local
complications are secondary bacterial infection, very rarely
local purpura with necrosis (purpura fulminans), generalized
zoster, and posteriorpenticial myelitis. Myelitis, meningoen-
cephalitis and motor radiculopathy (usually lumbar or bra-
chial) can follow varicella zoster. Treatment is with aciclovir
or its pro-drug, famciclovir or valaciclovir. Bromovinyl deoxy-
uridine, an oral thymidine analogue, has recently been intro-
duced. It is given as easily as possible for one week. It should
only be used in immunocompetent patients and is contrain-
dicated for use with all forms of 5-fluorouracil.

**Postherpetic neuralgia**

Postherpetic neuralgia is pain in a previous shingles zone;
this occurs in some 10% of patients (often elderly). Burning,
continuous pain responds poorly to analgesics. Treatment is
unsatisfactory but there is a trend towards gradual recovery
over 2 years. Amitriptyline is commonly used. Methylpred-
nisolone intrathecally is sometimes helpful.

**Vaccination.** The Centers for Disease Control (CDC) in
America have suggested that all adults over 60 years old
should be vaccinated against herpes zoster (even those who
have had shingles previously) as it reduces the incidence of
shingles by about 50%.

**NEUROSYMPHILIS**

Many neurological symptoms occur, sometimes mixed. (See
also syphilis, p. 177.)

**Asymptomatic neurosyphilis**

This means positive CSF serology without signs.

**Meningovascular syphilis**

This causes:

- subacute meningitis with cranial nerve palsies and
  papilloma
- a gumma – a chronic expanding intracranial mass
- paraparesis – a spinal meningovasculitis.

**Tabes dorsalis**

Demyelination in dorsal roots causes a complex deafferent-
ation syndrome. The elements of tabs are:

- lightning pains (p. 1116)
- ataxia, stamping gait, reflex/sensory loss, wasting
- neuropathic (Charcot) joints
- Argyll Robertson pupils (p. 1104)
- ptosis and optic atrophy.

**General paralysis of the insane (GPI)**

The grandiose title describes dementia and weakness. GPI
dementia is typically similar to Alzheimer’s (p. 1167). Pro-
gressive cognitive decline, seizures, brisk reflexes, extensor
plantar reflexes and tremor develop. Death follows within 3
years. Argyll Robertson pupils are usual. GPI and tabs are
rarities in the UK.

**Other forms of neurosyphilis**

In congenital neurosyphilis (acquired in utero), features of com-
bined tabs and GPI develop in childhood – taboparesis.

Secondary syphilis can be symptomless or cause a self-
limiting subacute meningitis.

**Treatment**

Benzylpenicillin 1 g daily i.m. for 10 days in primary infection
eliminates any risk of neurosyphilis. Allergic (Jarisch–
Herxheimer) reactions can occur; steroid cover is usually
given with penicillin (p. 179). Established neurological disease
is arrested but not reversed by penicillin.

**NEUROCYSTICERCOSIS**

The adult pork tapeworm, *Taenia solium*, is endemic in Latin
America, non-Muslim African countries, India and much of
South East Asia. This is a major global health challenge (p.
170, p. 1140). Epilepsy is a feature of neurocysticercosis.
Other neurological patterns include brainstem dysfunction,
cerebellar ataxia, hydrocephalus, and rarely dementia, arach-
noiditis and vasculitis. Most infected people remain
symptomless.

Brain CT and MRI are helpful, but sometimes not diag-
nostic. Serological tests indicate infection but not activity.
Biopsy of a lesion may be necessary.

Management is primarily the control of seizures with anti-
convulsants. The case for taenicide (e.g. praziquantel,
albendazole) is debated, but evidence supports their use.
Surgery is sometimes needed for giant brain cysts or
hydrocephalus.
HIV and Neurology (p. 188)

HIV-infected individuals frequently present with or develop neurological conditions. Immunosuppression leads to indolent, atypical clinical patterns. HIV patients also have a high incidence of stroke. The pattern of disease is changing where antiretroviral therapy is available.

Brain and meningeal disease in HIV

Acute aseptic meningitis is a primary HIV infection, with spontaneous recovery.

Chronic meningitis occurs with fungi (e.g. Cryptococcus neoformans or Aspergillus), TB, listeria, coliforms or other organisms. Aggressive treatment is essential.

AIDS-dementia complex (ADC). This diffuse, progressive, HIV-related dementia, sometimes with cerebellar signs, is still seen where antiretroviral therapy is unavailable.

Encephalitis and brain abscess. Toxoplasma, cytomegalovirus, herpes simplex and other organisms cause severe encephalitis. Multiple brain abscesses develop in HIV infection.

CNS lymphoma: this is typically fatal (p. 483).

Progressive multifocal leucoencephalopathy (PML) is due to papovavirus (JC virus, p. 108).

Spinal cord disease

Paraparesis with HIV occurs in several settings:
- acute transverse myelitis – primary HIV myelitis with spontaneous recovery
- myelopathy due to infection, e.g. herpes simplex, zoster, cytomegalovirus or TB
- CNS lymphoma.

Peripheral nerve disease

Many HIV neuropathies occur:
- mononeuropathy (e.g. common peroneal, facial)
- mononeuritis multiplex (p. 1172)
- polyneuropathy (p. 1172)
- autonomic neuropathy (p. 1176)
- neuropathies caused by treatment (Table 4.53).

Management of HIV

This is described on page 191.

Other infections

Many other infections involve the CNS and are discussed in Chapter 4, e.g. rabies, tetanus, botulism, Lyme disease and leprosy.

Transmissible spongiform encephalopathies

Creutzfeldt–Jakob diseases (CJDs)

CJDs are rare, progressive dementias recognized pathologically by spongiform changes in the brain (p. 121) caused by prions. Prions (proteinaceous infectious particle, PrP) are transmissible and resistant to many sterilization processes. All PrP diseases are associated with accumulation of a disease-related protein isoform, PrPSc, derived from a normal cellular precursor, PrPC.

Sporadic CJD cases develop progressive dementia, usually over the age of 50 years.

Iatrogenic CJD is transmitted from surgical specimens, autopsy, transplant material (e.g. corneal grafts) and the old pituitary derived growth hormone from cadavers. Iatrogenic CJD has a long incubation period, up to 5 years. Death is usual within approximately 6 months of clinical onset in both sporadic and iatrogenic forms. CJD pathology is very similar to that of bovine spongiform encephalopathy (BSE, mad cow disease), recognized first in the UK in the 1980s and in 2003 in the USA.

Incidence. Sporadic CJD occurs world-wide with an annual incidence of less than 1 per million; some 30–55 cases occur annually in the UK. Numbers have not been rising. Iatrogenic CJD is rarer: 0–6 UK cases annually. Familial CJD cases (0–4 annually in the UK) are associated with PrP gene mutations. Another rare form, Gerstmann–Sträussler–Scheinker syndrome, is an inherited autosomal recessive condition typified by chronic progressive ataxia and terminal dementia, with a duration of 2–10 years. Familial fatal insomia is a rare familial prion disease presenting with prolonged progressive insomnia.

Variant CJD (vCJD). This condition was first seen in the UK in 1995. The incidence is not increasing. vCJD patients are younger than sporadic cases with a mean age of 29. Early symptoms are neuropsychiatric, followed by ataxia and dementia with myoclonus or chorea. The diagnosis can be confirmed by tonsil biopsy and CSF gel electrophoresis. vCJD has a longer course than sporadic CJD – up to several years. vCJD and BSE are caused by the same prion strain, giving rise to speculation that transmission from animal to human food chain occurred, i.e. infection from BSE-infected cattle to humans (p. 122). Transmission via blood transfusion may occur.

Kuru. This prion dementia and cerebellar ataxia of New Guinea transmitted by cannibalism is described on page 122 and is now virtually extinct.

Other inflammatory conditions

Subacute sclerosing panencephalitis (SSPE)

Persistence of measles antigen in the CNS is associated with this rare late sequel of measles. Progressive mental deterioration, fits, myoclonus and pyramidal signs develop, typically in a child. Diagnosis is made by high measles antibody titre in blood and CSF. Measles immunization protects against SSPE, which has now been almost eliminated in the UK.

Progressive rubella encephalitis

Some 10 years after primary rubella infection, this causes progressive mental impairment, fits, optic atrophy, cerebellar and pyramidal signs. Antibody to rubella viral antigen is produced locally within the CNS. It is even rarer than SSPE and is not a complication of rubella immunization.
Reye’s syndrome
This severe encephalitic illness of children (p. 364) is accompanied by fatty infiltration of liver with hypoglycaemia.

Mollaret’s meningitis
This is recurrent self-limiting episodes of aseptic meningitis (i.e. no bacterial cause is found) over many years. Viral (possibly herpes simplex) infection is postulated.

Vogt–Koyanagi–Harada syndrome
This obscure recurrent inflammation of cells of neural crest origin causes uveitis, meningoencephalitis, vitiligo, deafness and alopecia.

Progressive multi-focal leucoencephalopathy (PML)
PML, seen in HIV and in immunosuppression, is due to JC virus and is described on page 108.

Whipple’s disease
CNS Whipple’s disease is characterized by myoclonus, dementia and supranuclear ophthalmoplegia (p. 281).

Neurosarcoidosis
Neurosarcoid with or without systemic sarcoid causes chronic meningoencephalitis, cord lesions, cranial nerve palsies, particularly bilateral VIIIth nerve lesions, polynuropathy and myopathy (p. 869).

Behçet’s syndrome (see also p. 552)
Behçet’s principal features are recurrent oral and/or genital ulceration, inflammatory ocular disease (uveitis, p. 1092) and neurological syndromes. Brainstem and cord lesions, aseptic meningitis (p. 1156), encephalitis and cerebral venous thrombosis occur.

Granulomatous (primary cerebral) angiitis
In this rare condition there is necrotising inflammation in the brain and meningeal vessels. Stroke, seizures and confusional states develop. There is some response to steroid and immunosuppressive therapy.

Multiple abscesses develop, particularly in HIV. Fungi also cause brain abscesses. A parameningeal infective focus (e.g. ear, nose, paranasal sinus, skull fracture) or a distant source of infection (e.g. lung, heart, abdomen) may be present. Frequently no underlying cause is found. An abscess is more than 10 times rarer than a brain tumour in the UK.

Clinical features
Headache, focal signs (e.g. hemiparesis, aphasia, hemianopia), epilepsy and raised intracranial pressure develop. Fever, leucocytosis and raised ESR are usual though not invariable. Cerebral abscesses may be indolent, developing over weeks. Cerebellar abscesses tend to develop rapidly over days or hours, producing hydrocephalus.

Management
Urgent imaging is essential. Contrast enhanced CT shows a thin high-attenuation rim, virtually diagnostic of an abscess. The search for a focus of infection should include a detailed examination of the skull, ears, paranasal sinuses and teeth, and distant sites such as heart and abdomen. Lumbar puncture is dangerous and usually unhelpful. Aspiration with stereotactic guidance allows the infective organism to be identified.

Treatment requires liaison between neurosurgeon and microbiologist. Streptococcal and anaerobic infections are treated with cefuroxime 1.5 g i.v. plus metronidazole 500 mg i.v. 8 hourly. For staphylococcal infections, flucloxacinil 2–3 g i.v. 6 hourly with cefuroxime is given. Surgical decompression may be necessary if parenteral antibiotics are unsuccessful. Despite treatment, mortality remains high at approximately 25%. Epilepsy is common in survivors.

Brain tuberculosis
TB causes chronic caseating intracranial granulomas – tuberculomas. These are the commonest intracranial masses in countries where TB is common, e.g. India. Brain tuberculomas either present as mass lesions de novo or develop during tuberculous meningitis; they are also found as symptomless intracranial calcification on imaging. Spinal cord tuberculomas also occur. Treatment is described on page 866.

Subdural empyema and intracranial epidural abscess

Intracranial subdural empyema is a collection of subdural pus, usually secondary to local skull or middle ear infection. Features are similar to those of a cerebral abscess. Imaging is diagnostic.

In intracranial epidural abscess a layer of pus, 1–3 mm thick, tracks along the epidural space causing sequential cranial nerve palsies, typically without raised intracranial pressure. There is usually local infection, e.g. in the middle ear. MRI outlines the abscess; CT is typically normal. Drainage is required, with antibiotics.

Spinal epidural abscess

Staphylococcus aureus is the usual organism, reaching the spine via the bloodstream, e.g. from a boil. Fever and back
pain are followed by paraparesis and/or root lesions. Emergency imaging and antibiotics are essential and surgical decompression is often necessary.

## BRAIN TUMOURS

Primary intracranial tumours account for some 10% of neoplasms. The most common tumours are outlined in Table 21.46. Metastases are the commonest intracranial tumours (Fig. 21.37). Symptomless meningiomas (benign) are also found on imaging or at autopsy.

### Gliomas (Fig. 21.38)

These malignant tumours of neuroepithelial origin are usually seen within the hemispheres, but occasionally in the cerebellum, brainstem or cord. Their cause is unknown. Glioma is occasionally associated with neurofibromatosis. They tend to spread by direct extension, virtually never metastasizing outside the CNS.

- **Astrocytomas** are gliomas that arise from astrocytes. They are classified histologically into grades I–IV. Grade I astrocytomas grow slowly over many years, while grade IV tumours (*glioblastoma multiforme*) cause death within several months. Cystic astrocytomas of childhood are relatively benign, and usually cerebellar.

- **Oligodendrogliaomas** arise from oligodendrocytes. They grow slowly, usually over several decades. Calcification is common.

### Meningiomas

These benign tumours (Figs 21.39–21.41) arise from the arachnoid membrane and may grow to a large size, usually over years. Those close to the skull erode bone. They often occur along the intracranial venous sinuses, which they may invade. They are unusual below the tentorium. Common sites are the parasagittal region, sphenoidal ridge, subfrontal region, pituitary fossa and skull base.

### Neurofibromas (Schwannomas)

These solid benign tumours arise from Schwann cells and occur principally in the cerebellopontine angle, where they arise from the VIIIth nerve sheath (acoustic neuroma, p. 1109).

### Other neoplasms

Other less common neoplasms include cerebellar haemangioblastoma, ependymoma of the IVth ventricle, colloid cyst of the IIIrd ventricle, pinealoma, chordoma of the skull base, glomus tumour of the jugular bulb, medulloblastoma (a cerebellar childhood tumour), craniopharyngioma (p. 972) and primary CNS lymphoma (p. 483). For pituitary tumours, see page 972.

Clinical features
Mass lesions within the brain produce symptoms and signs by three mechanisms:

- by direct effect – brain is destroyed and local function impaired
- by secondary effects of raised intracranial pressure and shift of intracranial contents (e.g. papilloedema, vomiting, headache)
- by provoking generalized and/or partial seizures.

Although neoplasms, either secondary or primary, are the commonest mass lesions in the UK, cerebral abscess, tuberculosis, neurocysticercosis, subdural and intracranial haematoma can also produce features that are clinically similar.

Direct effects of mass lesions
The hallmark of a direct effect of a mass is local progressive deterioration of function. Tumours can occur anywhere within the brain. Three examples are given:

- A left frontal meningioma caused a frontal lobe syndrome over several years with vague disturbance of personality, apathy and impaired intellect. Expressive aphasia developed, followed by progressive right hemiparesis as the corticospinal pathways became involved. As the mass enlarged further, pressure headaches and papilloedema developed.
- A right parietal lobe glioma caused a left homonymous field defect (optic radiation). Cortical sensory loss in the left limbs and left hemiparesis followed over 3 months. Partial seizures (episodes of tingling of the left limbs) developed.
- A left VIth nerve sheath neurofibroma (an acoustic neuroma, Schwannoma) in the cerebellopontine angle caused, over 3 years, progressive perceptive deafness (VIII), vertigo (VII), left facial numbness (V) and weakness (VII), followed by cerebellar ataxia on the same side. Papilloedema was a late sequel.

With a hemisphere tumour, epilepsy and the direct effects commonly draw attention to the problem. The rate of progression varies greatly, from a few days or weeks in a highly malignant glioma, to several years with a slowly enlarging mass such as a meningioma. Cerebral oedema surrounds mass lesions: its effect is difficult to distinguish from that of the tumour itself.

Raised intracranial pressure
Raised intracranial pressure causing headache, vomiting and papilloedema is a relatively unusual presentation of a mass lesion in the brain. These symptoms often imply hydrocephalus – obstruction to CSF pathways. Typically this is produced early by posterior fossa masses that obstruct the aqueduct and IVth ventricle but only later with lesions above the tentorium. Shift of the intracranial contents produces features that coexist with the direct effects of any expanding mass:

- Distortion of the upper brainstem, as midline structures are displaced either caudally or laterally by a hemisphere mass (Fig. 21.38). This causes impairment of consciousness.
- Compression of the medulla, by herniation of the cerebellar tonsils caudally through the foramen magnum – an example of coning. This causes impaired consciousness, respiratory depression, bradycardia, decerebrate posturing and death.

False localizing signs – false only because they do not point directly to the site of the mass.

Three examples of false localizing signs are:

- A VIth nerve lesion, first on the side of a mass and later bilaterally as the VIth nerve is compressed during its long intracranial course.
- A IInd nerve lesion develops as the temporal lobe uncus herniates caudally, compressing III against the petroclinoïd ligament. The first sign is ipsilateral pupil dilatation as parasympathetic fibres are compressed.
- Hemiparesis on the same side as a hemisphere tumour, i.e. the side you might not expect, from compression of the contralateral cerebral peduncle on the edge of the tentorium.

These false localizing signs, though unusual, indicate that shift of the brain has occurred.

Seizures
Partial seizures, simple or complex, that may evolve into generalized tonic–clonic seizures, are characteristic of many hemisphere masses, whether malignant or benign. The pattern of partial seizure is of localizing value (p. 1140).

Investigations

Imaging
Both CT and MRI are useful in detecting brain tumours; MRI is much more accurate for posterior fossa lesions. Benign and malignant tumours, brain abscess, TB, neurocysticercosis and infarction have characteristic, but not entirely reliable, appearances and refined imaging techniques and biopsy are often necessary. MR angiography is used occasionally to define blood supply and MR spectroscopy to study patterns typical of certain gliomas. PET is sometimes helpful to locate an occult primary tumour with metastases.

Plain skull X-rays have no value in brain tumour diagnosis.

Routine tests
Since metastases are common, routine tests, e.g. chest X-ray, should be performed.

Lumbar puncture
This is contraindicated when there is any possibility of a mass lesion as withdrawing CSF may provoke immediate herniation of the cerebellar tonsils. CSF examination is rarely helpful and has been superseded by imaging.

Biopsy and tumour removal
Stereotactic biopsy via a skull burr-hole is carried out to ascertain the histology of most suspected malignancies. With a benign tumour, e.g. a symptomatic, accessible meningioma, craniotomy is performed.

Management
Cerebral oedema surrounding a tumour is reduced rapidly by steroids: i.v. or oral dexamethasone. Mannitol, an osmotic diuretic, is also used intravenously to reduce oedema. Epilepsy is treated with antiepileptic drugs.

Whilst complete surgical removal of a tumour is an objective, it is often not possible, nor is surgery always necessary. Follow-up with serial imaging is sometimes preferable. At exploration, some benign tumours can be entirely removed.
(e.g. acoustic neuromas, some parasagittal meningiomas). With a brain malignancy it is not possible to remove an infiltrating mass. Biopsy and debulking are performed.

Within the posterior fossa, tumour removal is often necessary because of raised pressure and danger of coning. Overall mortality for posterior fossa exploration remains around 10%.

For gliomas and metastases, radiotherapy is usually given and improves survival, if only slightly. An isolated posterior fossa metastasis can sometimes be excised successfully. Chemotherapy has little real value in the majority of primary or secondary brain tumours. Vincristine, procarbazine and temozolomide have been used. Temozolomide has an active metabolite that interrupts DNA replication by methylation of the 06 position of guanine, and is used for gliomas that have relapsed following radiotherapy. Most brain malignancies have a poor prognosis despite advances in imaging, surgery, chemotherapy and radiotherapy – less than 50% survival for high-grade gliomas at 2 years.

Idiopathic intracranial hypertension (IIH)

This syndrome, benign intracranial hypertension or pseudo-tumor cerebi, is included with tumours because marked papilloedema develops. There is neither a mass nor an increase in ventricular size. IIH develops mainly in obese young women with vague menstrual irregularities. Headaches and visual blurring with papilloedema are common features. A Vth nerve lesion may develop – a false localizing sign (p. 1106). CSF pressure is elevated, with normal constituents. Imaging is normal. Steroid therapy is sometimes thought to be a cause: many other drugs have occasionally been implicated. Other causes of papilloedema should be excluded. Sagittal sinus thrombosis can cause a similar picture.

IIH is benign in the sense that it is not fatal: it is usually self-limiting. However, optic nerve infarction can follow, with consequent blindness when papilloedema is severe and long-standing. Repeated lumbar puncture, acetazolamide, and thiazide diuretics are used in an attempt to reduce the intracranial pressure. Weight reduction is helpful. Surgical decompression or shunting is sometimes necessary.

Hydrocephalus in adult life

Hydrocephalus is sometimes an unexpected finding on imaging. However, infantile hydrocephalus can become apparent in adult life (e.g. aqueduct stenosis). Combinations of headache, cognitive impairment, vomiting, papilloedema, ataxia and bilateral pyramidal signs develop. Hydrocephalus may develop in other circumstances:

- Posterior fossa and brainstem tumours obstruct the aqueduct or Vth ventricular outflow.
- Following subarachnoid haemorrhage, head injury or meningitis (particularly tuberculous).
- A IIIrd ventricle colloid cyst causes lateral ventricle enlargement, headache and papilloedema. These rare intraventricular tumours also sometimes produce intermittent hydrocephalus – recurrent prostrating headaches with episodes of lower limb weakness.
- Choroid plexus papilloma (rare) secretes CSF.

Frequently the underlying cause for hydrocephalus remains obscure.

Treatment

Ventriculo-atrial or ventriculo-peritoneal shunting is necessary when progressive hydrocephalus causes symptoms. Neurosurgical removal of tumours is carried out when appropriate, sometimes urgently.

Normal pressure hydrocephalus (NPH)

NPH describes a syndrome of enlarged lateral ventricles, dementia, urinary incontinence and gait apraxia, usually in the elderly. CSF pressure and constituents are typically normal. There is some debate about the reality of NPH as a true entity. Ventriculo-peritoneal shunting is occasionally carried out.

TRAUMATIC BRAIN INJURY

In most western countries head injury accounts for about 250 hospital admissions per 100 000 population annually. Trau-
matic brain injury (TBI) describes injuries with potentially permanent consequences. For each 100 000 people, 10 die annually following TBI; 10–15 are transferred to a neurosurgical unit – the majority of these require rehabilitation for a prolonged period of 1–9 months. The prevalence of survivors with a major persisting handicap is around 100 per 100 000. Road traffic accidents and alcohol abuse are the principal aetiological factors in this major cause of morbidity and mortality, in many countries.

Skull fractures
Linear skull fracture of the vault or base is one indication of the severity of a blow, but is itself not necessarily associated with any brain injury. Healing of linear fractures takes place spontaneously. Depressed skull fracture is followed by a high incidence of post-traumatic epilepsy. Surgical elevation and debridement are usually necessary.

Principal local complications of skull fracture are:
- meningal artery rupture – causing extradural haematoma (p. 1135)
- dural vein tears – causing subdural haematoma (p. 1135)
- CSF rhinorrhoea/otorrhoea and consequent meningitis.

Mechanisms of brain damage
Older classifications attempted to separate concussion, transient coma for hours followed by apparent complete clinical recovery, from brain contusion, i.e. bruising, with prolonged coma, focal signs and lasting damage. Pathological support for this division is poor. Mechanisms of TBI are complex and interrelated:
- diffuse axonal injury – shearing and rotational stresses on decelerating brain, sometimes at the site opposite impact (the contrecoup effect)
- neuronal and axonal damage from direct trauma
- brain oedema and raised intracranial pressure
- brain hypoxia
- brain ischaemia.

Clinical course
In a mild TBI a patient is stunned or dazed for a few seconds or minutes. Following this the patient remains alert without post-traumatic amnesia. Headache can follow; complete recovery is usual. In more serious injuries duration of unconsciousness and particularly of post-traumatic amnesia (PTA) helps grade severity. PTA of more than 24 hours defines severe TBI. The Glasgow Coma Scale (GCS, p. 1123) is used to record the degree of coma; this has prognostic value. A GCS below 5/15 at 24 hours implies a serious injury; 50% of such patients die or remain in a vegetative or minimal conscious state (p. 1125). However, prolonged coma of up to some weeks is occasionally followed by good recovery.

Recovery after severe TBI takes many weeks or months. During the first few weeks, patients are often intermittently restless or lethargic and have focal deficits such as hemiparesis or aphasia. Gradually they become more aware, though they may remain in post-traumatic amnesia, being unable to lay down any continuous memory despite being awake. This amnesia may last some weeks or more, and may not be obvious clinically. PTA is one predictor of outcome. PTA over a week implies that persistent organic cognitive deficit is almost inevitable, although return to unsupported paid work may be possible.

Late sequelae
Sequelae of TBI are major causes of morbidity and can have serious social and medicolegal consequences. They include:
- Incomplete recovery, e.g. cognitive impairment, hemiparesis.
- Post-traumatic epilepsy (p. 1141).
- The post-traumatic (post-concussional) syndrome. This describes the vague complaints of headache, dizziness and malaise that follow even minor head injuries. Litigation is frequently an issue. Depression is prominent. Symptoms may be prolonged.
- Benign paroxysmal positional vertigo (BPPV, p. 1079).
- Chronic subdural haematoma (p. 1135).
- Hydrocephalus (p. 1162).
- Chronic traumatic encephalopathy. This follows repeated and often minor injuries. It is known as the punch-drunk syndrome and consists of cognitive impairment, extrapyramidal and pyramidal signs, seen typically in professional boxers.

Immediate management
Attention to the airway is vital. If there is coma, depressed fracture or suspicion of intracranial haematoma, CT imaging and discussion with a neurosurgical unit are essential. Indications for CT imaging vary from imaging all minor head injuries in some UK centres to more stringent criteria elsewhere.

In many severe TBI cases, assisted ventilation will be needed. Intracranial pressure monitoring is valuable. Hypothermia lowers intracranial pressure when used early after a TBI; an effect on outcome has only been seen in specialized neurotrauma centres. Care of the unconscious patient is described on page 1124. Prophylactic antiepileptic drugs have been shown to be of no value in prevention of late post-traumatic epilepsy.

Rehabilitation
TBI cases require skilled, prolonged and energetic support. Survivors with severe physical and cognitive deficits require rehabilitation in specialized units. Rehabilitation includes care from a multidisciplinary team with physiotherapeutical, psychological and practical skills. Many survivors are left with cognitive problems (amnesia, neglect, disordered attention and motivation) and behavioural/emotional problems (temper dyscontrol, depression and grief reactions). Long-term support for both patients and families is necessary.

SPINAL CORD DISEASE
The cord extends from C1, the junction with the medulla, to the vertebral body of L1 where it becomes the conus medularis. Blood supply is from the anterior spinal artery and a plexus on the posterior cord. This network is supplied by vertebral arteries, the thyrocervical trunk and several branches from lumbar and intercostal vessels.

SPINAL CORD COMPRESSION
Principal features of chronic and subacute cord compression are spastic paraparesis or tetraparesis, radicular pain at the
level of compression, and sensory loss below the compression (Table 21.47).

For example, in compression at T4 (Fig. 21.14) a band of pain radiates around the thorax, characteristically worse on coughing or straining. Spastic paraparesis develops over months, days or hours, depending upon underlying pathology. Numbness commencing in the feet rises to the level of compression. This is called the sensory level. Retention of urine and constipation develop.

Cord compression is a medical emergency. It is sometimes difficult on clinical grounds alone to distinguish chronic progressive cord compression from other, non-surgical causes of worsening paraparesis and tetraparesis. One reason for this is that pain at the level of compression can be absent.

**Causes**

**Spinal cord neoplasms.** Extramedullary tumours, both extradural and intradural, cause cord compression (Table 21.48 and Fig. 21.43) gradually over weeks to months, often with root pain and a sensory level (p. 1197).

The rarer intramedullary tumours (e.g. glioma) typically progress slowly, sometimes over many years. Sensory disturbances similar to syringomyelia may develop (p. 1164).

**Tuberculosis.** Spinal TB is the commonest cause of cord compression in countries where TB is common. There is destruction of vertebral bodies and disc spaces, with local spread of infection. Cord compression and paraparesis follow, culminating in paralysis – Pott’s paraplegia.

**Disc and vertebral lesions.** Central cervical disc and thoracic disc protrusion cause cord compression (p. 1177).

**Spinal epidural abscess.** This is described on page 1159.

**Epidural haemorrhage and haematoma.** These are rare sequelae of anticoagulant therapy, bleeding disorders or trauma and can follow lumbar puncture when clotting is abnormal. A rapidly progressive cord or cauda equina lesion develops.

**Management**

Early recognition of cord compression is vital. MRI shows spinal cord pathology extremely well and is the imaging technique of choice. Plain spinal films show degenerative bone disease and vertebral destruction by infection or neoplasm. Routine tests (e.g. chest X-ray) may indicate a primary neoplasm or infection. Surgical exploration is frequently necessary; if decompression is not performed promptly, irreversible cord damage tends to follow. Results are excellent if benign tumours and haematomas are removed early. Radiotherapy is used to treat cord malignancies, with largely poor outcome.

**OTHER CAUSES OF PARAPARESIS**

Paraparesis (and tetraparesis) occurs in many conditions recognizable by their clinical patterns. The elucidation of the cause of paraparesis has a pivotal place in neurology (see Table 21.13).

**Syringomyelia and syringobulbia**

The syrinx, a fluid-filled cavity within the cervical or thoracic spinal cord, is the essential feature. Syringobulbia means a cavity in the brainstem.
Aetiology and mechanism
Syringomyelia is frequently associated with the Arnold–Chiari malformation (p. 1169). The abnormality at the foramen magnum probably allows normal pulsatile CSF pressure waves to be transmitted to fragile tissues of the cervical cord and brainstem, causing secondary cavity formation. The syrinx is in continuity with the central canal of the cord.

Pathological anatomy
The expanding cavity in the cord, usually between C2 and T9, gradually destroys spinothalamic neurones, anterior horn cells and lateral corticospinal tracts. In the medulla (syringobulbia), trigeminal nuclei, sympathetic trunk, IXth, Xth, XIth and XIIth nerve nuclei and the vestibular connections are destroyed by the expanding syrinx.

Clinical features
Syringomyelia cases with the Arnold–Chiari malformation usually develop symptoms around the age of 20–30. Upper limb pain exacerbated by exertion or coughing is typical. Spinothalamic sensory loss – pain and temperature – leads to painless upper limb burns and trophic changes. Paraparesis develops. The following are typical signs of a substantial cervical syrinx (Fig. 21.44):

- Areas of dissociated sensory loss, i.e. spinothalamic loss without loss of light touch. Bizarre patterns are seen.
- Loss of upper limb reflexes.
- Muscle wasting in the hand and forearm.
- Spastic paraparesis – initially mild.
- Neuropathic joints, trophic skin changes (scars, nail dystrophy) and ulcers.
- Brainstem signs – as the syrinx extends into the brainstem (syringobulbia) there is tongue atrophy and fasciculation, bulbar palsy, nystagmus, Horner’s syndrome, hearing loss and impairment of facial sensation.

Course, investigation and management
MRI demonstrates the cavity and herniation of cerebellar tonsils. Syringomyelia is gradually progressive over several decades. Sudden deterioration sometimes follows minor trauma, or occurs spontaneously.

There is no curative treatment. Surgical decompression of the foramen magnum sometimes slows deterioration.

Other causes of syrinx formation are bony anomalies at the foramen magnum, spina bifida (p. 1169), arachnoiditis, hydrocephalus (p. 1162), intrinsic cord tumours (e.g. glioma and ependymoma) and trauma.

Metabolic, toxic, inflammatory and vascular cord disease
Vitamin B12 deficiency
Subacute combined degeneration of the cord resulting from vitamin B12 deficiency (p. 399) is the most common example of metabolic disease causing spinal cord damage. Copper deficiency is an exceedingly rare cause of a similar picture. Cord lesions probably due to multiple B vitamin deficiencies are also seen in severe malnutrition.

Lathyism
This is an endemic spastic paraparesis of central India caused by the toxin β-(M)-oxalamino-L-alanine. It occurs when excessive quantities of a drought-resistant pulse, Lathyrus sativa, are consumed.

Konzo (tropical ataxic neuropathy)
In West Africa and the Caribbean inadequate preparation of cassava root leads to ingestion of cyanogenic glycosides. A subacute spastic paraparesis or quadraparesis, called konzo, follows. Tropical ataxic neuropathy consists of sensory ataxia, loss of reflexes, deafness and optic atrophy, probably due to chronic low-level exposure to these glycosides.

Acute transverse myelopathy
(Transverse myelitis)
This term is used to describe a cord lesion and paraparesis (or paraplegia) occurring with viral infections, MS, mixed connective tissue disease and other inflammatory and vascular disorders, e.g. HIV, sarcoid, syphilis, radiation myelopathy and anterior spinal artery occlusion. MRI is usually required to exclude cord compression.

Anterior spinal artery occlusion
Cord infarction, causing an acute paraplegia or tetraplegia (or paraparesis), occurs in many thrombotic or embolic vascular diseases, e.g. endocarditis, severe hypotension, atheroma, diabetes mellitus, polycythaemia, syphilis and polyarteritis. Cord infarction sometimes occurs during surgery to the posterior mediastinum, or follows aortic dissection and trauma. It also occurs as an isolated event.

Radiation myelopathy
Paraparesis with sensory loss sometimes develops within several weeks to a year following radiotherapy; precautions should be taken to shield the cord during radiotherapy.

Management of paraplegia
General considerations
General health and morale should be reviewed carefully and regularly. Any intercurrent infection is potentially dangerous and should be treated early. Chronic renal failure is a common cause of death. The paraplegic patient needs skilled and prolonged nursing care and training to be aware of problems. Particular issues are discussed below.

Bladder. Catheterization is usually necessary initially. Many patients self-catheterize, or develop reflex bladder emptying, helped by abdominal pressure. Free urinary drainage is essential to avoid stasis, subsequent infection and calculi.
**Bowel.** Constipation and impaction must be avoided. Following acute paraplegia, manual evacuation is necessary; reflex emptying develops later.

**Skin care.** Risks of pressure sores and their sequelae are serious. Meticulous attention must be paid to cleanliness and to turning every 2 hours. The sacrum, iliac crests, greater trochanters, heels and malleoli should be inspected frequently (p. 1262). Ripple mattresses/water beds are useful. If pressure sores develop, plastic surgical repair may be required. Pressure palsies, e.g. of ulnar nerves, must be avoided.

**Lower limbs.** Passive physiotherapy helps to prevent contractures. Severe spasticity, with flexor or extensor spasms, may be helped by baclofen, diazepam, dantrolene, tizanidine or botulinum toxin injections.

**Rehabilitation**

Many patients with traumatic paraplegia or tetraplegia return to self-sufficiency. Specialist advice from a skilled rehabilitation unit is necessary. Lightweight, specially adapted wheelchairs are available. Patients with paraplegia have substantial practical, psychological and sexual needs.

## DEGENERATIVE NEURONAL DISEASES

Degenerative underlines our incomplete understanding of these progressive CNS diseases. Their molecular and genetic basis is the subject of intense study.

### MOTOR NEURONE DISEASE (MND)

In this common disease, seen world-wide, there is progressive degeneration of lower and upper motor neurones in the spinal cord, in cranial nerve motor nuclei and within the cortex. Most MND is sporadic and of unknown cause. It is thought that relentless degeneration of motor neurones may be programmed genetically. Abnormal mRNA splicing of the excitatory amino-acid transporter (EAAT2) gene, a major glial transporter, was once thought to be specific for MND, but is sometimes found in normal people. Oxidative neuronal damage, aggregation of abnormal neuronal proteins, glutamate mishandling and abnormalities of neurofilament-mediated axonal transport are also involved. Apoptosis and prolonged neuronal caspase activity (p. 27) are the final pathways of cell destruction.

There is a rare familial form of MND in which there are mutations in the gene (chromosome 21q) encoding the free radical scavenging enzyme copper/zinc superoxide dismutase (SOD-1).

Incidence of the sporadic form is around 2 per 100000 per year, with a slight male predominance. Onset occurs typically in the over 50s.

### Clinical features

The sensory system is not involved. In the common, sporadic form of MND, four broad patterns are seen:

- progressive bulbar and pseudobulbar palsy
- primary lateral sclerosis (rare)

Although useful as a means of recognizing MND, these are not distinct aetiological or pathological variants and usually merge as MND progresses. Awareness is preserved; dementia sometimes develops.

### Amyotrophic lateral sclerosis (ALS)

Lateral sclerosis means disease of the lateral corticospinal tracts (i.e. one cause of spastic paraparesis). Amyotrophy means muscle atrophy, i.e. wasting, unusual in most other forms of spastic tetraparesis or paraparesis. The course is progressive spastic tetraparesis or paraparesis with added lower motor neurone signs and fasciculation. ALS is the term used for MND in the USA.

### Progressive muscular atrophy

Wasting beginning in the small muscles of one hand (or both) spreads inexorably. Although it may commence unilaterally, wasting soon follows on the opposite side. Fasciculation is common. It is due to spontaneous firing of abnormally large motor units formed by branching fibres of surviving axons that are striving to innervate muscle fibres that have lost their nerve supply. Cramps may occur.

Physical signs are of wasting and weakness, with fasciculation – often widespread. Tendon reflexes are lost when the reflex arc is interrupted by anterior horn cell loss, but are preserved or exaggerated when there is loss of corticospinal motor neurones. Sphincter disturbance occurs late, if at all.

### Progressive bulbar and pseudobulbar palsy

The lower cranial nerve nuclei and their supranuclear connections are initially involved. Dysarthria, dysphagia, nasal regurgitation of fluids and choking are common symptoms. This form of MND is more common in women. Characteristic features are bulbar and pseudobulbar palsy (p. 1110), with mixed upper and lower motor neurone signs in lower cranial nerves – for example, a wasted fibrillating tongue with a spastic weak palate. Eye movements remain unaffected in all forms of MND. There are neither cerebellar nor extrapyramidal signs.

### Primary lateral sclerosis

This describes the least common form of MND confined to upper motor neurones. There is progressive tetraparesis with terminal pseudobulbar palsy.

### Diagnosis

Diagnosis is largely clinical. There are no specific tests. Usually MND is easily identifiable clinically. Denervation, a feature of all forms of MND except primary lateral sclerosis, is confirmed by EMG. Chronic partial denervation with preserved motor conduction velocity is characteristic. CSF constituents are normal.

Cervical radiculopathy with myelopathy, syringomyelia and the rare, almost extinct, syphilitic cervical pachymeningitis can cause diagnostic difficulty. Motor neuropathies and spinal muscular atrophies sometimes resemble the progressive muscular atrophy form of MND – their course is more prolonged. Kennedy’s syndrome, an X-linked bulbar and spinal muscular atrophy, sometimes causes confusion: upper motor neurone signs are not seen in this condition.
Bulbar myasthenia gravis (p. 1180) may sometimes appear similar in the early stages.

Multifocal motor neuropathy can appear like motor neurone disease (see p. 1172).

**Course and management**

Remission is unknown. MND progresses, spreading gradually, and causes death, often from bronchopneumonia. Survival for more than 3 years is unusual, although there are rare MND cases who survive for a decade or longer.

No treatment has been shown to influence outcome substantially. Riluzole, a sodium-channel blocker that inhibits glutamate release, slows progression slightly, particularly with disease of bulbar onset. Spasticity may be helped by baclofen, and drooling by propantheline or amitriptyline. Ventilatory support and feeding via gastrostomy helps prolong survival. Giving accurate prognostic advice to MND patients is particularly difficult. Shared-care protocols between patient, primary care physician, carers and support groups are helpful.

**Spinal muscular atrophies**

These rare genetic disorders of motor neurones give rise to slowly progressive, usually symmetrical, muscle wasting and weakness. An acute infantile type (Werdnig–Hoffmann disease), a chronic childhood type (Kugelberg–Welander disease) and adult forms are recognized. Clinically these conditions may be confused initially with muscular dystrophies (p. 1181), hereditary motor neuropathies or MND.

**Dementia**

*Dementia* describes progressive decline of cognitive function, usually affecting the cortex as a whole, though sometimes patchily. Memory is especially affected; intellect gradually fails. There is loss of emotional control, deterioration of social behaviour and loss of motivation. There are many causes of this syndrome, common in later life (Table 21.49). Dementia is a substantial cause of morbidity in any ageing population, with profound social and economic effects. Dementia affects some 10% of any population over 65, and 20% over 80. The commonest causes are Alzheimer’s disease, fronto-temporal dementia, vascular dementia and dementia with Lewy bodies (DLB).

In practice it is often difficult to recognize each type of dementia, and to define landmarks that separate dementia from the mild decline in memory and cognitive function seen during ageing.

**Differential diagnosis**

This includes depression with pseudodementia, in which many of the features of an early dementia (especially memory impairment, slowed thinking and lack of spontaneity) are apparent. Patients with pseudodementia often have a previous history of depression or a family history of mood disorder. Successful treatment of the mood disorder results in restoration of intellectual function. Delirium and mild or moderate learning difficulties are also differential diagnoses.

**Alzheimer’s disease**

This is the commonest dementia, a degenerative disease of the cortex, accounting for over 65% of dementia in any age group. The cardinal clinical features are:

- progressive loss of ability to learn, retain and process new information (i.e. memory loss)
- decline in language – difficulty in naming and in understanding what is being said (various aphasias, p. 1099)
- apraxia – impaired ability to carry out skilled motor activities (p. 1097)
- agnosia – failure to recognize objects, e.g. clothing, places or people
- progressive loss of executive function – organizing, planning and sequencing
- behavioural change – agitation, aggression, wandering and persecutory delusions
- loss of insight, relative or complete
- depression – though severe depression is unusual, perhaps because of loss of insight.

The onset is gradual. Alzheimer’s disease (AD) is rare below the age of 50 but increasingly common thereafter. Disturbance of gait, motor and occasionally sensory abnormalities and seizures occur late. The course is progressive over
several to 10 or more years, with death in a state of extreme cognitive decline.

**Neuropathology and neurochemical changes**

Loss of neurones, neurofibrillary tangles, senile plaques and amyloid angiopathy are seen, especially within the frontal, temporal and parietal cortex, hippocampi, substantia innominata and locus caeruleus.

Neurofibrillary tangles in neuronal cell bodies are made up of the microtubular-associated tau protein in paired helical filaments. Ubiquitin is also seen in association with tangles. Aggregation of beta-amyloid (Aβ) appears to play a central role, developing progressively in extracellular senile plaques. These plaques contain deposits of Aβ-protein, produced by enzymes, β and γ secretase. Apoptosis follows, leading to cell death with a marked reduction in choline acetyltransferase, acetylcholine itself, noradrenaline and serotonin.

**Aetiology**

The cause of AD is unknown. No environmental toxin has been found. Incidence is increased in Down’s syndrome. Increase in free radical formation and failure of antioxidant defences may contribute to neuronal degeneration. Superoxide dismutase (SOD), the free radical defence enzyme, is reduced by some 25% in AD frontal cortex and hippocampi.

AD is occasionally familial. Genetic studies have shown linkage between familial (presenile) AD and loci on chromosome 1 (presenilin, PS1 gene), chromosome 14 (presenilin, PS2 gene) and chromosome 21 (amyloid β-protein precursor, APP gene).

Late-onset AD (the great majority) is probably a heterogeneous disorder. Evidence suggests a link between AD and atherosclerosis, inflammation and cholesterol. Linkage has been found in some cases to a gene locus on chromosome 19q. The gene encoding apolipoprotein E is a possible candidate. This has three alleles, e2, e3 and e4. The e4 allele is a major risk factor for AD and the e2 allele is under-represented. It is possible that Aβ accumulation is more extensive in those with the e4 allele than in those lacking it.

**Dementia with Lewy bodies (DLB)**

This accounts for some 25% of dementias and is characterized by fluctuating cognition with pronounced variation in attention and alertness. Prominent or persistent memory loss may not occur in the early stages. Impairment in attention, frontal, subcortical and visuospatial ability is often prominent. Depression and sleep disorders occur. Recurrent visual hallucinations, e.g. strange faces, frightening creatures, are a common feature. Parkinsonism, i.e. slowing and rigidity, is common, with repeated falls. Delusions and transient loss of consciousness occur. Cortical Lewy bodies are prominent at autopsy. These inclusions, first described in idiopathic Parkinson’s, are a hallmark of DLB.

**Vascular dementia (multi-infarct dementia)**

This common cause of dementia is distinguished from AD by its clinical features and imaging. Dementia can be progressive and similar to AD. There is sometimes a history of TIAs or the dementia follows a succession of cerebrovascular events. Widespread vessel disease seen on MRI is the typical finding and may produce a variety of cognitive deficits reflecting the site of ischaemic damage.

**Frontotemporal dementia**

Progressive deterioration of social behaviour, disinhibition and personality develops in middle life, followed by decline in memory, intellect and language. This accounts for some 3% of dementias. Imaging shows selective atrophy of frontal and temporal lobes. There is no excess of either senile plaques or neurofibrillary tangles. Cytoplasmic inclusion bodies – silver-staining, Pick’s bodies – are seen. These changes separate this condition pathologically from AD.

**Other dementias**

Subcortical encephalopathies comprise disorders that affect subcortical structures such as the basal ganglia. They include dementia occurring in idiopathic Parkinson’s, Huntington’s, progressive supranuclear palsy (p. 1148) and dementia occurring in rarities such as cerebral vasculitis.

Rarer conditions such as Creutzfeldt–Jakob disease (p. 121), Wilson’s disease (p. 357) and Whipple’s (p. 281) cause progressive dementia. Dementia also occurs commonly in the late stages of MS (p. 1152). Dementia is usually one feature of these conditions, i.e. they are suspected or recognized by their clinical patterns.

*Primary progressive aphasia* – a language-based dementia – is recognized increasingly; there is a relentless deterioration of language skills with relative initial preservation of memory.

**Investigations**

Dementia is diagnosed from the history and basic examination, especially cognitive testing (p. 1189), and confirmed by psychometric testing. The history should be taken from someone who has known the patient for a long time. On MRI, bilateral atrophy in the hippocampi is seen in AD, with increased tau protein in the CSF and a reduction of glucose metabolism in bilateral tempo-parietal regions on PET scanning.

In later life, few cases of dementia are investigated in great detail. Defined medical conditions should be excluded (Table 21.50). Investigations in younger patients with dementia include detailed imaging, psychometry, EEG, CSF examination and brain biopsy, the latter only usually carried out in units specializing in dementia.

**Management and social consequences**

It is rare that a treatable cause for dementia is found, for example hypothyroidism. Management is supportive, to preserve dignity and to provide care for as long as possible in the familiar home environment. The burden of illness falls frequently on relatives. In an ageing population, medical problems of the carers themselves deserve particular attention. Some evidence suggests that participation in cognitively demanding activities in later life may protect against or delay the onset of dementia.

Treatment with antioxidants, mainly vitamin E, has shown some possible, slight benefit. Anticholinesterase inhibitors (donepezil, rivastigmine and galantamine) and memantine, an N-methyl D-aspartate (NMDA) receptor antagonist that affects glutamate transmission, have been shown to slow, if slightly, the rate of cognitive decline in AD. Whilst there is dispute about the place for these drugs – all are costly – they contribute in some cases to dementia patients being able to prolong independence and remain at home for longer than might otherwise be the case. There are complex cost-benefit debates.

DYSRAPHISM

Failure of normal fusion of the fetal neural tube leads to a group of congenital anomalies. Folate deficiency during pregnancy is contributory; supplements should always be given (p. 223). Antiepileptic drugs, e.g. valproate, are also implicated (p. 1143). If there is access from the skin, e.g. a sinus connecting to the subarachnoid space, bacterial meningitis may follow.

- Anencephaly is absence of brain and skull – incompatible with life.
- Meningoencephalocele. Brain and meninges extrude through a midline skull defect – protrusion can be minor or massive.
- Spina bifida is failure of lumbosacral neural tube fusion. Several varieties occur.
- Spina bifida occulta is isolated failure of vertebral arch fusion (usually lumbar), often seen incidentally on X-rays (3% of the population). A dimple or a tuft of hair may overlie the anomaly; clinical abnormalities are unusual.
- Meningomyelocele with spina bifida. Meningomyelocele consists of elements of spinal cord and lumbosacral roots within a meningeal sac. This herniates through a vertebral defect. In severe cases both lower limbs and sphincters are paralysed. The lumbosacral defect is visible at birth. Meningocele is a meningeal defect alone. The defect should be closed in the first 24 hours after birth. Subsequent abscess formation can develop.

BASILAR IMPRESSION OF SKULL (PLATYBASIA)

Platybasia is usually a congenital anomaly. There is upward invagination of the foramen magnum and skull base. Lower cranial nerves, medulla, upper cervical cord and roots are affected. A syrinx may be present. The Arnold–Chiari malformation may coexist, with aberrant cerebellar tonsils extending through the foramen magnum. Basilar invagination also develops in Paget’s disease and rarely in osteomalacia (p. 567).

Clinical features are spastic tetraparesis, cerebellar and lower brainstem signs.

NEUROECTODERMAL SYNDROMES

Tissue derived from ectoderm forms tumours and hamartomas, with lesions in the skin, eye and nervous system.

Neurofibromatosis type 1 (von Recklinghausen’s disease, NF-1)

This is characterized by multiple skin neurofibromas and pigmentation (café-au-lait patches). The neurofibromas arise from the neurilemmal sheath. One new case occurs in every 4000 live births. The mode of inheritance is autosomal dominant with complete penetrance.

NF-1 is autosomal with an abnormal gene on chromosome 17 (q11.2) which encodes for a protein, neurofibromin. This protein plays a role in cell growth.
Skin neurofibromas present as soft subcutaneous, sometimes pedunculated, lumps (p. 1253). They increase in number throughout life. Multiple café-au-lait patches are present (p. 1265). Plexiform neurofibromas appear on major nerves and proximal nerve roots, sometimes involving the spinal cord. Treatment is surgical removal if pressure symptoms develop.

**Neurofibromatosis type 2 (NF-2)**

This is much less common than NF-1. It is also autosomal dominant; the gene for NF-2 is located on chromosome 22 (q12.2). The gene product (Merlin or Schwannomin) is a cytoskeletal protein. Many neural tumours occur:

- meningioma
- acoustic neuroma (often bilateral)
- glioma (including optic nerve gloma)
- plexiform neuroma (massive cutaneous overgrowth)
- cutaneous neurofibroma (30%).

Rarely, the benign tumours undergo sarcomatous change.

**Associated abnormalities**

- Scoliosis
- Orbital haemangioma
- Local gigantism of a limb
- Phaeochromocytoma and ganglioneuroma
- Renal artery stenosis
- Pulmonary fibrosis
- Obstructive cardiomyopathy
- Fibrous dysplasia of bone.

**Treatment**

Tumours causing pressure symptoms within the nervous system require excision, if feasible (e.g. VIIth nerve schwannomas).

**Tuberous sclerosis (epiloia)**

This rare autosomal dominant condition comprises adenoma sebaceum (see p. 1253 for other skin lesions), epilepsy and cognitive impairment. Retinal phakomas (glial masses), renal tumours and glial overgrowth in the brain develop.

**Sturge–Weber syndrome (encephalofacial angiomatosis)**

There is an extensive port-wine naevus on one side of the face, usually in the distribution of a division of the Vth nerve, with a meningeal angioma. Epilepsy is common. Familial occurrence is exceptional.

**von Hippel–Lindau syndrome (retinocerebellar angiomatosis)**

This is dominantly inherited. Retinal and cerebellar haemangioblastomas develop or, less commonly, haemangioblastomas of the cord and cerebrum. Renal, adrenal and pancreatic tumours (and haemangioblastomas) may also be found. Polycythaemia sometimes develops.

There are numerous other rare disorders.

---

**SPINOCEBERELLAR DEGENERATIONS (SCAs)**

The classification of this group of inherited disorders is complex. SCAs are of interest; over 20 genetically defined SCAs have been recognized.

**Friedreich’s ataxia**

This is an autosomal recessive progressive degeneration of dorsal root ganglia, spinocerebellar tracts, corticospinal tracts and cerebellar Purkinje cells. Most patients are homozygous for the GAA triplet expansion in the Friedreich’s ataxia gene. This gene, mapped to chromosome 9q13, encodes a mitochondrial protein (fraxatin) of unknown function. There is abnormal function of mitochondrial ATP. The expression of fraxatin is decreased in Friedreich’s patients. Progressive difficulty in walking occurs around the age of 12. Death is usual before 40. With the identification of the gene, mildly affected cases have been diagnosed in middle age.

Clinical findings are:

- ataxia of gait and trunk
- nystagmus (25%)
- dysarthria
- absent lower limb joint position and vibration sense
- absent lower limb reflexes
- optic atrophy (30%)
- pes cavus
- cardiomyopathy.

**Ataxia telangiectasia**

This rare, autosomal recessive condition is a progressive ataxic syndrome in childhood and early adult life (p. 70). There is striking telangiectasia of conjunctiva, nose, ears and skin creases. There are also defects in cell-mediated immunity and antibody production. A defect in DNA repair has been demonstrated. Death is usual by the third decade, either from infection or due to the development of lymphoma.

**Hereditary spastic paraparesis with ataxia**

Progressive paraparesis runs in some families. Additional features include prominent cerebellar signs, sometimes with pes cavus, wasted hands and optic atrophy. Various genetic linkages have been found. Paraparesis is usually mild, and with ataxia progresses slowly over years. Some cases have dystonic features and respond to levodopa.

**PERIPHERAL NERVE DISEASE**

The various nerve fibre types are shown in Table 21.51. All are myelinated except C fibres that carry impulses from pain receptors.

**Mechanisms of damage to peripheral nerves**

Peripheral nerves consist of two principal cellular structures – the nerve nucleus with its axon and the myelin sheath, which is produced by Schwann cells between each node.
of Ranvier (Fig. 21.1). Blood supply is via vasa nervorum. Six principal mechanisms, some coexisting, cause nerve malfunction.

**Demyelination**
Schwann cell damage leads to myelin sheath disruption. This causes marked slowing of conduction, seen for example in Guillain–Barré syndrome, post-diphtheritic neuropathy and many hereditary sensorimotor neuropathies.

**Axonal degeneration**
Axon damage leads to the nerve fibre dying back from the periphery. Conduction velocity initially remains normal (cf. demyelination) because axonal continuity is maintained in surviving fibres. Axonal degeneration occurs typically in toxic neuropathies.

**Wallerian degeneration**
This describes changes following nerve section. Both axon and distal myelin sheath degenerate, over several weeks.

**Compression**
Focal demyelination at the point of compression causes disruption of the myelin sheath. This occurs typically in entrapment neuropathies, e.g. carpal tunnel syndrome (p. 508).

**Infarction**
Microinfarction of vasa nervorum occurs in diabetes and arteritis, e.g. polyarteritis nodosa, Churg–Strauss syndrome (p. 870). Wallerian degeneration occurs distal to the ischaemic zone.

**Infiltration**
Infiltration of peripheral nerves by inflammatory cells occurs in leprosy and granulomas, e.g. sarcoid, and by neoplastic cells, causing neural metastases.

**Nerve regeneration**
Regeneration occurs either by remyelination – recovering Schwann cells spin new myelin sheaths around an axon – or by axonal growth down the nerve sheath with sprouting from the axonal stump. Axonal growth takes place at up to 1 mm/day.

**Definitions** (Fig. 21.45)
- **Neuropathy** simply means a pathological process affecting a peripheral nerve or nerves.
- **Mononeuropathy** means a process affecting a single nerve.

**Mononeuritis multiplex** (multiple mononeuropathy and/or multifocal neuropathy) affects several or multiple nerves.

**Polyneuropathy** describes diffuse, symmetrical disease, usually commencing peripherally. The course may be acute, chronic, static, progressive, relapsing or towards recovery. Polyneuropathies are motor, sensory, sensorimotor and autonomic. They are classified broadly into demyelinating and axonal types, depending upon which principal pathological process predominates. It is often impossible to separate these clinically. Many systemic diseases cause neuropathies. Widespread loss of tendon reflexes is typical, with distal weakness and distal sensory loss.

**Radiculopathy** means disease affecting nerve roots andplexopathy, the brachial or lumbosacral plexus.

**Myelopathy** means disease of the cord.

Terms such as radiculomyelopathy and radiculoneuropathy describe various combinations of these processes.

Diagnosis is made by clinical pattern, nerve conduction/EMG, nerve biopsy, usually sural or radial, and identification of systemic or genetic disease.

**MONONEUROPATHIES**

**Peripheral nerve compression and entrapment** (Table 21.52)

Nerve damage by compression is either acute, e.g. due to a tourniquet, or chronic, such as in entrapment neuropathies. In both, focal demyelination predominates at the compression site, and some distal axonal degeneration occurs. Acute compression usually affects nerves exposed anatomically, e.g. the common peroneal nerve at the head of the fibula, or the ulnar nerve at the elbow. Entrapment develops in relatively tight anatomical passages, e.g. the carpal tunnel.

These neuropathies are recognized largely by clinical features. Diagnosis is confirmed by nerve conduction studies.

</table>
The commonest are mentioned here. All are seen more frequently in people with diabetes.

**Carpal tunnel syndrome (CTS)** (p. 508)
This common mononeuropathy, median nerve entrapment at the wrist, is usually known as carpal tunnel syndrome (CTS). CTS is typically not associated with any underlying disease. CTS is, however, seen in:
- hypothyroidism
- diabetes mellitus
- pregnancy (third trimester)
- obesity
- rheumatoid disease
- acromegaly
- amyloid
- renal dialysis patients.

CTS also occurs following wrist trauma.

There is nocturnal tingling and pain in the hand and/or forearm, followed by weakness of thenar muscles. Sensory loss in the palm and radial three-and-a-half fingers develops, followed by wasting of abductor pollicis brevis. *Tinel’s sign* is often present and *Phalen’s test* positive. Tinel’s is elicited by tapping the flexor aspect of the wrist: this causes tingling and pain. In Phalen’s, symptoms are reproduced on passive maximal wrist flexion.

A wrist splint at night or a local steroid injection (p. 509) in the wrist gives relief in mild cases. In pregnancy CTS is often self-limiting as fluid retention subsides postpartum. Reduction in obesity usually alleviates CTS. Surgical decompression of the carpal tunnel is the definitive treatment.

**Ulnar nerve compression**
The nerve is compressed in the cubital tunnel at the elbow. This follows prolonged or recurrent pressure and elbow fracture.

Weakness and wasting of ulnar innervated muscles leads to clawing of the hand – hypothenar muscles, interossei and medial two lumbricals – with sensory loss in the ulnar one-and-a-half fingers. Decompression and transposition of the nerve at the elbow is sometimes helpful.

The deep, solely motor branch of the ulnar nerve can be damaged in the palm by repeated trauma, e.g. from a crutch, screwdriver handle, or cycle handlebars.

**Radial nerve compression**
The radial nerve is compressed acutely against the humerus, e.g. when the arm is draped over a hard chair for several hours, known as Saturday night palsy. Wrist drop and weakness of brachioradialis and finger extension follow. Recovery is usual, though not invariably, within 1–3 months. Posterior interosseous nerve compression in the forearm also leads to wrist drop, without weakness of brachioradialis.

**Lateral cutaneous nerve of the thigh compression**
This is also known as meralgia paraesthetica and is described on page 512.

**Common peroneal nerve palsy**
The common peroneal nerve (lateral popliteal nerve) is compressed against the head of the fibula following prolonged squatting, yoga, pressure from a cast, prolonged bed rest or coma, or for no apparent reason. There is foot drop and weakness of ankle eversion. The ankle jerk (S1) is preserved. A patch of numbness develops on the anterolateral border of the dorsum of the foot and/or lower shin – the nerve has a small sensory twig. Recovery is usual, though not invariably, within several months.

**Multifocal neuropathy (mononeuritis multiplex, multiple mononeuropathy)**

This occurs in:
- diabetes mellitus
- leprosy
- vasculitis
- sarcoidosis
- amyloidosis
- malignancy
- neurofibromatosis
- HIV infection
- Guillain–Barré syndrome – usually polyneuropathy, see page 1172
- idiopathic multifocal motor neuropathy.

**Diagnosis** is largely clinical, supported by electrical studies. Several nerves become affected sequentially or simultaneously, e.g. ulnar, median, radial and lateral popliteal nerves. When multifocal neuropathy is symmetrical, there is difficulty distinguishing it from polyneuropathy. Where leprosy is prevalent, e.g. in India, a single nerve lesion can be the presenting feature.

**Idiopathic multifocal motor neuropathy**

A distal motor neuropathy (often asymmetrical and predominantly in the hands) of unknown cause develops gradually over months with profuse fasciculation, hence confusion with motor neuron disease (p. 1166). Conduction block and denervation are seen electrically. Antibodies to the ganglioside GM1 are found in over 50% of cases; this is non-specific – antibodies are sometimes seen in other neuropathies, e.g. Guillain–Barré syndrome.

Steroids and/or cyclophosphamide and intravenous immunoglobulin slow the condition in some cases.

**POLYNEUROPATHIES**

Many diseases cause polyneuropathy, though the aetiology sometimes remains obscure. The most common presentations are acute, chronic or subacute sensorimotor neuropathies. A classification is given in Table 21.53. Antibodies to different gangliosides are emerging as diagnostic tools.

**Guillain–Barré syndrome (GBS)**

**Clinical features**

GBS is the most common acute polyneuropathy (3/100000/year); it is usually demyelinating but occasionally axonal and probably has an autoallergic basis. GBS is monophasic – it does not recur. GBS is also known as acute inflammatory or postinfective neuropathy, acute inflammatory demyelinating polyradiculoneuropathy and Landry-GBS. The clinical spec-
of GBS extends to an acute motor axonal neuropathy and the Miller Fisher syndrome – a rare proximal form causing ocular muscle palsies and ataxia.

Paralysis follows 1–3 weeks after an infection that is often trivial and seldom identified. *Campylobacter jejuni* and cytomegalovirus infections are well-recognized causes of severe GBS. Infecting organisms induce antibody responses against peripheral nerves. Molecular mimicry, i.e. sharing of homologous epitopes between microorganism liposaccharides and nerve gangliosides (e.g. GM₃), is the possible mechanism.

The patient complains of weakness of distal limb muscles and/or distal numbness. These symptoms progress proximally, over several days to 6 weeks. Loss of tendon reflexes is almost invariable. In mild cases there is mild disability before spontaneous recovery begins, but in some 20% respiratory and facial muscles become weak, sometimes progressing to complete paralysis. Autonomic features sometimes develop.

**Diagnosis**

This is established on clinical grounds and confirmed by nerve conduction studies; these show slowing of conduction in the common demyelinating form, prolonged distal motor latency and/or conduction block. CSF protein is often raised to 1–3 g/L; cell count and glucose level remain normal.

In the Miller Fisher syndrome antibodies against GQ1b (ganglioside) have a sensitivity of 90%.

Differential diagnosis includes other acute paralytic illnesses, e.g. botulism, cord compression, muscle disease and myasthenia.

**Course and management**

Paralysis may progress rapidly (hours/days) to require ventilatory support. It is essential that ventilation (vital capacity, blood gases) is monitored repeatedly to recognize emerging respiratory muscle weakness. Subcutaneous heparin (p. 444) should be given to reduce the risk of venous thrombosis.

Immunoglobulin given intravenously within the first 2 weeks reduces duration and severity of paralysis. There is concern about using this expensive pooled blood product. Patients should be screened for IgA deficiency before immunoglobulin is given – severe allergic reactions due to IgG antibodies may occur when congenital IgA deficiency is present. Angina or myocardial infarction can be precipitated by i.v. immunoglobulin. Plasma exchange is also of proven benefit in shortening disability, though seldom used. Steroids used to be given, but are valueless. Recovery begins, with or without treatment, between several days and 6 weeks from the outset. Prolonged ventilation may be necessary. Improvement towards independent mobility is gradual over many months but may be incomplete. Some 15% either die or are left disabled.

**Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)**

CIDP develops over weeks or months, usually relapsing and remitting, but generally persists long term. There are several CIDP varieties: the usual demyelinating form, an axonal form and multifocal neuropathy. In some cases plaques resembling MS lesions are seen on MRI, both in the brain and cord, but typically without the clinical features of MS. CSF protein is raised and segmental demyelination usually seen in nerve biopsy specimens. CIDP responds to long-term, low-dose steroids and to i.v. immunoglobulin, which is used for exacerbations.

Progress is variable; with drug therapy most CIDP cases run a mild course over many years. Recovery occasionally occurs.

**Chronic sensorimotor neuropathy: no cause found**

This situation is not uncommon – progressive symmetrical numbness and tingling occurs in hands and feet, spreading proximally in a glove and stocking distribution. Distal weakness also ascends. Tendon reflexes are lost. Symptoms may progress, remain static or occasionally remit. Autonomic features are sometimes seen.

Nerve conduction studies show either axonal degeneration or demyelination, or features of both, and no underlying cause is found. Nerve biopsy helps to classify some cases, for example diagnosing CIDP, unsuspected vasculitis or hereditary neuropathy.

**Diphtheritic neuropathy**

Palatal weakness followed by pupillary paralysis and a sensorimotor neuropathy occur several weeks after the throat infection (p. 126).

**Cranial polyneuropathy**

This means multiple cranial nerve lesions. These can develop in diabetes, malignant infiltration, particularly with nasopharyngeal and breast carcinoma, lymphomas, sarcoidosis, as part of a paraneoplastic syndrome and occasionally with giant cell arteritis. Relapsing and remitting cranial polyneuropathy of unknown cause is sometimes seen in South East Asia.

**Metabolic, toxic and vitamin deficiency neuropathies**

Causes of the most common neuropathies are shown in Table 21.54.
Metabolic neuropathies

**Diabetes mellitus.** Several varieties of neuropathy occur (p. 1055):
- symmetrical sensory polyneuropathy
- acute painful neuropathy
- mononeuropathy and multiple mononeuropathy:
  - cranial nerve lesions
  - isolated peripheral nerve lesions (e.g. carpal tunnel syndrome)
- diabetic amyotrophy
- autonomic neuropathy.

**Uraemia.** Progressive sensorimotor neuropathy develops in chronic uraemia. Response to dialysis is variable; the neuropathy usually improves after transplantation.

**Thyroid disease.** A mild chronic sensorimotor neuropathy is sometimes seen in both hyperthyroidism and hypothyroidism (pp. 988 and 986). Myopathy also occurs in hyperthyroidism (p. 986).

**Porphyria.** In acute intermittent porphyria (p. 1073) there are episodes of a severe, mainly proximal neuropathy in the limbs, sometimes with abdominal pain, confusion and coma. Alcohol, barbiturates and intercurrent infection can precipitate attacks.

**Amyloidosis.** Polyneuropathy or multifocal neuropathy develops (p. 1072).

**Refsum’s disease**
This is an autosomal recessive rarity. It is a treatable sensorimotor polyneuropathy with ataxia, retinal damage and deafness, due to defective phytanic acid metabolism.

**Toxic neuropathies**

**Alcohol**
Polyneuropathy, mainly in the lower limbs, occurs with chronic alcohol abuse. Calf pain is common. The response to thiamin treatment is variable, even with complete alcohol abstention. Recurrence and progression occur with even small amounts of alcohol.

**Drugs and industrial toxins**
Many drugs (Table 21.55) and a wide variety of industrial toxins cause polyneuropathy. Toxins include:
- lead – motor neuropathy
- acrylamide (plastics industry), trichlorethylene, hexane, fat-soluble hydrocarbons, e.g. glue-sniffing, page 1214
- arsenic and thallium – polyneuropathy, initially sensory.

**Vitamin deficiencies**
Vitamin deficiencies cause nervous system damage that is potentially reversible if treated early, and inexorably progressive if not. Deficiencies, often of multiple vitamins, develop in malnutrition.

**Thiamin (vitamin B1)**
Dietary deficiency causes beriberi (p. 220). Its principal features are polyneuropathy and cardiac failure. Thiamin deficiency also leads to amnestic syndrome (Wernicke–Korsakoff psychosis, see below). Alcohol is the commonest cause in western countries and, rarely, anorexia nervosa. For other neurological consequences of alcohol, see Table 21.56.

**Wernicke–Korsakoff syndrome.** This thiamin-responsive encephalopathy is due to ischaemic damage in the brainstem and its connections. It consists of:
- **eye signs** – nystagmus, bilateral lateral rectus palsies, conjugate gaze palsies, fixed pupils and, rarely, papilloedema
- **ataxia** – broad-based gait, cerebellar signs and vestibular paralysis with absent caloric
- **cognitive change** – amnestic syndrome with confabulation, restlessness, stupor and coma

</tbody>
</table>

- **delirium tremens** (p. 1213)
- **hypothermia and hypotension** – due to hypothalamic involvement (rare).

Wernicke–Korsakoff syndrome is underdiagnosed. Thiamin should be given parenterally if the diagnosis is a possibility. The vitamin is harmless but should be given slowly as ana-phylaxis can occur (p. 221). Untreated Wernicke–Korsakoff syndrome commonly leads to an irreversible amnestic state (Table 21.4, p. 1150). Erythrocyte transketolase activity is reduced but the test is rarely available.

**Pyridoxine (vitamin B₆)**

Deficiency causes a mainly sensory neuropathy. In practical terms this is seen as limb numbness developing during anti-TB therapy in slow isoniazid acetylators (p. 925). Prophylactic pyridoxine 10 mg daily is given with isoniazid.

**Vitamin B₁₂ (cobalamin)**

Deficiency causes damage to the spinal cord, peripheral nerves and brain.

**Subacute combined degeneration of the cord (SACD).** Combined cord and peripheral nerve damage is a sequel of Addisonian pernicious anaemia and rarely other causes of vitamin B₁₂ deficiency (p. 399). Initially there is numbness and tingling of fingers and toes, distal sensory loss, particularly posterior column, absent ankle jerks and, with cord involvement, exaggerated knee jerks and extensor plantars. Optic atrophy and retinal haemorrhage may occur. In later stages spastic disturbance, severe generalized weakness and dementia develop. Exceptionally, dementia develops in the early stages. Macrocystosis with megaloblastic marrow is usual though not invariably in SACD. Parenteral B₁₂ reverses nerve damage but has little effect on the cord and brain. Without treatment, SACD is fatal within 5 years. Copper deficiency is a very rare cause of a similar picture.

**Hereditary sensorimotor neuropathies (HSMN)**

These are large and complex groups, phenotypically similar but genetically separate.

**Charcot–Marie–Tooth disease**

Charcot–Marie–Tooth (CMT) disease is also called peroneal muscular atrophy. CMT describes the common clinical phenotype (1 in 2500 persons), distal limb wasting and weakness that slowly progresses over many years, mostly in the legs, with variable loss of sensation and reflexes. In advanced disease, distal wasting is so marked that the legs are said to resemble inverted champagne bottles. Mild cases have pes cavus and toe clawing that can pass unnoticed. Multiple genetic variants of the CMT phenotype are recognized, e.g.:

- **HSMN Ia (CMT 1A)** – the commonest (70% of CMT; 1:2500 births), autosomal dominant demyelinating neuropathy caused by duplication (or point mutation) of a 1.5 megabase portion p11.2 of chromosome 17 encompassing the peripheral myelin protein 22 gene (PMP-22, 17p11.2).
- **HSMN Ib (CMT 1B)** – the second commonest, an autosomal dominant demyelinating neuropathy due to mutations in the myelin protein zero gene (MPZ) on chromosome 1 (1q22).
- **HSMN II (CMT 2)** – rare axonal polyneuropathies also caused by MFN2 or KIF1B on chromosome 1p36 and other mutations. There is prominent sensory involvement with pain and paraesthesia.
- **Distal spinal muscular atrophy** – a rare cause of CMT phenotype.
- **CMT with optic atrophy**, deafness, retinitis pigmentosa and spastic paraparesis.
- **CMTX** is an X-linked dominant HSMN on chromosome Xq13.1. The gene product is a gap junction B1 protein (GJB1) or connexin 32 (p. 26).

**HSMN III**

HSMN III is a rare childhood demyelinating sensory neuropathy (Dejérine–Sottas disease) leading to severe incapacity during adolescence. Nerve roots become hypertrophied. CSF protein is greatly elevated to 10 g/L or more. Point mutations either of PMP-22 gene or of P0 can generate this phenotype.

**Other polyneuropathies**

**Neuropathy in cancer**

Polyneuropathy is seen as a paraneoplastic syndrome (non-metastatic manifestation of malignancy), sometimes with anti-neuronal antibodies (Box 9.1). Polyneuropathy occurs in myeloma and other dysproteininaemic states, probably owing to impaired perfusion of nerve trunks or to demyelination associated with allergic reactions affecting peripheral nerves. Individual nerves are sometimes infiltrated with malignant cells.

**Neuropathies in systemic diseases**

Vasculitic neuropathy occurs in SLE (p. 541), polyarteritis nodosa (p. 550), Churg–Strauss syndrome (p. 870), rheumatoid disease (p. 528), sarcoidosis and giant cell arteritis (p. 550). Both multifocal neuropathy and symmetrical sensorimotor polyneuropathy occur.
POEMS syndrome. This rarity consists of chronic inflammatory demyelinating Polyneuropathy, Organomegaly (hepatomegaly 50%), Endocrinopathy (gynaecomastia and atrophic testes), an M protein band, and Skin hyperpigmentation.

Autonomic neuropathy
Autonomic neuropathy causes postural hypotension, urinary retention, erectile dysfunction, diarrhoea or occasionally constipation, diminished sweating, impaired pupillary responses and cardiac arrhythmias. This can develop in diabetes and amyloidosis and may complicate Guillain–Barré syndrome. Many varieties of neuropathy cause autonomic problems in a mild form. Occasionally, with severe damage to small myelinated and non-myelinated B and C fibres, features of the autonomic neuropathy predominate, e.g. disabling postural hypotension.

HIV-associated polyneuropathies
Several neuropathies occur. Inflammatory demyelinating neuropathies similar to Guillain–Barré syndrome and CIDP are seen early in HIV infection, particularly during seroconversion. The most common neuropathy seen later in HIV is a chronic distal neuropathy that is symmetrical and painful.

Severe lumbosacral polyradiculoneuropathy develops, with profound lower limb flaccid paralysis, areflexia and sphincter dysfunction.

All HIV-associated neuropathies respond poorly to retroviral therapy; the drugs themselves cause neuropathies (p. 192).

Critical illness polyneuropathy (p. 916)
Some 50% of critically ill ITU patients with multiple organ failure and/or sepsis develop an axonal polyneuropathy. The severe inflammatory response impairs neural metabolism. Typically distal weakness and absent reflexes are seen during recovery from critical illness. Resolution is usual.

PLEXUS AND NERVE ROOT LESIONS
The common conditions that cause these are summarized in Table 21.57.

Cervical and lumbar degeneration
Spondylosis (Tables 10.3 and 10.6) describes vertebral and ligamentous degenerative changes occurring during ageing or following trauma. Several factors produce neurological signs and symptoms:
- osteophytes – local overgrowth of bony spurs or bars
- thickening of spinal ligaments
- congenital narrowing of the spinal canal
- disc degeneration and protrusion (posterior and lateral protrusion: cord and root compression)
- vertebral collapse (osteoporosis, infection)
- rheumatoid synovitis (p. 525)
- ischaemic changes within cord and nerve roots.

Narrowing of disc spaces, osteophytes, narrowing of exit foramina, and narrowing of the spinal canal are also seen on X-rays and MRI in the symptomless population, commonly in the mid and lower cervical and lower lumbar region, and imaging must not be falsely interpreted.

Lateral cervical disc protrusion (Fig. 21.46)
The patient complains of pain in the arm. A C7 protrusion is the most common problem. There is root pain that radiates to the C7 myotome (triceps, deep to scapula and extensor aspect of forearm), with a sensory disturbance, tingling and numbness in the C7 dermatome.

In an established C7 root lesion there is:
- weakness/wasting – triceps, wrist and finger extensors
- loss of the triceps jerk (C7 reflex arc)
- C7 dermatome sensory loss.

Although the initial pain can be very severe, most cases recover with rest and analgesics. It is usual to immobilize the neck. Disc protrusion with root compression is seen on MRI. Root decompression is sometimes helpful.

Lateral lumbar disc protrusion
The L5 and S1 roots are commonly compressed by lateral prolapse of L4–L5 and L5–S1 discs – the root number below a disc interspace is compressed. There is low back pain and sciatica, i.e. pain radiating from the back to buttock and leg. Onset is typically acute. This can follow lifting, bending or minor injury. When pain follows such an event, it is tempting to ascribe the disc protrusion to it. However, lateral lumbar disc protrusion is commonly apparently spontaneous – lifting or injury is usually only bringing forward an inevitable disc prolapse.

Straight-leg raising is limited. There is reflex loss, e.g. ankle jerk in an S1 root lesion, weakness of plantar flexion

Fig. 21.46 Central and lateral disc protrusions. (a) Central disc protrusion compressing cord. (b) Lateral disc protrusion compressing nerve roots.
(S1) or great toe extension (L5). Sensory loss is found in the affected dermatome.

Most sciatica resolves with initial rest and analgesia followed by early mobilization. MRI is sometimes appropriate: surgery is indicated when a substantial persistent symptomatic disc lesion is shown.

**Acute low back pain**

Acute low back pain is extremely common. Most pain is of disc or facet joint origin. Significant nerve root compression is unusual. Bed rest on hard boards, corsets or casts have long been advocated: the evidence for this is scanty. Activity and a trial of gentle manipulation is preferred (see also p. 511).

**Central disc protrusion** (p. 509)

**Central cervical disc protrusion (cervical myelopathy)**

Posterior disc protrusion (Fig. 21.47), common at C4–5, C5–6 and C6–7 levels, causes spinal cord compression. Congenital spinal canal narrowing, osteophytic bars, ligamentous thickening and ischaemia are contributory. Frequently there are no or few neck symptoms. The patient complains of difficulty walking. Spastic paraparesis or tetraparesis is found, with variable sensory loss. A reflex level in the upper limbs and evidence in the arms of lateral disc protrusion may coexist. MRI demonstrates the level and extent of cord compression. Neck manipulation should be avoided.

Cervical laminectomy or anterior fusion of the vertebral bodies with removal of the disc may be necessary when cord compression is severe or progressive. The results of surgery are variable. Complete recovery of the pyramidal signs is unusual; progression may be halted.

**Central thoracic disc protrusion**

Central protrusion of a thoracic disc is an unusual cause of paraparesis.

**Central lumbosacral disc protrusion**

A central disc protrusion causes a *cauda equina syndrome*, i.e. bilateral flaccid (cf. spasticity in higher lesions) lower limb weakness, sacral numbness, retention of urine, erectile dysfunction and areflexia – usually with back pain. Many lumbosacral nerve roots are involved. Onset is either acute – an acute flaccid paraparesis – or chronic, sometimes with intermittent claudication. A central lumbosacral protrusion should be suspected if a patient with back pain develops retention of urine or sacral numbness. Urgent imaging and surgical decompression is indicated for this emergency. Neoplasms in the lumbosacral region can present with similar features.

**Spinal stenosis**

A narrow spinal canal is developmental and frequently symptomless but a congenital narrowing of the cervical canal predisposes the cervical cord to damage from minor disc protrusion later.

In the lumbosacral region, further narrowing of the canal by disc protrusion causes root pain, and/or buttock and lower limb claudication. As the patient walks, nerve roots become hyperaemic and swell, producing buttock and lower limb pain with numbness. Surgical decompression is required.

**Neuralgic amyotrophy**

This is a clearly recognizable entity – severe pain in muscles around one shoulder is followed by wasting, usually of infraspinatus, supraspinatus, deltoid and serratus anterior. A demyelinating brachial plexopathy develops over several days. The cause is unknown; an allergic or viral basis is postulated. Rarely, a similar condition develops in distal upper limb muscles or in a lower limb. Recovery of wasted muscles is usual, but not invariable, over some months.

**Thoracic outlet syndrome**

A fibrous band or cervical rib extending from the tip of the C7 transverse process towards the first rib compresses the lower brachial plexus roots, C8 and T1. There is forearm pain (ulnar border), T1 sensory loss and thenar muscle wasting, principally abductor pollicis brevis. Horner’s syndrome may develop. The rib or band can be excised. Frequency of this diagnosis varies widely – thoracic outlet problems are sometimes invoked to explain ill-defined arm symptoms, typically on poor evidence.

A rib or band can also produce subclavian artery or venous occlusion. Neurological and vascular problems rarely occur together.

**Malignant infiltration and radiation plexopathy**

Metastatic disease of nerve roots, the brachial or lumbosacral plexus causes a painful radiculopathy and/or plexopathy. An example is apical bronchial carcinoma (Pancoast’s tumour) causing a T1 and sympathetic outflow lesion – wasting of small hand muscles, pain and T1 sensory loss with ipsilateral Horner’s syndrome. This also occurs in apical TB. In the upper limb, radiotherapy following breast cancer can produce a plexopathy.

**Paraneoplastic Syndromes**

Neurological disease may accompany malignancy in the absence of metastases. These paraneoplastic syndromes are associated with anti-neuronal antibodies, believed to be involved in generation of signs and symptoms. Numerous anti-neuronal antibodies have been described.

Clinical pictures include:
sensorimotor neuropathy (p. 1173)
mononeuritis multiplex (p. 1172)
cranial polyneuropathy (p. 1173)
Lambert–Eaton myasthenic–myopathic syndrome (LEMS, p. 1181)
motor neurone disease variants (p. 1166)
spastic paraparesis (p. 1112)
cerebellar syndrome (p. 1114)
limbic encephalitis, dementia and encephalopathy (p. 1167)
progressive multifocal leucoencephalopathy (p. 108)
paraneoplastic stiff person syndrome.

The neurological syndrome sometimes precedes evidence of the neoplasm – often a small-cell bronchial carcinoma, breast or ovarian cancer. Diagnosis is based on the clinical pattern and antibody profile. Neuroimaging is typically normal. Treatment is often unsatisfactory.

## Muscle diseases

### Definitions
- **Myopathy** means a disease of voluntary muscle.
- **Myositis** indicates inflammation.
- **Muscular dystrophies** are inherited disorders of muscle cells.
- **Myasthenia** means fatiguable (worse on exercise) weakness – seen in neuro-muscular junction diseases.
- **Myotonia** is sustained contraction/slow relaxation.
- **Channelopathies** are ion channel disorders of muscle cells.

Weakness is the predominant feature of muscle disease. A selection of these conditions is mentioned here (Table 21.58).

### Pathophysiology

Muscle fibres are affected by:
- acute inflammation and fibre necrosis (e.g. polymyositis, infection)
- genetically determined metabolic failure (e.g. Duchenne muscular dystrophy)
- infiltration by inflammatory tissue (e.g. sarcoidosis)
- fibre hypertrophy and regeneration
- mitochondrial diseases
- immunological damage
- ion channel disorders.

Examples of immunological damage, ion channel and mitochondrial disorders are:
- In *myasthenia gravis*, antibodies to the postsynaptic membrane acetylcholine receptor protein block neuromuscular transmission.
- In Lambert–Eaton myasthenic–myopathic syndrome (LEMS), antibodies to muscle calcium channel components are found.
- In myotonias, defective chloride ion membrane conductance is associated with delayed muscle relaxation.
- In McArdle’s syndrome, myophosphorylase deficiency produces weakness after exercise.
- In mitochondrial disease, various ATP enzyme defects cause weakness.

### Recognition

Diagnosis is often made from the distribution of weakness, wasting or hypertrophy, and muscle consistency (e.g. induration). Tendon reflexes are typically preserved.

### Serum muscle enzymes

Serum creatine phosphokinase (CPK) is greatly elevated in many dystrophies, e.g. Duchenne, and in inflammatory muscle disorders, e.g. polymyositis. CPK remains normal in myasthenia gravis and LEMS, and usually remains normal in myotonias.

### Neurogenetic tests

These are used in muscular dystrophies and mitochondrial disease.

### Electromyography

The normal interference pattern is reduced. Changes in interference pattern indicate:
- **Myopathy**: Short-duration spiky polyphasic muscle action potentials are seen. Spontaneous fibrillation is occasionally recorded.
- **Myotonic discharges**: A characteristic high-frequency whistle is heard on the loudspeaker.
- **Decrement and increment**: In myasthenia gravis, a characteristic decrement in evoked muscle action potential follows repetitive motor nerve stimulation. The reverse occurs, i.e. increment, following repetitive stimulation in LEMS, page 1181.
- In *denervation*, profuse fibrillation potentials (c. 1 ms duration, 50–200 mV in amplitude) are typical.

### Muscle biopsy

Histology and muscle histochemistry of fibre types (type 1, slow; type 2, fast) indicates denervation, inflammation and

---

**FURTHER READING**
Muscle diseases

Dystrophies. Electron microscopy is often valuable. In dystrophies and myositis, muscle fibres are diffusely abnormal, nuclei become central, and invasion by inflammatory cells and/or necrosis occurs; hypertrophic fibres are seen. In acute denervation, small angulated muscle fibres are scattered randomly, between normal fibres. In chronic partial denervation, fibre type grouping is seen, i.e. groups of atrophic fibres of the same type. Much experience is needed to interpret these changes.

**Imaging**

MRI shows signal changes within muscles in some cases of myositis.

**INFLAMMATORY MYOPATHIES**

**Polymyositis**

Polymyositis is characterized by non-suppurative skeletal muscle inflammation. The aetiology is unknown, though HLA-B8/DR3 phenotypes have a predisposition to develop polymyositis, and Coxackie (and other) viruses are possibly implicated. It is described on page 547.

**Differential diagnosis**

Muscular dystrophies rarely progress as rapidly as polymyositis and there is no muscle pain. Pseudohypertrophy, seen in some dystrophies, does not occur in polymyositis. There is no family history. Motor neurone disease is always eventually accompanied by upper motor neurone signs, and prominent fasciculation is common.

**Treatment**

Steroids with azathioprine or cyclophosphamide reduce symptoms in about 75% of cases. Only rarely does polymyositis cause death.

**Dermatomyositis**

This is described on page 547.

**Inclusion body myositis**

This is described on page 548.

**Viral, bacterial and parasitic myositis**

Muscle tissue is involved in many infections (Table 21.59).

**Myopathy in sarcoidosis and rheumatoid disease**

In sarcoidosis, a subacute myopathy can develop, either with muscle swelling and induration or wasting. This is usually during pulmonary sarcoidosis, but occasionally it is isolated. Sarcoid nodules are seen on muscle biopsy. Treatment is with steroids.

In rheumatoid disease, a rare localized nodular myositis causes painful swelling of limb, trunk and facial muscles.

**METABOLIC AND ENDOCRINE MYOPATHIES**

**Corticosteroids and Cushing’s syndrome**

Proximal weakness occurs with prolonged high-dose steroid therapy, particularly with 9-α-fluorinated steroids, e.g. dexamethasone and triamcinolone, and in Cushing’s syndrome (p. 1012). Selective type-2 fibre atrophy is seen on biopsy.

**Thyroid disease** (see also p. 988)

Several myopathies occur. Thyrotoxicosis can be accompanied by severe proximal myopathy. There is also an association between thyrotoxicosis and myasthenia gravis, and between thyrotoxicosis and hypokalaemic periodic paralysis (p. 1182). Both associations are seen more frequently in South East Asia. In ophthalmic Graves’ disease, there is swelling and lymphocytic infiltration of extraocular muscles (p. 987).

*Hypothyroidism* is sometimes associated with muscle pain and stiffness, resembling myotonia. A proximal myopathy also occurs.

**Disorders of calcium metabolism**

Proximal myopathy develops in hypocalcaemia, rickets and osteomalacia (p. 567).

**Hypokalaemia**

Acute hypokalaemia (e.g. with diuretics) causes flaccid paralysis reversed by potassium, given slowly (p. 665). Chronic hypokalaemia leads to mild, mainly proximal, weakness. See also periodic paralysis (p. 1182).

**Alcohol and drugs of abuse**

Severe myopathy with muscle pain, necrosis and myoglobinuria occurs in acute excess. A subacute proximal myopathy occurs with chronic alcohol abuse. A similar syndrome occurs in diamorphine and amphetamine addicts.

**Drugs**

Drug-induced muscle disorders include proximal myopathy (steroids), muscle weakness (lithium), painful muscles (fibrate), rhabdomyolysis (fibrate combined with a statin) and malignant hyperpyrexia (p. 1182). All are rare, and most respond to drug withdrawal.
**NEUROMUSCULAR JUNCTION CONDITIONS**

**Myasthenia gravis (MG)**

MG is an acquired and probably heterogeneous condition. It is characterized by weakness and fatigability of proximal limb, bulbar and ocular muscles, the latter sometimes in isolation. The heart is not affected. The prevalence is about 4 in 100,000. MG is twice as common in women as in men, with a peak age incidence around 30. The underlying cause is unknown.

Antibodies to acetylcholine receptor protein (anti-AChR antibodies) are commonly found. Immune complexes of anti-AChR IgG and complement are deposited at the postsynaptic membranes, causing interference with and later destruction of AChRs.

A second group of antibodies against muscle-specific receptor tyrosine kinase (anti-MuSK antibodies) has more recently been identified in anti-AChR antibody negative cases. Ocular muscle MG is another subgroup.

Thymic hyperplasia is found in 70% of MG patients below the age of 40. In some 10% a thymic tumour is found, the incidence increasing with age; antibodies to striated muscle can be demonstrated in some of these patients. Young patients without a thymoma have an increased association with HLA-B8 and DR3.

There is an association between MG and thyroid disease, rheumatoid disease, pernicious anaemia and SLE. Transient MG is sometimes caused by β-lactam antibiotic treatment.

**Clinical features**

Fatigability is typical. Limb muscles (proximal), extraocular, speech, facial expression and mastication muscles are commonly affected. Respiratory difficulties can be prominent. The clinical picture of fluctuating, fatiguable weakness is usually diagnostic. Muscle pain is typically absent. Early complaints of fatigue are frequently dismissed.

Complex extraocular palsies, ptosis and fluctuating proximal weakness are found. The reflexes are initially preserved but may be fatiguable, i.e. disappear following repetitive activity. Wasting is sometimes seen after many years.

**Investigations**

- **Serum anti-AChR and anti-MuSK antibodies.** Anti-AChR antibodies are present in some 80–90% of cases of generalized MG. These antibodies are not found in healthy controls but are seen rarely in other muscle disorders. In pure ocular MG, anti-AChR antibodies are detectable in less than 30% of cases.

- **Anti-MuSK antibodies** define a subgroup of MG patients characterized by weakness predominantly in bulbar, facial and neck muscles.

- **Repetitive nerve stimulation.** A characteristic decrement occurs in the evoked muscle action potential during repetitive stimulation. EMG is otherwise normal.

- **Tensilon (edrophonium) test.** This is seldom required and the drug is not available world-wide. Edrophonium 10 mg is given intravenously following a 1–2 mg test dose from the 10 mg vial. When the test is positive, there is substantial improvement in weakness within seconds and this lasts for up to 5 minutes. It is prudent to perform a control using saline and to have an observer. The sensitivity of the test is 80% but there are false negative and positive tests. Occasionally edrophonium (an anticholinesterase) causes bronchospasm and syncope. Resuscitation facilities must be available.

- **Imaging and other tests.** Mediastinal MR provides optimal structural imaging for thymoma. Routine blood studies are normal: the ESR is not raised, and CPK is normal. Antibodies to striated muscle suggest a thymoma; intrinsic factor and thyroid antibodies may be found. Rheumatoid factor and anti-nuclear antibody tests can be positive. Muscle biopsy is usually not performed, though ultrastructural neuromuscular junction abnormalities are well described.

**Course and management**

Myasthenia gravis fluctuates in severity; most cases have a protracted, lifelong course. Respiratory impairment, nasal regurgitation and dysphagia occur; emergency assisted ventilation may be required. Simple monitoring tests, such as the duration for which an arm can be held outstretched, and the vital capacity are useful.

Exacerbations are usually unpredictable and unprovoked but may be brought on by infections and by aminoglycosides. Magnesium sulphate enemas can provoke severe weakness.

**Treatment**

**Oral anticholinesterases**

Pyridostigmine (60 mg tablet) is widely used. The duration of action is 3–4 hours, the dose (usually 4–16 tablets daily) determined by response. Pyridostigmine prolongs acetylcholine action by inhibiting cholinesterase. Overdose of anticholinesterases causes severe weakness (cholinergic crisis). Muscarinic side-effects, e.g. colic and diarrhoea, are common; oral atropine (antimuscarinic) 0.5 mg helps reduce this. Anticholinesterases help weakness but do not alter the natural history of myasthenia.

**Immunosuppressant drugs**

These drugs are used in patients who do not respond to pyridostigmine or who relapse on treatment. Steroids are often used. There is improvement in 70%, although this may be preceded by an initial relapse. Azathioprine, mycophenolate and other immunosuppressants are also used.

**Thymectomy**

Thymectomy improves prognosis, more so in women than men below 50 years with positive AChR antibodies, even in patients without a thymoma. Cases positive for anti-MuSK antibodies tend not to improve following thymectomy. When a thymoma is present, the potential for malignancy also makes surgery necessary.

**Plasmapheresis and intravenous immunoglobulin**

During exacerbations these interventions are of value.

Other rare myasthenic syndromes exist, e.g. congenital myasthenia.
Lambert–Eaton myasthenic–myopathic syndrome (LEMS)

This paraneoplastic manifestation of small-cell bronchial carcinoma is due to defective acetylcholine release at the neuromuscular junction. Proximal limb muscle weakness, sometimes with ocular/bulbar muscles develops, with some absent tendon reflexes, a cardinal sign. Weakness tends to improve after a few minutes of muscular contraction, and absent reflexes return (cf. myasthenia). Diagnosis is confirmed by EMG and repetitive stimulation (increment, see above). Antibodies to P/Q-type voltage-gated calcium channels are found in most cases (90%). 3,4-Diaminopyridine (DAP) is a reasonably safe and sometimes effective treatment.

MUSCULAR DYSTROPHIES

These progressive genetically determined disorders of skeletal and sometimes cardiac muscle have a complex clinical and neurogenetic classification.

Duchenne muscular dystrophy (DMD) and Becker's muscular dystrophy

These are inherited as X-linked recessive disorders, though one-third of cases are spontaneous mutants. DMD occurs in 1 in 3000 male infants. The gene locus has been localized to the Xp21 region (X chromosome); there is absence of the gene product dystrophin, a rod-shaped cytoskeletal muscle protein in DMD. In Becker's dystrophy dystrophin levels are present but low. DMD is usually obvious by the fourth year, and often causes death by 20.

Dystrophin is essential for cell membrane stability. Deficiency leads to reduction in three glycoproteins (α-, β- and γ-sarcoglycans) in the dystrophin-associated protein complex (DAP-complex) that link dystrophin to laminin within cell membranes.

Becker’s muscular dystrophy is less severe than Duchenne and weakness only becomes apparent in young adults.

Clinical features

A boy with DMD is noticed to have difficulty running and rising to his feet – he uses his hands to clump up his legs (Gowers’ sign). There is initially a proximal limb weakness with calf pseudohypertrophy. The myocardium is affected. Severe disability is typical by the age of 10.

Investigations

The diagnosis is often suspected clinically. CPK is grossly elevated (100–200× normal). Biopsy shows variation in muscle fibre size, necrosis, regeneration and replacement by fat, and on immunohemochromatography staining, absence of dystrophin. EMG shows a myopathic pattern.

Management

There is no curative treatment. Passive physiotherapy helps prevent contractures in the later stages. Portable respiratory support improves life expectancy.

Carrier detection. Females with an affected brother have a 50% chance of carrying the DMD gene. In carriers, 70% have a raised CPK, usually EMG abnormalities and/or changes on biopsy. Carrier and prenatal diagnosis (cDNA probes, co-inheritance with DMD locus) are available.

Genetic advice should be given. Many carriers choose not to have offspring. Determination of fetal sex and selective abortion of a male fetus is sometimes carried out.

Limb-girdle and facioscapulohumeral dystrophy

These less severe but disabling dystrophies are summarized in Table 21.60. There are many other varieties of dystrophy. Many are associated with a sarcoglycan deficiency. Genes for various limb-girdle muscular dystrophies (LGMD) have been located; some proteins coded are known, e.g. calpain. Type 1 LGMD is a rare autosomal dominant condition. Type 2 LGMD includes all recessive varieties, with complex subdivisions, e.g. LGMD2A (calpain III deficiency), LGMD2C (γ-sarcoglycan deficiency).

MYOTONIAS

Myotonia is characterized by continued, involuntary muscle contraction after cessation of voluntary effort. EMG is characteristic (p. 1121). The two most common myotonias are mentioned below. Since there is defective skeletal muscle cell chloride ion membrane conductance, myotonias are also classified as channelopathies (see below). Patients with myotonia tolerate general anaesthetics poorly.

Dystrophia myotonica (DM) or myotonic dystrophy (MD)

This autosomal dominant condition is a genetic disorder with two different triple repeat mutations. There is an expanded CTG repeat in the DM protein-kinase (DMPK) gene on chromosome 19q13.3 (DM1). The less common variety (DM2) is caused by expanded CCTG repeat in the zinc finger protein 9 (ZNF9 gene). There is a correlation between disease severity, age at onset and approximate size of triple repeat mutations. There is progressive distal muscle weakness, with ptosis, weakness and thinning of the face and sternomastoids. Myotonia is typically present. Muscle disease is part of a syndrome comprising:

- cataracts
- frontal baldness
- cognitive impairment (mild)
- oesophageal dysfunction (and aspiration)
- cardiomyopathy and conduction defects (sudden death can occur in type 1)
- small pituitary fossa and hypogonadism
- glucose intolerance
- low serum IgG.

This gradually progressive condition usually becomes evident between 20 and 50 years. Phenytoin or procainamide sometimes helps the myotonia.

**Myotonia congenita (Thomsen’s disease)**

An isolated autosomal dominant myotonia, usually mild, becomes evident in childhood. The gene, CLC1, is on chromosome 7q35. The myotonia, which persists, is accentuated by rest and by cold. Diffuse muscle hypertrophy occurs – the patient has bulky muscles.

**CHANNELLOPATHIES**

Many conditions are now included in this group, e.g. myotonia (see above) and Lambert–Eaton myasthenic–myopathic syndrome (p. 1181).

**Hypokalaemic periodic paralysis**

This channelopathy is characterized by generalized weakness, including bulbar muscles, that often starts after a heavy carbohydrate meal or following exertion. Attacks last for several hours. It often first comes to light in the teenage years and tends to remit after the age of 35. Serum potassium is usually below 3.0 mmol/L in an attack. The weakness responds to (slow) i.v. potassium chloride. It is usually an autosomal dominant trait caused by mutation in a muscle voltage-gated calcium channel gene (CACLN1A3). Other mutations in the sodium channel (SCNA4 on chromosome 17q13.1–13.3) and potassium channel (KCNE3) also occur. Acetazolamide sometimes helps prevent attacks. Weakness can be caused by diuretics. A similar condition can also occur with thyrotoxicosis.

**Hyperkalaemic periodic paralysis**

This condition, also autosomal dominant, is characterized by attacks of weakness, sometimes with exercise. Attacks start in childhood and tend to remit after the age of 20; they last about 30–120 minutes. Myotonia may occur. Serum potassium is elevated. An attack can be terminated by i.v. calcium gluconate or chloride. There are point mutations in a muscle voltage-gated sodium channel gene (SCN4A, chromosome 17q13.1–13.3). Acetazolamide or a thiazide diuretic can be helpful.

A very rare normokalaemic, sodium-responsive periodic paralysis also occurs.

**Stiff person syndrome**

Stiff person syndrome (SPS) is a rare disease, commoner in females, of varying muscular stiffness with abnormal postur-

INTRODUCTION

Psychiatry is concerned with the study and management of disorders of mental function: primarily thoughts, perceptions, emotions and purposeful behaviours. Psychological medicine, or liaison psychiatry, is the discipline within psychiatry that is concerned with psychiatric and psychological disorders in patients who have physical complaints or conditions. This chapter will primarily concern itself with this particular branch of psychiatry.

The long-held belief that diseases are either physical or psychological has been broken down by the accumulated evidence that the brain is functionally or anatomically abnormal in most if not all psychiatric disorders. Physical, psychological and social factors, and their interactions must be considered in order to understand psychiatric conditions. This philosophical change of approach rejects the Cartesian dualistic approach of the mind/body medical model and replaces it with the more integrated biopsychosocial model.

Epidemiology (Box 22.1)
The prevalence of psychiatric disorders in the community in the UK is about 20%, mainly composed of depressive and anxiety disorders and substance misuse (mainly alcohol). The prevalence is about twice as high in patients attending the general hospital, with the highest rates in the accident and emergency department and medical wards. The higher rates in the general hospital are due to several factors, such as admission for deliberate self-harm, a psychiatric disorder or treatment causing physical harm (e.g. alcohol-induced hepatitis), and physical presentations of psychiatric disorders (such as weight loss due to anorexia nervosa). Patients with medical conditions are also more, rather than less, likely to have psychiatric disorders and vice versa.

Culture and ethnicity
These can alter either the presentation or the prevalence of psychiatric ill-health. Biological factors in mental illness are usually similar across cultural boundaries, whereas psychological and social factors will vary. For example, the prevalence and presentation of schizophrenia vary little between countries, suggesting that biological/genetic factors are operating independently of cultural factors. In contrast, conditions in which social factors play a greater role vary between cultures, so that anorexia nervosa is found more often in developed cultures. Culture can also influence the presentation of illnesses, such that physical symptoms are more

common presentations of depressive illness in Asia than in Europe. Similarly culture will influence the healthcare sought for the same condition.

**THE PSYCHIATRIC HISTORY**

The purpose of the history is to help to make a diagnosis, determine possible aetiology, and estimate prognosis. Data may be taken from several sources, including interviewing the patient, a friend or relative (usually with the patient’s permission), or the patient’s general practitioner. The patient interview enables a doctor to establish a relationship with the patient and is the principal means to make a psychiatric diagnosis. Box 22.2 gives essential guidance on how to safely conduct such an interview, although it is unlikely that a patient will physically harm a healthcare professional. When interviewing a patient for the first time, follow the guidance outlined in Chapter 1 (see p. 11).

The history consists of:

- **Reason for referral** – a brief statement of why and how the patient came to the attention of the doctor.
- **Complaints** – as reported by the patient.
- **Present illness** – a detailed account of the illness from the earliest time at which a change was noted until the patient came to the attention of the doctor.
- **Past psychiatric history** – previous episodes of psychiatric illness and their treatments, including responses and adverse reactions. Always ask about previous episodes of self-harm.
- **Past medical history** – this should include emotional reactions to illness and procedures.
- **Family history** – focusing on the way the parents or carers cared (physically and emotionally) for the patient, and the occurrence of both mental and physical illnesses in first-degree relatives.
- **Personal (biographical) history** – a short biography that covers childhood difficulties including both abuse and neglect, educational problems (e.g. bullying and truancy), qualifications (to judge premorbid intelligence), job problems, sexual relationships, children, present housing, financial situation, bereavements and life stresses.
- **A reproductive history** in women should include menstrual problems, pregnancies, terminations, miscarriages, contraception and the menopause, if relevant.

**Box 22.2 The essentials of a safe psychiatric interview**

- **Beforehand**: Ask someone of experience who knows the patient whether it is safe to interview the patient alone.
- **Access to others**: If in doubt, interview in the view or hearing of others, or accompanied by another member of staff.
- **Setting**: If safe; in a quiet room alone for confidentiality, not by the bed.
- **Seating**: Place yourself between the door and the patient.
- **Alarm**: If available, find out where the alarm is and how to use it.

**THE MENTAL STATE EXAMINATION (MSE)**

The history will already have assessed several aspects of the MSE, but the interviewer will need to expand several areas as well as test specific areas, such as cognition.

**Appearance and general behaviour**

State and colour of clothes, facial appearance, eye contact, posture and movement provide information about a patient’s affect. Patients with psychomotor retardation due to a depressive illness sit with shoulders hunched, immobile, tearful, with a downcast gaze. Depressed individuals tend to wear clothes with dark colours. Agitation and anxiety cause an easy startle response, sweating, tremor, restlessness, fidgeting, visual scanning (for danger) and even pacing up and down. Patients with mania are often physically overactive and disinhibited, wearing colourful clothes. Someone who is actively hallucinating will seem distracted and suddenly stop talking or listening and stare intently at a particular place in the room.

**Mood and affect**

The patient has an emotion or feeling, tells the doctor about their mood, and the doctor observes the patient’s affect. In psychiatric disorders, mood may be altered in three ways:

- **Personality** – this may help to determine prognosis. The doctor should find out how other people would describe the patient. Is the patient generally a worrier, shy, introverted, dependent on others, passive, aggressive, irritable, over-emotional, prone to moodiness, conscientious, or perfectionist? These are all personality traits that may predict a poorer outcome in both medical and psychiatric disorders.
- **Drug history** – both prescribed and over-the-counter medication, the use (units per week) of alcohol, tobacco, caffeine, and illicit drugs.
- **Forensic history** – you should explain that you need to ask about this since ill-health can sometimes lead to problems with the law. Particularly note any violent or sexual offences. This is part of a risk assessment and is necessary in order to assess potential risks to those close to the patient as well as staff. Ask the patient what is the worst harm they have ever inflicted on someone else, which will give an indication of the potential for violence.
- **A systematic review** of physical symptoms is particularly necessary in patients complaining of physical symptoms.

- **Depression** is a lowering of mood, such as feeling sad, tearful, melancholic or low in spirits. Some patients report anhedonia, which is a lack of positive pleasure or loss of interest. Depression is the cardinal feature of depressive illness. Sometimes the word ‘depression’ is used as shorthand to describe a depressive illness. **Diurnal variation** in mood, feeling worse on waking,
suggests a more severe illness, whereas a reactive mood, in which the patient can sometimes respond positively, indicates less severity.

- **Anxiety** is a feeling of constant, inappropriate or excessive worry, fear, apprehension, tension or inner restlessness, seen in anxiety and depressive disorders as well as drug withdrawal.
- **Elation** is a feeling of high spirits, exuberant happiness, vitality and even ecstasy, seen in mania and acute drug intoxication.
- **Irritability** can be either expressed (as in a temper or impatience) or an internal feeling of exasperation or anger, seen in both mania and depressive illness, especially in men.
- **Blunting of affect** is a total absence of emotion, seen most commonly in chronic schizophrenia.

**Fluctuating or labile mood**
This occurs when different emotions rapidly follow one another, so that a patient is crying one moment and laughing the next. This can occur in mixed affective states (see p. 1198). Alternatively, the patient is easily and excessively emotional over banal events or news, but the emotion is transient. This is seen both in a pseudobulbar palsy, commonly following a stroke (see p. 1111), and with mild depressive illnesses.

**Incongruous mood**
This occurs when emotional expression fails to match thoughts and actions. For example, a patient may laugh when describing the death of a close relative. This can occur in schizophrenia.

**Speech**
Disorders of thinking are usually recognized from the patient’s speech.

**Disorders of the stream of thought**
These are abnormalities in the amount and speed of the thoughts experienced.

- **Pressure of speech** occurs in mania and can be recognized by loudness, rapidity, and difficulty in interrupting speech.
- **Poverty of speech** is the opposite experience, when there appears to be an absence of any thought and patients report their minds to be empty. It occurs in depressive illness.
- **Thought block** occurs in schizophrenia. There is an abrupt and complete interruption of the stream of thought, so the mind goes blank. Patients may interpret the experience in an unusual way (e.g., thought withdrawal; see below).

**Disorders of the form of thought**
**Flight of ideas.** The patient’s thoughts rapidly jump from one topic to another, such that one train of thought is not completed before another appears. It is often produced by clang associations (the use of two or more words with a similar sound: ‘sun, son, song’), punning, rhyming, and responding to distracting cues in the immediate surroundings. Flight of ideas is characteristic of mania and often accompanies pressure of speech.

- **Perseveration** is the persistent and inappropriate repetition of the same thoughts or actions. It occurs in frontal lobe disorders.

  *Thought broadcast* is when the patient experiences their thoughts as being understood by others without talking, as though their thoughts are literally being broadcast to all around them.

  *Thought insertion* occurs when a patient’s thought is perceived as being planted in their mind by someone else.

  *Thought withdrawal* occurs when a patient experiences their thoughts being taken away from them, without their control.

**Thought content**
Thought content refers to the worries and preoccupations expressed by the patient. Abnormal beliefs are, of course, part of the thought content, but are regarded as sufficient to be discussed separately (see below).

- **An obsessional rumination** is a recurrent, persistent thought, impulse, image or musical theme that occurs despite the patient’s effort to resist it. The patient recognizes that the obsessional thought is their own, but it is usually unpleasant and often ‘out of character’. Common obsessions concern dirt, contamination and orderliness.

- **A compulsion** is a repetitive and seemingly purposeful action performed in a stereotypical way, referred to as a compulsive ritual. Compulsions are accompanied by a subjective sense that they must be carried out (or the patient will be overwhelmed by either anxiety or a superstitious belief that something bad will occur) and by an urge to resist. Compulsive rituals are used to counteract ruminations, so patients repetitively wash their hands to diminish the fear of contamination with dirt. Obsessions and compulsions are characteristic of obsessive compulsive disorder (see below).

**Insight and illness beliefs**
**Insight** is the degree to which a person recognizes that he or she is unwell, and is minimal in patients with a psychosis. **Illness beliefs** are the patient’s own explanations of their ill-health, including diagnosis and causes. These beliefs should be elicited because they can help to determine prognosis and adherence with treatment, with any disease.

**Abnormal beliefs**
The main form of abnormal belief is the delusion (Box 22.3). Delusions can be primary or secondary.

- **Primary delusions** are rare and appear suddenly and with full conviction but without any preceding event. For example, a patient on being offered a glass of wine suddenly believes that this means that he is Jesus Christ.

<table>
<thead>
<tr>
<th>Box 22.3 Delusion</th>
</tr>
</thead>
</table>

Delusion is defined as an abnormal belief that is:

- held with absolute conviction
- not amenable to reason or modifiable by experience
- not shared by those of a common cultural or social background
- experienced as a self-evident truth of great personal significance
- usually false.
Secondary delusions are derived from a preceding morbid experience, such as an auditory hallucination. Delusions are also classified according to their content, and include delusions of persecution, self-reference, guilt, worthlessness, nihilism, religion, grandeur, jealousy or control.

Feelings, thoughts or actions may also be interpreted by the patient as being under the control of some external power. Such passivity experiences are first rank symptoms and are regarded as diagnostic of schizophrenia (see p. 1216). Patients may develop secondary delusions that explain this alien control, such as witchcraft, hypnosis, radio waves or television – so-called ‘delusions of passivity’.

Delusions should be distinguished from overvalued ideas – deeply held personal convictions that are understandable when the individual’s background is known.

Ideas of self-reference that fall short of delusions are held by people who are particularly self-conscious. Such individuals cannot help feeling that people take particular notice of them in public places, laugh at them or pass comment about them. Such a feeling is not delusional in that patients realize that the feeling originates within themselves and that they are no more noticeable than anyone else, but nevertheless they cannot dismiss the feeling.

Abnormal perceptions

Illusions are misperceptions of external stimuli and are most likely to occur when the general level of sensory stimulation is reduced.

Hallucinations are defined in Box 22.4. Healthy people occasionally experience hallucinations, such as in normal grief, or during the transition between sleeping and waking (hypnagogic and hypnopompic). Hallucinations may affect any of the perceptions: auditory, visual, tactile, gustatory, olfactory or of deep sensation.

Pseudohallucinations are usually auditory, and are either true externally sited hallucinations, but with insight into their imaginary nature, or are sited within internal space (e.g. ‘I heard a voice in my head speaking to me’). They can occur in mood disorders and do not indicate a psychosis.

Depersonalization is a change in self-awareness such that the person feels unreal or detached from their body. The individual is aware, however, of the subjective nature of this alteration.

Derealization is the unpleasant feeling that the external environment has become unreal and/or remote: patients may describe themselves as though they are in a dream-like state. Both this and depersonalization can occur in healthy people when they are tired, after sensory deprivation and when using hallucinogenic drugs. They also occur in anxiety disorders, schizophrenia and temporal lobe epilepsy.

Increased sensitivity of perceptions, such as photosensitivity and phonosensitivity, occurs in anxiety disorders (e.g. increased sensitivity to the neon strip-lights and noise in a supermarket in agoraphobia) as well as migraine.

Cognitive state

Examination of the cognitive state is necessary to diagnose organic brain disorders, such as delirium and dementia. Poor concentration, confusion and memory problems are the most common subjective complaints. Clinical testing involves the screening of cognitive functions, which may suggest the need for more formal psychometry. A premorbid estimate of intelligence, necessary to judge changes in cognitive abilities, can be made from asking the patient the final year level of education and the highest qualifications or skills achieved.

Testing can be divided into tests of diffuse and focal brain functions.

Diffuse functions

Orientation in time, place and person. Consciousness can be defined as the awareness of the self and the environment. Clouding of consciousness is more accurately a fluctuating level of awareness and is commonly seen in delirium.

Attention is tested by saying the months or days backwards.

Verbal memory. Ask the patient to repeat a name and address with 10 or so items, noting how many times it takes to recall it 100% accurately (normal is 1 or 2) (immediate recall or registration).

Ask the patient to try to remember it and then ask it of them again after 5 minutes (0 or 1 error is normal) (short-term memory).

Long-term memory. Ask the patient to recall the news of that morning or recently. If they are not interested in the news, find out their interests and ask relevant questions (about their football team or favourite soap opera). Amnesia is literally an absence of memory and dysnnesia indicates a dysfunctioning memory.

Focal functions

Frontal, temporal and parietal function tests are covered on page 1099. Note any disinhibited behaviour not explained by another psychiatric illness. Sequential tasks are tested by asking the patient to alternate making a fist with one hand at the same time as a flat hand with the other. Ask the patient to tap a table once if you tap twice and vice versa. Note any motor perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration, in which the patient repeats the same answer as given previously for a different question. Abstract thinking is measured by asking the meaning of common proverbs, a literal meaning suggesting frontal lobe dysfunction, assuming reasonable premorbid intelligence.

Mini-mental state examination

Box 22.5 gives the ‘mini-mental state’ examination of cognitive function. This is a 5-minute bedside test that is useful as a screen and in assessing the degree of cognitive dysfunc-
Displacement involves the transferring of emotion from a situation or object with which it is properly associated to another that gives less distress.

Identification refers to the unconscious process of taking on some of the characteristics or behaviours of another person, often to reduce the pain of separation or loss.

Projection involves the attribution to another person of thoughts or feelings that are in fact one's own.

Regression is the adoption of primitive patterns of behaviour appropriate to an earlier stage of development. It can be seen in ill people who become child-like and highly dependent.

Repression is the exclusion from awareness of memories, emotions and/or impulses that would cause anxiety or distress if allowed to enter consciousness.

Sublimation refers to the unconscious diversion of unacceptable behaviours into acceptable ones.

The relevant physical examination

This should be guided by the history and mental state examination. Particular attention should usually be paid to the neurological and endocrinological examinations when organic brain syndromes and affective illnesses are suspected.

Summary or formulation

When the full history and mental state have been assessed, the doctor should make a concise assessment of the case, which is termed a formulation. In addition to summarizing the essential features of the history and examination, the formulation includes a differential diagnosis, a discussion of possible causal factors, and an outline of further investigations or interviews needed. It concludes with a concise plan of treatment and a statement of the likely prognosis.

**CLASSIFICATION OF PSYCHIATRIC DISORDERS**

The classification of psychiatric disorders into categories is mainly based on symptoms and behaviours, since there are currently few diagnostic tests for psychiatric disorders. There currently exists an unhelpful dualistic division of psychiatric disorders from neurological diseases, since the pathologies of at least the majority of each group of conditions are located in the brain, such as Alzheimer’s disease causing dementia and a pseudobulbar palsy causing emotional lability.

Psychiatric classifications have traditionally divided up disorders into neuroses and psychoses.

**Neuroses** are illnesses in which symptoms vary only in severity from normal experiences, such as depressive illness. **Psychoses** are illnesses in which symptoms are qualitatively different from normal experience, with little insight into their nature, such as schizophrenia. There are several problems with a neurotic-psychotic dichotomy. First, neuroses may be as severe in their effects on the patient and their family as psychoses. Second, neuroses may cause symptoms that fulfill the definition of psychotic symptoms. For instance,
someone with anorexia nervosa may be convinced that they are fat when they are thin, and this belief would meet all the criteria for a delusional belief. Yet we would traditionally classify the illness as a neurosis. The International Classification of Mental and Behavioural Disorders (ICD-10) has been published by the World Health Organization. This system has largely abandoned the traditional division between neurosis and psychosis, although the terms are still used. The disorders are now arranged in groups according to major common themes (e.g. mood disorders and delusional disorders). A classification of psychiatric disorders derived from ICD-10 is shown in Table 22.1, and this is the classification mainly used in this chapter.

The Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-IV-TR) is an alternative classification system.

### CAUSES OF A PSYCHIATRIC DISORDER

A psychiatric disorder may result from several causes which may interact. It is most helpful to divide causes into the three ‘P’s: predisposing, precipitating and perpetuating factors.

- **Predisposing factors** often stem from early life and include genetic, pregnancy and delivery, previous emotional traumas and personality factors.
- **Precipitating (triggering) factors** may be physical, psychological or social in nature. Whether they produce a disorder depends on their nature, severity and the presence of predisposing factors. For instance a death of a close, rather than distant, family member is more likely to precipitate a pathological grief reaction in someone who has not come to terms with a previous bereavement.
- **Perpetuating (maintaining) factors** prolong the course of a disorder after it has occurred. Again they may be physical, psychological or social, and several are often active and interacting at the same time. For example, high levels of criticism at home combined with taking cannabis, as relief from the criticism, may help to maintain schizophrenia.

### PSYCHIATRIC ASPECTS OF PHYSICAL DISEASE

Patients with non-psychiatric, ‘physical’ diseases are more likely to suffer from psychiatric disorders than those who are well. The most common psychiatric disorders in physically unwell patients are mood or adjustment disorders and acute organic brain disorders (delirium). The relationship between psychological and physical symptoms may be understood in one of four ways:

- Psychological distress and disorders can precipitate physical diseases (e.g. anorexia nervosa causing cardiac arrhythmias, due to hypokalaemia).
- Physical diseases and their treatments can cause psychological symptoms or ill-health (Table 22.2).
- Both the psychological and physical symptoms are caused by a common disease process (e.g. Huntington’s chorea).
- Physical and psychological symptoms and disorders may be independently co-morbid, particularly in the elderly.

Factors that increase the risk of a psychiatric disorder in someone with a physical disease are shown in Table 22.3.

### Differences in treatment

Although the basic principles are the same as in treating psychiatric illnesses in the physically healthy, there are some differences:

- **Uncertainty regarding the physical diagnosis or prognosis**, with its attendant tendency to imagine the worst, is often a triggering or maintaining factor, particularly in an adjustment or mood disorder. Good two-way communication between doctor and patient, with time taken to listen to the patient’s concerns, is often the most effective ‘antidepressant’ available.
- The history may reveal the role of a physical disease or treatment exacerbating the psychiatric condition, which should then be addressed (see Table 22.2). For example, the dopamine agonist bromocriptine can precipitate a psychosis.
- When prescribing psychotropic drugs, the dose should be reduced in disorders affecting pharmacokinetics, e.g. fluoxetine in renal or hepatic failure.
**SEVERE BEHAVIOURAL DISTURBANCE**

Patients with aggressive or violent behaviour cause understandable apprehension in all staff, and are most commonly seen in the accident and emergency department. Information from anyone accompanying the patient, including police or carers, can help considerably. Box 22.6 gives the main causes of disturbed behaviour.

**Management of the severely disturbed patient**

The primary aims of management are control of dangerous behaviour and establishment of a provisional diagnosis. Three specific strategies may be necessary when dealing with the violent patient:

- Drug intoxication (especially alcohol)
- Delirium (acute confusional state)
- Acute psychosis
- Personality disorder

**Drug interactions** should be of particular concern, e.g. lithium and non-steroidal anti-inflammatory drugs.

- Sometimes a physical treatment may be planned that may exacerbate the psychiatric condition. An example would be high-dose steroids as part of chemotherapy in a patient with leukaemia and depressive illness.
- Always consider the risk of suicide in an inpatient with a mood disorder and take steps to reduce that risk; for example, moving the patient to a room on the ground floor and/or having a registered mental health nurse attend the patient while at risk.

**THE SICK ROLE AND ILLNESS BEHAVIOUR**

The sick role describes behaviour usually adopted by ill people. Such people are not expected to fulfil their normal social obligations. They are treated with sympathy by others and are only obliged to see their doctor and take medical advice or treatments.

**Illness behaviour** is the way in which given symptoms may be differentially perceived, evaluated and acted (or not acted) upon by different kinds of persons. We all have illness behaviour when we choose what to do about a symptom. Going to see a doctor is generally more likely with more severe, distressing and numerous symptoms. It is also more likely in introspective individuals who focus on their health.

**Abnormal illness behaviour** occurs when there is a discrepancy between the objective somatic pathology present and the patient’s response to it, in spite of adequate medical investigation and explanation.
FUNCTIONAL OR PSYCHOSOMATIC DISORDERS: MEDICALLY UNEXPLAINED SYMPTOMS

So-called ‘functional’ (in contrast to ‘organic’) disorders are illnesses in which there is no obvious pathology or anatomical change in an organ and there is a presumed dysfunction in an organ or system. The psychiatric classification of these disorders would be somatoform disorders, but they do not fit easily within either medical or psychiatric classification systems, since they occupy the hinterland between them. This classification also implies a dualistic ‘mind or body’ dichotomy, which is not supported by neuroscience. Since current classifications still support this outmoded understanding, this chapter will address these conditions in this way.

The word psychosomatic has had several meanings, including psychogenic, ‘all in the mind’, imaginary and malingering. The modern meaning is that psychosomatic disorders are syndromes of unknown aetiology in which both physical and psychological factors are likely to be causative. Medically unexplained symptoms and syndromes are very common in both primary care and the general hospital (over half the outpatients in gastroenterology and neurology clinics have these syndromes). Because orthodox medicine has not been particularly effective in treating or understanding these disorders, many patients perceive their doctors as unsympathetic and seek out complementary or even alternative treatments of uncertain efficacy. Examples of functional disorders are shown in Table 22.4.

Because epidemiological studies suggest that having one of these syndromes significantly increases the risk of having another, some doctors believe that these syndromes represent different manifestations of ‘one functional syndrome’, which is indicative of a somatization process. Functional disorders also have a significant association with psychiatric disorders, especially depressive and anxiety disorders. Against this view is the evidence that the majority of primary care patients with most of these disorders do not have either a psychiatric disorder or another functional disorder. It seems that it requires a major stress or the development of a co-morbid psychiatric disorder in order for such sufferers to see their doctor, which might explain why doctors are so impressed with the associations with both stress and psychiatric disorders. Doctors have historically tended to diagnose ‘stress’ or ‘psychosomatic disorders’ in patients with symptoms that they cannot explain. History is full of such disorders being reclassified as research clarifies the pathology. An example is writer’s cramp (p. 1150) which most neurologists now agree is a dystonia rather than a neurosis.

The likelihood is that these so-called ‘functional somatoform disorders’ will be reclassified as their causes and pathophysiology are revealed. Functional brain scans suggest enhancement of brain activity during interoception in more than one syndrome. Interoception is the perception of internal (visceral) phenomena, such as a rapid heartbeat.

Chronic fatigue syndrome (CFS)

There has probably been more controversy over the existence and cause of CFS than any other ‘functional’ syndrome in recent years. This is reflected in its uncertain classification as neurasthenia in the psychiatric classification and myalgic encephalomyelitis (ME) under neurological diseases. There is now good evidence for the independent existence of this syndrome, although the diagnosis is made clinically and by exclusion of other fatiguing disorders. Its prevalence is 0.5% in the UK, but it is found world-wide, while varying in prevalence. The symptom of abnormal fatigue occurs in 10–20%. It occurs most commonly in women between the ages of 20 and 50 years, particularly in ethnic minority groups in the UK. The cardinal symptom is chronic fatigue made worse by minimal exertion. The fatigue is usually both physical and mental, associated most commonly with poor concentration, impaired registration of memory, alteration in sleep pattern (either insomnia or hypersomnia), and muscular pain. Mood disorders are present in a large minority of patients, and can cause problems in diagnosis because of the large overlap in symptoms. These mood disorders may be secondary, independent (co-morbid), or primary (with a misdiagnosis of CFS).

Aetiology

Functional disorders often have some aetiological factors in common with each other (see Table 22.5), as well as more

</tbody>
</table>
specific aetiologies. For instance, CFS can be triggered by certain infections, such as infectious mononucleosis and viral hepatitis. About 10% of patients with infectious mononucleosis have CFS 6 months after the onset of infection, yet there is no evidence of persistent infection in these patients. Those fatigue states which clearly do follow on a viral infection can also be classified as post-viral fatigue syndromes. Other aetiological factors are uncertain. Immune and endocrine abnormalities noted in CFS may be secondary to the inactivity or sleep disturbance commonly seen. The role of stress is uncertain, with some indication that the influence of stress is mediated through subsequent psychiatric disorders exacerbating fatigue, rather than any direct effect.

Management
The general principles of the management of functional disorders are given in Box 22.7. Specific management of CFS should include a mutually agreed and supervised programme of gradually increasing activity. However, only a quarter of patients recover after treatment. It is sometimes difficult to persuade a patient to accept what are inappropriately perceived as ‘psychological therapies’ for such a physically manifested condition. Antidepressants do not work in the absence of a mood disorder or insomnia.

Prognosis
This is poor without treatment, with less than 10% of hospital attenders recovered after 1 year. Outcomes are worse with greater severity, increasing age, co-morbid mood disorders, and the conviction that the illness is entirely physical. With rehabilitative treatments some 60% make a significant improvement.

Fibromyalgia (chronic widespread pain: CWP)
This controversial condition of unknown aetiology overlaps with chronic fatigue syndrome, with both conditions causing fatigue and sleep disturbance (see p. 1192). Diffuse muscle and joint pains are more constant and severe in CWP, although the ‘tender points’, previously considered to be pathognomonic, are now known to be ubiquitous, associated with psychological distress, and of no diagnostic importance (p. 516). CWP occurs most commonly in women aged 40–65 years, with a prevalence in the community of between 1 and 11%. There are associations with depressive and anxiety disorders, other functional disorders, physical deconditioning and a possibly characteristic sleep disturbance (see Table 22.5). Functional brain scans suggest that patients actually perceive greater pain, supporting the idea of abnormal sensory processing.

Management
Apart from the general principles in Box 22.7, management also consists of symptomatic analgesia, reversing the sleep disturbance, and a physically orientated rehabilitation programme. A meta-analysis suggests that tricyclic antidepressants that inhibit reuptake of both serotonin (5-hydroxytryptamine – 5-HT) and noradrenaline (e.g. amitriptyline, dosulepin) have the greatest effect on sleep, fatigue and pain. The doses used are too low for antidepressant effect and the drugs may work through their hypnotic and analgesic effects.

Other chronic pain syndromes
A chronic pain syndrome is a condition of chronic disabling pain for which no medical cause can be found. The psychiatric classification would be a persistent somatoform pain disorder, but this is unsatisfactory since the criteria include the stipulation that emotional factors must be the main cause, and it is clinically difficult to be that certain. The main sites of chronic pain syndromes are the head, face, neck, lower back, abdomen, genitalia or all over (CWP: fibromyalgia). ‘Functional’ low back pain is the commonest ‘physical’ reason for being off sick long-term in the UK (p. 509). Quite often a minor abnormality will be found on investigation (such as mild cervical spondylosis on the neck X-ray), but this will not be severe enough to explain the severity of the pain and resultant disability. These pains are often unremitting and respond poorly to analgesics. Sleep disturbance is almost universal and co-morbid psychiatric disorders are commonly found.

Aetiology
The perception of pain involves sensory (nociceptive), emotional and cognitive processing in the brain. Functional brain scans suggest that the brain responds abnormally to pain in these conditions, with increased activation in response to chronic pain. This could be related to conditioned behavioural and physiological responses to the initial acute pain. The brain may then adapt to the prolonged stimulus of the pain by changing its central processing. The prefrontal cortex, thalamus and cingulate gyrus seem to be particularly affected and some of these areas are involved in the emotional appreciation of pain in general. Thus it is possible to start to understand how beliefs, emotions and behaviours might influence the perception of chronic pain (see Table 22.5).

Management
Management involves the same principles as used in other functional syndromes (Box 22.7). Since analgesics are rarely effective, and can cause long-term harm, patients should be encouraged to gradually reduce their use. It is often helpful to involve the patient’s immediate family or partner, to ensure
that the partner is also supported and not unconsciously discouraging progress.

Specific drug treatments are few. Nerve blocks are not usually effective. Anticonvulsants such as carbamazepine and gabapentin may be given a therapeutic trial if the pain is thought to be neuropathic (see p. 1118). The antidepressant dosulepin is an effective treatment in half of patients with atypical facial pain, and this effect seems to be independent of dosulepin’s effect on mood. Another tricyclic antidepressant, amitriptyline, is helpful in tension headaches, which might be related to its independent analgesic effect. Amitriptyline has the added bonus of increasing slow wave sleep, which may be why it is more effective than NSAIDs in chronic widespread pain. Tricyclic antidepressants that affect both serotonin and norepinephrine (noradrenaline) reuptake (e.g. p. 1202) seem to be more effective than more selective norepinephrine reuptake inhibitors, e.g. in neuropathic pain. There is some evidence that tricyclics are generally superior to SSRIs in chronic pain syndromes.

Irritable bowel syndrome

This is one of the commonest functional syndromes, affecting some 10–30% of the population world-wide. The clinical features and management of the syndrome and the related functional bowel disorders are described in more detail on page 311. Although the majority of sufferers with the irritable bowel syndrome (IBS) do not have a psychiatric disorder, depressive illness should be excluded in patients with constipation and a poor appetite. Anxiety disorders should be excluded in patients with nausea and diarrhoea. Persistent abdominal pain or a feeling of emptiness may occasionally be the presenting symptom of a severe depressive illness, particularly in the elderly, with a nihilistic delusion that the body is empty or dead inside (see p. 1199).

Management

This is dealt with in more detail on page 312 and in Box 22.7. Seeing a physician who provides specific education that particularly addresses individual illness beliefs and concerns can provide lasting benefit. Psychological therapies that help the more severely affected include biofeedback, hypnotherapy, cognitive behaviour therapy and brief interpersonal psychotherapy. If indicated, the choice of antidepressant should be determined by the effects of these drugs on bowel transit times, with tricyclic antidepressants normally slowing and selective serotonin reuptake inhibitors (SSRIs) (p. 1202) normally speeding up transit times.

Multiple chemical sensitivity, Candida hypersensitivity, and food allergies

Some complementary health practitioners, doctors and patients themselves make diagnoses of multiple chemical sensitivities (MCS) (e.g. to foods, smoking, perfumes, petrol), Candida hypersensitivity, and allergies (to food, tap-water and even electricity). Symptoms and syndromes attributed to these putative disorders are numerous and variable and include all the functional disorders, mood disorders and arthritis. Scientific support for the existence of these disorders is weak, particularly when double-blind methodologies have been used.

Type 1 hypersensitivities to foods such as nuts certainly exist, although they are fortunately uncommon (approximately 3 per 1000) (see p. 72). Direct specific food intolerances also occur (e.g. chocolate with migraine, caffeine with IBS).

Candidiasis can occur in the gastrointestinal tract in immunocompromised individuals, such as those with AIDS. Vaginal candidiasis can occur after antibiotic treatment in otherwise healthy women. A double-blind and controlled study of nystatin in women diagnosed as having candidiasis hypersensitivity syndrome showed that vaginitis was the only condition relieved more by nystatin than placebo. There is little evidence of Candida having a systemic role in other symptoms.

In spite of this evidence, the patient is often convinced of the legitimacy and usefulness of these diagnoses and their treatments.

Aetiology

Surveys of patients diagnosed with MCS or food allergies have shown high rates of current and previous psychiatric disorders (especially mood and anxiety disorders) (see Table 22.5). Eating disorders (p. 1219) should be excluded in patients with food intolerances. Some patients taking very low carbohydrate diets as putative treatments may develop reactive hypoglycaemia after a high carbohydrate meal, which they then interpret as a food allergy. It has been shown that classical conditioning can produce intolerance to foods and smells in healthy people and this may be a causative mechanism in some patients with intolerance. This supports the existence of these intolerance conditions, but suggests they may be conditioned responses with attendant physiological consequences. This might explain why double-blind ing abolishes the reaction to the stimulus.

Management

The general principles in Box 22.7 apply. If one assumes a phobic or conditioned response is responsible, graded exposure (systematic desensitization) to the conditioned stimulus may be worthwhile. Preliminary studies do suggest that this approach may successfully treat such intolerances, in the context of cognitive behaviour therapy.

Premenstrual syndrome

The premenstrual syndrome (PMS) consists of both physical and psychological symptoms that regularly occur during the premenstrual phase and substantially diminish or disappear soon after the period starts. Physical symptoms include headache, fatigue, breast tenderness, abdominal distension and fluid retention. Psychological symptoms can include irritability, emotional lability or low mood, and tension. The premenstrual (late luteal) dysphoric disorder (PMDD) is a severe form of PMS with marked mood swings, irritability, depression and anxiety accompanying the physical symptoms. Women who generally suffer from mood disorders may be more prone to experience this disorder. The prevalence of PMS does not vary between cultures and is reported by the majority (75%) of women at some time in their lives. Severely disabling PMS (PMDD) occurs in about 3–8% of women. The cause of the premenstrual syndrome remains unclear, although exacerbating factors include some of those outlined in Table 22.5. Research suggests that abnormalities of reproductive hormone receptors may play a role.
Management
The general principles in Box 22.7 apply. Treatments with vitamin B_6_ (p. 223), diuretics, progesterone, oral contraceptives, oil of evening primrose and oestrogen implants or patches (balanced by cyclical norethisterone) remain empirical. Psychotherapies aimed at enhancing the patient’s coping skills can reduce disability. Two trials suggest that graded exercise therapy improves symptoms. Several studies have demonstrated that SSRI (p. 1202) are effective treatments for the premenstrual dysphoric disorder.

The menopause
The clinical features and management of the menopause are described on page 997. A prospective study has shown that there is no increased incidence of depressive disorders at this time. Such a significant bodily change, sometimes occurring at the same time as children leaving home, is naturally accompanied by an emotional adjustment that does not normally amount to a pathological state.

SOMATOFORM DISORDERS
As explained in the section on functional disorders (p. 1192), the classification of somatoform disorders is unsatisfactory because of the uncertain nature and aetiology of these disorders. However, there are certain disorders, beyond those described in ‘functional disorders’, that present frequently and coherently enough to be usefully recognized.

Somatization disorder
One in ten patients presenting with a functional disorder will fulfil the criteria of a chronic somatization disorder, sometimes known as Briquet’s syndrome. The condition is composed of multiple, recurrent, medically unexplained physical symptoms, usually starting early in adult life. Exhaustion, dizzy spells, headaches, hypersensitivity to light and noise, paraesthesiae, abdominal, neck and back pain, nausea, sexual symptoms, and abnormal skin sensations are among the most common complaints, but symptoms may be referred to almost any part or bodily system. The patient, usually female, has often had multiple medical opinions and repeated negative investigations. Medical reassurance that the symptoms do not have a demonstrable physical cause fails to reassure the patient, who will continue to ‘doctor-shop’. The patient is usually reluctant to accept a psychological and/or social explanation for the symptoms even when such a link seems obvious. Abnormal illness behaviour is evident and patients can be attention-seeking and dependent on doctors. Yet they can complain about the medical care and attention they have previously received.

The aetiology is unknown, but both mood and personality disorders are often also present. It is often associated with dependence upon or misuse of prescribed medication, usually sedatives and analgesics. There is often a history of significant childhood traumas, or chronic ill-health in the child or parent, which may play an aetiological role (see Table 22.5). The condition is probably the somatic presentation of psychological distress, although iatrogenic damage (from postoperative and drug-related problems) soon complicates the clinical picture. The course of the disorder is chronic and disabling, with long-standing family, marital and/or occupational problems.

Hypochondriasis
The conspicuous feature is a preoccupation with an assumed serious disease and its consequences. Patients commonly believe that they suffer from cancer or AIDS, or some other serious condition. Characteristically, such patients repeatedly request laboratory and other investigations to either prove they are ill or reassure themselves that they are well. Such reassurance rarely lasts long before another cycle of worry and requests begins. The symptom of hypochondriasis may be secondary to or associated with a variety of psychiatric disorders, particularly depressive and anxiety disorders. Occasionally the hypochondriasis is delusional, secondary to schizophrenia or a depressive psychosis. Hypochondriasis may coexist with physical disease but the diagnostic point is that the patient’s concern is disproportionate and unjustified.

Management of somatoform disorders
The principles outlined in Box 22.7 apply to these disorders. Patients appreciate a discussion and explanation of their symptoms. Further management consists of ceasing reassurance that no serious disease has been uncovered, since this simply reinforces dependence on the doctor. The doctor should sensitively explore possible psychological and social difficulties, if possible by demonstrating links between symptoms and stresses. Useful questions to ask include:

‘When were you last completely well and happy?’
Such a patient may have trouble remembering such a time, which helps to support the diagnosis, and leads to a discussion as to why they have never been well or happy.

‘What can’t you do now because you are unwell?’

‘What changes has your ill-health caused in your close relationships?’

These questions usually give information that can be used to formulate an agreed plan of management. Repeated laboratory investigations should be discouraged. It is vital that all members of staff and close family members adopt the same approach to the patient’s problems. Such patients often consciously or unconsciously split both medical staff and family members into ‘good’ and ‘bad’ (or caring and uncaring) people, as a way of projecting their distress. Since these disorders have a poor prognosis, the aim is to minimize disability. A contract of mutually agreed care involving the appropriate professionals (general practitioner, and a choice of psychotherapist, health psychologist, complementary health professional, physician or psychiatrist), with agreed frequency of visits and a review date, can be helpful in managing the condition.

Cognitive behaviour therapy has been shown to provide effective rehabilitation in significant numbers of patients suffering from a somatoform disorder.

DISSOCIATIVE/CONVERSION DISORDERS
Until recently these disorders were known as ‘hysteria’, but because the word hysteria is sometimes used pejoratively to describe extravagant behaviour, the term is inappropriate.
A dissociative disorder is a condition in which there is a profound loss of awareness or cognitive ability without medical explanation. The term dissociative indicates the disintegration of different mental activities, and covers such phenomena as amnesia, fugues and pseudoseizures (non-epileptic fits).

Conversion was introduced by Freud to explain how an unresolved conflict could be converted into usually symbolic physical symptoms as a defence against it. Such symptoms commonly include paralysis, abnormal movements, sensory loss, aphony, disorders of gait and pseudocyesis (false pregnancy). The lifetime prevalence has been estimated at 3–6 per 1000 in women, with a lower prevalence in men. Most cases begin before the age of 35 years. Dissociation is unusual in the elderly.

**Clinical features**

The various symptoms are usually divided into dissociative and conversion categories (Table 22.6). Dissociative disorders have the following four characteristics that are necessary in order to make the diagnosis:

- They occur in the absence of physical pathology that would fully explain the symptoms.
- They are produced unconsciously.
- The illness is triggered by one or more unresolved conflicts or life events.
- Symptoms are not caused by overactivity of the sympathetic nervous system.

Other characteristics include:

- Symptoms and signs often reflect a patient’s ideas about illness.
- Patients may take up the symptoms of a relative/friend who has been ill.
- There is usually abnormal illness behaviour, with obvious exaggeration of disability.
- There may have been significant childhood traumas.
- Primary gain is the immediate relief from the emotional conflict.
- Secondary gain refers to the social advantage gained by the patient by being ill and disabled (sympathy of family and friends, being off work, disability pension).
- Physical disease is not uncommonly also present (e.g. pseudoseizures are more common in someone with epilepsy).

**Dissociative amnesia** commences suddenly. Patients are unable to recall long periods of their lives and may even deny any knowledge of their previous life or personal identity. In a dissociative fugue, patients not only lose their memory but wander away from their usual surroundings, and, when found, deny all memory of their whereabouts during this wandering. The differential diagnosis of a fugue state includes post-ictal automatism, depressive illness and alcohol abuse.

**Multiple personality disorder** is rare, but dramatic, and may be triggered by suggestion on the part of a psychotherapist. There are rapid alterations between two or more ‘personalities’ in the same person, each of which is repressed and dissociated from the other ‘personalities’. A differential diagnosis is rapid cycling manic depressive disorder which would explain sudden apparent changes in personality.

**Epidemic** or ‘mass hysteria’ usually occurs in institutions for girls or young women, in which the combined effects of suggestion and shared anxiety produce outbreaks of sickness or disturbed behaviour, often following sudden illnesses in leaders of the group at a time of threatened or actual social change.

**Differential diagnosis**

Dissociation is usually a stable and reliable diagnosis over time, although high rates of co-morbid mood and personality disorders are found in chronic sufferers. Particular care should be taken to make the diagnosis on positive grounds, and not simply on the basis of an absence of a medical diagnosis. Care should also be taken to exclude or treat co-morbid psychiatric disorders.

**Aetiology**

Functional brain scans differ between healthy controls feigning a motor abnormality and patients with a similar conversion motor symptom, which suggests that dissociation involves different areas of the brain from simulation (Fig. 22.1). This supports the theory of unconscious mechanisms.

**Table 22.6** Common dissociative/conversion symptoms

**Fig. 22.1** Statistical parametric maps superimposed on an MRI scan of the anterior surface of the brain, orientated as though looking at a person head on. Red region shows hypofunction of patients with conversion motor symptoms. Green region shows hypofunction of healthy controls feigning the same motor abnormality. Reproduced from Spence SA, Crimlisk HL, Cope H et al. Discrete neurophysiological correlates in prefrontal cortex during hysterical and feigned disorders of movement. *Lancet* 2000; **355**: 1243–1244, © The Lancet Ltd. 2000, with permission.
first suggested by Charcot. Functional brain scanning of a patient with conversion paralysis has shown that recalling a past trauma not only activated the emotional areas, such as the amygdala, but also reduced motor cortex activity. This would suggest that conversion involves a disinhibition of voluntary will at an unconscious level, so that the patient can no longer will something to happen.

The psychoanalytical theory of dissociation is that it is the result of emotionally charged memories that are repressed into the unconscious at some point in the past. Symptoms are explained as the combined effects of repression and the symbolic conversion of this emotional energy into physical symptoms. This hypothesis is difficult to test, although there is some evidence that patients with dissociative disorders are more likely to have suffered childhood abuse, particularly when the abuse was both sexual and physical and started early in childhood. Caution should be taken with such a history obtained by therapies that ‘recover’ childhood memories that were previously completely unknown to the patient.

Patients with dissociative disorders by definition adopt both the sick role and abnormal illness behaviour, with consequent secondary gains that help to maintain the illness.

**Management**

The treatment of dissociation is similar to the treatment of somatof orm disorders in general, outlined above and in Box 22.7. The first task is to engage the patient and their family with an explanation of the illness that makes sense to them, is acceptable, and leads to the appropriate management. An invented example of a suitable explanation is given below:

*You told me about the tremendous shock you felt when your mother suddenly died. This was particularly the case since you hadn’t spoken to her for so long beforehand, after that big disagreement with her over your wedding to John. You weren’t able to say good-bye before she died. Your brain was overloaded with grief, guilt and anger all at once. I wonder whether that is why you aren’t able to speak now. I wonder whether it’s difficult to think of anything to say that would make things right, particularly since you can’t speak with your mother now.*

Such an explanation would be modified by mutual discussion until an agreed understanding was achieved, which would serve as a working model for the illness. Provision of a rehabilitation programme that addresses both the physical and psychological needs and problems of the patient would then be planned. A graded and mutually agreed plan for a return to normal function can usually be led by the appropriate therapist (e.g. speech therapist for dysphonia, physiotherapist for paralysis). At the same time, a psychotherapeutic assessment should be made in order to determine the appropriate form of psychotherapy. For instance, couple therapy will address a significant relationship difficulty; individual psychotherapy could ease an unresolved conflict from childhood.

*Abreaction* brought about by *hypnosis* or by intravenous injections of small amounts of midazolam may produce a dramatic, if short-lived, recovery. In the abreactive state, the patient is encouraged to relive the stressful events that provoked the disorder and to express the accompanying emotions, i.e. to abreact. Such an approach has been useful in the treatment of acute dissociative states in wartime, but appears to be of much less value in civilian life. It should only be contemplated in the presence of an anaesthetist with suitable resuscitation equipment to hand.

_Hypnotherapy_ is psychotherapy while the patient is in a hypnotic trance, the idea being that therapy is more possible because the patient is relaxed and not using repression. This may allow the therapist access to the previously unconscious emotional conflicts or memories. There are no published trials of this technique in dissociation, which Freud gave up as unsuccessful in order to found psychoanalysis, but some hypnotherapists claim good results. Care should be taken to avoid a catastrophic emotional reaction when the patient is suddenly faced with the previously repressed memories.

**Prognosis**

Most cases of recent onset recover quickly with treatment, which is why a positive diagnosis should be made early. Those cases that last longer than a year are likely to persist, with entrenched abnormal illness behaviour patterns. A recent study found that 83% were still unwell at 12 years’ follow-up.

---

**SLEEP DIFFICULTIES (p. 1145)**

Sleep is divided into _rapid eye movement_ (REM) and non-REM sleep. As drowsiness begins, the alpha rhythm on an EEG disappears and is replaced by deepening slow wave activity (non-REM). After 60–90 minutes, this slow wave pattern is replaced by low amplitude waves on which are superimposed rapid eye movements lasting a few minutes. This cycle is repeated during the duration of sleep, with the REM periods becoming longer and the slow-wave periods shorter and less deep (Fig. 22.2). REM sleep is accompanied by dreaming and physiological arousal. Slow wave sleep is associated with release of anabolic hormones and cytokines, with an increased cellular mitotic rate. It helps to maintain host defences, metabolism and repair of cells. For this reason slow wave sleep is increased in those conditions where growth or conservation is required (e.g. adolescence, pregnancy, thyrotoxicosis).

*Insomnia* is difficulty in sleeping; a third of adults complain of insomnia and in a third of these it can be severe.

*Primary sleep disorders* include sleep apnoea (p. 1145), narcolepsy (see p. 1145), _the restless legs syndrome_
(Ekomb’s) (see p. 626) and the related periodic leg movement disorder, in which the legs (and sometimes the arms) jerk while asleep.

Delayed sleep phase syndrome occurs when the circadian pattern of sleep is delayed so that the patient sleeps from the early hours until mid-day or later, and is most common in young people. Night terrors, sleep-walking and sleep-talking are non-REM phenomena, most commonly found in children, which can recur in adults when under stress or suffering from a mood disorder.

Psychophysiological insomnia commonly occurs with functional, mood and substance misuse disorders, and when under stress (Box 22.8). It can often be triggered by one of these factors, but then become a habit on its own, driven by anticipation of insomnia and day-time naps. Insomnia causes day-time sleepiness and fatigue, with consequences such as road traffic accidents. Assessment should pay particular attention to mood, life difficulties and drug intake (especially alcohol, nicotine and caffeine). Initial insomnia (trouble getting off to sleep) is common in mania, anxiety, depressive disorders and substance misuse. Middle insomnia (waking up in the middle of the night) occurs with medical conditions such as sleep apnoea and prostatism. Late insomnia (early morning waking) is caused by depressive illness and malnutrition (anorexia nervosa).

Habitual alcohol consumption should be carefully estimated since even a small excess can be a potent cause of insomnia, as well as recent withdrawal. Caffeine is perhaps the most commonly taken drug in the UK, and its effects are easily underestimated. Six cups of real coffee a day are likely to cause insomnia in the average healthy adult. Caffeine is not only found in tea and coffee, but is also found in chocolate, cola drinks and some analgesics. Prescription drugs that can either disturb sleep or cause vivid dreams include most appetite suppressants, glucocorticoids, dopamine agonists, lipid-soluble beta-blockers (e.g. propranolol) and certain psychotropic drugs (especially when first prescribed, e.g. fluoxetine, reboxetine, risperidone).

Hypersomnia is not uncommon in adolescents with depressive illness, occurs in narcolepsy, and may temporarily follow infections such as infectious mononucleosis.

Management of insomnia

This is determined by diagnosis. Where none is immediately apparent, it is worth educating the patient about sleep hygiene. Simple measures such as decreasing alcohol intake, having supper earlier, exercising daily, having a hot bath prior to going to bed and establishing a routine of going to bed at the same time should all be tried. Relaxation techniques and cognitive behaviour therapy have a role in those with intratable insomnia. Short half-life benzodiazepines can be useful for acute insomnia, but should not be used for more than 2 weeks continuously to avoid dependence. Non-benzodiazepine hypnotics ( zaleplon, zopiclone, zolpidem) act at the benzodiazepine receptors and occasional dependence has been reported. Certain antihistamines (e.g. diphenhydramine and promethazine) and antidepressants (e.g. amitriptyline, trimipramine, trazodone, mirtazapine) are not addictive and can be used as hypnotics in low dose, with the added advantage of improving slow wave sleep. The commonest side-effects are morning sedation and weight gain.

MOOD (AFFECTIVE) DISORDERS

Classification

The central and common feature of these disorders is an abnormality of mood. Mood is best considered in terms of a continuum ranging from severe depression at one extreme to severe mania at the other, with the normal, stable mood in the middle. Mood disorders are divided into bipolar and unipolar affective disorders.

Bipolar affective disorder (otherwise known as manic-depressive disorder). Patients suffer bouts of both depression and mania. Although mania can rarely occur by itself without depressive mood swings (thus being ‘unipolar’) it is far more commonly found in association with depressive swings, often if sometimes it takes several years for the first depressive illness to appear. Hypomania is mild mania.

- Bipolar I disorder is defined as depression alternating with mania.
- Bipolar II is defined as depression alternating with hypomania.

About 10% of patients with depressive illness are eventually found to have a bipolar illness.

Unipolar affective disorders. Patients suffer from depressive mood swings alone, although they are commonly recurrent.

DEPRESSIVE DISORDERS

Depressive disorders or ‘episodes’ are classified by the ICD-10 as mild, moderate or severe, with or without somatic symptoms. Severe depressive episodes are divided according to the presence or absence of psychotic symptoms. Dysthymia is a chronic low-grade unipolar depressive illness.

Clinical features of depressive disorder

Whereas everyone will at some time or other feel cheesed off, fed up or down in the dumps, it is when such symptoms become qualitatively different, pervasive or interfere with normal functioning that a depressive illness has occurred. Depressive disorder, clinical or ‘major’ depression, is characterized by disturbances of mood, speech, energy and ideas (Table 22.7). Patients often describe their symptoms in physi-

### Box 22.9 Screening questions for depressive illness

- During the last month, have you often been bothered by feeling down, depressed or hopeless?  
- During the last month, have you often been bothered by having little interest or pleasure in doing things?

If one or both of the answers is ‘yes’, assess further for depressive illness.

Clinical terms. Marked fatigue and headache are the two most common physical symptoms in depressive illness and may be the first symptoms to appear. Patients describe the world as looking grey, themselves as lacking a zest for living, being devoid of pleasure and interest in life (anhedonia). Anxiety and panic attacks are common; secondary obsessional and phobic symptoms may emerge. Symptoms should last for at least 2 weeks and should cause significant incapacity (e.g. trouble working or relating to others) to be considered an illness.

In the more severe forms, diurnal variation in mood can occur, feeling worse in the morning, after waking in the early hours with apprehension. Suicidal ideas are more frequent, intrusive and prolonged. Delusions of guilt, persecution and bodily disease are not uncommon, along with second person auditory hallucinations insulting the patient or suggesting suicide. In severe depressive illness, particularly in the elderly, concentration and memory can be so badly affected that the patient appears to have dementia (pseudodementia). Delusions of poverty and non-existence (nihilism) occur particularly in this age group. Suicide is a real risk, with the lifetime risk being approximately 5% in primary care patients, but 15% in those with depressive illness severe enough to warrant admission to hospital. Patients with bipolar disorder are also at greater risk of suicide. Screening questions for depressive illness are shown in Box 22.9.

### Epidemiology

About a third of the population will feel unhappy at any one time, but this is not the same as depressive illness; the middle-aged feel least happy compared to the young and elderly. The point prevalence of depressive illness is 5% in the community, with a further 3% having dysthymia (see below). It is more common in women, but there is no increase with age, and no difference by ethnic group or socio-economic class (apart from an inverse relationship only with dysthymia). Married and never married people have similar prevalence rates, with separated and divorced people having two to three times the prevalence. Some studies have suggested that depressive illness is becoming more common.

Depressive illnesses are more common in the presence of:

- physical diseases, particularly if chronic, stigmatizing or painful
- excessive and chronic alcohol use (probably the most depressing drug humans use)
- social stresses, particularly loss events, such as separation, redundancy and bereavement
- interpersonal difficulties with those close to the patient, especially when socially humiliated
- lack of social support, with no confiding relationship

Depressed patients with another physical disorder view themselves as more sick, visit their doctors almost four times as often as the non-depressed physically ill, stay in hospital longer, comply less with medical advice and medication, and undergo more medical and surgical procedures. Depressive illness may be associated with increased mortality (excluding suicide) in patients with physical illness, such as myocardial infarct.

### Dysthymia

Dysthymia is a mild or moderate depressive illness that lasts intermittently for 2 years or more and is characterized by tiredness and low mood, lack of pleasure, low self-esteem and a feeling of discouragement. The mood relapses and remits, with several weeks of feeling well, soon followed by longer periods of being unwell. It can be punctuated by depressive episodes of greater severity, so-called ‘double depression’.

### Seasonal affective disorder

Seasonal affective disorder is characterized by recurrent episodes of depressive illness occurring during the winter months in the northern hemisphere. Symptoms are similar to those found with atypical depressive illness, in that patients complain of hypersomnia, increased appetite (with carbohydrate craving) and weight gain, with profound fatigue. Such patients have a higher prevalence of bipolar affective disorder, and some doctors are uncertain whether the condition is different from normal depressive illness, with the accentuation of mood that naturally occurs by season. However, there is evidence that seasonal depressive illness can be successfully treated with bright light therapy given in the early morning, which causes a phase advance in the circadian rhythm of melatonin. In contrast, the same treatment given in the early evening, with consequent phase delay of melatonin secretion, is less antidepressant. Selective serotonin reuptake inhibitors (SSRIs) are alternative treatments.

### Puerperal affective disorders

Affective illnesses and distress are common in women soon after they have given birth.

‘Maternity blues’ describe the brief episodes of emotional lability, irritability and tearfulness that occur in about 50% of women 2–3 days postpartum and resolve spontaneously in a few days.
Postpartum psychosis occurs once in every 500–1000 births. Over 80% of cases are affective in type and the onset is usually within the first 2 weeks following delivery. In addition to the classical features of an affective psychosis, disorientation and confusion are often noted. Severely depressed patients may have delusional ideas that the child is deformed, evil or otherwise affected in some way, and such false ideas may lead to either attempts to kill the child or suicide. The response to speedy treatment is generally good. The recurrence rate for a psychosis in a subsequent puerperium is 20–30%.

Non-psychotic postnatal depressive disorders occur during the first postpartum year in 10% of mothers, especially in the first 3 months. Risk factors are first pregnancy, poor relationship with the partner, ambivalence about the pregnancy, and emotional personality traits. The Edinburgh Postnatal Depression Scale (EPDS) is a 10-item questionnaire and can be used as an effective screening tool. Depressive illness after childbirth is clinically similar to other depressive illnesses, but lack of emotional bonding with the baby is common.

**Differential diagnosis**
The differential diagnoses of depressive illness are shown in Table 22.8. Other psychiatric disorders are the most common misdiagnoses. Ninety per cent of patients presenting with a depressive illness while misusing alcohol will no longer be depressed 2 weeks after their last drink.

Pathological (abnormal) and normal grief are described on page 1209. Pathological grief is closely associated with depressive illness.

**Investigations**
A corroborative history can be valuable in helping to exclude differential diagnoses such as alcohol misuse and elucidating maintaining factors such as a poor relationship with a partner. Physical investigations should be guided by the history and examination. They will often include measurement of free T4 and TSH (particularly in women), calcium, sodium, potassium, mean corpuscular volume, γ-glutamyl transpeptidase, haemoglobin, white cell count, ESR or plasma viscosity. Less commonly a chest X-ray, anti-nuclear antibody, morning and evening cortisols, electroencephalogram or a brain scan are indicated.

**The aetiology of unipolar depressive disorders**
The aetiology of unipolar depressive disorders is multifactorial and a mixture of genetic and environmental factors.

**Genetic**
Unipolar depression is probably polygenic, but no linkage has been firmly identified. The risk of unipolar depression in a first-degree relative of a patient is approximately three times the risk of the non-affected. The concordance of unipolar depression in monozygotic twins is between 30 and 60%, the concordance increasing with more recurrent illnesses. Polymorphisms that increase the risk of depression involve monoamines and their receptors. The issue is complicated by the genetic influence on sleep habits, ‘neurotic’ personality, and even life events, which are all involved in the genesis of depressive illness.

**Biochemical**
The monoamine deficiency theory of depressive illness is supported by the efficacy of monoamine reuptake inhibitors and the depressive effect of dietary tryptophan depletion. Neuroendocrine tests also suggest that the serotonin neurotransmitter system is downregulated. 5-HT1A and 5-HT2 receptor subtypes are thought most likely to be involved. Receptor-labelled functional brain scans suggest that dopamine underactivity is related to psychomotor retardation.

**Hormonal**
Cushing’s syndrome is the most potent cause of so-called ‘organic’ depressive illness, with 50–80% of patients with Cushing’s suffering from a depressive illness. Corticosteroid treatment causes significant mood disturbance. Nearly half of patients with ‘functional’ depressive illness have raised cortisol levels, and this is associated with adrenal gland enlargement. Hypercortisolaemia can cause hippocampal damage, which has been found in chronic severe depressive illness. All these data suggest that cortisol may play a role in causing depressive illness.

In contrast, *atypical depressive illness*, with prominent hypomnia and weight gain, is associated with a down-regulated hypothalamic–pituitary–adrenal axis, supporting the heterogeneity of depressive disorders.

**Neural changes and neuronal growth**
The use of functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) has revealed a number of abnormalities in the brains of patients with major depression. Increased brain ventricle volume, orbitofrontal, dorso-lateral frontal and anterior cingulate cortex altered activation have all been implicated. The hippocampus is smaller in several stress-related neuropsychiatric disorders such as recurrent depression. This may be related to hypercortisolaemia. Both emotional and cognitive functions are therefore involved in the neural basis of depression.

Recent work suggests that depressive illness is associated with reduced growth of new neurones in parts of the brain involved with emotional expression, such as the hippocampus.

**Sleep**
A reduced time between onset of sleep and REM sleep (shortened REM latency) and reduced slow wave sleep both...
occur in depressive illness. These abnormalities persist in some patients when they are not depressed. Families with several sufferers of depressive illness can share these traits, suggesting that sleep patterns may be inherited and predispose to depression.

Childhood traumas and personality
Physical, sexual and emotional abuse or neglect in childhood all predispose adults to depressive illness, but the effect is non-specific. Both ‘neurotic’ (emotional) and perfectionist personality traits are risks for depressive illness, and these may be determined as much by genetic factors as childhood environment.

Social
Thirty per cent of women will develop a depressive illness after a severe life event or difficulty, such as a divorce, and this is compounded by low self-esteem and a lack of a confiding relationship. Unemployment is a significant risk factor in men.

An integrated model of aetiology
Stress is more likely to trigger depressive illness in a person predisposed by lack of social support and/or certain personality traits. Stress in turn triggers various brain changes in both stress hormones (such as the release of corticotrophin-releasing hormone) and neurotransmitters (e.g. serotonin) that are both known to be altered in depressive illness. We can thus start to glimpse the model of an integrated biopsychosocial model of depressive illness. This model challenges dualistic ideas that depressive illnesses are either psychological or physical; depressive illnesses involve both the mind and the body, which are themselves indivisible.

Treatment of depressive illness
The patient needs to know the diagnosis to provide understanding and rationalization of the overwhelming distress inherent in depressive illness. Knowing that self-loathing, guilt and suicidal thoughts are caused by the illness can be ‘antidepressant’ on its own. The further treatment of depressive disorders involves physical, psychological and social interventions (Box 22.10). Patients who are actively suicidal, severely depressed or with psychotic symptoms should be admitted to hospital (necessary for perhaps 1 in 1000 patients with clinical depression in primary care). This provides the patient a break from self-care, and allows support, listening, observation, prevention of suicide and close monitoring of treatments. Avoid the pitfall of not treating a depressive illness just because it seems an ‘understandable’ reaction to serious illness or difficult circumstances. This is particularly likely to happen if the patient is elderly, severely or even terminally ill.

Exercise
There is good evidence that regular exercise, particularly involving other people, can help relieve depressive illness of mild or moderate severity. The benefit is independent of a physical training effect.

Drugs used in the treatment of clinical depression
- Recreational drugs such as alcohol should be stopped.
- Prescribed medicines suspected of exacerbating depression, such as corticosteroids, should be gradually stopped or reduced to a safe minimum.
- The first course of antidepressant drugs is effective in relieving clinical depression in 60–70% of patients, if given in adequate doses for a sufficient time to the correctly diagnosed patient. Such treatment is more successful when accompanied by sufficient patient education and regular follow-up, particularly a week after starting treatment and throughout the following 6 weeks. Dysthymia responds less well to antidepressants than does a depressive episode.
- The commonest two pharmacological types of antidepressants are tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs). All antidepressants have similar efficacy and speed of onset. Choice depends on their side-effects, which can be used to positive effect (sedating drugs given at night to enhance sleep), and their safety. Patients should be warned about side-effects and that it will take two or more weeks before a positive benefit is apparent. This is much slower than the time taken to alter neurotransmitter release and reuptake. The longer time is consistent with receptor adaptation, although recent animal work shows that antidepressants are growth factors that increase the development of new neurones from progenitor cells in the hippocampus. Drugs should normally be started at a low dose and increased, depending on side-effects and efficacy. A course of antidepressants should be given until 4 months after recovery to prevent relapse. The two greatest problems with these drugs are persuading the patient to take them and adherence, since 80% of the UK public wrongly believe that they are addictive.
- Psychotic depression needs either electroconvulsive therapy or a combination of an antidepressant and an antipsychotic drug.
- Bipolar depressive illness is best treated initially with mood stabilizers (see p. 1205).
Selective serotonin reuptake inhibitors (SSRIs)

SSRIs selectively inhibit the reuptake of the monoamine serotonin (5-HT) within the synapse, and are thus termed ‘selective serotonin reuptake inhibitors’ or SSRIs. Citalopram and its laevo isomer escitalopram, fluvoxamine, fluoxetine, paroxetine and sertraline have the advantage of causing less serious or disabling side-effects than tricyclics. For instance, SSRIs do not usually cause significant weight gain. Because of their long half-lives they can also be given just once a day, normally in the morning after breakfast. For these reasons patients adhere more to treatment and therefore SSRIs are now first-line treatments for depressive disorders. Normal doses are between 20 and 60 mg, with sertraline and fluvoxamine needing higher doses. The most common side-effects resemble a ‘hangover’ and include nausea, vomiting, headache, diarrhoea and dry mouth. Insomnia and paradoxical agitation can occur when first starting the drugs. Recent studies suggest that adolescents, in particular, may develop suicidal thoughts with SSRIs. Further studies suggest that this is a small risk, if present, and no study has shown a significant increased risk of suicide itself. One in five patients also has sexual side-effects, such as erectile dysfunction and loss of libido. Uncommon side-effects include restless legs syndrome (see p. 626) and hyponatraemia.

A toxic hyperserotonergic state (‘serotonin syndrome’) can be caused by the ingestion of two or more drugs that increase serotonin levels, e.g. an SSRI combined with a monoamine oxidase inhibitor (MAOI), dopaminergic drugs (e.g. selegiline) or a tricyclic antidepressant. Symptoms include agitation, confusion, tremor, diarrhoea, tachycardia and hypertension; hyperthermia is characteristic. Treatment is supportive.

SSRIs have also been associated with a specific withdrawal syndrome (discontinuity syndrome). This is characterized by shivering, anxiety, dizziness, ‘electric shocks’, headache and nausea. Patients should be warned not to leave out a dose and to gradually reduce SSRIs when stopping them. All antidepressants have the potential to cause a withdrawal syndrome if suddenly stopped.

Tricyclic antidepressants (TCAs)

Dosulepin, imipramine and amitriptyline are the three most commonly used in the UK, but many related compounds have been introduced, some having fewer autonomic and cardiotoxic effects (e.g. lofepramine). These drugs potentiate the action of the monoamines, noradrenaline (norepinephrine) and serotonin, by inhibiting their reuptake into nerve terminals (Fig. 22.3). Other tricyclics in common use include nortriptyline, doxepin and clomipramine. Depending on the particular drug, normal doses are between 75 and 150 mg. Having been available for more than 40 years, there is more evidence of the effectiveness of TCAs in depressive illness than for any other group of antidepressants. They are the drugs most commonly used in severe depressive illness.

TCAs have a number of side-effects (Table 22.9). In long-term treatment or prophylaxis, weight gain is most troublesome. Because of their toxicity in overdose, it is wisest not to prescribe them to outpatients with suicidal thoughts without monitoring or giving the drugs to a reliable family member to look after.

Trazodone is different from other tricyclic antidepressants and acts by blockade of 5H2 receptors.

![Fig. 22.3 Sites of action of antidepressants with examples.](image)

SNRIs, NSSAs and NRIs: antidepressants

The latest generation of antidepressants block a number of different neurotransmitter receptors both at the synapse and elsewhere. Their different receptor profiles cause different side-effects.

Venlafaxine is a potent blocker of both serotonin and noradrenaline (norepinephrine) reuptake (SNRI). It has negligible affinity for other neurotransmitter receptor sites and so produces less sedation and fewer antimuscarinic effects. It can be given in slow-release form with the advantage of once-daily dosage. Nausea is the commonest side-effect and patients should be monitored for hypertension. It should not be prescribed in those with either uncontrolled hypertension or in those prone to cardiac arrhythmias.

</table>

**Mirtazapine** is a 5-HT₂ and 5-HT₃ receptor antagonist and a potent α₂-adrenergic blocker. The consequent effect is to increase both noradrenaline (norepinephrine) and selective serotonin transmission: an NSSA. It can be given at night to aid sleep and rarely causes sexual side-effects. Mirtazapine can be sedating in low dose and can cause weight gain. An uncommon adverse effect is agranulocytosis.

**Reboxetine** is a selective noradrenaline (norepinephrine) reuptake inhibitor (NaRI). It is not sedating and may help reduced motivation and energy. Weight gain is not reported. Dry mouth, insomnia, constipation, urinary hesitancy and tachycardia are reported side-effects.

**Monoamine oxidase inhibitors (MAOIs)**

These act by irreversibly inhibiting the intracellular enzymes monoamine oxidase A and B, leading to an increase of nor-epinephrine (noradrenaline), dopamine and 5-HT in the brain (see Fig. 22.3). Because of their side-effects and restrictions while taking them, they are rarely used by non-psychiatrists. MAOIs also produce a dangerous hypertensive reaction with foods containing tyramine or dopamine and therefore a restricted diet is prescribed. Tyramine is present in cheese, pickled herrings, yeast extracts, certain red wines, and any food, such as game, that has undergone partial decomposi-
tion. Dopamine is present in broad beans. MAOIs interact with drugs such as pethidine and can also occasionally cause liver damage.

**Reversible inhibitors of monoamine oxidase A (RIMAs)**

An example is moclobemide; usual dose 300 mg daily. These drugs appear to have fewer side-effects (insomnia and headache, but some sexual problems) and constitute a low risk in overdose. Patients prescribed such antidepressants should be told that they can eat a normal diet, but should be careful to avoid excessive amounts of food rich in tyramine (see above).

**Antidepressant augmentation**

If two trials of antidepressants have failed, adding a second concomitant drug, e.g. lithium, can sometimes be helpful.

**Antidepressant use in general medicine**

- **Cardiac disease.** In patients with cardiac disease, SSRIs, lofepramine and trazodone are preferred over more quinidine-like compounds. MAOIs and mirtazapine do not affect epileptic thresholds. SSRIs are metabolized by the cytochrome P450 system, unlike venlafaxine, mirtazapine and reboxetine; the latter therefore have fewer drug interactions.

  - **Herbal medicine.** Care should be taken not to prescribe antidepressants while a patient is taking the herbal antidepressant St John’s wort, which interacts with serotonergic drugs in particular.

  - **Elderly.** Doses of antidepressants should initially be halved in the elderly and in patients with renal or hepatic failure.

  - **Pregnancy.** Antidepressants should be avoided if possible in pregnancy and breast-feeding. If other treatments are ineffective, the risks of drug therapy should be balanced against taking no treatment, since depression can affect fetal progress and future mother-child bonding. Tricyclic antidepressants are generally believed to be safe in pregnancy, with no significant increase in congenital malformations in fetuses exposed to them. However, occasionally their antimuscarinic side-effects produce jitteriness, sucking problems and hyperexcitability in the newborn. Postpartum plasma levels of babies breast-fed by treated mothers are negligible. SSRIs do not seem to be teratogenic but manufacturers advise against their use in pregnancy until more data are available. Pulmonary hypertension in the newborn is a rare complication. MAOIs should be avoided during pregnancy because of the possibility of a hypertensive reaction in the mother.

**Electroconvulsive therapy (ECT)**

Although the use of ECT is declining in the UK, it is still the treatment of choice in severe life-threatening depressive illness, particularly when psychotic symptoms are present. It is sometimes essential treatment when the patient is dangerously suicidal or refusing to eat and drink. The treatment involves the passage of an electric current across two electrodes applied to the anterior temporal areas of the scalp, in order to induce an epileptic fit. The fit is the essential part of the treatment. Before the treatment is given, the patient is given a general anaesthetic and receives a muscle relaxant to prevent injury during the fit. Treatments are normally given twice a week for 3–6 weeks.

ECT is a controversial treatment, yet it is remarkably safe and free of serious side-effects. Post-ictal confusion and headache are not uncommon, but transient. Short-term retrograde amnesia and a temporary defect in new learning can occur during the weeks of treatment, but these are short-lived effects.

**Uncommonly used treatments**

Transcranial magnetic stimulation (TMS) shows moderate efficacy, but is uncommonly used. Psychosurgery is very occasionally considered in patients with severe intractable depressive illness, when all other treatments have failed (see p. 1211). A third improve remarkably, while a further third improve somewhat. Vagal nerve and deep brain stimulation may represent major advances in the management of chronic and treatment-refractory depressive disorders, but definitive trials are awaited.
Psychological treatments

Cognitive behaviour therapy (CBT)
Beck developed CBT to reverse the negative cognitive triad with which patients regarded themselves, their situation and their futures. It involves the identification of the negative automatic thoughts that maintain the negative perceptions that feed depression. They commonly include catastrophizing (e.g., making a ‘mountain out of a molehill’), overgeneralizing (e.g., ‘I failed an exam; therefore I am a failure as a person.’), categorical (‘black or white’) thinking (e.g., ‘My work is either perfect or abysmal.’). CBT then involves identifying the links between these thoughts, consequent behaviour, and feeling low, and then testing their logic. This is done by considering the evidence either in the therapy sessions (e.g., Q: ‘Did you pass the other exams you took?’ A: ‘Yes, I guess I did.’) or by empirical ‘experiments’ (e.g., showing the ‘abysmal’ work to a colleague and asking their opinion).

There is good evidence that individual CBT is as effective as antidepressant drugs for mild and moderate depressive illness. CBT is also effective in preventing a relapse of clinical depression. Individual CBT is more effective than group delivered therapy, and there is preliminary evidence that computer delivered CBT programmes are also helpful.

Interpersonal psychotherapy
This psychotherapy is probably as effective as both antidepressants and CBT in mild and moderate clinical depression. The therapist focuses on a patient’s interpersonal relationships involved in, or affected by, their illness (particularly relationship changes or deficiencies), using problem-solving techniques to help the patient to find solutions.

Other psychotherapies
Couple therapy is particularly effective when a patient is in a relationship with problems; both the patient and partner attend therapy. Family therapy is effective not only in a family with problems, but also as a way of helping the family to help the patient get better. It may involve understanding one family member’s ‘depression’ as a systemic ‘solution’ for a wider problem within the family.

Social treatments
Many patients with clinical depression have associated social problems (see Box 22.10). Assistance with social problems can make a significant contribution to clinical recovery. Other social interventions include the provision of group support, social clubs, occupational therapy and referral to a social worker. Educational programmes, self-help groups, and informed and supportive family members can help improve outcome.

Prognosis
People with major depressive illness are between 1.5 and 2 times more likely to die than not depressed people in the next 16 years, and the risks are not only suicide, but also cardiovascular, which makes effective treatment and prevention imperative.

The majority of patients have recovered by 6 months in primary care and 12 months in secondary care. About a quarter of patients attending hospital with depressive illnesses will have a recurrence within a year, and three-quarters will have a relapse within 10 years. Patients with recurrent depressive illnesses should be offered prevention. This may involve CBT that concentrates on relapse prevention, other forms of psychotherapy, antidepressant medication and advice on lifestyle activities such as regular exercise. Full-dose antidepressants are the most effective prophylaxis in recurrent depressive disorders.

FURTHER READING

MANIA AND HYPOMANIA

Mania and hypomania almost always occurs as part of a bipolar disorder. The clinical features of mania include a marked elevation of mood, characterized by euphoria, overactivity and disinhibition (Table 22.10). Hypomania is the mild form of mania. Hypomania lasts a shorter time and is less severe, with no psychotic features and less disability. Hypomania can be distinguished from normal happiness by its persistence, non-reactivity (not provoked by good news and not affected by bad news) and social disability. The social disability of mania can be severe, with disinhibited behaviour leading to significant debts (from overspending), lost relationships (from promiscuity or irritability), social ostracism and lost employment (from reckless or disinhibited behaviour).

Some patients have a rapid cycling illness, with frequent swings from one mood state to another. A mixed affective state occurs when features of mania and depressive illness are seen in the same episode. Cyclothymia is a personality trait with spontaneous swings in mood not sufficiently severe or persistent to warrant another diagnosis.

Table 22.10 Clinical features of mania
Differential diagnosis

Acute intoxication with recreational drugs such as amphetamines, amphetamine derivatives (MDMA: Ecstasy), and cocaine can mimic mania. Long-term use of cannabis can also induce an illness with manic features. In one study a quarter of patients with Cushing’s syndrome had mania. Similarly corticosteroids can induce mania less commonly than depressive illness. Dopamine agonists (e.g. bromocriptine) are also known to sometimes induce mania. The excited phase of catatonic schizophrenia can sometimes be mistaken for mania.

Epidemiology

The lifetime prevalence of bipolar affective disorder is 1% across the world. Unlike unipolar depressive illness, it is equally common in men and women, supporting its different aetiology. There is no variation by socio-economic class or race. The mean age of onset is 21; earlier than unipolar depression. The higher prevalence found in divorced people is probably a consequence of the condition.

Aetiology

Genetic

There is strong evidence for a genetic aetiology in this disorder. There is a 60–80% concordance rate in monozygotic twins, compared to 15% in dizygotic twins, suggesting a high rate of heritability. Adoption studies show similar rates, so this high rate is probably genetic and not due to the family environment. Linkage studies have so far proved disappointing, with several suggestive chromosome linkages being found, suggesting there is no single gene with a large effect. Instead it is likely that the condition will prove to be polygenic.

Biochemical

Brain monoamines, e.g. serotonin, seem to be increased in mania. Dexamethasone tends not to suppress cortisol levels in patients with mania, suggesting a similar pattern of non-suppression to that seen in severe depressive illness. Antidepressants (especially tricyclics) may induce a manic episode in someone with bipolar disorder.

Psychological

The effect of life events is much weaker in bipolar compared to unipolar illnesses, with most effect apparent at first onset. Similarly, personality does not seem to be a major influence, in contrast to unipolar depression, although there is some evidence of a link with the creativity and divergent thinking that is an advantage in the right occupation.

Treatment

Acute mania

- First, stop any antidepressant being taken.
- Acute mania is treated with an atypical antipsychotic (neuroleptic), sodium valproate or lithium. The atypical antipsychotics olanzapine, quetiapine and risperidone are particularly recommended, especially with behavioural disturbance. Doses are similar to those used in schizophrenia. The behavioural excitement and overactivity are usually reduced within days, but elation, grandiosity and associated delusions often take longer to respond.
- Severe mania is best treated with a combination of valproic acid or lithium and a neuroleptic, allowing the neuroleptic to be withdrawn after the first 2 or 3 weeks. First attacks of mania usually require treatment for up to 3 months.
- Valproic acid is also helpful in hypomania or in rapidly cycling illnesses (see below). Recent work suggests it can be sometimes helpful to add to the regimen a benzodiazepine, such as lorazepam.

Prevention in bipolar disorders

Since bipolar illnesses tend to be relapsing and remitting, prevention of recurrence is the major therapeutic challenge in management. A patient who has experienced more than two episodes of affective disorder within a 5-year period is likely to benefit from preventative treatments. Recommendations include lithium, olanzapine, and valproic acid (so long as the patient is not a woman at risk of pregnancy).

Lithium (carbonate or citrate) is one of the two main agents used for prophylaxis in patients with repeated episodes of bipolar illness. It is rapidly absorbed into the gastrointestinal tract and more than 95% is excreted by the kidneys; small amounts are found in the saliva, sweat and breast milk. Renal clearance of lithium correlates with renal creatinine clearance. Lithium is a mood-stabilizing drug that prevents mania more than depression. It reduces the frequency and severity of relapses by half and significantly reduces the likelihood of suicide. Its mode of action is unknown, but lithium is known to act on the serotoninergic system. Poor responses to lithium are associated with a negative family history, an unstable premorbid personality, and a rapid cycling illness. Recent pharmacogenetic work suggests that certain polymorphisms may predict response. Screening prior to starting lithium:

- Thyroid disease (free T₄, TSH and thyroid autoantibodies). Lithium interferes with thyroid function and can produce frank hypothyroidism. The presence of thyroid autoantibodies increases the risk.
- Renal disease (serum urea and creatinine, estimated creatinine clearance and 24-hour urinary volume). Long-term treatment with lithium causes two renal problems: nephrogenic diabetes insipidus (DI) and reduced glomerular function (see p. 575). The best screen for DI is to ask the patient about polyuria and polydipsia. Tests should include serum urea and creatinine, and 24-hour urinary volume if DI is suspected.

The therapeutic range for prophylaxis is 0.5–1.0 mmol/L. Lithium levels should be checked every 3 months, along with regular thyroid (free T₄ and TSH) and renal function tests.

Patients should carry a lithium card with them at all times, be advised to avoid dehydration, and be warned of drug interactions, such as NSAIDs and diuretics.

Other side-effects of lithium include:

- nausea and diarrhoea
- a fine tremor (15%)
- polyuria and polydipsia (see above)
- weight gain, mainly through increased appetite.

Lithium toxicity begins to occur when the serum concentration exceeds 1.5 mmol/L. Symptoms include drowsiness, nausea, vomiting, blurred vision, a coarse tremor, ataxia and dysarthria. Toxicity is more likely when the patient is dehydrated or with a drug interaction. Such symptoms progress to delirium and convulsions, and coma and death can occur. As a rule, lithium is not advised during pregnancy, particularly in the first trimester, because of an increased risk of fetal malformation (Ebstein’s anomaly). Between 25% and 30% of women with a history of bipolar disorder relapse within 2
weeks of delivery. Restarting lithium within 24 hours of delivery (if the mother is prepared to forego breast-feeding) markedly reduces the risk of relapse.

**Valproic acid** (as the semisodium salt) is recommended both in prophylaxis and treatment of manic states. Second-line treatments include carbamazepine and lamotrigine. Some patients who do not respond to lithium may respond to these anticonvulsants or a combination of both. Patients with rapid cycling illnesses show a better response to anticonvulsants than to lithium. For antimanic treatment, dosage in the initial stage of treatment will be 200 mg twice daily of carbamazepine, increasing to a normal dose of 800–1000 mg. Other drugs which appear to exert a prophylactic mood-stabilizing effect include olanzapine and risperidone. Both carbamazepine and valproate can be teratogenic (neural tube defects) and should be avoided in pregnancy. Other side-effects of these drugs are given on page 1143.

**Prognosis**
The average duration of a manic episode is 2 months, with 95% making a full recovery in time. Recurrence is the rule in bipolar disorders, with up to 90% relapsing within 10 years.

**SUICIDE AND DELIBERATE SELF-HARM** *(see also p. 933)*

Suicide accounts for 2% of male and 1% of female deaths in England and Wales each year, equivalent to a rate of 8 per 100 000. The rate increases with age, peaking for women in their sixties and for men in their seventies. Suicide is the second most common cause of mortality in 15- to 34-year-olds. Approximately 15% of people who have suffered a severe depressive disorder (requiring admission) will eventually commit suicide, with 6% doing so in the 10 years after their first admission. Suicide rates in schizophrenia sufferers are likewise high, being 20–50 times the rate in the general population; 20–40% of people with schizophrenia make suicide attempts, and 9–13% are successful. The highest rates of suicide have been reported in rural southern India (148 per 100 000 in young women and 58 per 100 000 in young men) and in eastern Europe (30–40 per 100 000), while the lowest are those of Spain (3.9 per 100 000) and Greece (2.8 per 100 000), but such variations may reflect differences in reporting, which may be related to religion, as much as genuine differences. Factors that increase the risk of suicide are indicated in Table 22.11.

A distinction must be drawn between those who attempt suicide – deliberate self-harm (DSH) – and those who succeed (suicides):

- The majority of cases of DSH occur in people under 35 years of age.
- The majority of suicides occur in people aged over 60.
- Suicides are more common in men, while DSH is more common in women.
- Suicides are more common in older men, although rates are falling. Rates in young men are rising fast throughout the UK and Western Europe.
- Suicides in women are slowly falling in the UK.
- Approximately 90% of cases of DSH involve self-poisoning.
- A formal psychiatric diagnosis usually can be made retrospectively in suicide, but is unusual in DSH.

There is, however, an overlap between DSH and suicide. Between 1% and 2% of people who attempt suicide will kill themselves in the year following DSH. The risk of suicide stays elevated in those with DSH, with 0.5% per annum committing suicide in the following 20 years. In the UK, there are 100 000 cases of DSH each year, and the overwhelming majority of these are seen and treated within accident and emergency departments.

The guidelines (Box 22.11) for the assessment of such patients will help ensure that the risk factors relating to suicide are covered. Indications for referral to a psychiatrist before discharge from hospital are also given.

In general, it is worth trying to interview a family member or close friend and check these points with them. Requests for immediate re-prescription on discharge should be denied, except in cases of essential medication. In such cases, however, only 3 days’ supply of medication should be given, and the patient should be requested to report to their general practitioner or to their psychiatric outpatient clinic for further supplies. Occasionally involuntary admission under the Mental Health Act may be required (p. 1222).

**ANXIETY DISORDERS**

These are conditions in which anxiety dominates the clinical symptoms. They are classified according to whether the anxiety is persistent (general anxiety) or episodic, with the episodic conditions classified according to whether the episodes are regularly triggered by a cue (phobia) or not (panic disorder). The differential diagnoses of anxiety disorders are given in Table 22.12. A patient with one anxiety disorder may well in time develop others.

**General anxiety disorder**

This occurs in 4–6% of the population and is more common in women. Symptoms are persistent and often chronic. General anxiety disorder (GAD) and its related panic disorder are differential diagnoses for functional somatic syndromes, owing to the many physical symptoms that are caused by these conditions.

**Clinical features**

The physical and psychological symptoms are outlined in Table 22.13. The patient looks worried, has a tense posture,
restless behaviour and a pale and sweaty skin. The patient takes time to go to sleep, and when asleep wakes intermit-
tently with worry dreams. Associated conditions include the hyperventilation syndrome, which is even more common in panic disorder (Box 22.12). The patient will sigh deeply, partic-
cularly when talking about the stresses in their life.

Mixed anxiety and depressive disorder

This disorder is probably the commonest mood disorder in primary care, in which there are equal elements of both

Suicide and deliberate self-harm

Anxiety disorders

Box 22.11 Guidelines for the assessment of patients who harm themselves

Questions to ask: be concerned if positive answer

- Was there a clear precipitant/cause for the attempt?
- Was the act premeditated or impulsive?
- Did the patient leave a suicide note?
- Did the patient make the attempt in strange surroundings (i.e. away from home)?
- Would the patient do it again?

Other relevant factors

- Has the precipitant or crisis resolved?
- Is there continuing suicidal intent?
- Does the patient have any psychiatric symptoms?
- What is the patient’s social support system?
- Has the patient inflicted self-harm before?
- Has anyone in the family ever taken their life?
- Does the patient have a physical illness?

Indications for referral to a psychiatrist

Absolute indications include:

- Clinical depression
- Psychotic illness of any kind
- Clearly preplanned suicidal attempt which was not intended to be discovered
- Persistent suicidal intent (the more detailed the plans, the more serious the risk)
- A violent method used.

Other common indications include:

- Alcohol and drug abuse
- Patients over 45 years, especially if male, and young adolescents
- Those with a family history of suicide in first-degree relatives
- Those with serious (especially incurable) physical disease
- Those living alone or otherwise unsupported
- Those in whom there is a major unresolved crisis
- Persistent suicide attempts
- Any patients who give you cause for concern.

anxiety and depression, showing how closely associated these two abnormal mood states are.

Panic disorder

Panic disorder is diagnosed when the patient has repeated sudden attacks of overwhelming anxiety, accompanied by severe physical symptoms, usually related to both hyperven-
tilation (Box 22.12) and sympathetic nervous system activity (palpitations, tremor, restlessness and sweating). The lifetime prevalence is 5%. Patients with panic disorder often have catastrophic illness beliefs during the panic attack, such as convictions that they are about to die from a stroke or heart attack. The fear of a stroke is related to dizziness and head-
ache. Fear of a heart attack accompanies chest pain (atypical chest pain). The occasional patient with long-standing attacks may deny feeling anxious and simply report the physical symptoms.

Aetiology

General anxiety and panic disorders occur four or more times, as commonly in first-degree relatives of affected patients,
Box 22.12 The hyperventilation syndrome

Features
Panic attacks – fear, terror and impending doom – accompanied by some or all of the following:
- dyspnoea (trouble getting a good breath in)
- palpitations
- chest pain or discomfort
- suffocating sensation
- dizziness
- paraesthesiae in hands and feet
- peri-oral paraesthesiae
- sweating
- carpopedal spasms

Cause
Overbreathing leading to a decrease in \( \text{Paco}_2 \) and an increase in arterial \( \text{pH} \), leading to relative hypocalcaemia.

Diagnosis
A provocation test – voluntary overbreathing for 2 minutes – provokes similar symptoms; rebreathing from a large paper bag relieves them.

Management
- Explanation and reassurance is given.
- The patient is trained in relaxation techniques and slow controlled breathing.
- The patient is asked to breathe into a closed paper bag.

Box 22.13 Phobias

A phobia is an abnormal fear and avoidance of an object or situation. Phobias are common (8% prevalence), disabling and treatable with behaviour therapy.

Phobic (anxiety) disorders
Phobias are common conditions in which intense fear is triggered by a stimulus, or group of stimuli, that are predictable and normally cause no particular concern to others (e.g. agoraphobia, claustrophobia, social phobia). This leads to avoidance of the stimulus (Box 22.13). The patient knows that the fear is irrational, but cannot control it. The prevalence of all phobias is 8%, with many patients having more than one. Many phobias of ‘medical’ stimuli exist (e.g. of doctors, dentists, hospitals, vomit, blood and injections) which affect the patient’s ability to receive adequate healthcare.

Aetiology
Phobias may be caused by classical conditioning, in which a response (fear and avoidance) becomes conditioned to a previously benign stimulus (a lift), often after an initiating emotional shock (being stuck in a lift). In children, phobias can arise through imagined threats (e.g. stories of ghosts told in the playground). Women have twice the prevalence of most phobias than men. Phobias aggregate in families, with increasing evidence of the importance of genetic factors being published.

Agoraphobia
Translated as ‘fear of the market place’, this common phobia (4% prevalence) presents as a fear of being away from home, with avoidance of travelling, walking down a road and supermarkets being common cues. This can be a very disabling condition, since the patient can be too unwell to ever leave home, particularly by themselves. It is often associated with claustrophobia, a fear of enclosed spaces.

Social phobia
This is the fear and avoidance of social situations: crowds, strangers, parties and meetings. Public speaking would be the sufferer’s worst nightmare. It is suffered by 2% of the population.

Simple phobias
The commonest is the phobia of spiders (arachnophobia), particularly in women. The prevalence of simple phobias is 7% in the general population. Other common phobias include insects, moths, bats, dogs, snakes, heights, thunderstorms and the dark. Children are particularly phobic about the dark, ghosts and burglars, but the large majority grow out of these fears.

Treatment of anxiety disorders

Psychological treatments
For many people with brief episodes of an anxiety disorder, a discussion with a doctor concerning the nature of anxiety is usually sufficient.

- Relaxation techniques can be effective in mild/moderate anxiety. Relaxation can be achieved in many ways, including complementary techniques such as meditation and yoga. Conventional relaxation training involves slowing down the rate of breathing, muscle relaxation and mental imagery.
- Anxiety management training involves two stages. In the first stage, verbal cues and mental imagery are used to arouse anxiety to demonstrate the link with symptoms. In the second stage, the patient is trained to reduce this anxiety by relaxation, distraction and reassuring self-statements.
- Biofeedback is useful for showing patients that they are not relaxed, even when they fail to recognize it, having become so used to anxiety. Biofeedback involves feeding back to the patient a physiological measure that is abnormal in anxiety. These measures may include electrical resistance of the skin of the palm, heart rate, muscle electromyography or breathing pattern.
- Behaviour therapies are treatments that are intended to change behaviour and thus symptoms. The most common and successful behaviour therapy (with 80% success in some phobias) is graded exposure, otherwise known as systematic desensitization. First, the patient rates the phobia into a hierarchy or ‘ladder’ of worsening fears (e.g. in agoraphobia: walking to the front door with a coat on; walking out into the garden; walking to the end of the road). Second, the patient practices exposure to the least fearful stimulus until no fear is felt. The patient then moves ‘up the ladder’ of fears until they are cured.
Cognitive behaviour therapy (CBT) (see p. 1204) is the treatment of choice for panic disorder and general anxiety disorder because the therapist and patient need to identify the mental cues (thoughts and memories) that may subtly provoke exacerbations of anxiety or panic attacks. CBT also allows identification and alteration of the patient’s ‘schema’, or way of looking at themselves and their situation, that feeds anxiety.

Drug treatments
Initial ‘drug’ treatment should involve advice to gradually cease taking anxiogenic recreational drugs such as caffeine and alcohol (which can cause a rebound anxiety and withdrawal). Prescribed drugs used in the treatment of anxiety can be divided into two groups: those that act primarily on the central nervous system, and those that block peripheral autonomic receptors.

Benzodiazepines are centrally acting anxiolytic drugs. They bind to specific receptors that stimulate release of the inhibitory transmitter γ-aminobutyric acid (GABA). Diazepam (5 mg twice daily, up to 10 mg three times daily in severe cases), alprazolam (250–500 μg three times daily) and chlordiazepoxide have relatively long half-lives (20–40 hours) and are used as anti-anxiety drugs in the short term. Side-effects include sedation and memory problems, and patients should be advised not to drive while on treatment. They can cause dependence and tolerance within 4–6 weeks, particularly in dependent personalities. The withdrawal syndrome (Table 22.14) can occur after just 3 weeks of continuous use and is particularly severe when high doses have been given for a longer time. Thus, if a benzodiazepine drug is prescribed for anxiety, it should be given in as low a dose as possible, preferably on an ‘as necessary’ basis, and for not more than 2–4 weeks. A withdrawal programme from chronic use includes changing the drug to the long-acting diazepam, followed by a very gradual reduction in dosage.

Most SSRIs (e.g. fluoxetine, paroxetine, sertraline, escitalopram, citalopram) are useful symptomatic treatments for general anxiety and panic disorders, as well as some phobias (social phobia). Imipramine and clomipramine are alternative symptomatic treatments for panic disorder and GAD. Treatment response is often delayed several weeks; a trial of treatment should last 3 months.

Many of the symptoms of anxiety are due to an increased or sustained release of epinephrine (adrenaline) and norepinephrine (noradrenaline) from the adrenal medulla and sympathetic nerves. Thus, beta-blockers such as propranolol (20–40 mg two or three times daily) are effective in reducing peripheral symptoms such as palpitations, tremor and tachycardia, but do not help central symptoms such as anxiety.

### Acute stress reactions and adjustment disorders

#### Acute stress reaction
This occurs in individuals without any other psychiatric disorder, in response to exceptional physical and/or psychological stress. While severe, such a reaction usually subsides within days. The stress may be an overwhelming traumatic experience (e.g. accident, battle, physical assault, rape) or a sudden change in the social circumstances of the individual, such as a bereavement. Individual vulnerability and coping capacity play a role in the occurrence and severity of an acute stress reaction, as evidenced by the fact that not all people exposed to exceptional stress develop symptoms. Symptoms usually include an initial state of feeling ‘dazed’ or numb, with inability to comprehend the situation. This state may be followed either by further withdrawal from the situation or by anxiety and overactivity. No treatments beyond reassurance and support are normally necessary.

#### Adjustment disorder
This disorder can follow an acute stress reaction and is common in the general hospital. This is a more prolonged (up to 6 months) emotional reaction to a significant life event, with low mood joining the initial shock and consequent anxiety, but not of sufficient severity or persistence to fulfil a diagnosis of a mood or anxiety disorder. Supportive counseling is usually a successful treatment, allowing facilitation of unexpressed feelings, elucidation of unspoken fears, and education about the likely future.

#### Pathological (abnormal) grief
This is a particular kind of adjustment disorder. It can be characterized as excessive and/or prolonged grief, or even absent grieving with abnormal denial of the bereavement. Usually a relative will be stuck in grief, with insomnia and repeated dreams of the dead person, anger at doctors or even the patient for dying, consequent guilt in equal measure, and an inability to ‘say good-bye’ to the loved person by dealing with their effects. **Guided mourning** uses cognitive and behavioural techniques to allow the relative to stop grieving and move on in life.

Normal grief immediately follows bereavement, is expressed openly, and allows a person to go through the social ceremonies and personal processes of bereavement. The three stages are, first, shock and disbelief, second, the emotional phase (anger, guilt and sadness) and, third, acceptance and resolution. This normal process of adjustment may take up to a year, with movement between all three stages occurring in a sometimes haphazard fashion.

#### Post-traumatic stress disorder (PTSD)
This arises as a protracted response to a stressful event or situation of an exceptionally threatening nature, likely to cause pervasive distress in almost anyone. Causes include natural or human disasters, war, serious accidents, witnessing the violent death of others, being the victim of sexual abuse, rape, torture, terrorism or hostage-taking. Predisposing factors such as personality, previously unresolved

traumas, or a history of psychiatric illness may prolong the course of the syndrome. These factors are neither necessary nor sufficient to explain its occurrence, which is most related to the intensity of the trauma, the proximity of the patient to the traumatic event, and how prolonged or repeated it was. Functional brain scan research suggests a possible neurophysiological relationship with obsessive compulsive disorder (p. 1210).

Clinical features
The typical symptoms of PTSD include:
- ‘flashbacks’ – repeated vivid reliving of the trauma in the form of intrusive memories, often triggered by a reminder of the trauma
- insomnia, usually accompanied by nightmares, the nocturnal equivalent of flashbacks
- emotional blunting, emptiness or ‘numbness’, alternating with
- intense anxiety at exposure to events that resemble an aspect of the traumatic event, including anniversaries of the trauma
- avoidance of activities and situations reminiscent of the trauma
- emotional detachment from other people
- hypervigilance with autonomic hyperarousal and an enhanced startle reaction.

This clinical picture represents the severe end of a spectrum of emotional reactions to trauma, which might alternatively take the form of an adjustment or mood disorder. The course is often fluctuating but recovery can be expected in two-thirds of cases at the end of the first year. Complications include depressive illness and alcohol misuse. In a small proportion of cases the condition may show a chronic course over many years and a transition to an enduring personality change.

Treatment and prevention
Compulsory psychological debriefing immediately after a trauma does not prevent PTSD and may be harmful. Prevention is better achieved by the support offered by others who were also involved. Trauma focused CBT is often effective. Eye movement desensitization and reprocessing (EMDR) is equally effective treatment and may require fewer sessions. SSRIs and venlafaxine have a place in the management of chronic PTSD, but drop-out from pharmacotherapy is common.

The adult consequences of childhood sexual and physical abuse
Estimates of the prevalence of childhood sexual abuse vary depending on definition but there is reasonable evidence that 20% of women and 10% of men suffered significant, coercive and inappropriate sexual activity in childhood. The abuser is usually a member of the family or known to the child, and preadolescent girls are at greatest risk. The likelihood of long-term consequences is determined by:
- an earlier age of onset
- the severity of the abuse
- the repeated nature and duration of the period of abuse
- the association with physical abuse.

Consequent adult psychiatric disorders include depressive illness, substance misuse, eating disorders, borderline personality disorder and deliberate self-harm. Other negative outcomes include a decline in socio-economic status, sexual problems, prostitution and difficulties in forming adult relationships.

Repeated childhood physical and emotional abuse or neglect may also affect emotional and personality development, predisposing the adult to similar psychiatric disorders. Those with repeated abuse are more likely to have long-term physical stress related consequences, such as hypothalamic–pituitary–adrenal axis downregulation and smaller brain hippocampal sizes.

Psychodynamic psychotherapy
Psychodynamic psychotherapy is derived from psychoanalysis and is based on a number of key analytical concepts. These include Freud’s ideas about psychosexual development, defence mechanisms, free association as the method of recall, and the therapeutic techniques of interpretation, including that of transference, defences and dreams. Such therapy usually involves once-weekly sessions, the length of treatment varying between 3 months and 2 years. The long-term aim of such therapy is twofold: symptom relief and personality change. Psychodynamic psychotherapy is classically indicated in the treatment of unresolved conflicts in early life, as might be found in non-psychotic and personality disorders, but there is no convincing evidence concerning its superiority over alternative forms of treatment.

Cognitive analytical therapy is an integration of cognitive behaviour therapy and psychodynamic therapy. It is a short-term therapy that involves the patient and therapist recognizing the origins of a recurrent problem, reformulating how it continues to occur, and revising other ways of coping and internalizing it, using both the transference of the patient–therapist relationship and behavioural experiments.

Obsessive-compulsive disorder (OCD) is characterized by obsessional ruminations and compulsive rituals. It is particularly associated with and/or secondary to both depressive illness and Gilles de la Tourette syndrome (p. 1150). The prevalence is between 1% and 2% in the general population, and patients often do not seek help. There is an equal distribution by gender, and the mean age of onset ranges from 20 to 40 years.

Clinical features
The obsessions and compulsions are time consuming and intrusive so that they affect functioning and cause considerable distress. Ruminations are often unpleasant repetitive thoughts, out of character, such as being dirty or violent. This can lead to a constant need to check that everything and everyone is alright and that things have been done correctly, and reassurance cannot remove the doubt that persists. Some rituals are derived from superstitions, such as actions repeated a fixed number of times, with the need to start again if interrupted. When severe and primary, OCD can last for many years and may be resistant to treatment. However, obsessional symptoms commonly occur in other disorders, most notably depressive illness and schizophrenia, and remit with the resolution of the primary disorder.

Minor degrees of obsessional symptoms and compulsive rituals or superstitions are common in people who are not ill or in need of treatment, particularly in times of stress.
The mildest grade is that of obsessional personality traits such as over-conscientiousness, tidiness, punctuality and other attitudes and behaviours indicating a strong tendency towards conformity and inflexibility. Such individuals are perfectionists who are intolerant of shortcomings in themselves and others, and take pride in their high standards. When such traits are so marked that they dominate other aspects of the personality, in the absence of clear-cut OCD, the diagnosis is obsessional (anankastic) personality (see p. 1222).

Aetiology

Genetic
OCD is found in 5–7% of the first-degree relatives. Twin studies showed 80–90% concordance in monozygotic twins and about 50% in dizygotic twins.

Basal ganglia dysfunction
OCD is associated with a number of neurological disorders involving dysfunction of the striatum, including Parkinson’s disease, Sydenham’s and Huntington’s chorea. OCD can follow head trauma. Neuroimaging suggests that abnormalities exist in the frontal lobe and basal ganglia (Fig. 22.4). Hyperactivity of the orbitofrontal cortex has been a consistent finding in brain imaging research on OCD patients. Other work suggests the caudate nucleus is smaller than in healthy controls.

Serotonin
Serotonin function is probably abnormal in patients with OCD. Serotonin reuptake inhibitors are effective drugs. Postsynaptic serotonin receptor hypersensitivity may follow chronically low levels of synaptic serotonin.

Conditioning
This suggests that compulsive rituals are classically conditioned avoidance responses, which therefore lend themselves to treatment with graded exposure therapy.

Treatment

Psychological treatments
A behaviour therapy that is particularly effective for rituals is response prevention. Patients are instructed not to carry out their rituals. There is an initial rise in distress but with persistence both the rituals and the distress diminish. Patients are encouraged to practise response prevention, while returning to situations that normally make them worse.

Modelling involves the therapist demonstrating to the patient what is required and encouraging the patient to follow this example. In the case of hand-washing rituals, this might involve holding an allegedly contaminated object and carrying out other activities without washing, the patient being encouraged to follow suit.

Thought stopping can reduce obsessional ruminations. The patient is taught to arrest the obsessional thought by arranging a sudden intrusion (e.g. snapping an elastic band, clicking the fingers).

Cognitive behaviour therapy combines repeated exposure to the provocative stimulus and thought stopping techniques.

Physical treatment
Selective serotonin reuptake inhibitors are the mainstay of drug treatment. Their efficacy is independent of their antidepressant action but the doses required are usually some 50–100% higher than those effective in depression. Three months’ treatment with high doses may be necessary for a positive response. Positive correlations between reduced severity of OCD and decreased orbitofrontal and caudate metabolism following behavioural and SSRI treatments have been demonstrated in a number of studies. Clomipramine (a tricyclic) is an alternative agent commonly used in the UK.

Psychosurgery
Psychosurgery is very occasionally recommended in cases of chronic and severe OCD that has not responded to other treatments. The development of stereotactic techniques has led to the replacement of the earlier, crude leucotomies with more precise surgical interventions such as subcaudate tractotomy and cingulotomy, with small yttrium radioactive implants, which induce lesions in the cingulate area or the ventromedial quadrant of the frontal lobe. Psychosurgery is performed only in a few specialist centres in the UK, and formal and detailed consent requirements are laid down in the appropriate mental health act.

Prognosis
Two-thirds of cases improve within a year. The remainder run a fluctuating or persistent course. The prognosis is worse when the personality is anankastic and the OCD is primary and severe.

ALCOHOL MISUSE AND DEPENDENCE

A wide range of physical, social and psychiatric problems are associated with excessive drinking. Alcohol misuse occurs when a patient is drinking in a way that regularly causes problems to the patient or others.

- The problem drinker is one who causes or experiences physical, psychological and/or social harm as a consequence of drinking alcohol. Many problem drinkers, while heavy drinkers, are not physically addicted to alcohol.
- Heavy drinkers are those who drink significantly more in terms of quantity and/or frequency than is safe to do so long term.
■ **Binge drinkers** are those who drink excessively in short bouts, usually 24–48 hours long, separated by often quite lengthy periods of abstinence. Their overall monthly or weekly alcohol intake may be relatively modest.

■ **Alcohol dependence** is defined by a physical dependence on or addiction to alcohol. The term ‘alcoholism’ is a confusing one with off-putting connotations of vagrancy, ‘merts’ drinking and social disintegration. It has been replaced by the term ‘alcohol dependence syndrome’.

### Epidemiology of alcohol misuse

Twenty per cent of men and 10% of women drink more than double the recommended limits of 3 units a day of alcohol for men and 2 units for women in the UK. Some 4% of men and 2% of women report alcohol withdrawal symptoms, suggesting dependence. Approximately one in five male admissions to acute medical wards is directly or indirectly due to alcohol. Between 33% and 40% of accident and emergency attenders have blood alcohol concentrations above the present UK legal limit for driving. People with serious drinking problems have a two to three times increased risk of dying compared to members of the general population of the same age and sex.

Table 22.15 provides an approximate estimate of what can be expected in an average individual in the way of behavioural impairment resulting from a particular blood alcohol level. The amount of alcohol is measured for convenience in units which contain about 8 g of absolute alcohol and raises the blood alcohol concentration by about 15–20 mg/dL, the amount that is metabolized in 1 hour. One unit of alcohol is found in half a pint of ordinary beer (3.5% alcohol by volume – ABV) and 125 mL of 9% wine. However, some beer and most lager is now 5% ABV – 3 units per pint. Wine is often 13% ABV and sold in 175 mL glasses – 2–3 units per glass.

### Detection

Alcohol misuse should be suspected in any patient presenting with one or more physical problems commonly associated with excessive drinking (see p. 238). Alcohol misuse may also be associated with a number of psychiatric symptoms/disorders and social problems (Table 22.16).

### Guidelines

The patient’s frequency of drinking and quantity drunk during a typical week should be established. Alcohol consumption can be assessed on the basis of units of alcohol.

■ Drinking up to 21 units of alcohol a week for men and 14 units for women carries no long-term health risk.

■ There is unlikely to be any long-term health damage with 21–35 units (men) and 14–24 units (women), provided the drinking is spread throughout the week.

■ Beyond 36 units a week in men and 24 units a week in women, damage to health becomes increasingly likely.

■ Drinking above 50 units a week in men (35 units in women) is a definite health hazard.

### Diagnostic markers of alcohol misuse

Laboratory parameters indicating alcohol misuse in recent weeks include elevated γ-glutamyl transpeptidase (γ-GT) and mean corpuscular volume (MCV). Blood or breath alcohol tests are useful in anyone suspected of very recent drinking.

### Alcohol dependence syndrome

Dependence is a pattern of repeated self-administration that usually results in tolerance, withdrawal and compulsive drug-taking behaviour, the essential element of which is the continued use of the substance despite significant substance-related problems. Figure 22.5 outlines the main characteristics of the syndrome but these do not necessarily present in any particular order. Symptoms of alcohol dependence in a typical order of occurrence are shown in Table 22.17. Diagnostic criteria for alcohol withdrawal syndrome are shown in Table 22.18.

![Fig. 22.5 Elements of the alcohol dependence syndrome.](image-url)
The course of the alcohol dependence syndrome

About 25% of all cases of alcohol misuse will lead to chronic alcohol dependence. This most commonly ends in social incapacity, death or abstinence. Alcohol dependence syndrome usually develops after 10 years of heavy drinking (3–4 years in women). In some individuals who use alcohol to alter consciousness, obliterate conscience and defy social mores, dependence and loss of control may appear in only a few months or years.

Delirium tremens (DTs)
Delirium tremens is the most serious withdrawal state and occurs 1–3 days after alcohol cessation, so is commonly seen a day or two after admission to hospital. Patients are disorientated, agitated, and have a marked tremor and visual hallucinations (e.g. insects or small animals coming menacingly towards them). Signs include sweating, tachycardia, tachypnoea and pyrexia. Complications include dehydration, infection, hepatic disease or the Wernicke–Korsakoff syndrome (p. 221).

Causes of alcohol dependence

Genetic factors. Sons of alcohol-dependent people who are adopted by other families are four times more likely to develop drinking problems than are the adopted sons of non-alcohol misusers. Genetic markers include dopamine-2 receptor allele A1, alcohol dehydrogenase subtypes and monoamine oxidase B activity, but they are not specific.

Environmental factors. One in ten boys who grow up in a household where neither parent misused alcohol subsequently become alcohol dependent, compared with one in four of those reared by alcohol-misusing fathers and one in three of those reared by alcohol-misusing mothers.

Biochemical factors. Several factors have been suggested, including abnormalities in alcohol dehydrogenase, neurotransmitter substances and brain amino acids, such as GABA. There is no conclusive evidence that these or other biochemical factors play a causal role.

Psychiatric illness. This is an uncommon cause of addictive drinking but it is a treatable one. Some depressed patients drink excessively in the hope of raising their mood. Patients with anxiety states or phobias are also at risk.

Excess consumption in society. The prevalence of alcohol dependence and problems correlates with the general level (per capita consumption) of alcohol use in a society. This, in turn, is determined by factors that may control overall consumption – including price, licensing laws, availability, and the societal norms concerning the use and misuse of alcohol.

Treatment

Psychological treatment of problem drinking

Successful identification at an early stage can be a helpful intervention in its own right. It should lead to:

- the provision of information concerning safe drinking levels
- a recommendation to cut down where indicated
- simple support and advice concerning associated problems.

Such a brief intervention is effective in its own right. Successful alcohol misuse treatment involves motivational enhancement (motivational therapy), feedback, education about adverse effects of alcohol, and agreeing drinking goals. A motivational approach is based on five stages of change: precontemplation, contemplation, determination, action and maintenance. The therapist uses motivational interviewing and reflective listening to allow the patient to persuade himself along the five stages to change.

This technique, cognitive behaviour therapy and 12-step facilitation (as used by Alcoholics Anonymous (AA)) have all been shown to reduce harmful drinking. With addictive drinking, self-help group therapy, which involves the long-term support by fellow members of the group (e.g. AA), is helpful in maintaining abstinence. Family and marital therapy involving both the alcohol misuser and spouse may also be helpful. Families of drinkers find meeting others in a similar situation helpful (Al-Anon).

Drug treatments of problem drinking

Alcohol withdrawal and DTs

Addicted drinkers often experience considerable difficulty when they attempt to reduce or stop their drinking. Withdrawal symptoms are a particular problem and delirium tremens needs urgent treatment (Box 22.14). In the absence of DTs, alcohol withdrawal can be treated on an outpatient basis, using one of the fixed schedules in Box 22.14, so long as the patient attends daily for medication and monitoring.

### Table 22.18  Diagnostic criteria for alcohol withdrawal syndrome

Any three of the following:

- Tremor of outstretched hands, tongue or eyelids
- Sweating
- Nausea, retching or vomiting
- Tachycardia or hypertension
- Anxiety
- Psychomotor agitation
- Headache
- Insomnia
- Malaise or weakness
- Transient visual, tactile or auditory hallucinations or illusions
- Grand mal convulsions
and has good social support. Outpatient schedules are sometimes given over 5 days. Long-term treatment with benzodiazepines should not be prescribed in those patients who continue to misuse alcohol. Some alcohol misusers add dependence on diazepam or clomethiazole to their problems.

Drugs for prevention of alcohol dependence

**Naltrexone**, the opioid antagonist (50 mg per day), reduces the risk of relapse into heavy drinking and the frequency of drinking. **Acamprosate** (1–2 g per day) acts on several receptors including those for GABA, norepinephrine (noradrenaline) and serotonin. There is reasonable evidence that it reduces drinking frequency. Neither drug seems particularly helpful in maintaining abstinence. Both drug effects are enhanced by combining them with counselling, but their moderate efficacy precludes regular use.

Drugs such as **disulfiram** react with alcohol to cause unpleasant acetaldehyde intoxication and histamine release. A daily maintenance dose means that the patient must wait until the disulfiram is eliminated from the body before drinking safely. There is mixed evidence of efficacy.

One trial has suggested that fluoxetine is helpful in the treatment of patients who have both a depressive illness and alcohol dependence. Oral thiamin (300 mg a day) can prevent Wernicke–Korsakoff syndrome (p. 221) in heavy drinkers.

**Outcome**

Research suggests that 30–50% of alcohol-dependent drinkers are abstinent or drinking very much less up to 2 years following traditional intervention. It is too early to be certain of the long-term outcome of patients treated with the latest psychological and pharmacological therapies.

---

**Box 22.14 Management of delirium tremens (DTs)**

**General measures**

Admit the patient to a medical bed.
Correct electrolyte abnormalities and dehydration.
Treat any co-morbid disorder (e.g. infection).
Give parenteral thiamin slowly (250 mg daily for 3–5 days in the absence of Wernicke–Korsakoff (W–K) syndrome).
Give parenteral thiamin slowly (500 mg daily for 3–5 days with W–K encephalopathy. NB beware anaphylaxis).
Give prophylactic phenytoin or carbamazepine, if previous history of withdrawal fits.

**Specific drug treatment**

One of the following orally:

- Diazepam 10–20 mg
- Chloridiazepoxide 30–60 mg

Repeat 1 hour after last dose depending on response.

**Fixed-schedule regimens**

- Diazepam 10 mg every 6 hours for 4 doses, then 5 mg 6-hourly for 8 doses OR
- Chloridiazepoxide 30 mg every 6 hours for 4 doses, then 15 mg 6-hourly for 8 doses

Provide additional benzodiazepine when symptoms and signs are not controlled.

**DRUG MISUSE AND DEPENDENCE**

In addition to alcohol and nicotine, there are a number of psychotropic substances that are taken for their effects on mood and other mental functions (Table 22.19).

**Causes of drug misuse**

There is no single cause of drug misuse and/or dependence. Three factors appear commonly, in a similar way to alcohol problems:

- the availability of drugs
- a vulnerable personality
- social pressures, particularly from peers.

Once regular drug-taking is established, pharmacological factors determine dependence.

**Solvents**

One per cent of adolescents in the UK sniff solvents for their intoxicating effects. Tolerance develops over weeks or months. Intoxication is characterized by euphoria, excitement, a floating sensation, dizziness, slurred speech and ataxia. Acute intoxication can cause amnesia and visual hallucinations. About 100 young people die in the UK each year from use of these drugs.

**Amphetamines and related substances**

These have temporary stimulant and euphoriant effects that are followed by fatigue and depression, with the latter sometimes prolonged for weeks. Psychological rather than true physical dependence occurs with 'Speed'. In addition to a
manic-like presentation, amphetamines can produce a paranoid psychosis indistinguishable from schizophrenia.

**Ecstasy**

‘Ecstasy’ (E, white burger, white dove) is the street name for 3,4-methylenedioxymethamphetamine (MDMA), a psychoactive phenylisopropylamine, synthesized as an amphetamine derivative. It is a psychedelic drug which is often used as a ‘dance drug’. It has a brief duration of action (4–6 hours). There is evidence that repeated use of MDMA can cause permanent neurotransmitter changes in the brain. Deaths have been reported from malignant hyperpyrexia and dehydration. Acute renal and liver failure can occur.

**Cocaine**

Cocaine is a central nervous system stimulant (with similar effects to amphetamines) derived from **Erythroxylon coca** trees grown in the Andes. In purified form it may be taken by mouth, snorted or injected. If cocaine hydrochloride is converted to its base (‘crack’) it can be smoked. This causes an intense stimulating effect, and ‘free-basing’ is common. Compulsive use and dependence occur more frequently among users who are free-basing. Dependent users take large doses and alternate between withdrawal phenomena of depression, tremor and muscle pains, and the hyper-arousal produced by increasing doses. Prolonged use of high doses produces irritability, restlessness, paranoid ideation and occasionally convulsions. Persistent sniffing of the drug can cause perforation of the nasal septum. Overdoses cause death through myocardial infarction, cerebrovascular disease, hyperthermia and arrhythmias (p. 942).

**Hallucinogenic drugs**

Hallucinogenic drugs, such as lysergic acid diethylamide (LSD) and mescaline, produce distortions and intensifications of sensory perceptions, as well as frank hallucinations in acute intoxication. Psychosis is a long-term complication.

**Cannabis**

Cannabis (grass, pot, skunk, spliff, reefer) is a drug widely used in some subcultures. It is derived from the dried leaves and flowers of the plant *Cannabis sativa*. It can cause tolerance and dependence. Hashish is the dried resin from the flower tops whilst marijuana refers to any part of the plant. The drug, when smoked, seems to exaggerate the pre-existing mood, be it depression, euphoria or anxiety. It has specific analgesic properties. Cannabis use has increased in the UK recently, especially use of more potent ‘skunk’. An amotivational syndrome with apathy and memory problems has been reported with chronic daily use. Cannabis may of itself sometimes cause psychosis in the right circumstances (see below).

**Tranquillizers**

Drugs causing dependence include barbiturates and benzodiazepines. Benzodiazepine dependence is common and may be iatrogenic, when the drugs are prescribed and not discontinued. Discontinuing treatment with benzodiazepines may cause withdrawal symptoms (see Table 22.14). For this reason, withdrawal should be supervised and gradual.

**Opiates**

Physical dependence occurs with morphine, heroin and codeine as well as with synthetic and semisynthetic opiates such as methadone, pethidine and fentanyl. These substances display cross-tolerance – the withdrawal effects of one are reduced by administration of another. The psychological effect of such substances is of a calm, slightly euphoric mood associated with freedom from physical discomfort and a flattening of emotional response. This is believed to be due to the attachment of morphine and its analogues to endorphin receptors in the CNS. Tolerance to this group of drugs is rapidly developed and marked, but is rapidly lost following abstinence. The opiate withdrawal syndrome consists of a constellation of signs and symptoms (Table 22.20) that reaches peak intensity on the second or third day after the last dose of the opiate. These rapidly subside over the next 7 days. Withdrawal is dangerous in patients with heart disease or other chronic debilitating conditions.

Opiate addicts have a relatively high mortality rate, owing to both the ease of accidental overdose and the blood-borne infections associated with shared needles. Heart disease (including infective endocarditis), tuberculosis and AIDS are common causes of death, while the complications of hepatitis B and C are also common.

**Treatment of chronic misuse**

Blood and urine screening for drugs is required in circumstances where drug misuse is suspected (Table 22.21). When a patient with an opiate addiction is admitted to hospital for another health problem, advice should be sought from a psychiatrist or the patient’s drug clinic regarding management of their addiction while an inpatient.

The treatment of chronic dependence is directed towards helping the patient either to live without drugs or to prevent secondary ill-health. Patients need help and advice in order to avoid a withdrawal syndrome. Some patients with opiate

addiction who cannot manage abstinence may be maintained on oral methadone. In the UK, only specially licensed doctors may legally prescribe heroin and cocaine to an addict for maintenance treatment of addiction. An overdose should be treated immediately with the opioid antagonist naloxone.

**Drug psychoses**

Drug-induced psychosis has been reported with amphetamine and its derivatives, cocaine and hallucinogens. It can occur acutely after drug use, but is more usually associated with chronic misuse. Psychoses are characterized by vivid hallucinations (usually auditory, but often in more than one sensory modality), misidentifications, delusions and/or ideas of reference (often of a persecutory nature), psychomotor disturbances (excitement or stupor) and an abnormal affect. ICD-10 requires that the condition occurs within 2 weeks and usually within 48 hours of drug use and that it should persist for more than 48 hours but not more than 6 months.

Cannabis use can result in anxiety, depression or hallucinations. Manic-like psychoses occurring after long-term cannabis use have been described, but seem more likely to be related to the toxic effects of heavy ingestion. However, a meta-analysis suggests that ever taking cannabis increases the risk of psychosis by 40%, daily cannabis use doubles the risk of psychosis, and that 14% of schizophrenia in the UK would be prevented if cannabis use ceased. The risk is higher in people taking cannabis early in their lives and with a heavy consumption.

by an interaction of genetic and multiple environmental factors that affect brain development. It is likely that daily cannabis use is a risk factor. The genetic aetiology is likely to be polygenic and non-mendelian. Schizophrenia has a heritability of about 80%. The genetic risk in the general population and relatives of affected individuals is shown in Table 22.22. Brain scans and histology often show ventricular enlargement and disorganized cytoarchitecture in the hippocampus, supporting the neurodevelopmental theory of aetiology. Dopamine receptors are upregulated in the mesolimbic system, but the serotonin system may also be involved.

**Clinical features**

The illness can begin at any age but is rare before puberty. The peak age of onset is in the early twenties. The symptoms that have been considered as diagnostic of the condition have been termed first rank symptoms and were described by the German psychiatrist Kurt Schneider. They consist of:

- auditory hallucinations in the third person, and/or voices commenting on their behaviour
- thought withdrawal, insertion and broadcast
- primary delusion (arising out of nothing)
- delusional perception
- somatic passivity and feelings – patients believe that thoughts, feelings or acts are controlled by others.

The more of these symptoms a patient has, the more likely the diagnosis is schizophrenia, but these symptoms may also occur in other psychoses. Other symptoms of acute schizophrenia include behavioural disturbances, hallucinations, secondary (usually persecutory) delusions and blunting of mood. Schizophrenia is sometimes divided into ‘positive’ (type 1) and ‘negative’ (type 2) types:

- **Positive schizophrenia** is characterized by acute onset, prominent delusions and hallucinations, normal brain structure, a biochemical disorder involving dopaminergic transmission, a good response to neuroleptics, and a better outcome.

- **Negative schizophrenia** is characterized by a slow, insidious onset, a relative absence of acute symptoms, the presence of apathy, social withdrawal, lack of motivation, underlying brain structure abnormalities, and poor neuroleptic response.

**Chronic schizophrenia**

This is characterized by long duration and ‘negative’ symptoms of underactivity, lack of drive, social withdrawal and emotional emptiness.
**Differential diagnosis**

Schizophrenia should be distinguished from:

- organic mental disorders (e.g. partial complex epilepsy)
- mood (affective) disorders (e.g. mania)
- drug psychoses (e.g. amphetamine psychosis)
- personality disorders (schizotypal).

In older patients, any acute or chronic brain syndrome can present in a schizophrenia-like manner. A helpful diagnostic point is that altered consciousness and disturbances of memory do not occur in schizophrenia, and visual hallucinations are unusual.

A *schizoaffective psychosis* describes a clinical presentation in which clear-cut affective and schizophrenic symptoms coexist in the same episode.

**Prognosis**

The prognosis of schizophrenia is variable. A review of treatment studies suggests that 15–25% of people with schizophrenia recover completely, about 70% will have relapses and may develop mild to moderate negative symptoms, and about 10% will remain seriously disabled.

**Treatment**

The best results are obtained by combining drug and social treatments.

**Antipsychotic (neuroleptic) drugs**

These act by blocking the D₁ and D₂ groups of dopamine receptors. Such drugs are most effective against acute, positive symptoms and are least effective in the management of chronic, negative symptoms. Complete control of positive symptoms can take up to 3 months, and premature discontinuation of treatment can result in relapse.

As antipsychotic drugs block both D₁ and D₂ dopamine receptors, they usually produce extrapyramidal side-effects. This limits their use in maintenance therapy of many patients. They also block adrenergic and muscarinic receptors and thereby cause a number of unwanted effects (Table 22.23).

**The neuroleptic malignant syndrome** is an infrequent but potentially dangerous unwanted effect. This occurs in 0.2% of patients on *neuroleptic drugs*, particularly the potent dopaminergic antagonists, e.g. haloperidol. Symptoms occur a few days to a few weeks after starting therapy and consist of hyperthermia, muscle rigidity, autonomic instability (tachycardia, labile BP, pallor) and a fluctuating level of consciousness. Investigations show a raised creatine kinase, raised white cell count and abnormal liver biochemistry. Treatment consists of stopping the drug and general resuscitation, e.g. temperature reduction. Bromocriptine enhances dopaminergic activity and dantrolene will reduce muscle tone but no treatment has proven benefit.

**Pregnancy**. Data on the potential teratogenicity of antipsychotic (neuroleptic) medications are still limited. The disadvantages of not treating during pregnancy have to be balanced against possible developmental risks to the fetus. The butyrophenones (e.g. haloperidol) are probably safer than the phenothiazines. Subsequent management decisions on dosage will depend primarily on the ability to avoid side-effects, since the antiparkinsonian agents are still believed to be teratogenic and should be avoided.

**Phenothiazines**

Phenothiazines were the first group of neuroleptics used extensively. Chlorpromazine (100–1000 mg daily) is the drug of choice when a more sedating drug is required. Triflupromazine is used when sedation is undesirable. Fluphenazine decanoate is used as a long-term prophylactic to prevent relapse, as a depot injection (25–100 mg i.m. every 1–4 weeks).

**Butyrophenones**

The butyrophenones (e.g. haloperidol 2–30 mg daily) are also powerful antipsychotics, used in the treatment of acute schizophrenia and mania. They are likely to cause a dystonia and/or extrapyramidal side-effects, but are much less sedating than the phenothiazines. A third of patients with acute schizophrenia will have a good response to haloperidol and a further third will make a partial response.

**Atypical antipsychotics**

These drugs are ‘atypical’ in that they block D₂ receptors less than D₁, and thus cause fewer extrapyramidal side-effects and less tardive dyskinesia. They are now recommended as first-line drugs for newly diagnosed schizophrenia and for patients taking typical antipsychotics but with significant adverse effects.

**Clozapine**. Clozapine is used in patients with intractable schizophrenia who have failed to respond to at least two conventional antipsychotic drugs or as first-line therapy. This drug is a dibenzodiazepine with a relative high affinity for D₁ rather than D₂ dopamine receptors, muscarinic and α-adrenergic receptors. It also blocks 5-HT₂ and 5-HT₁ receptors.
Functional brain scans have shown that clozapine selectively blocks limbic dopamine receptors more than striatal ones, which is probably why it causes considerably fewer extrapyramidal side-effects.

Clozapine has been shown to exercise a dramatic therapeutic effect on both intractable positive and negative symptoms. However, clozapine is expensive and produces severe agranulocytosis in 1–2% of patients. Therefore it can only be prescribed in the UK to registered patients by doctors and pharmacists registered with the Clozaril patient-monitoring service. The starting dose is 25 mg per day with a maintenance dose of 150–300 mg daily. White cell counts should be monitored weekly for 18 weeks and then 2-weekly for the length of treatment. In addition to its antipsychotic actions, clozapine may also help reduce aggressive and hostile behaviour and the risk of suicide. It can cause considerable weight gain and sialorrhoea. There is an increased risk of diabetes mellitus.

Risperidone is a benzisoxazole derivative with combined dopamine D2 receptor and 5-HT2A-receptor blocking properties. Dosage ranges from 6 to 10 mg per day. The drug is not markedly sedative and the overall incidence and severity of extrapyramidal side-effects is lower than with more conventional antipsychotics.

Olanzapine has affinity for 5-HT2, D, D2, D4, and muscarinic receptor sites. Clinical studies indicate it to have a lower incidence of extrapyramidal side-effects. The apparent better compliance with the drug may be related to its lower side-effect profile and its once-daily dosage of 5–15 mg. Weight gain is a problem with long-term treatment and there is an increased risk of diabetes mellitus.

Neither risperidone nor olanzapine seems as specific a treatment for intractable chronic schizophrenia as clozapine.

Other atypical antipsychotics include amisulpride, sulpiride, zotepine, ziprasidone and quetiapine, the latter causing less hyperprolactinaemia. Those taking atypical antipsychotics should be regularly monitored for the development of diabetes mellitus. No more than one antipsychotic should be prescribed routinely.

**Psychological treatment**

This consists of reassurance, support and a good doctor–patient relationship. Psychotherapy of an intensive or exploratory kind is contraindicated. In contrast, individual cognitive behaviour therapy can help reduce the intensity of delusions.

**Social treatment**

Social treatment involves attention being paid to the patient’s environment and social functioning. Family education can help relatives and partners to provide the optimal amount of emotional and social stimulation, so that not too much emotion is expressed (a risk for relapse). Sheltered employment is usually necessary for the majority of sufferers if they are to work. Assertive outreach mental health teams will follow up those poorly adhering to treatment.

**Medical presentations related to treatment**

The motor side-effects of neuroleptics are the commonest reason for a patient with schizophrenia to present to a physician, followed by deliberate self-harm. Acute dystonia normally arises in patients newly started on neuroleptics, causing a torticollis. Extrapyramidal side-effects are common and present in the same way as Parkinson’s disease. They remit on stopping the drug and with antimuscarinic drugs, e.g. procyclidine. Akathisia is a motor restlessness, most commonly affecting the legs. It is similar to the restless legs syndrome, but apparent during the day.

Amenorrhoea and galactorrhoea can be caused by dopamine antagonists. Postural hypotension can affect the elderly, and neuroleptics can be the cause of delirium in the elderly, if their antimuscarinic effects are prominent.

---

**ORGANIC MENTAL DISORDERS**

Organic brain disorders result from structural pathology, as in dementia (see p. 1167), or from disturbed central nervous system (CNS) function, as in fever-induced delirium. They do not include mental and behavioural disorders due to alcohol and misuse of drugs, which are classified separately.

**Delirium**

Delirium, also termed toxic confusional state and acute organic reaction, is an acute or subacute brain failure in which impairment of attention is accompanied by abnormalities of perception and mood. It is the most common psychosis seen in the general hospital. Ten to 20 per cent of older surgical and medical inpatients have delirium during their admission. Confusion is usually worse at night, with consequent sleep reversal, so that the patient is asleep in the day and awake all night. During the acute phase, thought and speech are incoherent, memory is impaired and misperceptions occur. Episodic visual hallucinations (or illusions) and persecutory delusions occur. As a consequence, the patient may be frightened, suspicious, restless and uncooperative.

A developing, deteriorating or damaged brain predisposes a patient to develop delirium (Table 22.24).

A large number of diseases may cause delirium, particularly in elderly patients. Some causes of delirium are listed in Table 22.25. Delirium tremens should be considered in the differential diagnosis (p. 1167) as well as Lewy body dementia (p. 1167). Diagnostic criteria are given in Box 22.15.

**Management**

History should be taken from a witness. Examination may reveal the cause. Investigation and treatment of the underlying physical disease should be undertaken (Table 22.25).

treatment of the causative disease, but also on the underlying state of the brain. Twenty-five per cent of the elderly with delirium will have an underlying dementia; 15% of patients do not survive their underlying illness; 40% are in institutional care at 6 months.

**EATING DISORDERS**

**Obesity**

This is the commonest eating disorder (see p. 228) and has become epidemic in some developed countries. It is usually caused by a combination of constitutional and social factors, but a binge eating disorder and psychological determinants of ‘comfort eating’ should be excluded.

**Anorexia nervosa**

The main clinical criteria for diagnosis are:

- a bodyweight more than 15% below the standard weight, or a body mass index (BMI) below 17.5 (ICD-10)
- weight loss is self-induced by avoidance of fattening foods, vomiting, purging, exercise, or appetite suppressants
- a distortion of body image so that the patient regards herself as fat when she is thin
- a morbid fear of fatness
- amenorrhoea in women.

Clinical features include:

- onset usually in adolescence
- a previous history of faddish eating
- the patient generally eats little, yet is obsessed by food
- excessive exercising.

The physical consequences of anorexia include sensitivity to cold, constipation, hypotension and bradycardia. In most cases, amenorrhoea is secondary to the weight loss. In those who also binge and vomit or abuse purgatives there may be hypokalaemia and alkalosis.

**Prevalence**

Case register data suggest an incidence rate of 19 per 100 000 females aged between 15 and 34 years. Surveys have suggested a prevalence rate of approximately 1% among schoolgirls and university students. However, many more young women have amenorrhoea accompanied by less weight loss than the 15% required for the diagnosis. The condition is much less common among men (ratio of 1:10).

**Aetiology**

**Biological factors**

- Genetic. Six to 10 per cent of siblings of affected women suffer from anorexia nervosa. There is an increased concordance amongst monozygotic twins, suggesting a genetic predisposition.

- Hormonal. The reductions in sex hormones and downregulation of the hypothalamic–pituitary–adrenal axis are secondary to malnutrition and usually reversed by refeeding.
Psychological factors

Individual. Anorexia nervosa has often been seen as an escape from the emotional problems of adolescence and a regression into childhood. Patients will often have had dietary problems in early life. Perfectionism and low self-esteem are common antecedents. Studies suggest that survivors of childhood sexual or other abuse are at greater risk of developing an eating disorder, usually anorexia nervosa, in adolescence.

Family. Families of such patients are allegedly characterized by overprotection, inflexibility and lack of conflict resolution. Anorexia is alleged to prevent dissension in families. However, a case control study suggested that there is no more evidence of these factors in families of patients with anorexia nervosa than in control families with a child with an established physical disease, suggesting that, if present, these features are secondary.

Social and cultural factors
There is a higher prevalence in higher social classes, westernized families and in certain occupational groups (e.g. ballet dancers and nurses) and in societies where cultural value is placed on thinness.

Prognosis
The condition runs a fluctuating course, with exacerbations and partial remissions. Long-term follow-up suggests that about two-thirds of patients maintain normal weight and that the remaining one-third are split between those who are moderately underweight and those who are seriously underweight. Indicators of a poor outcome include:

- a long initial illness
- severe weight loss
- older age at onset
- binging and purging
- personality difficulties
- difficulties in relationships.

Suicide has been reported in 2–5% of patients with chronic anorexia nervosa. The mortality rate per year is 0.5% from all causes. The illness can quickly cause osteopenia, and later osteoporosis. More than one-third have recurrent affective illness, and various family, genetic and endocrine studies have found associations between eating disorders and depression.

Treatment
Treatment can be conducted on an outpatient basis unless the weight loss is severe and accompanied by marked cardiovascular signs and/or electrolyte and vitamin disturbances. Hospital admission may then be unavoidable and may need to be on a medical ward initially. Uncommonly, the patient’s weight loss may be so severe as to be life-threatening. If the patient cannot be persuaded to enter hospital, compulsory admission may have to be used. Inpatient treatment goals include:

- establishing a therapeutic relationship with both the patient and her family
- restoring the weight to a level between the ideal bodyweight and the patient’s ideal weight
- the provision of a balanced diet, aimed at gaining 0.5–1 kg weight per week
- the elimination of purgative and/or laxative use and vomiting

Outpatient treatment should include cognitive behavioural or interpersonal psychotherapies. Setting up a therapeutic alliance is vital. Family therapy is more effective than individual psychotherapy in adolescents and those still at home, and less effective in those who have left home. Motivational enhancement techniques are being used with some success.

Drug treatment has met with limited success, and those drugs that increase the QTc interval should be avoided. Vitamins and minerals may need replacement.

Bulimia nervosa
This refers to episodes of uncontrolled excessive eating, which are also termed ‘binges’, accompanied by means to lose weight. There is a preoccupation with food and habitual behaviours to avoid the fattening effects of periodic binges. These behaviours include:

- self-induced vomiting
- misuse of drugs – laxatives, diuretics, thyroid extract or anorectics.

Additional clinical features include:

- physical complications of vomiting:
  - (a) cardiac arrhythmias
  - (b) renal impairment
  - (c) muscular paralysis
  - (d) tetany – from hypokalaemic alkalosis
  - (e) swollen salivary glands – from vomiting
  - (f) eroded dental enamel
- associated psychiatric disorders:
  - (a) depressive illness
  - (b) alcohol misuse
- fluctuations in bodyweight within normal limits
- menstrual function – periods irregular but amenorrhoea rare
- personality – perfectionism and/or low self-esteem present premorbidly.

The prevalence of bulimia in community studies is high; it affects between 5% and 30% of girls attending high schools, colleges or universities in the USA. Bulimia is sometimes associated with anorexia nervosa. A premorbid history of dieting is common. The prognosis for bulimia nervosa is better than for anorexia nervosa.

Treatment
Individual cognitive behaviour therapy is more effective than both interpersonal psychotherapy and drug treatments. SSRIs (e.g. fluoxetine) are also an effective treatment, even in the absence of a depressive illness, but may require high doses.

Atypical eating disorders
These include eating disorders that do not conform clinically to the diagnostic criteria for anorexia nervosa or bulimia nervosa. Binge eating disorders consist of bulimia without the vomiting and other weight-reducing strategies.

FURTHER READING
SEXUAL DISORDERS

Sexual disorders can be divided into sexual dysfunctions and deviations and gender role disorders (Table 22.26).

Sexual dysfunction

Sexual dysfunction in men refers to repeated inability to achieve normal sexual intercourse, whereas in women it refers to a repeatedly unsatisfactory quality of sexual satisfaction. Problems of sexual dysfunction can usefully be classified into those affecting sexual desire, arousal and orgasm. Among men presenting for treatment of sexual dysfunction, erectile dysfunction is the most frequent complaint. The prevalence of premature ejaculation is low, except in young men, while ejaculatory failure is rare.

Sexual drive is affected by constitutional factors, ignorance of sexual technique, anxiety about sexual performance, medical and psychiatric conditions and certain drugs (Tables 22.27 and 22.28).

The treatment of sexual dysfunction involves careful assessment of both physical and psychosocial factors, the participation (where appropriate) of the patient’s partner, sex education, and specific therapeutic techniques, including relaxation, behavioural therapy and couple therapy. The introduction of phosphodiesterase type 5 inhibitors (e.g. sildenafil) has provided an effective therapy for the treatment of erectile dysfunction (see p. 1000).

Sexual deviation

Sexual deviations are regarded as unusual forms of behaviour rather than as an illness. Doctors are only likely to be involved when the behaviour involves breaking the law (e.g. paedophilia) and when there is a question of an associated mental or physical disorder. Men are more likely than women to have sexual deviations.

Alcohol increases the desire but diminishes the performance

Gender role disorders

Transsexualism involves a disturbance in gender identity in which the patient is convinced that their body is the wrong gender. A person’s gender identity refers to the individual’s sense of masculinity or femininity as distinct from sex. It is thought to arise from a biological component (prenatal endocrine influences), psychological imprinting and social conditioning. Disturbances in these three areas have variously been blamed for the cause of transsexualism.

For males, treatment includes oestrogen administration and, if surgery is to be recommended, a period of living as a woman as a trial beforehand. In the case of female transsexuals, treatment involves surgery and the use of methyltestosterone.

PERSONALITY DISORDERS

These disorders comprise enduring patterns of behaviour which manifest themselves as inflexible responses to a broad range of personal and social situations. Personality disorders are developmental conditions that appear in childhood or adolescence and continue into adult life. Their prevalence is about 15% in the population. They are not secondary to another psychiatric disorder or brain disease, although they may precede or coexist with other disorders. In contrast, personality change is acquired, usually in adult life, following severe or prolonged stress, extreme environmental deprivation, serious psychiatric disorder or brain injury or disease.

Personality disorders are usually subdivided according to clusters of traits that correspond to the most frequent or obvious behavioural manifestations, but many will show the characteristics of more than one category. The main categories of personality disorder are described below.

Borderline (emotionally unstable). Such people act impulsively and develop intense, but short-lived, emotional attachments to others. They describe chronic internal emptiness with frequent self-harm, self-abuse (eating disorders, substance misuse) and they may develop transient psychotic features of uncertain significance. There is often a strong family history of mood disorders.

Paranoid. Characterized by extreme sensitivity, suspiciousness, litigiousness, a tendency to excessive self-importance, and a preoccupation with unsubstantiated conspiracy theories.

Schizoid. Characterized by emotional coldness and detachment, a limited capacity to express emotions, indifference to praise or criticism, a preference for solitary activities, lack of close friendships, and a marked insensitivity to prevailing social norms and conventions.

Antisocial. An antisocial personality has a callous unconcern for the feelings of others, an incapacity to maintain enduring relationships, a very low tolerance of frustration, an incapacity to experience guilt and to profit from experience, and a tendency to blame others.

Histrionic. Characterized by self-dramatization, theatricality, suggestibility, shallow and labile emotions, a continual seeking for excitement and appreciation by others, and an inappropriate seductiveness in appearance or behaviour.

Narcissistic. Such individuals have an inflated sense of self-importance, a need to be admired, and are self referenced and arrogant.

Anankastic (obsessive-compulsive). Such a personality is characterized by feelings of excessive doubt and caution, preoccupation with details, rules and order, perfectionism, excessive conscientiousness, scrupulousness, pedantry and rigidity.

Dependent. People with such a personality encourage others to make their personal decisions, subordinate their needs to others on whom they are dependent, are unwilling to make demands on others, feel unable to care for themselves, and are preoccupied with fears of being abandoned.

MENTAL HEALTH ACT

The law in most developed countries provides for the compulsory admission and treatment of mentally disordered persons for their own protection and/or the protection of others and for mitigation in the case of mentally disordered individuals who commit a criminal offence (see also p. 5). In England and Wales a new Mental Health Act was implemented in 2008. It amends the previous 1983 Act. Changes include a widening of the definition of mental disorder to include ‘any disorder or disability of the mind. It abolishes the treatability provision to simply appropriate medical treatment (including care) being available ‘to alleviate, or prevent a worsening of, the disorder or one or more of its symptoms or manifestations’, and a supervised community treatment order. The Responsible Medical Officer is now ‘the responsible clinician’, and an ‘approved clinician’ rather than just a doctor can also sign a medical recommendation. The Mental Health (Scotland) Act 2003 and the Mental Health (Northern Ireland) Order 2004 contain clauses broadly similar to those in England and Wales.

There are three conditions that need to be met before an appropriate compulsory section form is signed. The patient must be:

- suffering from a mental disorder
- at risk to his/her health or safety and/or other people’s safety
- unwilling to accept hospitalization voluntarily.

Learning disability by itself and alcohol/drug dependence are specific exclusions. Any registered medical practitioner may sign a medical recommendation under the Act, but the added signature of an approved mental health professional is needed for compulsory orders lasting for more than 72 hours. Unless the patient is already in hospital, the nearest relative or an approved mental health professional is also required to sign the application form. Relevant sections of the Act are detailed in Table 22.29.

Physicians are likely to be involved in sections 5(2) and 2. It should be remembered that a section does not give a doctor the right to treat a physical disease, although it could be argued that a section would apply if the physical disease was causing the mental disorder (e.g. delirium). This has never been legally tested.

MENTAL CAPACITY ACT

Mental capacity is the ability to make decisions about all aspects of one’s life, including but not exclusively healthcare. All doctors need to be able to assess capacity. In England and Wales a new act was passed in 2005, which, for the first time, formally protects patients who lack capacity. Some 3% of people in the UK are thought to lack capacity due to conditions affecting brain function, such as dementia. However, the assessment of capacity is specific to an individual decision, so it is possible to have capacity to make one decision but not another. The assessment of capacity is outlined in Box 22.16. Capacity is assumed unless there is evidence to the contrary. In the absence of capacity, the doctor should act in the best interests of the patient and provide the least restrictive management, after consulting an independent advocate.

Box 22.16  Assessment of mental capacity to make a decision

The patient has a demonstrated impairment or disturbance of their mind/brain and a demonstrated inability to do any of the following:
- understand relevant information
- retain that information for sufficient time to make the decision
- use or weigh that information
- communicate their decision.

Introduction

Skin diseases have a high prevalence throughout the world. In developing countries infectious diseases such as tuberculosis, leprosy and onchocerciasis are common, whereas in developed countries inflammatory disorders such as eczema and acne are common. Skin disorders can be inherited, e.g. Ehlers-Danlos syndrome, a part of normal development, e.g. acne vulgaris, or may present as part of a systemic disorder, e.g. systemic lupus erythematosus (SLE). Approximately 25% of the UK population will develop a skin problem and although self-medication is common, skin disease still accounts for 10% of the workload of family doctors. The common reasons for this are itching or pain, which can interfere with people’s ability to function normally or to sleep; rashes which cause anxiety, depression and lack of self-confidence and can lead to social isolation if obviously visible; and an inability to work, because certain dermatoses (such as allergic hand eczema in a builder or hairdresser) can interfere with or even prevent working.

Rarely skin disease can be fatal. Examples are malignant melanoma, toxic epidermal necrolysis and pemphigus.

STRUCTURE AND FUNCTION OF THE SKIN

The skin consists of four distinct layers: the epidermis, the basement membrane zone, the dermis and the subcutaneous layer (Fig. 23.1). The functions are summarized in Box 23.1.

The epidermis

The epidermis is a stratified epithelium of ectodermal origin that arises from dividing basal keratinocytes. The downward projections of the epidermis into the dermis are called the ‘rete ridges’. The lower epidermal cells (basal layer) produce a variety of keratin filaments and desmosomal proteins (e.g. desmoglein and desmoplakins), which make up the ‘cytoskeleton’. This confers strength to the epidermis and prevents it shedding off. Higher up in the granular layer, complex lipids are secreted by the keratinocytes and these form into intercellular lipid bilayers, which act as a semipermeable skin barrier. The upper cells (stratum corneum) lose their nuclei and become surrounded by a tough impermeable ‘envelope’
of various proteins (loricrin, involucrin, filaggrin and keratin). Changes in lipid metabolism and protein expression in the outer layers allow normal shedding of keratinocytes.

Keratinocytes can secrete a variety of cytokines (e.g. interleukins, gamma-interferon, tumour necrosis factor alpha) in response to tissue injury or in certain skin diseases. These play a role in specific immune function, cutaneous inflammation and tissue repair. There is a further layer of protection against microbial invasion called the innate immune system of the skin. This comprises neutrophils and macrophages as well as keratinocyte-produced antimicrobial peptides (called β-defensins and cathelicidins). Expression of these peptides is both constitutive and induced by skin inflammation and they are active against bacterial, viral and fungal pathogens. There is evidence to suggest a deficiency of these peptides may account for the susceptibility of patients with atopic eczema to skin infection.

**Other cells in the epidermis**

Melanocytes are found in the basal layer and secrete the pigment melanin. These protect against UV irradiation. Racial differences are due to variation in melanin production, not melanocyte numbers.

Merkel cells are also found in the basal layer and originate either from neural crest or epidermal keratinocytes. They are numerous on finger tips and in the oral cavity and play a role in sensation.

Langerhans’ cells are dendritic cells found in the suprabasal layer. They derive from the bone marrow and as they express the cytokine CCR6, they are guided to normal skin, which contains a CCR6 agonist called macrophage inflammatory protein 3α. Langerhans’ cells endocytose extracellular antigens in the skin and then migrate to local lymph nodes for T-cell presentation and thus act as antigen-presenting cells.
Basement membrane zone (see Fig. 23.27)
The basement membrane zone is a complex proteinaceous structure consisting of type IV, VII and XVII (previously called BP180) collagen, hemidesmosomal proteins, integrins and laminin. Collectively they hold the skin together, keeping the epidermis firmly attached to the dermis. Inherited or autoimmune-induced deficiencies of these proteins can cause skin fragility and a variety of blistering diseases (see p. 1255).

The dermis
The dermis is of mesodermal origin and contains blood and lymphatic vessels, nerves, muscle, appendages (e.g. sweat glands, sebaceous glands and hair follicles) and a variety of immune cells such as mast cells and lymphocytes. It is a matrix of collagen and elastin in a ground substance.

The sweat glands
**Eccrine sweat glands** are found throughout the skin except the mucosal surfaces.

**Apocrine sweat glands** are found in the axillae, anogenital area and scalp and do not function until puberty.

The sweat glands and vasculature are involved in temperature control.

The sebaceous glands
These are inactive until puberty. They are responsible for secreting sebum or grease onto the skin surface (via the hair follicle) and are found in high numbers on the face and scalp.

Nerves
The skin is richly innervated. Nerve fibres enable sensation of touch, pain, itch, vibration and change in temperature.

Hair
Hairs arise from a downgrowth of epidermal keratinocytes into the dermis. The hair shaft has an inner and outer root sheath, a cortex and sometimes a medulla. The lower portion of the hair follicle consists of an expanded bulb (which also contains melanocytes) surrounding a richly innervated and vascularized dermal papilla. The hair regrows from the bulb after shedding. There are three types of hair:

- **terminal** – medullated coarse hair, e.g. scalp, beard, pubic
- **vellus** – non-medullated fine downy hairs seen on the face of women and in prepubertal children
- **lanugo** – non-medullated soft hair on newborns (most marked in premature babies) and occasionally in people with anorexia nervosa.

All hair follicles follow a growth cycle: anagen (growth phase), catagen (involution phase), telogen (shedding phase). At any one time most hairs (>90%) will be in the anagen phase which is typically 3–5 years for scalp hair.

Grey hair is due to decreased tyrosinase activity in the hair bulb melanocytes. White hair is due to total loss of these melanocytes.

Nails
Nails are tough plates of hardened keratin which arise from the nail matrix (just visible as the moon-shaped lunula) under the nail fold. It takes 6 months for a finger-nail to grow out fully and 1 year for a toe-nail.

The subcutaneous layer
The subcutaneous layer consists predominantly of adipose tissue as well as blood vessels and nerves. This layer provides insulation and acts as a lipid store.

**Approach to the Patient**
The history should aim to elicit the following points:

- time course of rash
- distribution of lesions
- symptoms (e.g. itch or pain)
- family history (especially of atopy and psoriasis)
- drug/allergy history
- past medical history
- provoking factors (e.g. sunlight or diet)
- previous skin treatments.

Examination entails looking and feeling a rash (for terminology, see Table 23.1). It should include an assessment of nails, hair and mucosal surfaces even if these are recorded as unaffected. The following terms are used to describe distribution: flexural, extensor, acral (hands and feet), symmetrical, localized, widespread, facial, unilateral, linear, centripetal.

**Investigation.** With regard to investigation, clinical acumen remains the most useful tool in dermatology but a variety of tests are useful in confirming a diagnosis (Table 23.2).

### INFECTIONS

#### BACTERIAL INFECTIONS  (see also p. 123)

The skin’s normal bacterial flora prevents colonization by pathogenic organisms. A break in epidermal integrity by trauma, leg ulcers, fungal infections (e.g. athlete’s foot) or abnormal scaling of the skin (e.g. in eczema) can allow infection. If reinfection occurs this may be due to asymptomatic nasal carriage of bacteria or the presence of other infected close contacts.

**Impetigo**

Impetigo is a highly infectious skin disease most common in children (Fig. 23.2). It presents as weeping, exudative areas with a typical honey-coloured crust on the surface. It is spread by direct contact. The term ‘scrum pox’ refers to impetigo spread between rugby players. Staphylococci or group A β-haemolytic streptococci are the causative agents: skin swabs should be taken.

**Prevention**

Prevention is by good personal hygiene, particularly hand washing with soap.

**Treatment**

Localized disease is treated with topical fusidic acid, and mupirocin is used for meticillin-resistant staphylococci (MRSA) three times daily. Extensive disease is treated with oral antibiotics for 7–10 days (flucloxacillin 500 mg four times daily for *Staphylococcus*; phenoxymethylpenicillin 500 mg four times daily for *Streptococcus*). Other close contacts should be examined and children should avoid school for 1 week after starting therapy. If impetigo appears resistant to treatment or recurrent, take nasal swabs and check other family members. Nasal mupirocin (three times daily for 1 week) is useful to eradicate nasal carriage, especially in hospital staff. Community acquired MRSA (p. 124) is increasingly recognized as a cause of superficial skin infections.

**Bullous impetigo/staphylococcal scalded skin syndrome**

Rarely *Staphylococcus* releases an exfoliating toxin which acts high up in the epidermis: toxin A causes blistering at the site of infection (bullous impetigo), toxin B spreads through the body causing more widespread blistering (staphylococcal scalded skin syndrome, SSSS). The latter is more common in childhood with very low mortality rates. In adults it is often associated with renal disease or immunosuppression, and mortality rates increase to 50%. Both these toxins cleave desmoglein 1 (a desmosomal protein) so mucosal involvement does not occur (this is analogous to pemphigus foliaceus which has the same target antigen, p. 1255).

**Fig. 23.2 Impetigo** – crusted blistering lesions on the chin.
SSSS can mimic toxic epidermal necrolysis (TEN, see p. 1266) on clinical grounds but can be differentiated in two ways: mucosal involvement does not occur in SSSS, and on skin biopsy a frozen section shows a superficial intraepidermal split in SSSS which is deeper and subepidermal in TEN.

Both bullous impetigo and SSSS are treated with antistaphylococcal antibiotics (e.g. flucloxacillin) and supportive care.

**Cellulitis**

Cellulitis presents as a hot, sometimes tender area of confluent erythema of the skin due to infection of the deep subcutaneous layer. It often affects the lower leg, causing an upward-spreading, hot erythema, and occasionally will blister, especially if oedema is prominent. It may also be seen affecting one side of the face. Patients are often unwell with a high temperature. It is usually caused by a streptococcus, rarely a staphylococcus, and sometimes community acquired MRSA (p. 124). In the immunosuppressed or diabetic patient Gram-negative organisms or anaerobes should be suspected.

There may be an obvious portal of entry for infection such as a recent abrasion or a venous leg ulcer. The web spaces of the toes should be examined for evidence of fungal infection. Skin swabs are usually unhelpful. Confirmation of infection is best done serologically by streptococcal titres: antistreptolysin O titre (ASOT) and antiDNAse B titre (ADB).

*Erysipelas* is the term used for a more superficial infection (often on the face) of the dermis and upper subcutaneous layer that clinically presents with a well-defined edge. However, erysipelas and cellulitis overlap so it is often impossible to make a meaningful distinction.

*Necrotizing fasciitis* (see p. 126).

**Treatment** is with phenoxy methylpenicillin (or erythromycin) and flucloxacillin (all 500 mg four times daily). If disease is widespread, treatment with antibiotics should be given intravenously for 3–5 days followed by at least 2 weeks of oral therapy. It is also necessary to treat any identifiable underlying cause. If cellulitis is recurrent, low-dose antibiotic prophylaxis (e.g. phenoxy methylpenicillin 500 mg twice daily) is used as each episode will cause further lymphatic damage. Post-cellulitic oedema is common and predisposes to further episodes of cellulitis.

**Ecthyma**

Ecthyma is also an infection due to *Streptococcus* or *Staphylococcus aureus* or occasionally both. It presents as chronic well-demarcated, deep ulcerative lesions sometimes with an exudative crust. It is commoner in developing countries, being associated with poor nutrition and hygiene. It is rare in the UK but is seen more commonly in intravenous drug abusers and people with HIV.

**Treatment** is with phenoxy methylpenicillin and flucloxacillin (both 500 mg four times daily) for 10–14 days.

**Erythrasma**

Erythrasma is caused by *Corynebacterium minutissimum*. It usually presents as an orange-brown flexural rash, and is often seen in the axillae or toe web spaces (Fig. 23.3). It is frequently misdiagnosed as a fungal infection. The rash shows a dramatic coral pink fluorescence under Wood’s (ultraviolet) light.

**Treatment** is with topical sodium fusidate 3 times daily for 7 days or oral erythromycin 500 mg four times daily for 7–10 days.

**Folliculitis**

Folliculitis is an inflammation of the hair follicle. It presents as itchy or tender papules and pustules. *Staphylococcus aureus* is frequently implicated. It is commoner in humid climates and when occlusive clothes are worn. A variant occurs in the beard area (called ‘sycoosis barbae’), which is commoner in black Africans. This is probably caused by the ability of shaved hair to grow back into the skin, especially if the hair is naturally curly. Extensive, itchy folliculitis of the upper trunk and limbs should alert one to the possibility of underlying HIV infection. Folliculitis following use of hot tubs is due to *Pseudomonas ovale*.

**Treatment** is with topical antiseptics, topical antibiotics (e.g. sodium fusidate) or oral antibiotics (e.g. flucloxacillin 500 mg or erythromycin 500 mg both four times daily for 2–4 weeks).

**Boils (furuncles)**

Boils are a rather more deep-seated infection of the skin, often caused by *Staphylococcus*. These can cause painful red swellings. They are commoner in teenagers and often recurrent. Recurrent boils may rarely occur in diabetes mellitus or in immunosuppression. Large boils are sometimes called ‘carbuncles’. Swabs should be taken to check antibiotic sensitivity as community acquired MRSA is an increasingly common cause.

**Treatment** is with oral antibiotics (e.g. erythromycin 500 mg four times daily for 10–14 days) and occasionally by incision and drainage.

Antiseptics such as povidone iodine or chlorhexidine (as soap) and using a bath oil can be useful in prophylaxis.
**Hidradenitis suppurativa**

This condition is characterized by a painful, discharging, chronic inflammation of the skin at sites rich in apocrine glands (axillae, groins, natal cleft). The cause is unknown but it is commoner in females and within some families it appears to be inherited in an autosomal dominant fashion. The initial lesion is occlusion of the hair follicle producing an inflammatory reaction that spreads to the apocrine glands. Clinically it presents after puberty with papules, nodules and abscesses which often progress to cysts and sinus formation. With time, scarring may arise. The condition follows a chronic relapsing/remitting course and is often worse in obese individuals.

*Treatment* is difficult but weight loss, ‘prophylactic’ antibiotics, oral retinoids, zinc and co-cyprindiol (2 mg cyproterone acetate + 35 μg ethinylestradiol in females only) have been tried. They should be used as for acne vulgaris (p. 1245). Severe recalcitrant cases have been treated with intravenous infliximab, a monoclonal antibody (p. 76). Surgery and skin grafting is sometimes required.

**Pitted keratolysis**

This is a superficial infection of the horny layer of the skin caused by a corynebacterium. It frequently involves the soles of the forefoot and appears as numerous small punched-out circular lesions of a rather macerated skin (e.g. as seen after prolonged immersion). There may be an associated hyperhidrosis of the feet and a prominent odour.

*Treatment*. Topical antibiotics (e.g. sodium fusidate or clindamycin, applied three times daily for 2–4 weeks) and topical anti-sweating lotions are effective therapies.

**MYCOBACTERIAL INFECTIONS**

**Leprosy (Hansen’s disease)** (p. 140)

Leprosy usually involves the skin, and the clinical features depend on the body’s immune response to the organism *Mycobacterium leprae*.

*Indeterminate leprosy* is the commonest clinical type, especially in children. This presents as small, hypopigmented or erythematous circular macules with occasional mild anaesthesia and scaling. This may resolve spontaneously or progress to one of the other types. Biopsy reveals a perineural granulomatous infiltrate and scant acid-fast bacilli.

*Tuberculoid leprosy* presents with a few larger, hypopigmented (see Fig. 4.30) or erythematous plaques with an active erythematous, often raised, rim. Lesions are usually markedly anaesthetic, dry and hairless, reflecting the nerve damage. Nerves may be enlarged and palpable. Biopsy shows a granulomatous infiltrate centred on nerves but no organisms.

*Lepromatous leprosy* presents with multiple inflammatory papules, plaques and nodules. Loss of the eyebrows (‘madarosis’) and nasal stuffiness are common. Skin thickening and severe disfigurement may follow. Anaesthesia is much less prominent. Biopsy shows numerous acid-fast bacilli.

*Diagnosis and treatment* are discussed on page 141.

**Skin manifestations of tuberculosis**

Tuberculosis can occasionally cause skin manifestations:

- *Lupus vulgaris* usually arises as a post-primary infection. It usually presents on the head or neck with red-brown nodules that look like apple jelly when pressed with a glass slide (‘discscopy’). They heal with scarring and new lesions slowly spread out to form a chronic solitary erythematous plaque. Chronic lesions are at high risk of developing squamous cell carcinoma.
- *Tuberculosis verrucosa cutis* arises in people who are partially immune to tuberculosis but who suffer a further direct inoculation in the skin. It presents as warty lesions on a ‘cold’ erythematous base.
- *Scrofuloderma* arises when an infected lymph node spreads to the skin causing ulceration, scarring and discharge.
- The *tuberculides* are a group of rashes caused by an immune manifestation of tuberculosis rather than direct infection. Erythema nodosum is the commonest and is discussed on page 1250. Erythema induratum (‘Bazin’s disease’) produces similar deep red nodules but these are usually found on the calves rather than the shins and they often ulcerate.

**Atypical mycobacteria**

Atypical (non-tuberculous) mycobacteria can occasionally infect the skin. *Mycobacterium marinum* is found in fish tanks and occasionally swimming pools. It can gain access via a break in the skin and then causes deep granulomatous nodules, often in a linear fashion.

**VIRAL INFECTIONS**

**Viral exanthem**

This is probably the commonest type of virus-induced rash and presents clinically as a widespread non-specific erythematous maculopapular rash. It probably arises due to circulating immune complexes of antibody and viral antigen localizing to dermal blood vessels. The rash can be caused by many different viruses (e.g. echovirus, erythrovirus, human herpes virus-6, Epstein–Barr virus; see p. 107) and so is rarely diagnostic. The rash will resolve spontaneously in 7–10 days.

**Slapped cheek syndrome (erythema infectiosum, fifth disease)**

This affects children and is caused by erythrovirus B19 (see p. 109). It is a mild viral illness which is followed by an intense erythema on the cheeks (‘slapped cheeks’) and a reticulate erythema on the proximal limbs.

**Herpes simplex virus** (see also p. 104)

Herpes simplex virus (HSV) occurs as two genomic subtypes. HSV type 1 is spread by direct contact and droplet infection. Most people are affected in early childhood but the infection is usually subclinical. Occasionally it can cause a self-limiting pyrexial primary illness with either clusters of painful blisters on the face or a painful gingivostomatitis.
Once the person is infected, cell-mediated immunity develops. In some individuals this response is poor and they get recurrent attacks of HSV, often manifest as cold sores. Immunosuppression can also cause a recrudescence of HSV. HSV can also autoinoculate into sites of trauma and present as painful blisters/pustules which may be seen for example on the fingers of healthcare workers (‘herpetic whitlow’).

HSV type 2 infections occur mainly after puberty and usually affect the genital area. Infections are often symptomatic and transmitted sexually. However, HSV type 1 can also be found in the genital area due to orogenital contact.

Other rare complications of HSV infection include corneal ulceration, eczema herpeticum, chronic perianal ulceration in AIDS patients and erythema multiforme (p. 1250).

**Treatment**

Oral valaciclovir (500 mg twice daily for 5 days) is used for primary HSV and painful genital HSV. Cold sores are treated with aciclovir cream but this must be used early to be effective in shortening an attack; recurrent sores are treated with oral therapy. Attacks of genital herpes become less frequent with time. Intravenous aciclovir must be used in immunosuppressed patients.

**Varicella zoster virus**

Varicella zoster virus (VZV) causes the common childhood infection called chickenpox. It is discussed on page 107. It also causes herpes zoster.

**Herpes zoster (shingles)**

‘Shingles’ results from a reactivation of VZV. It may be preceded by a prodromal phase of tingling or pain, which is then followed by a painful and tender blistering eruption in a dermatomal distribution (Fig. 23.4 and Fig. 4.17, p. 106). The blisters occur in crops, may become pustular and then crust over. The rash lasts 2–4 weeks and is usually more severe in the elderly. Occasionally more than one dermatome is involved.

Complications of shingles include severe, persistent pain (post-herpetic neuralgia), ocular disease (if the ophthalmic nerve is involved) and rarely motor neuropathy.

**Treatment**

Herpes zoster requires adequate analgesia and antibiotics (if secondary bacterial infection is present). Valaciclovir 1 g or famciclovir 250 mg three times daily for 7 days is used, or oral aciclovir 800 mg, five times daily for 7 days helps shorten the attack if given early in the illness. High-dose intravenous aciclovir is used in immunosuppressed patients. It remains unclear how useful aciclovir therapy is in preventing prolonged post-herpetic neuralgia. Centers for Disease Control (CDC) have recommended herpes zoster vaccination in people over 60 years.

**Human papilloma virus**

Human papilloma virus (HPV) is responsible for the common cutaneous infection of ‘viral warts’. There are more than 70 subtypes as detected by DNA hybridization. All can cause overgrowth of differentiated squamous epithelium.

**Common warts** are papular lesions with a coarse roughened surface, often seen on the hands and feet, but also on other sites. Small black dots (bleeding points) are often seen within the lesion (Fig. 23.5). Children and adolescents are usually affected. Spread is by direct contact and is also associated with trauma.

Plantar warts (verrucae) is the term used for lesions on the soles of the feet. They often appear flat (‘inward growing’) although they have the same papillomatous surface change and black dots are often revealed if the skin is pared down (unlike callosities). Warts may be painful or tender if they are over pressure points or around nail folds.

Filiform warts occur on the face, at the nasal vestibule or around the mouth. They are elongated with a horny cap.

**Plane warts** are much less common and are caused by certain HPV subtypes. They are clinically different and appear as very small, flesh-coloured or pigmented, flat-topped lesions (best seen with side-on lighting) with little in the way of surface change and no black dots within them. They are usually multiple and are frequently found on the face or the backs of the hands.

Anogenital warts are usually seen in adults and are normally transmitted by sexual contact. They are rare in childhood and, whilst child sex abuse should always be considered, it should be remembered they may well have been transmitted through non-sexual contact. HPV subtypes 16 and 18 are potentially oncogenic and are associated with cervical and anal carcinomas.

**Treatment**

Common warts on the skin are surprisingly difficult to treat effectively but they almost always resolve spontaneously after months to years (with no scarring), presumably due to cell-mediated immune recognition. When they do resolve, they tend to do so rapidly within a few days.

![Fig. 23.4 Herpes zoster in an African](courtesy of Dr P Matondo, Lusaka, Zambia).

**Fig. 23.5** Viral wart.
Regular use of a topical keratolytic agent (e.g. 2–10% salicylic acid) over many months with weekly paring of the lesion helps speed up resolution in some patients and remains the mainstay of treatment. A course of cryotherapy (freezing) can also help. Cautery, surgery, carbon dioxide laser, alpha-interferon injection and bleomycin injection have all been used with variable success but are not recommended, as treatments may be very painful and can cause permanent scarring.

Genital warts (see p. 181) are usually treated with cryotherapy, trichloroacetic acid, 5% imiquimod cream or topical podophyllin. Patients with genital warts (and their sexual partners) must be screened for other sexually transmitted diseases.

HPV vaccines against the high risk oncogenic subtypes (6, 11, 16 and 18) have recently become available; they should help protect against cervical neoplasia but will have no impact on common warts. It remains controversial whether this vaccine should be given to girls and boys routinely.

**Molluscum contagiosum (‘water blisters’)**

Molluscum contagiosum is a common cutaneous infection of childhood caused by the pox virus. Clinically, lesions are multiple small (1–3 mm) translucent papules which often look like fluid-filled vesicles but are in fact solid. Individual lesions may have a central depression called a punctum. They exhibit the Köbner phenomenon (p. 1241). They can occur at any body site including the genitalia. Transmission is by direct contact. Occasionally lesions may be up to 1 cm in diameter (‘giant molluscum’). They are said to be more extensive in children with atopic eczema, which may just reflect that scratching aids their spread.

They usually continue to occur in crops over 6–12 months and rarely require treatment as they spontaneously resolve. Any form of localized trauma, including scratching, helps speed up resolution, and cryotherapy is used in older children. One per cent stabilized hydrogen peroxide cream or 5% imiquimod cream is used in younger children. Molluscum in an adult, especially if giant, should raise the underlying possibility of immunosuppression, especially HIV infection.

**Orf**

Orf is a disease of sheep (and occasionally goats) due to a pox virus infection. It causes a vesicular and pustular rash around the mouths of young lambs. People who come into contact with the affected fluid may develop lesions on the hands. Clinically these appear as 1–2 cm reddish papules with a surrounding erythema which usually become pustular. The lesion(s) resolves spontaneously after 4–6 weeks and immunity is lifelong. Occasionally orf is complicated by erythema multiforme (p. 1250).

**Fungal Infections**

Fungi are primitive, saprophytic organisms found throughout our environment. Fungal skin disease (mycosis) has a high prevalence in humans with ‘thrush’ and ‘athlete’s foot’ being two of the commonest examples. In the immunosuppressed, mycoses can be widespread and life-threatening. There are three groups of pathogenic fungi that commonly affect the outer layer of skin or keratinizing epithelium: dermatophytes, *Candida albicans* and pityrosporum.

**Dermatophyte infection**

By definition, dermatophytes cause a ‘ringworm’ type of rash. The three main genera responsible are *Trichophyton*, *Microsporum* and *Epidermophyton*. These organisms are identified by microscopy and culture of skin, hair or nail samples. The clinical appearance of mycoses depends in part on the organism involved, the site affected and the host reaction. All are spread by direct contact from other humans or from infected animals. The use of communal showers and swimming baths and the sharing of towels or sportswear aids indirect fomite transmission.

**Tinea corporis**

Ringworm of the body usually presents with slightly itchy, asymmetrical, scaly patches which show central clearing and an advancing, scaly, raised edge. Occasionally vesicles or pustules may be seen in the edge. Central clearing is not a universal feature and it is recommended that all asymmetrical scaly lesions should be scraped for fungus. Ringworm of the face (tinea faciei) often arises after the use of topical steroids. It tends to be more erythematous and less scaly than trunk lesions and it may become itchy after sun exposure.

**Tinea cruris**

Ringworm of the groin is extremely common world-wide. Early on, the lesions appear as well-demarcated red plaques with an arc-like border extending down the upper thigh (Fig. 23.6). Central clearing may appear and a few pustules or vesicles may be seen if inflammation is intense. Satellite lesions, suggestive of *Candida*, are not present.

**Tinea pedis**

Athlete’s foot may be confined to the toe clefts where the skin looks white, macerated and fissured. It may also be more diffuse, usually causing a diffuse scaly erythema of the soles spreading on to the sides of the foot. Annular lesions are rarely present. There may be an associated hyperhidrosis and fungal involvement of one or more toe nails. In severe infection a strong inflammatory reaction can occur causing pustules or blistering and this often leads to a misdiagnosis of pompholyx-type eczema.

![Fig. 23.6 Tinea cruris — ringworm of the groin.](image-url)
**Tinea manuum**

Ringworm of the hands also presents with a diffuse erythematous scaling of the palms with variable skin peeling and skin thickening. Annular lesions are rare at this site.

**Tinea capitis**

Scalp ringworm infections are continuing to increase in developed countries although the rate of increase is beginning to slow. Fungus may confine itself to within the hair shaft (endothrix) or spread out over the hair surface (ectothrix). The latter can cause fluorescence under a Wood’s lamp (ultraviolet light). Scalp ringworm is spread by close contact (especially in schools and households) and may also be spread indirectly by hairdressers. The number of new cases has risen enormously in the large cities in developed countries. Increase in travel and immigration has allowed the spread of different pathogenic fungi (e.g. *Trichophyton tonsurans* from Central America, *Trichophyton violaceum* from India and Pakistan) into new countries where there is overcrowding and poor social conditions. The majority of UK cases are due to *T. tonsurans* (which does not show fluorescence).

Tinea capitis is much commoner in children, especially those of black African origin whose scalp and hair seems more susceptible to fungal invasion. The clinical appearance of scalp ringworm is highly variable from a mild diffuse scaling with no hair loss (similar to dandruff) to the more typical appearance of circular scaly patches in the scalp with associated alopecia and broken hairs. As the host’s immune response increases a few pustules may appear and an exudate may be present. At worst, a full-blown ‘kerion’ develops; a boggy swollen mass with copious quantities of discharging pus and exudate accompanied by severe alopecia. This is still poorly recognized and inappropriately treated with antibiotics and attempted surgical drainage.

Extensive infection is occasionally accompanied by a widespread papulopustular rash on the trunk. This is a so-called ‘id reaction’ and probably relates to the host immune response to the fungus. It seems commoner in black African children. It resolves when the fungal infection is treated.

**Tinea unguium**

Ringworm of the nails is increasingly common with age and frequently ignored as it is often asymptomatic. Clinically this presents as asymmetrical whitening (or yellowish black discoloration) of one or more nails which usually starts at the distal or lateral edge before spreading throughout the nail (Fig. 23.7). The nail plate appears thickened. Crumbly white material appears under the nail plate and this is the best specimen to obtain for mycology sampling. The nail plate may become destroyed with advanced disease.

*Tinea incognito*

This is the term used to describe a fungal skin infection that has been modified by therapy with a topical steroid. The clinical appearance is variable but may show a non-specific erythema with little in the way of scaling or a few reddish nodules. The history of the rash improving with treatment (owing to the suppression of inflammation) but worsening and spreading every time it is stopped is typical. Skin scrapings for mycology or even a biopsy should confirm the diagnosis.

**Treatment**

Localized ringworm of the body or flexures is treated with topical antifungal creams ( clotrimazole, miconazole, terbinafine or amorolfine applied three times daily for 1–2 weeks). More widespread infection, tinea pedis, tinea manuum and tinea capitis require oral antifungal therapy. Itraconazole (100 mg daily) and terbinafine (250 mg daily) are the most effective drugs used for periods of 1–2 months. High-dose griseofulvin is still used in children for scalp ringworm (15–20 mg/kg per day for 8 weeks).

Tinea unguium of the toe-nails is the most resistant to treatment. Itraconazole (100 mg daily or 200 mg twice daily for 1 week per month ‘pulsed therapy’) or terbinafine (250 mg daily) given for 3–6 months will cure up to about 80% of cases.

**Candida albicans** (see also p. 149)

*Candida albicans* is a yeast that is sometimes found as part of the body’s flora, especially in the gastrointestinal tract. It acts as an opportunist, taking hold in the skin when there is a suitable warm moist environment such as in nappy rash (p. 1268) or intertrigo in obese individuals (Fig. 23.8).

The flexural areas affected are red with a rather ragged peeling edge that may contain a few small pustules. Small circular areas of erythema or small papules and pustules may be seen in front of the advancing edge (satellite lesions).
Candida may also affect the moist interdigital clefts of the toes and mimic tinea pedis. In people who have their hands immersed frequently in water (e.g. cleaners, nurses) Candida may cause infection in the macerated skin of the finger web spaces or the damaged skin around the nail folds (‘chronic paronychia’). Nail infection may mimic tinea unguium. Candida can infect mucosal surfaces of the mouth or genital tract. This tends to occur in patients taking broad-spectrum antibiotics (due to suppression of protective bacterial flora) or in immunosuppressed patients. Clinically, superficial white or creamy pseudomembranous plaques appear which can be scraped off leaving raw areas underneath.

Treatment
Treatment is aimed at removing any underlying predisposing factor and applying topical antifungal creams, e.g. clotrimazole or miconazole (or the equivalent as mouth lozenges/pessaries). Candida nail infections require systemic antifungal therapy with an imidazole such as itraconazole (100 mg daily for 3–6 months). Recurrent candidiasis is relatively common, especially in women. Diabetes mellitus should always be excluded. Repeated topical treatment or an oral imidazole may be needed.

Pityrosporum
This yeast occurs as part of the normal flora of human skin. Colonization is prominent in the scalp, flexures and upper trunk. There are two morphological variants, Pityrosporum ovale and Pityrosporum orbiculare, and the mycelial form of this yeast is called Malassezia furfur. Pityrosporum can overgrow in some individuals and has been implicated in three dermatoses:

- pityriasis versicolor
- seborrhoeic eczema (p. 1238)
- pityrosporum folliculitis.

Pityriasis versicolor
This is a relatively common condition of young adults caused by infection with Pityrosporum. In Caucasians it presents most commonly on the trunk with reddish brown scaly macules, which are asymptomatic. In black-skinned individuals (or in whites who are sun-tanned) it more commonly presents as macular areas of hypopigmentation. Inappropriate use of topical steroids tends to spread the rash.

Diagnosis can be confirmed by skin scrapings or Wood’s light examination (yellow fluorescence).

Treatment is with selenium sulphide or 2% ketoconazole shampoo (apply to body and remove after 30–60 minutes and repeat daily for 1 week) or a topical imidazole cream (twice daily for 10 days). Oral itraconazole (100 mg twice daily for 1 week) can be used for resistant cases. The pigmentation takes months to recover even after successful treatment. The condition may recur but can be re-treated.

Pityrosporum folliculitis
This is common in young adult males and characterized by small itchy papules and pustules on the upper back which are centred on hair follicles. It is commoner in people with Down’s syndrome. It responds well to ketoconazole shampoo or a topical imidazole cream (twice daily for 2 weeks).

INFESTATIONS

Scabies
Scabies is an intensely itchy rash caused by the mite Sarcoptes scabiei. It can affect all races and people of any social class. It is most common in children and young adults but can affect any age group. There are 300 million cases of scabies in the world each year. It is commoner in poorer countries with social overcrowding.

Scabies is spread by prolonged close contact such as within households or institutions, and by sexual contact. It presents clinically with itchy red papules (or occasionally vesicles and pustules) which can occur anywhere in the skin but rarely on the face, except in neonates. The distribution of lesions is often suggestive of the diagnosis (Fig. 23.9). Sites of predilection are between the web spaces of the fingers and toes, on the palms and soles, around the wrists and axillae, on the male genitalia, and around the nipples and umbilicus.

The pathognomonic sign is of linear or curved skin burrows but these are not always present. The pruritus is normally worse at night. Excoriations and secondary bacterial infection may complicate the rash. Scabies can be confirmed by taking skin scrapings of a lesion and examining a potassium hydroxide preparation for the mite and/or its eggs by microscopy. Sometimes mites and eggs can be seen with a dermatoscope. Sometimes mites and eggs can be seen with a dermatoscope.

Treatment
This involves application of a topical scabicide (e.g. 5% permethrin) which is washed off after 10 hours. For the treatment to be successful the following factors should be noted:

- All the skin below the neck should be treated, including the genitalia, palms and soles, and under the nails. Treat the head and neck regions in infants (up to age 2 years).
- All close contacts should be treated at the same time even if asymptomatic.
- Reapply scabicide to the hands if they are washed during the treatment period.
- Washing or cleaning of recently worn clothes (preferably at 60°C) is recommended to avoid re-infection.

Fig. 23.9 Scabies – itchy papules and pustules centred on the web spaces of the hand.
Patients should be warned that the pruritus may persist for up to 4 weeks after successful treatment. Adjunct treatment with crotamiton cream, an emollient or a topical steroid is helpful.

The application should be repeated after one week.

A patient information leaflet about therapy helps improve compliance.

Malathion can be used if permethrin is unavailable; benzyl benzoate is used occasionally but is very irritating and should not be used in children. Lindane is a cheap therapy which is still used in many countries but there are concerns about resistance to this drug and possible neurotoxic side-effects.

**Crusted scabies (Norwegian scabies)**

Crusted scabies is a clinical variant that occurs in immuno-suppressed individuals where huge numbers of mites are carried in the skin. Patients are not always itchy but they are extremely infectious after relatively minimal contact, which is unfortunate as the diagnosis is often delayed. Clinically the condition presents as hyperkeratotic crusted lesions, especially on the hands and feet. Lesions may progress such that the patient has a widespread erythema with irregular crusted plaques. It can therefore mimic infected eczema or psoriasis.

*Treatment* is with careful barrier nursing, repeated applications of a scabicide and, in resistant cases, oral ivermectin (200 µg/kg – two doses 1 week apart).

**Lice infection**

Lice are blood-sucking ectoparasites that can affect man in three ways.

**Head lice (pediculosis capitis)**

Head lice is a common infection world-wide affecting predominantly children and being commoner in females. Spread is by direct contact and encouraged by overcrowding. It usually presents with itch or scalp excoriations. Occasionally erythematous papules on the neck may be seen.

*Diagnosis* can be confirmed by the presence of eggs (‘nits’) seen tightly bound to the hair shaft. Adult lice may be seen rarely in heavy infection. School nurses and parents are usually adept at detecting the lice.

*Treatment*. Eradication is difficult because of non-compliance as well as resistance patterns. Malathion, carbaryl and phenothrin (two applications 7 days apart with a contact time of 12 hours) are the most commonly used agents. Nit combing of wet hair alone is not as effective as chemical treatments and is now not used. Policies of rotating insecticides are also outmoded. If one treatment fails, a different insecticide is used for the next course in an individual. Treatment is usually repeated after 7 days and metal nit combs may help remove the eggs.

**Body lice (pediculosis corporis)**

Infestation with body lice is a disease of poverty and neglect. It is rarely seen in developed countries except in homeless individuals and vagrants. It is spread by direct contact or sharing infested clothing. The lice and eggs are rarely seen on the patient but are commonly found on the clothing. It presents with itch, excoriations and sometimes post-inflammatory hyperpigmentation of the skin.

*Treatment* consists of malathion or permethrin for the patient and high-temperature washing and drying of clothing.

**Pubic lice (crabs, phthiriasis pubis)** (p. 183)

Pubic lice are transmitted by direct contact, usually sexual. Infestation presents with itching, especially at night. Lice can be seen near the base of the hair with eggs somewhat further up the shaft. Occasionally eyebrows, eyelashes and the beard area are affected.

*Treatment* is as for head lice but all sexual contacts should be treated and other sexually transmitted diseases should be screened for. Pubic lice of the eyelashes is treated with white soft paraffin three times daily for 1–2 weeks.

**Arthropod-borne diseases (‘insect bites’ or papular urticaria)**

These depend on contact with an animal (e.g. dog, cat, bird) that is infested with fleas (*Cheyletiella*) or on bites from flying insects (e.g. midges, mosquitoes). In the case of flea bites the animal itself may be itchy with scaly and thickened skin. These fleas can also live in soft furnishings (e.g. carpets and beds) even after the animal has been removed. Bites present as itchy urticated lesions, which are often grouped in clusters. The legs are most commonly affected. It is not unusual for an individual to react badly to bites when other family members seem unaffected. Anti-flea treatment of the animal and furnishings is required. Insect repellents and appropriate clothing help lessen bites from flying insects.

Infestations with bed bugs have increased enormously in the past decade in the developed world, possibly due to being imported from foreign travel/tourism. They can be seen as small brown/black lentil-sized insects at night-time as they are attracted to warmth and carbon dioxide of sleeping humans. Infestations require professional insecticide treatments of properties. Advice can be obtained from the National Pest Technicians Association (www.npta.org.uk).

PAPULO-SQUAMOUS/INFLAMMATORY RASHES

ECZEMA

Introduction

The term ‘eczema’ derives from the Greek word for ‘boiling’, which reflects that the skin can become so acutely inflamed that fluid weeps out or vesicles appear. It is synonymous with the term dermatitis and the two words are interchangeable.

In the developed world eczema accounts for a large proportion of skin disease, both in hospital and community based populations. It is estimated that 10% of people have some form of eczema at any one time, and up to 40% of the population will have an episode of eczema during their lifetime.

All eczemas (see Table 23.3) have some features in common and there is a spectrum of clinical presentation from acute through to chronic. Vesicles or bullae may appear in the acute stage if inflammation is intense. In subacute eczema the skin can be erythematous, dry and flaky, oedematous and crusted (especially if secondarily infected). Chronic persistent eczema is characterized by thickened or lichenified skin. Eczema is nearly always itchy. Histologically ‘eczematous change’ refers to a collection of fluid in the epidermis between the keratinocytes (‘spongiosis’) and an upper dermal perivascular infiltrate of lymphohistiocytic cells. In more chronic disease there is marked thickening of the epidermis (‘acanthosis’).

Atopic eczema

This type of eczema (often called ‘endogenous eczema’) occurs in individuals who are ‘atopic’ (p. 846). It is common, occurring in up to 5% of the UK population. It is commoner in early life, occurring at some stage during childhood in up to 10–20% of all children.

Aetiology

The exact pathophysiology is not fully understood but there is an initial selective activation of Th2-type CD4 lymphocytes in the skin which drives the inflammatory process. This precedes the chronic phase when Th0 and Th1 cells predominate. In at least 90% of cases there is a raised serum total IgE level. Atopic eczema is a genetically complex, familial disease with a strong maternal influence. A positive family history of atopic disease is often present: there is a 90% concordance in monozygotic twins but only 20% in dizygotic twins. If one parent has atopic disease, the risk for a child of developing eczema is about 20–30%. If both parents have atopic eczema the risk is greater than 50%.

Recent studies have shown abnormal skin-homing T cells in eczema compared to controls. However the latest genetic research points towards a primary problem of skin barrier function, suggesting the immunological changes are secondary. Loss-of-function mutations in the epidermal barrier protein filaggrin cause ichthyosis vulgaris but can predispose to atopic eczema in Caucasian individuals. Different mutations in the same gene filaggrin have been found in Japanese patients with eczema but this gene may not be significant in Bangladeshi or black African patients. Filaggrin is one of the genes in the epidermal differentiation complex on chromosome 1q. Very strong linkage to this region would suggest that other genes in this area are also involved in the development of atopic eczema (e.g. loricrin, involucrin, S100 calcium-binding proteins). Certainly filaggrin is only one of a number of genes involved in eczema – linkage is also found to 3q21, 3p22–24, 17q25, 20p. Other candidate genes under study include SPINK 5, mast cell chymotryptase and peptidoglycan recognition proteins.

Exacerbating factors

Infection either in the skin or systemically can lead to an exacerbation, possibly by a superantigen effect. Paradoxically, lack of infection (in infancy) may cause the immune system to follow a Th2 pathway and allow eczema to develop (the so-called ‘hygiene hypothesis’). Strong detergents, chemicals and even woollen clothes can be irritant and exacerbate eczema. Teething is another factor in young children. Severe anxiety or stress appears to exacerbate eczema in some individuals. Cat and dog fur can certainly make eczema worse, possibly by both allergic and irritant mechanisms. The role of house dust mites and diet is less clear cut. There is some evidence that food allergens may play a role in triggering atopic eczema and that dairy products cause exacerbation of eczema in a few infants under 12 months of age.

Clinical features

Atopic eczema can present as a number of distinct morphological variants. The commonest presentation is of itchy erythematous scaly patches, especially in the flexures such as in front of the elbows and ankles, behind the knees (Fig. 23.10) and around the neck. In infants eczema often starts on the face before spreading to the body. Very acute lesions may weep or exude and can show small vesicles. Scratching can produce excoriations, and repeated rubbing produces skin thickening (lichenification) with exaggerated skin markings.

In patients with pigmented skin, eczema often shows a reverse pattern of extensor involvement. Also the eczema

</tr>
</tbody>
</table>
may be papular or follicular in nature, and lichenification is common. A final problem in pigmented skin is of post-inflammatory hyper- or hypopigmentation which is often very slow to fade after control of the eczema.

**Associated features**

Involvement of the nail bed may produce pitting and ridging of the nails. In some atopic individuals the skin of the upper arms and thighs may feel roughened due to follicular hyperkeratosis (‘keratosis pilaris’). The palms may show very prominent skin creases (‘hyperlinear palms’). There may be an associated dry ‘fish-like’ scaling of the skin which is non-inflammatory and often prominent on the lower legs (‘ichthyosis vulgaris’).

**Complications**

Broken skin commonly becomes secondarily infected by bacteria, usually *Staphylococcus aureus*, although streptococci can colonize eczema, especially in macerated flexural areas such as the neck and groin. Clinically this infection may appear as crusted, weeping impetigo-like lesions. Occasionally *Pseudomonas* can be grown from skin swabs but this rarely causes a clinical problem. Cutaneous viral infections (e.g. viral warts and molluscum) are often widespread in atopic eczema and are probably spread by scratching. HSV can cause a widespread eruption called eczema herpeticum (Kaposi’s varicelliform eruption). This can occasionally be a very severe infection and rarely can be fatal. It appears as multiple small blisters or punched-out crusted lesions associated with malaise and pyrexia, and needs rapid treatment with oral (or intravenous if severe) aciclovir. Ocular complications of atopic eczema include conjunctival irritation and less commonly keratoconjunctivitis and cataract. Retarded growth may be seen in children with chronic severe eczema; it is due to the disease itself and not the use of topical steroids.

**Investigations**

The diagnosis of atopic eczema is normally clinical. Atopy is characterized by high serum IgE levels or high specific IgE levels to certain ingested or inhaled antigens. The latter can be tested by radio-immunoabsorbent assay (RAST tests) of blood, or indirectly by skin-prick testing (p. 853). A peripheral blood eosinophilia may also be seen.

**Prognosis**

The majority (80–90%) of children with early-onset atopic eczema will spontaneously improve and ‘clear’ before the teenage years, 50% being clear by the age of 6. A few will get a recurrence as adults, even if just as hand eczema. However, if the onset of eczema is late in childhood or in adulthood, the disorder follows a more chronic remitting/relapsing course.

**Treatment (Box 23.2)**

**General measures**

These include avoiding known irritants (especially soaps or furry animals), wearing cotton clothes, and not getting too hot. Manipulating the diet (e.g. dairy-free diet) is rarely beneficial except in a few children, especially those under 12 months of age. Any change in diet should be made under supervision, especially with growing children who may need supplements such as calcium.

**Topical therapies**

Topical therapies (p. 1270) are sufficient to control atopic eczema in most people. The ‘triple’ combination of topical steroid, frequent emollients (see Table 23.17) and bath oil and soap substitute (e.g. aqueous cream) helps.

Written information or a practical demonstration of how to apply these treatments improves compliance.

**Use of topical steroids.** Unjustified fear about the dangers of topical steroids has often led to undertreatment of eczema. Providing appropriate-strength steroid preparations are used for the right body site, these compounds can be used quite safely on a long-term intermittent basis. Topical steroids can be divided into five groups depending on their potency (Table 23.4).

The following guidelines should be followed to allow their safe use in common chronic inflammatory skin conditions.

- The face should be treated only with mild steroids.
- In adults the body should be treated with either mild, moderately potent or diluted potent steroids.
- In young children the body should be treated with mild and moderately potent steroids.
- Potent steroids are used for short courses (7–10 days).
- Treatment of the palms and soles (but not the dorsal surfaces) may require potent or very potent steroids as the skin is much thicker.
- Regular use of emollients may lessen the need for steroid use.
- Only use steroids on inflamed skin. Do not use as an emollient.
- ‘Apply sparingly’ means use sufficient to leave a glistening surface to the skin after application.
- Use weaker steroid preparations in flexures (e.g. the groin, and under breasts) as apposition of the skin at
these sites tends to occlude the treatment and increase absorption.

**Topical immunomodulators**

Tacrolimus ointment (0.1% and 0.03%) and the less potent pimecrolimus cream are used for atopic eczema in patients over 2 years old. They have the advantage over potent steroids of not causing skin atrophy and are thus very useful for treating sensitive areas such as the face and eyelids. They can be very irritating when first used (although this settles with continued use) and 9% of patients develop flushing after alcohol. The long-term side-effects remain unknown. They do not work so well on lichenified eczema, probably due to poor absorption. Current advice is to avoid vaccinations and sun exposure when using these agents. The milder potency steroid creams should still be considered as first-line therapy but tacrolimus is a useful alternative to excessive use of potent steroids.

**Antibiotics**

These are needed for bacterial infection and are usually given orally for 7–10 days. Fluclouxacinil (500 mg four times daily) is effective against *Staphylococcus* and phenoxymethylpenicillin (500 mg four times daily) acts against *Streptococcus*. Erythromycin (500 mg four times daily) is useful if there is allergy to penicillin. Topical antiseptics are used in cases of recurrent infection but they can be irritating. They are usually added to the bath water rather than applied directly to the skin. Combination topical steroid/antibiotic creams can also be used for short periods but there is little evidence that they are better than topical steroids alone.

**Sedating antihistamines**

These (e.g. oral hydroxyzine hydrochloride 25 mg) are useful at night-time. They help by their sedative properties not by their antihistamine activity.

**Bandaging**

Paste bandaging can be useful for resistant or lichenified eczema of the limbs. It helps absorption of treatment and acts as a barrier to prevent scratching. Wet tubular gauze bandages are used for in-patient therapy but are difficult and time-consuming to use at home.

**Second-line agents**

These are used in severe non-responsive cases, especially if the eczema is significantly interfering with an individual’s life (e.g. growth, sleeping, schoolwork or job). Ultraviolet phototherapy (see p. 1248), prednisolone (initial doses up to 30 mg daily), ciclosporin (3–5 mg/kg daily) and azathioprine (1–3 mg/kg daily) (p. 290) can all be effective treatments. However they all have side-effects and the risk/benefit ratio must be openly discussed with the patient before they are used.

**Use of ciclosporin.** Ciclosporin is a selective immunosuppressant that inhibits interleukin-2 production by T lymphocytes. A large number of other drugs interact with ciclosporin (e.g. erythromycin, NSAIDs) and should be avoided. Renal damage and hypertension are the two most serious side-effects so blood pressure and serum creatinine and eGFR should be measured every 6–12 weeks. Renal damage becomes increasingly common with time and tends to be dose-dependent but is mostly reversible. Hypertrichosis, paraesthesia and nausea are less serious side-effects. Pregnancy should be avoided.

**Discoid eczema (nummular eczema)**

Discoid eczema is a morphological variant of eczema characterized by well-demarcated scaly patches, especially on the limbs, and this can be confused sometimes with psoriasis. It is commoner in adults and can occur in both atopic and non-atopic individuals. It tends to follow an acute/subacute course rather than a chronic pattern. There is often an infective component (*Staphylococcus aureus*).

**Hand eczema**

Eczema may be confined to the hands (and feet). It can present with:

- itchy vesicles or blisters on the palm and along the sides of the fingers (also called ‘pompholyx’) (Fig. 23.11)
- a diffuse erythematous scaling and hyperkeratosis of the palms
- a scaling and peeling, most marked at the finger tips.

Hand eczema is not unusual in atotics but more frequently occurs in non-atopic individuals, and a cause is not always found. A history of contact with irritants (e.g. detergents, chemicals) and an occupational history should be sought, especially in finger-tip eczema. Patch testing for specific allergic or contact eczema should always be performed as up to 10% of individuals with hand eczema will show a positive test. Finally look for evidence of fungal infection as this can occasionally induce a secondary pompholyx of the hands or feet (a so-called ‘id reaction’).

**Seborrhoic eczema**

**Aetiology**

Overgrowth of *Pityrosporum ovale* (also called *Malassezia furfur* in its hyphal form) together with a strong cutaneous immune response to this yeast produces the characteristic inflammation and scaling of seborrhoeic eczema. The condition is more common in parkinsonism as well as in HIV disease.

**Clinical features**

Seborrhoeic eczema affects body sites rich in sebaceous glands, although these do not appear to be causal. Three age groups are affected:

![Fig. 23.11 Pompholyx eczema (courtesy of Dr A Bewley, London).](image-url)
In childhood it is common and presents in the first few months of life as ‘cradle cap’ in most babies. This may in part be due to the effect of maternal androgens on infant sebaceous glands. Yellowish, greasy, thick crusts are seen on the scalp. A more widespread erythematous, scaly rash can be seen over the trunk, especially affecting the nappy area. Unlike with atopic eczema, the child is normally unbothered as there is little associated pruritus. The rash normally improves spontaneously after a few weeks.

In young adults (especially males) it occurs in 1–3% of the population. The rash is more persistent and presents as an erythematous scaling along the sides of the nose (Fig. 23.12), in the eyebrows, around the eyes and extending into the scalp (which shows marked dandruff). It may affect the skin over the sternum, axillae and groins, and the glans penis. A blepharitis may also be present.

In elderly people seborrhoeic eczema can be more severe and progress to involve large areas of the body and even cause erythroderma.

Treatment
This is suppressive rather than curative. A combination of a mild steroid ointment (e.g. 1% hydrocortisone applied twice daily) and a topical antifungal cream (e.g. miconazole cream applied twice daily) will help to control the eruption. Two per cent sulphur and 2% salicylic acid can be added to help control resistant cases. Recent studies have shown 0.1% tacrolimus ointment to be very effective. Ketoconazole shampoo and arachis oil are useful for the scalp. Emollients and a soap substitute are useful adjuncts.

Venous eczema (varicose eczema, gravitational eczema)

This type of eczema occurs on the lower legs due to chronic venous hypertension (usually of more than 2 years’ duration) (see p. 1261). The exact cause remains unknown but it has been suggested that venous hypertension causes endothelial hyperplasia and extravasation of red and white blood cells which in turn causes inflammation, purpura and pigmentation.

Clinical features
Venous eczema tends to occur in older people, especially women. It usually appears on the lower legs around the ankles. There may be a past history of venous thrombosis or previous surgery for varicose veins. Brownish pigmentation (haemosiderin) may be seen in the skin and a venous leg ulcer or varicose veins may be present. Superimposed contact eczema is common in venous eczema patients, especially when there have been chronic venous leg ulcers. This is usually due to an allergic reaction to topical therapies or skin dressings. Patch testing should always be done in treatment-resistant cases.

Treatment
This should include emollients and a moderately potent topical steroid. Support stockings or compression bandages, together with leg elevation, help reverse the underlying venous hypertension (p. 1261).

Asteatotic eczema (winter eczema, eczema craquelé, senile eczema)

This is a dry plate-like cracking of the skin with a red, eczematous component which occurs in elderly people. It occurs predominantly on the lower legs and the backs of the hands, especially in winter. The exact cause is unknown but the repeated use of soaps in the elderly with the loss of the stratum corneum lipids with age is probably involved. Rarely asteatotic eczema can be the presenting sign of hypothyroidism or can follow the commencement of diuretic therapy.

Treatment
Avoidance of soaps, and the regular use of emollients and bath oils should be encouraged. Humidifying centrally heated rooms may help. If the skin is very inflamed, a mild topical steroid can be used.

Contact and irritant eczema

If the eczema is in an unusual or localized distribution (Fig. 23.13), especially if there is no personal or family history of atopic disease, one of a variety of environmental agents (exogenous eczema) is the likely cause. A history of an exacerbation of eczema at the workplace is also suggestive. There are two possible mechanisms: direct irritation or an allergic reaction (type IV delayed hypersensitivity). A detailed history of occupation, hobbies, cosmetic products, clothing and contact with chemicals is necessary.

Allergic contact eczema occurs after repeated exposure to a chemical substance but only in those people who are
susceptible to develop an allergic reaction. It is common, occurring in up to 4% of some populations. Many substances can cause this type of reaction but the commoner culprits are nickel (in costume jewellery and buckles), chromate (in cement), latex (in surgical gloves), perfume (in cosmetics and air fresheners), and plants (such as primula or compositae). A good history is necessary and if suspicious, patch testing should be arranged to prove any allergy.

Irritant contact eczema can occur in any individual. It often occurs on the hands after repeated exposures to irritants such as detergents, soaps or bleach. It is therefore common in housewives, cleaners, hairdressers, mechanics and nurses.

**Treatment**

Treatment is as for atopic eczema as well as strict avoidance of any causative agent. This may also involve wearing of protective clothing such as gloves or in extreme cases even changing occupation or hobbies.

**Photosensitive eczema**

This is discussed on page 1248.

**Lichen simplex/nodular prurigo (neurodermatitis)**

These terms are applied to a disorder characterized by chronic scratching or rubbing in the absence of an underlying dermatosis. They are more common in Asians and also in black African and Oriental patients.

Lichen simplex appears as thickened, scaly and hyperpigmented areas of lichenification (Fig. 23.14). It starts with intense itching that becomes tender with increased rubbing or scratching, and a self-perpetuating ‘itch-scratch cycle’ develops. It is rare before adolescence and is commoner in females. Common sites are the nape of the neck, the lateral calves, the upper thighs, the upper back and the scrotum or vulva but any accessible site can be affected.

Nodular prurigo is a different pattern of cutaneous response to scratching, rubbing or picking. Individual, itchy papules and domed nodules appear, especially on the upper trunk and the extensor surfaces of the limbs. They show significant surface damage from scratching. This is a chronic unremittent condition which is often resistant to treatment.

These two conditions overlap, with some patients showing mixed features. Atopic individuals seem predisposed to develop these conditions (in the absence of obviously active eczema). However they can occur in non-atopics. Emotional stress appears to be a contributory factor in many of these patients (hence the name neurodermatitis).

The diagnosis is made by exclusion of other pathologies and may require a skin biopsy. General medical causes of pruritus should be excluded (p. 1253). In the elderly, nodular prurigo may be an early sign of bullous pemphigoid, before the more typical blistering phase has appeared.

**Treatment**

Treatment is often difficult as symptoms can be intractable. Very potent topical steroids (e.g. 0.05% clobetasol propionate) with occlusive tar bandaging may sometimes help. Intralvesional steroids can also be useful but there is a risk of atrophy. For resistant cases (especially of prurigo lesions) topical doxepin, phototherapy (p. 1248) and even ciclosporin (3–5 mg/kg/day) are used but the risk/benefit ratio must be discussed with the patient as these therapies are potentially toxic.

**PSORIASIS**

Psoriasis is a common papulo-squamous disorder affecting 2% of the population and is characterized by well-demarcated, red scaly plaques. The skin becomes inflamed and hyperproliferates at about ten times the normal rate. It affects males and females equally and can affect all races. The age of onset occurs in two peaks. Early onset (age 16–22) is commoner and is often associated with a positive family history. Late-onset disease peaks at age 55–60 years.

**Aetiology**

The condition appears to be polygenic but is also dependent on certain environmental triggers. Twin studies show 73% concordance in monozygotic twins compared with 20% in dizygotic pairs. Nine genetic psoriasis susceptibility loci have been identified (PSORS 1–9). Some loci seem shared with other diseases: atopic eczema (1q21, 3q21, 17q25, 20p), rheumatoid arthritis (3q21, 17q24–25) and Crohn’s disease (16). The most studied locus, PSORS1, lies in the MHC region of chromosome 6 (HLA Cw6).

Infection (group A Streptococcus), drugs (e.g. lithium), ultraviolet light, alcohol abuse and possibly stress may be triggers or exacerbating factors in certain individuals. The exact aetiology is unknown but evidence suggests that psoriasis is a T-lymphocyte-driven disorder to an unidentified antigen(s). The initial T cell activation requires a complex interaction between T lymphocyte and antigen-presenting cell (dendritic/Langerhans) and this has provided a number of potential ‘targets’ for the newly developed biological therapies (Fig 23.15). This activation results in upregulation of Th1-type T cell cytokines, e.g. interferon-γ, interleukins (IL-1, 2, -8), growth factors (TGF-α and TNF-α) and adhesion molecules (ICAM-1). The pro-inflammatory cytokine TNF-α is also produced by keratinocytes and this may be involved in both initiation and maintenance of psoriatic lesions. TNF-α blockade seems to be the most promising of the new biological agents (Fig. 23.15).

**Pathology**

Skin biopsy shows epidermal acanthosis and parakeratosis, reflecting the increase in skin turnover, and the granular layer is often absent. Polymorphonuclear abscesses may be seen

![Fig. 23.14 Lichen simplex from chronic rubbing.](image-url)
in the upper epidermis. The epidermal rete ridges appear elongated and clubbed as they fold down into the dermis. Dermal changes include capillary dilation surrounded by a mixed neutrophilic and lymphohistiocytic perivascular infiltrate.

**Clinical features**
Psoriasis can present in different clinical patterns but there is overlap between the different forms. Certain drugs can make psoriasis worse, notably lithium, antimalarials and rarely beta-blockers.

**Chronic plaque psoriasis**
This is the ‘common’ type of psoriasis. It is characterized by pinkish red scaly plaques, with a silver scale seen, especially on extensor surfaces such as knees (Fig. 23.16a) and elbows. The lower back, ears and scalp are also commonly involved. New plaques of psoriasis occur at sites of skin trauma – the so-called ‘Köbner phenomenon’. The lesions can become itchy or sore.

**Flexural psoriasis**
This tends to occur in later life. It is characterized by well-demarcated, red glazed plaques confined to flexures such as the groin, natal cleft and sub-mammary area. As these sites are apposed there is rarely any scaling. In the absence of psoriasis elsewhere the rash is often misdiagnosed as candida intertrigo but the latter will normally show satellite lesions.

**Guttate psoriasis**
‘Raindrop-like’ psoriasis is a variant most commonly seen in children and young adults (Fig. 23.16b). An explosive eruption of very small circular or oval plaques appears over the trunk about 2 weeks after a streptococcal sore throat.
**Erythrodermic and pustular psoriasis**

These are the most severe types of psoriasis reflecting a widespread intense inflammation of the skin. They can occur together (‘Von Zumbusch’ psoriasis) and may be associated with malaise, pyrexia and circulatory disturbance. This form can be life-threatening. The pustules are not infected but are sterile collections of inflammatory cells. There is also a more localized variant of pustular psoriasis that confines itself to the hands and feet (palmo-plantar psoriasis) but is not associated with severe systemic symptoms. This latter type is more common in heavy cigarette smokers.

**Associated features**

**Nails.** Up to 50% of individuals with psoriasis develop nail changes (Fig. 23.17) and rarely these can precede the onset of skin disease. There are five types of nail change: (a) pitting of the nail plate; (b) distal separation of the nail plate (onycholysis); (c) yellow-brown discoloration; (d) subungual hyperkeratosis; (e) rarely a damaged nail matrix and lost nail plate. Treatment of nail dystrophy is very difficult.

**Arthritis.** Five to ten per cent of individuals develop psoriatic arthritis and most of these will have nail changes (p. 1266).

**Treatment**

This is concerned with control rather than cure. It should be tailored to the patient’s wishes and not just to the doctor’s assessment of disease severity. Severe cases may require hospitalization.

**Chronic plaque psoriasis:** emollients should always be used to hydrate the skin. Mild to moderate topical steroids, synthetic vitamin D₃ analogues (e.g. calcipotriol, calcitriol, tacalcitol), 0.05% tazarotene (a retinoid) and purified coal tar are the most popular therapies. Salicylic acid can be a useful adjunct. All should be applied once to twice daily to palpable lesions. Once lesions have flattened, therapy can be discontinued. Tazarotene and calcipotriol can be very irritating (calcitriol somewhat less so) as they are often used in combination with steroid creams. Vitamin D analogues should be used with caution in extensive psoriasis because there is a risk of hypercalcaemia if greater than 100 g is used per week.

Dithranol causes staining of the skin and clothing and it may prove difficult to use at home on a regular basis. It is normally applied for 20–60 minutes and then washed off. It must be applied carefully to the lesions as it causes irritation to normal skin. Dithranol is more likely to induce remission than other therapies but is being used less because of poor compliance.

Topical therapies are sometimes used in combination with UVB or PUVA. The ‘Goeckerman regimen’ consists of tar and UVB; the ‘Ingram regimen’ consists of dithranol and UVB. The latter has similar results to oral PUVA in terms of clearance rates and lengths of remission – approximately 75% in 6 weeks.

**Flexural psoriasis** is usually treated with mild steroid and/or tar topical creams. Calcitriol and 0.1% tacrolimus ointment are also useful for treating flexural (facial and genital) psoriasis where irritation can be a problem.

**Guttate psoriasis** is usually treated with topical therapies and/or UVB phototherapy.

**Palmo-plantar psoriasis** is treated with very potent topical steroids, coal tar paste or local hand and foot PUVA.

**Systemic therapy:** Agents such as methotrexate, acitretin, mycophenolate, ciclosporin or hydroxycarbamide (hydroxyurea) are used for resistant cases.

**Erythrodermic psoriasis** also requires systemic therapy (but not phototherapy) as well as general supportive measures (p. 1249). All systemic treatments must be monitored for toxicity.

**Use of methotrexate.** Methotrexate is normally given once weekly. Some patients experience severe nausea on the day they take it which can be lessened by folic acid therapy. Both men and women should avoid conception during and for 3 months after therapy. Some patients are allergic to methotrexate and develop a pyrexia and mouth ulceration. Regular blood tests need to be done to monitor for bone marrow suppression and liver damage. Alcohol must be avoided as this increases the risk of hepatotoxicity. NSAIDs should also be avoided as these inhibit excretion. Lower doses should be used in the elderly. Long-term use causes hepatic fibrosis, and regular monitoring of patients’ serum procollagen III peptide level or elastography (p. 326) is being used to assess fibrosis development. Patients with concomitant psoriatic arthritis are more likely to develop pulmonary fibrosis.

**Biological agents** (see Fig. 23.15)

- Etanercept (a TNF-α blocker) and efalizumab (an anti-CD11a monoclonal antibody) have recently been introduced in Europe. They are at present only used for patients with severe disease and those who have failed (or cannot tolerate due to toxicity) conventional systemic treatments. Two other TNF-α blockers, infliximab and adalimumab, have been approved.

- Alefacept (a dimeric fusion protein) has been licensed in some countries.

- Human interleukin-12/23 monoclonal antibody is being used in trials but may be limited by side-effects.

All these agents are given by injection and are very expensive.

The TNF-α blockers seem to be the most effective with almost 60–80% of patients having at least a 75% improvement within 12 weeks; efalizumab showed only a 50% similar improvement at 12 weeks but it had less serious side-effects.
Long-term side-effects of these new biological agents are unknown. TNF-α blockers’ side-effects are discussed on page 464.

**Prognosis**
Most individuals who develop chronic plaque psoriasis will have the condition lifelong but 80% will get a remission at times. It fluctuates in severity and there are no available tests to predict outcome. Guttate psoriasis resolves spontaneously and in up to a third of individuals does not recur. However, two-thirds will on to get recurrent guttate attacks or will progress to chronic plaque psoriasis.

**URTICARIA/ANGIO-OEDEMA**

Urticaria (hives, ‘nettle rash’) is a common skin condition characterized by the acute development of itchy weals or swellings in the skin due to leaky dermal vessels (Fig. 23.18). Urticaria is described as ‘acute’ if it lasts less than 6 weeks and ‘chronic’ if it persists beyond this. Angio-oedema is a similar condition but involves sub-dermal vessels.

**Aetiology**
The final event in pathogenesis involves degranulation of cutaneous mast cells which release a number of inflammatory mediators (including histamine) which in turn make the dermal and sub-dermal capillaries leaky. In most cases the underlying cause is unknown. Occasionally these conditions are secondary to viral or parasitic infection, drug reactions (e.g. NSAIDs, penicillin, ACE inhibitors, opiates), food allergy (e.g. to strawberries, food colourings or seafood), or rarely systemic lupus erythematosus. There is evidence for an autoimmune aetiology in some of the ‘idiopathic’ cases as certain individuals develop autoantibodies against the high-affinity IgE receptor α-subunit of the mast cell. Urticaria/angio-oedema is commoner in atopic individuals and usually presents in children and young adults.

**Clinical features**
*Urticaria* produces cutaneous swellings or weals developing acutely over a few minutes. They can occur anywhere on the skin and last between minutes and hours before resolving spontaneously. Lesions are intensely itchy and show no surface change or scaling. They are normally erythematous but if very acutely swollen, they may appear flesh-coloured or whitish and people often mistake them for blisters.

*Angio-oedema* with subcutaneous involvement presents as soft tissue swelling (oedema) especially around the eyes, the lips and the hands but this is rarely itchy. This can be very alarming to the patient. It can also be dangerous if mucosal areas such as the mouth and larynx are involved but fortunately this is very rare.

**Physical urticarias**
Occasionally urticaria can be caused by physical stimuli such as cold (cold urticaria), deep pressure (delayed pressure urticaria), stress or heat (cholinergic urticaria), sunlight (solar urticaria – p. 1249), water (aquagenic urticaria) or chemicals such as latex (contact urticaria).

Cholinergic urticaria is one of the commonest physical urticarias and has rather different clinical lesions from the other forms. Small itchy papules rather than weals appear on the upper trunk and arms after exercise or anxiety.

Pressure can cause two types of urticaria. More superficial pressure can cause demographism which is relatively common. This presents as urticulated weals occurring a few minutes after application of light pressure. Even scratching or rubbing will bring up linear weals in demographic individuals. Delayed pressure urticaria is rare and occurs as deep swellings some hours after pressure is removed (e.g. on the soles of the feet or under a tight belt).

**Investigations**
The history is the most useful factor in diagnosing urticaria. Routine investigation is probably not justified unless the history suggests one of the underlying causes listed above. The physical urticarias should be reproducible by applying the relevant stimulus.

**Treatment**
Any identifiable underlying cause should be treated appropriately. Patients should avoid salicylates and opiates as they can degranulate mast cells. Oral antihistamines (H₁ blockers) are the most useful in treating the idiopathic cases. Therapy should be started with regular use of a non-sedating antihistamine (e.g. cetirizine 10 mg daily or loratadine 10 mg daily). If control proves difficult, addition of a sedating antihistamine, an H₂ blocker or dapsone may be helpful. Dietary manipulation (e.g. additive and colouring free diets) may help a small proportion of patients with chronic urticaria but it is generally unrewarding. Angio-oedema of the mouth and throat may require urgent treatment with intramuscular epinephrine (adrenaline) and intravenous steroids (see Emergency box 3.1).

**Prognosis**
Most cases of ‘idiopathic’ urticaria last a few weeks to months before disappearing spontaneously. The majority of these will be controlled with an antihistamine. A small percentage of people go on to develop chronic urticaria which can last for several months or years. The physical urticarias (especially cholinergic urticaria) are more persistent, often lasting for years, and they are often resistant to therapy.

**Urticarial vasculitis**
This is a variant of urticaria and should be suspected if individual urticarial lesions last longer than 24 hours and leave bruising behind after resolution. There is often an associated arthralgia or myalgia, and a small proportion may go on to develop a connective tissue disease. The diagnosis is confirmed by skin biopsy. A full vasculitis screen should be carried out for an underlying cause (p. 548).
Treatment is with antihistamines, oral dapsone (50–100 mg daily) or immunosuppressants.

Hereditary angio-oedema

This is an extremely rare autosomal dominant condition due to an inherited deficiency of C1 esterase inhibitor (CI-INH), a component of the complement system. The defect may be due to either reduced function or reduced levels (<50% of normal levels in 85% of cases). Serum C2 and C4 levels are normally low but C1 and C3 are normal. Rarely this condition is acquired and associated with lymphoma or SLE. These types show low C1 esterase inhibitor levels but also low C1 levels.

Clinical features

Hereditary angio-oedema presents with attacks of non-itchy cutaneous angio-oedema (but no urticaria), which may last up to 72 hours. It may also present with recurrent abdominal pain (due to intestinal oedema) and there may be a family history of sudden death (due to laryngeal involvement). A non-specific erythematous rash may precede an attack of angio-oedema but urticaria is not a feature.

Treatment

In the acute setting treatment is with C1 esterase inhibitor concentrates and fresh frozen plasma. Adrenaline and steroids are often ineffective. Maintenance treatment with the anabolic steroid stanozolol or danazol stimulates an increase in hepatic synthesis of C1 esterase inhibitor but this should not be used in children. Family members should be screened.

PIGTYRIASIS ROSEA

Pityriasis rosea is a self-limiting rash seen in adolescents and young adults. The cause is unknown but it is thought to be a viral or post-viral rash. There is an increased incidence in spring and autumn and outbreaks may occur in institutions.

Clinical features

The rash consists of circular or oval pink macules with a collarette of scale and is more prominent on the trunk than the limbs. The long axis of the oval lesions tends to run along dermatomal lines giving a “Christmas tree” pattern on the back. The rash may be preceded by a large solitary patch with peripheral scaling (“herald patch”) and this is most commonly found on the trunk. The rash is usually asymptomatic and spontaneously resolves over 4–8 weeks.

Treatment

Treatment is not normally required but 1% menthol in aqueous cream may help relieve any itch. In persistent cases UVB (p. 1248) may be helpful.

LICHEN PLANUS

Lichen planus is a pruritic inflammatory dermatosis that is commonly associated with mucosal involvement and rarely with nail dystrophy and scarring alopecia.

The cause is unknown but is possibly a T-cell-driven immune mechanism as an almost identical rash can be caused by certain drugs (e.g. beta-blockers, gold, levamisole, ACE inhibitors or antimalarials) or by graft-versus-host disease and in chronic HBV, HCV liver disease.

Pathology

Hyperkeratosis with thickening of the granular cell layer is seen in the epidermis. A dense T cell infiltrate is seen at the dermo-epidermal junction, which becomes ragged and saw-toothed. The basal layer shows liquefactive degeneration with colloid (apoptotic) bodies in the upper dermis.

Clinical features

The rash is characterized by small, purple flat-topped, polygonal papules that are intensely pruritic (Fig. 23.19). It is common on the flexors of the wrists and the lower legs but can occur anywhere. There may be a fine lacy white pattern on the surface of lesions (Wickham’s striae). Lesions can fuse into plaques, especially on the lower legs and in black Africans. Hyperpigmentation is common after resolution of lesions, especially in patients with pigmented skin. Atrophic, hypertrophic and annular variants can occur. Lichen planus lesions often localize to scratch marks. If lesions occur in the scalp they may cause a scarring alopecia.

Mucosal involvement is common. The mouth is the most commonly affected but the anogenital region can be involved. It can present as lacy white streaks, white plaques or ulceration. The prominent mucosal symptom is of severe pain rather than itch. Nails may be dystrophic and can be lost altogether (with scarring and ‘wing’ formation) in severe disease.

Prognosis

The condition often clears by 18 months but can recur at intervals. The hypertrophic and atrophic variants and mucosal disease are more persistent, lasting for years. Ulcerative mucosal disease is pre-malignant.

Fig. 23.19 Lichen planus.
TREATMENT
This requires the use of potent topical steroids (0.05% clobetasol propionate) and occasionally oral prednisolone (30 mg daily for 2–4 weeks). Occlusion of topical treatments can be helpful. Mouth lesions also require high potency steroids as an ointment, gel or sprays; candidiasis is a complication. Resistant cases may respond to PUVA, oral retinoids (0.5 mg/kg/day) or azathioprine (1–2 mg/kg daily). Topical 0.1% tacrolimus ointment or pimecrolimus has proved a very useful therapy for painful mucosal disease.

GRANULOMA ANNULARE
Granuloma annulare is a dermatosis predominantly of children and young adults. It is characterized by clusters of small dermal papules (with no surface change) that often form into rings or part of a ring. They are common on the dorsal surface of the hands and feet. They are flesh coloured or slightly erythematous and are usually asymptomatic. As they heal, the centre becomes dusky and altered in texture. A deep form, which is tender, exists in children. Diffuse granuloma annulare may be associated with diabetes mellitus. The pathology shows a granulomatous dermal infiltrate with foci of degeneration of collagen (necrobiosis). Spontaneous resolution often occurs after months to years but cryotherapy or triamcinolone injection may help localized disease.

LICHEN SCLEROSUS
Lichen sclerosus is a common inflammatory dermatosis that occurs in all age groups and particularly affects the anogenital region. It is more common in post-menopausal females. It presents with atrophic ivory-white patches with a well-defined edge on the vulva, glans penis, foreskin or perianal skin. Telangiectasia may be seen over the surface. Occasionally lesions involve the shaft of the penis and the urethral meatus. Lesions are often itchy but may be sore at times. Long-standing vulval lesions may be associated with fissuring and a marked loss of architecture, especially of the clitoral hood and the labia minora, which may become fused. Early lesions in young girls may present as haemorrhagic blisters and these are occasionally mistaken as signs of sexual abuse. Involvement of the foreskin can cause phimosis, and urethral disease may interfere with micturition. Perianal lesions may fissure and cause constipation.

Rarely lichen sclerosus can affect non-genital skin. This is most common in females and clinically it may show rather more hyperkeratosis and follicular plugging than is seen in the anogenital region.

Diagnosis requires biopsy if the clinical picture is unclear. This shows thinning of the epidermis with acanthosis and elongation of the rete ridges. Vulval scarring can also occur with cicatricial pemphigoid (p. 1256) so occasionally immunofluorescence studies are needed.

The underlying cause is unknown but HLA associations and recent studies showing antibodies to extracellular matrix protein-1 suggest an autoimmune aetiology.

Treatment with very potent topical steroids helps control the symptoms. Hydroxychloroquine (200 mg twice daily) is used in resistant cases. The condition may burn itself out after many years, especially in children. There is a risk of developing squamous cell carcinoma in long-standing lesions. Male patients may require circumcision if phimosis does not respond to medical therapy.

FACIAL RASHES
Facial rashes often cause diagnostic confusion but a close examination of the clinical signs should help differentiate the underlying cause (Table 23.5). All facial rashes, by virtue of their visibility, can cause significant distress to the patient and this should never be underestimated.

Acne vulgaris
Acne is a very common facial rash occurring in over 85% of adolescents and frequently continuing into early and mid-adult life. Occasionally it can cause profound psychological
A number of clinical variants exist:

- **Infantile acne.** Facial acne is occasionally seen in infants and is sometimes cystic. It is thought to be due to the influence of maternal androgens and resolves spontaneously.

- **Steroid acne.** Acne may occur secondary to corticosteroid therapy or Cushing’s syndrome. Comedones and cysts are rare in this variant but involvement of the back and shoulders (rather than the face) is common. Clinically the rash often appears as a pustular folliculitis.

- **Oil acne.** This is an industrial disease seen in workers who have prolonged contact with oils or other hydrocarbons and is common on the legs and other exposed sites.

- **Acne fulminans.** This is a rare variant seen most commonly in young male adolescents. Severe necrotic and crusted acne lesions appear associated with malaise, pyrexia, arthralgia and bone pain (due to sterile bone cysts). It requires urgent treatment with oral prednisolone (30–40 mg daily) and analgesics followed by a course of oral isotretinoin (see below).

- **‘Follicular occlusion triad’.** This is a rare disorder most commonly seen in black Africans. It is characterized by the presence of severe nodulocystic acne, dissecting cellulitis of the scalp (p. 1267) and hidradenitis suppurativa (p. 1230). This may be caused by a problem of follicular occlusion rather than having an infective aetiology.

### Treatment

This is aimed at decreasing sebum production, decreasing bacteria, normalizing duct keratinization and decreasing inflammation.

Regular washing with acne soaps to remove excess grease is helpful (normal soaps can be comedogenic). ‘Picking’ should be discouraged.

#### First-line therapy

Mild acne can respond to a variety of topical agents, e.g. keratolytics (benzoyl peroxide, azelaic acid) or topical retinoids (tretinoin or isotretinoin) or retinoid-like agents (adapalene). Topical antibiotics, e.g. erythromycin or clindamycin, are used for inflammatory acne. All topical agents can cause problems with irritation.

#### Second-line therapy

- **Low-dose oral antibiotic therapy** often helps but must be given for at least 3–4 months. Oxytetracycline 500 mg twice daily is often used first. Minocycline 100 mg daily, erythromycin 500 mg twice daily or trimethoprim 100 mg twice daily are also used.

- An extra treatment, cyproterone acetate 2 mg/ethinyloestradiol 35 µg (co-cyprindol), is of value in females if there is no contraindication to oral contraception. This acts as a normal combined contraceptive but has antiandrogen activity. It may take 6–8 months to have its maximum effect.

- **UVB phototherapy** can be helpful but is rarely used now due to the development of retinoid drugs.

#### Third-line therapy

Third-line treatment with a retinoid drug (isotretinoin) should be given if:
- the above measures fail
- there is nodulocystic acne with scarring
- there is severe psychological disturbance.

Use of retinoids (isotretinoin or acitretin). Retinoids are synthetic vitamin A analogues that affect cell growth and differentiation. They are very teratogenic. Isotretinoin is a ‘hospital-only drug’ in most countries due to its teratogenicity and is restricted to the use of dermatologists and a few trained family doctors. A pregnancy test, contraceptive advice and signed consent are mandatory prior to its use in fertile women, and pregnancy testing must be repeated monthly during therapy. It is given as a 4-month course at a dose of 0.5–1 mg/kg/day. Over 90% of individuals will respond to this therapy and 65% of people will obtain a long-term ‘cure’.

Patients must avoid pregnancy during therapy and for 1 month after stopping isotretinoin (but for 2 years after stopping acitretin as it is very lipophilic). Both drugs cause drying of the skin, especially of the lips and nasal mucosa. Hair thinning and exercise-induced myalgia are not uncommon. Blood count, liver biochemistry and fasting lipids need to be monitored during therapy. In a few individuals retinoids may cause depression but it should also be remembered that acne itself has been a cause of suicide.

A number of physical techniques are currently under assessment (e.g. lasers, blue light, microdermabrasion) but they are not as effective as isotretinoin and can be very expensive as repeat treatments are often needed.

Rosacea

Rosacea (Fig. 23.21) is a common inflammatory rash predominantly affecting the face. The onset is usually in middle age and it is commoner in women. It often causes significant psychological distress.

The cause is unknown. Theories have suggested an underlying problem in vasomotor stability of blood vessels or a role of the skin mite Demodex.

Clinical features

The cardinal features are of facial flushing and inflammatory papules and pustules affecting the nose, forehead and cheeks. The flushing may precede the other signs by some years. There are no comedones. Additional features include dilated blood vessels (telangiectasia), inflammation of the eyelid margins (blepharitis), keratitis and sebaceous gland hypertrophy, especially of the nose. The latter is commoner in men and can cause a disfiguring enlargement of the nose called rhinophyma. The flushing may be exacerbated by alcohol, hot drinks, sunlight and changes in ambient temperature. Prolonged use of topical steroids can exacerbate or trigger the condition. As the disease progresses the flushing may be replaced by a permanent erythema.

Treatment

This is suppressive rather than curative. Long-term use of topical 0.075% metronidazole or topical 15% azelaic acid may help. Avoid topical steroids. A 3-month course of oral tetracycline (500 mg twice daily) is also helpful. Oral metronidazole (400 mg twice daily) or oral isotretinoin (0.5 mg/kg/day) is occasionally given in resistant cases (p. 1247). The papules and pustules tend to respond best to therapy but repeat courses may be necessary. The flushing and erythema are often resistant to treatment but cosmetic camouflage can be helpful for these features. Intense pulse light or pulsed dye laser therapy can help the erythema and telangiectasia but often needs to be repeated as rosacea tends to recur. Rhinophyma can be treated with plastic surgery or by carbon dioxide laser.

Perioral dermatitis

Perioral dermatitis is a common rash found around the mouth, especially in young females. The exact cause is unknown but it often has an iatrogenic component as topical steroids often exacerbate the condition in the long term.

Clinical features

It presents with erythema, scaling, papules and occasionally pustules around the mouth. It usually spares a halo of skin immediately adjacent to the lips. Rarely there is involvement around the eyes.

Treatment

Treatment involves stopping topical steroids although they may have to be withdrawn slowly to prevent too severe a rebound after withdrawal. The mainstay of treatment is with a 3–4-month course of low-dose oxytetracycline or erythromycin (both 500 mg twice daily) and topical metronidazole.

Blushing

Blushing is characterized by facial flushing in response to emotional stimuli and would be regarded as a normal physiological response. In some individuals it is very frequent and can become a debilitating disorder interfering with work and social interaction. The cause may be both psychological and physiological. Non-emotional causes of blushing should be excluded, e.g. post-menopause, drugs, alcohol, diet, carcinoma syndrome, rosacea and mastocytosis.

Treatment includes cognitive behavioural therapy, cosmetic camouflage, beta-blockers and clonidine. Selective serotonin reuptake inhibitors may help associated depression and anxiety. Botulinum toxin and surgical sympathectomy have been advocated by some but neither is universally accepted and the latter can have major side-effects such as compensatory hyperhidrosis in over 50% of cases.
**PHOTODERMATOLOGY**

Sunlight – light in the ultraviolet (UV) part of the spectrum – combines short, medium and long wavelengths (UVC, UVB and UVA respectively). Both UVB and UVA can penetrate the atmosphere and reach the skin. This light energy is potentially mutagenic and carcinogenic but it can also suppress cutaneous inflammation. Thus UV irradiation can both cause skin disease and be used to treat it.

Photosensitive rashes usually appear on sites exposed to the sun’s rays, such as the face, the anterior ‘V’ of the chest, the ears and the backs of the hands. Certain ‘protected’ areas are characteristically spared such as under the chin or the upper eyelid and between the finger webs. Porphyria, drug sensitivity and lupus erythematosus should be excluded in all photosensitive patients.

Photosensitive rashes may be divided into photoexacerbated/provoked rashes and the idiopathic photodermatoses (Table 23.6). The former are discussed on pages 542 (SLE), 222 (pellagra) and 1075 (porphyria).

**Phototherapy and photoprotection**

**Phototherapy**

UVB and UVA both have a suppressive effect on cutaneous inflammation and there is increasing evidence that they can suppress systemic immunoreactivity to some degree. However, both types can cause skin ageing and predispose to skin malignancy if excessive doses are used. This is more of a problem in white-skinned individuals. Unaffected regions of skin or high-risk areas like the scrotum can be screened during phototherapy.

*UVB* is less carcinogenic than UVA. Narrow-band UVB (311 nm) is used more than broad-band UVB because it is more effective and less likely to burn. It is used in the treatment of eczema and psoriasis (especially in children) and is usually given three times per week for 6–10 weeks. Eye protection needs to be worn during therapy.

*UVA* is relatively ineffective on its own so is used in conjunction with a photosensitizer (‘psoralen’), hence the term ‘PUVA’. The psoralen can be given by mouth or applied to the skin in bath water. PUVA is given twice a week and eye protection must be worn for the whole of the treatment day as the psoralen sensitizes the retina. It is more effective than broad-band UVB but is limited by its carcinogenic potential (especially induction of squamous cell carcinoma). A maximum dose is given over a lifetime depending on skin type (1000 joules or 200 sessions approximately). It is used for many conditions including psoriasis, eczema, cutaneous T-cell lymphoma, some photosensitive dermatoses and vitiligo.

Sunbeds are used for tanning and consist of predominantly UVA light and are therefore rarely effective in treating skin disease. If used frequently there is an increased risk of skin cancer and premature ageing.

**Photoprotection**

There are two broad classes of sunblock cream: they either absorb UV light (e.g. aminobenzoic acid or methoxycinnamate) or reflect it (e.g. titanium dioxide). Most modern creams protect against UVA and UVB to varying degrees. UVB protection is graded by the ‘sun protection factor’ (SPF): an SPF of 15 implies you can spend 15 times as long in the sun before burning providing it is applied correctly. SPF above 15 confer little extra protection. There is no standardized way of assessing efficiency against UVA. Some sunscreens (especially aminobenzoates) may rarely cause photosensitization. This can be proven by photopatch testing.

**IDIOPATHIC PHOTODERMATOSES**

**Polymorphic light eruption (PLE)**

This is the most common photosensitive eruption in temperate regions, affecting up to 10–20% of the population. It is most common in young women. In many it is mild and often goes undiagnosed. An itchy rash appears some hours after sun exposure which is strictly confined to the exposed sites. Lesions may be papules, vesicles or plaques. They can last for several hours or several days. The condition starts in spring and often improves during the summer because of skin ‘hardening’.
Treatment
Avoidance of sunlight and the use of sunblocks are helpful in mild cases. Topical steroids help treat an attack. In those individuals who only get PLE after very intense sun exposure (e.g. on sunny holidays) a short course of oral prednisolone (30 mg daily for 7–10 days) will often prevent or treat an attack. For resistant cases ‘desensitization’ with low-dose PUVA (or narrow-band UVB) in the springtime may be required but patients will need to ‘top up’ their sun exposure from natural sunlight during the summer to keep their skin desensitized.

Chronic actinic dermatitis (photosensitive eczema, actinic reticuloid)
This is a relatively rare type of eczema occurring in a photosensitive distribution over the face, neck and hands. It typically affects middle-aged or elderly males. There may be a pre-existing eczema so the subsequent development of photosensitivity is often missed. This is further confounded by the fact that the eczema usually will spread to affect skin not exposed to sunlight, and the patient can become erythrodermic. The skin has typical features of eczema but there is often marked skin thickening. Histology is often atypical and can look almost lymphoma-like. The diagnosis can be confirmed by specialist monochromator light-testing. The most severe cases can be exacerbated by even artificial lighting as these patients can become exquisitely photosensitive.

Treatment
This consists of strict avoidance of sunlight including high-factor sunblocks and screening of house and car windows. Topical steroids and emollients are useful in milder cases. Oral prednisolone may be needed and azathioprine (1–2 mg/kg daily) is used for long-term suppression. Low-dose PUVA under steroid cover may help with ‘desensitization’.

Solar urticaria
This is extremely rare. Itchy urticarial lesions occur within minutes of sun exposure and characteristically settle within 1–2 hours. Sun avoidance, sunblocks, H1 antihistamines and low-dose PUVA are all used in treatment.

symptoms are common such as malaise, pyrexia, widespread lymphadenopathy and other complications (see below). Erythroderma can occasionally lead to death so it should be regarded as a medical ‘emergency’.

Examination should specifically look for pustules and nail changes suggestive of psoriasis.

A skin biopsy may further help to elucidate the cause, especially of cutaneous lymphoma. T cell receptor gene rearrangement studies (looking for evidence of clonal T cell expansion in the skin and blood) are also useful in the diagnosis of lymphoma.

A number of cases defy an exact diagnosis. Lymph node biopsy should be considered in lymphoma. In non-malignant disease lymph nodes normally show non-specific, reactive (dermatopathic) changes.

Complications
The skin is one of the largest organs of the body, so perhaps it is no surprise that inflammation of the whole organ can cause metabolic and haemodynamic problems. Examples are:

- high-output cardiac failure from increased blood flow
- hypothermia from heat loss
- fluid loss by transpiration
- hypoalbuminaemia
- increased basal metabolic rate
- ‘capillary leak syndrome’.

Capillary leak syndrome is the most severe complication and has been responsible for a fatal outcome in some cases of psoriasis, although this is extremely rare. It is thought that the inflamed skin releases large quantities of cytokines that cause a generalized vascular leakage. This can cause cutaneous oedema and acute lung injury (p. 917).

Treatment
Treatment of erythroderma is best initiated in hospital. Patients must be kept very warm (with space blankets and heaters). Their vital signs should be monitored regularly, particularly fluid balance. Changes in serum electrolytes and albumin, as well as circulatory status, should be corrected. Swabs should be taken to detect any secondary skin infection.

The skin condition is treated with bed rest and either a bland emollient or a mild topical steroid. All non-essential
drugs should be stopped. Where known, the underlying cause should be treated. The blanket use of systemic steroid therapy for erythrodema remains controversial in view of possible side-effects.

Capillary leak syndrome will often require specialized haemodynamic management in an intensive care unit.

**CUTANEOUS SIGNS OF SYSTEMIC DISEASE**

Some dermatoses are associated with a variety of underlying systemic diseases. Furthermore, some medical conditions may present with cutaneous features.

**Erythema nodosum**

Erythema nodosum has a number of underlying causes (Table 23.8). It presents as painful or tender dusky blue-red nodules, commonly over the shins or lower limbs, which fade over 2–3 weeks leaving a bruised appearance (see Fig. 23.39). It is most common in young adults, especially females. It is often unilateral if associated with pregnancy. It may be associated with arthralgia, malaise and fever. Inflammation occurs in the dermis and the subcutaneous layer (panniculitis).

*Treatment* is of the symptoms with non-steroidal anti-inflammatory drugs (avoid in pregnancy), light compression bandaging and bed rest, as the condition resolves spontaneously. The underlying cause should be treated. In very persistent cases dapsone (100 mg daily), colchicine (500 mg twice daily) or prednisolone (up to 30 mg daily) can be useful.

**Erythema multiforme**

Erythema multiforme (EM) is a hypersensitivity rash of acute onset frequently caused by infection or drugs. A cell-mediated cutaneous lymphocytotoxic response is present.

In 50% of cases the cause is not found but the following should be considered:

- herpes simplex virus (the most common identifiable cause)
- other viral infections (e.g. EBV, orf)
- drugs (e.g. sulphonamide, anticonvulsants)
- mycoplasma infection

**Table 23.8 Causes of erythema nodosum**

*Common causes

Clinically the lesions can be erythematous, polycyclic, annular or show concentric rings (‘target lesions’) (Fig. 23.22). Frank blistering is not uncommon. The rash tends to be symmetrical and commonly affects the limbs, especially the hands and feet where palms and soles may be involved. Occasionally there is severe mucosal involvement leading to necrotic ulcers of the mouth and genitalia, and a conjunctivitis (‘EM major’ – not to be confused with Stevens–Johnson syndrome – see Table 23.9).

The term ‘EM minor’ is used for cases without mucosal involvement.

Erythema multiforme usually resolves in 2–4 weeks.

Rarely, recurrent erythema multiforme can occur and this is triggered by herpes simplex infection in 80% of cases.

**Treatment**

This is symptomatic and involves treating the underlying cause. Some advocate the use of oral steroids in severe mucosal disease but this remains controversial.

Recurrent erythema multiforme can be treated with prophylactic oral aciclovir (200 mg twice daily) even if no cause has been found, as 80% of cases appear to be driven by herpes simplex virus. In resistant cases, azathioprine (1–2 mg/kg daily) is used.

**Pyoderma gangrenosum**

Pyoderma gangrenosum is a condition of unknown aetiology that presents with erythematous nodules or pustules which frequently ulcerate (Fig. 23.23). The ulcers can be large and grow at an alarming speed. The ulcer has a typical bluish black (‘gangrenous’) undermined edge and a purulent surface (‘pyoderma’). There may be an associated pyrexia and malaise. Biopsy through the ulcer edge shows an intense neutrophilic infiltrate and occasionally a vasculitis but the diagnosis depends mostly on the clinical appearance. The main causes are:

- connective tissue disease (e.g. SLE, polyarteritis nodosa)
- HIV infection
- Wegener’s granulomatosis
- carcinoma, lymphoma.

**Treatment**

This is with very potent topical steroids or 0.1% tacrolimus ointment. High-dose oral steroids may be needed to prevent rapidly progressive ulceration. Oral dapsone and minocycline may help. Other immunosuppressants, such as ciclosporin, are useful in resistant cases. The underlying cause should be treated.

**Acanthosis nigricans**

Acanthosis nigricans presents as thickened, hyperpigmented skin predominantly of the flexures (Fig. 23.24). It can appear warty or velvety when advanced. In early life it is seen in obese individuals who have very high levels of insulin owing to insulin resistance (and this is sometimes termed ‘pseudo-acanthosis nigricans’). In older people it normally reflects an underlying malignancy (especially gastrointestinal tumours). Rarely it is associated with hyperandrogenism in females.

**Treatment**

Topical or oral retinoids (0.5 mg/kg/day) may help (p. 1247), and weight loss is advised in the obese. Any underlying malignancy should be treated.

**Dermatomyositis** (see also p. 547)

The rash is distinctive and often photosensitive. Facial erythema and a magenta-coloured rash around the eyes with associated oedema are usually present. Bluish red nodules or plaques may be present over the knuckles (Gottron’s papules) and extensor surfaces. The nail folds are frequently ragged with dilated capillaries. The diagnosis is made from the clinical appearance, muscle biopsy, electromyography (EMG) and a serum creatine phosphokinase. Skin biopsy is not diagnostic.

There is a childhood form which usually occurs before the age of 10 and which eventually resolves. This type is often associated with calcinosis in the skin and can cause significant long-term functional problems with weak muscles and contractures. Life-threatening bowel infarction can also occur in the childhood form. The adult form usually occurs after the age of 40. Some cases are associated with an underlying malignancy whereas some are associated with other autoimmune rheumatic disease. This latter group may overlap with scleroderma and lupus erythematosus.

**Treatment**

Skin disease may respond to sunscreens and hydroxychloroquine (200 mg twice daily) as well as immunosuppressants, e.g. azathioprine or ciclosporin.
Scleroderma (see also p. 545)

The term scleroderma refers to a thickening or hardening of the skin owing to abnormal dermal collagen. It is not a diagnostic entity in itself. Systemic sclerosis and morphea both show sclerodermatous changes but are separate conditions.

Systemic sclerosis (often called scleroderma) has cutaneous and systemic features and is discussed fully on page 546.

Morphea is confined to the skin and usually presents in children or young adults. It is commoner in females and the cause is unknown. Lesions are usually on the trunk and appear as bluish red plaques which progress to induration and then central white atrophy. A linear variant exists in childhood which is more severe as it can cause atrophy of underlying deep tissues and thus cause unequal limb growth or scarring alopecia.

Rarely sclerodermatous skin changes may be seen in Lyme disease (acrodynatitis chronica atrophicans), chronic graft-versus-host disease, polyvinyl chloride disease, eosinophilic myalgia syndrome (due to tryptophan therapy) and bleomycin therapy.

Lupus erythematosus (LE)

There are three clinical variants to this disease but some patients may show features of more than one type.

- Chronic discoid lupus erythematosus (CDLE).
- Subacute cutaneous lupus erythematosus (SCLE).
- Systemic lupus erythematosus (SLE).

The aetiology is unknown but is presumably a reflection of some abnormality in immune function as variable autoantibodies may be found in all types. Very rarely it can be induced by certain drugs such as phenothiazines, hydralazine, methyl dopa, isoniazid, tetracycline, mesalazine and penicillin.

Chronic discoid lupus erythematosus (CDLE)

CDLE is the most common type of LE seen by dermatologists and more frequently affects females. Clinically it presents with fixed erythematos, scaly, atrophic plaques with telangiectasia, especially on the face or other sun-exposed sites (Fig. 23.25). Hypopigmentation is common and follicular plugging may be apparent. Scalp involvement may lead to a scarring alopecia. Oral involvement (erythematous patches or ulceration) occurs in 25% of cases.

CDLE may be triggered and exacerbated by UV exposure. A few patients may also suffer with Raynaud’s phenomenon or unusual chilblain-like lesions (chilblain lupus). Only 5% of cases will go on to develop SLE but this is more common in children. Serum anti-nuclear factor (ANF) is positive in 30% of cases.

Skin biopsy shows a dense patchy, dermal cellular infiltrate (mostly T cells) which is often centred on appendages. Epidermal basal layer damage, follicular plugging and hyperkeratosis may be present. Direct immunofluorescence studies of lesional skin may show the presence of IgM and C3 in a granular band at the dermoepidermal junction (‘lupus band’).

Treatment

First-line therapy is with sunscreens and potent topical steroids. Certain oral antimalarials (hydroxychloroquine 100–200 mg twice daily and mepacrine 100 mg daily) can prove very useful and are generally safe for long-term intermittent use. Oral prednisolone is beneficial but its use is limited by its side-effect profile. Azathioprine, retinoids, ciclosporin and thalidomide can be useful in resistant cases.

Prognosis

The disease is usually chronic although it may fluctuate in severity. CDLE remains confined to the skin in most patients and it will eventually go into remission in up to 50% of cases (after many years).

Subacute cutaneous lupus erythematosus (SCLE)

SCLE is a rare cutaneous variant of LE. It presents with widespread indurated, sometimes urticated erythematous lesions, often on the upper trunk. The lesions can also be annular. Photosensitivity is often a prominent feature. Complications, such as arthralgia and mouth ulceration, are seen but significant organ involvement is rare. ANF and extractable nuclear antibodies (anti-Ro and anti-La) are usually positive (see p. 544).

Treatment is with oral dapsone, antimalarials or systemic immunosuppression (prednisolone and ciclosporin).

Systemic lupus erythematosus (SLE)

(see also p. 541)

The cutaneous involvement of SLE is one of the minor problems of the disease but it may be the presenting feature.

Features include macular erythema over the cheeks, nose and forehead (‘butterfly rash’ – Fig. 23.26). Palmar erythema, dilated nail fold capillaries, splinter haemorrhages and digital infarcts of the finger tips may also be seen but are not always noticed by the patient. Joint swellings, livedo reticularis and purpura are occasionally seen. Rarely SLE can be complicated by an atypical erythema multiforme-like rash (‘Rowell’s syndrome’).

Treatment (p. 544) is usually managed by a rheumatologist.
Pruritus

The pathophysiology of pruritus (itch) is poorly understood but may be due to peripheral mechanisms (as in skin disease), central or neuropathic mechanisms (as in multiple sclerosis), neurogenic (as in cholestasis/μ opioid receptor stimulation) or psychogenic mechanisms (e.g. parasitophobia). Evidence suggests that low stimulation of unmyelinated C-fibres in the skin is associated with the sensation of itch (high stimulation produces pain). Histamine, tachykinins (e.g. substance P) and cytokines (e.g. interleukin-2) may also play a role peripherally in the skin. The major nerve pathways for itch and the influence of the central nervous system are not well characterized but opioid μ-receptor-dependent processes can regulate the perception and intensity of itch.

Pruritus (see p. 1240, lichen simplex, nodular prurigo/neurodermatitis) in the absence of a demonstrable rash can be caused by a number of different medical problems (Table 23.10).

Asteatotic eczema and cholinergic urticaria are common causes of pruritus where the rash is often missed. The term idiopathic pruritus or ‘senile’ pruritus probably overlaps with astuteatic eczema and this is common in the elderly.

Treatment involves avoiding soaps and symptomatic measures (as for astuteatic eczema). Phototherapy, low-dose amitryptiline or gabapentin may help intractable cases. Underlying medical problems should be treated.

Sarcoidosis (see also p. 868)

Sarcoidosis is a multisystem granulomatous disorder of unknown aetiology. It may present as reddish brown dermal papules and nodules, especially around the eyelid margins and the rim of the nostrils. More polymorphic lesions (papules, nodules and plaques) may appear on the body. It is most common in black Africans where it is often accompanied by hypo- or hyperpigmentation. Rarely it can present with a bluish red infiltrate or swelling, especially of the nose or ears, called lupus pernio. Both these types of lesion can be seen anywhere on the body but are common on the face. Erythema nodosum is sometimes seen in acute-onset sarcoidosis. Erythema nodosum is an immunological reaction and not due to sarcoid tissue infiltration. Swollen fingers from a dactylitis may also be present. Whilst sarcoidosis may be confined to the skin, all patients should be investigated for evidence of systemic disease (p. 869).

Treatment of cutaneous lesions includes very potent topical steroids (0.05% clobetasol propionate), intralesional steroids, oral steroids and occasionally methotrexate or antimalarials.

Neurofibromatosis type 1 (von Recklinghausen’s disease)

(see also p. 1170)

Type 1 neurofibromatosis is an autosomal dominant condition with high levels of penetrance. It often presents in childhood with a variety of cutaneous features. Many cases are new mutations in the NF1 gene. Genetic testing is available but clinical evaluation is more helpful. Early signs include café-au-lait spots (brown macules, greater than 2.5 cm in diameter and more than five lesions) and axillary freckling. Lisch nodules (hyperpigmented iris hamartomas) may be seen in the eyes by slit lamp examination. Learning difficulties and skeletal dysplasia occur. Later on, fleshy skin tags and deeper soft tumours (neurofibromas) appear and they can progress to completely cover the skin causing significant cosmetic disability. A number of endocrine disorders are rarely associated including phaeochromocytoma, acromegaly and Addison’s disease.

Tuberous sclerosis (epiloia)

The tuberous sclerosis complex (TSC) is an autosomal dominant condition of variable severity which may not present until later childhood. It is characterized by a variety of hamartomatous growths. The three cardinal features are (a) mental retardation, (b) epilepsy, and (c) cutaneous abnormalities – but not all have to be present. In most cases it is due to a mutation in either the TSC1 gene (encodes hamartin) or the TSC2 gene (encodes tuberin). Genetic testing is available but the diagnosis still remains clinical, requiring two major features or one major and two minor features. The skin signs include:

- adenoma sebaceum (reddish papules/ﬁbromas around the nose)
- periungual ﬁbroma (nodules arising from the nail bed)
- shagreen patches (firm, ﬂesh-coloured plaques on the trunk)
- ash-leaf hypopigmentation (pale macules best seen with UV light)
- forehead plaque (indurated flesh-coloured patch)
- café-au-lait patches
- pitting of dental enamel.

Internal hamartomas can arise in the heart, lung, kidney, retina and CNS. Parents of a suspected case should be carefully examined (under UV light) as they may have a ‘forme fruste’ of the condition which can manifest just as hypopigmented patches. This and gonadal mosaicism can have genetic implications for future offspring. A large contiguous gene defect may involve TSC2 and PKD1 genes causing tuberous sclerosis and polycystic kidney disease together in the same patient.

**Diabetes mellitus** (see also p. 1057)

Diabetes mellitus can have a number of cutaneous features. Complications of diabetes itself include:

- fungal infection (e.g. candidiasis)
- bacterial infections (e.g. recurrent boils)
- xanthomas
- arterial disease (ulcers, gangrene)
- neuropathic ulcers.

Specific dermatoses of diabetes include:

- necrobiosis lipoidica (a patch of spreading erythema over the skin which becomes yellowish and atrophic in the centre and may ulcerate)
- diffuse granuloma annulare (p. 1254)
- diabetic dermopathy (red-brown flat-topped papules)
- blisters (usually on the feet or hands)
- diabetic stiff skin (tight waxy skin over the fingers with limitation of joint movement owing to thickened collagen – also called cheiroarthropathy).

**Chronic liver disease** (see also p. 328)

Chronic liver disease may present with jaundice, palmar erythema, spider naevi, white nails, hyperpigmentation and pruritus.

*Porphyria cutanea tarda* (PCT, p. 1074) is a rare genetic disorder associated with liver disease usually due to hepatic damage from excessive alcohol consumption or hepatitis C infection. Seventy per cent of cases are sporadic, 25% familial. Overall, 20% of cases have underlying hereditary haemochromatosis (p. 356). PCT presents clinically on exposed skin with sun-induced blisters, skin fragility, scarring, milia and hypertrichosis. Treatment of the cutaneous features is with repeated venesection and/or very low-dose chloroquine plus avoidance of alcohol. There is anecdotal evidence that specific treatment of hepatitis C (p. 341) will also help the skin, presumably by improving liver function. All patients with PCT are at risk of hepatic carcinoma.

**Chronic kidney disease (CKD)**

(see also p. 629)

Chronic kidney disease is commonly associated with intractable pruritus. Pallor, hyperpigmentation and ecchymoses are commonly seen. Rarely it is associated with non-inflammatory blisters, pseudo-porphyreria cutanea tarda and cutaneous calcification. Long-standing renal transplant patients often suffer with recurrent viral warts and squamous cell carcinomas due to the immunosuppression.

‘Nephrogenic fibrosing dermopathy’ (also known as nephrogenic systemic fibrosis) is a newly described severe scleroderma-like skin disease in a subset of patients with CKD (usually on dialysis). The disease is rapid in onset (days to weeks) with skin discoloration and thickening, joint contractures, muscle weakness and generalized pain. Widespread tissue fibrosis may ensue, causing severe morbidity. Patients may rapidly become wheelchair-bound. The condition is strongly associated with the contrast medium gadolinium used in MRI scans, and such contrast agents are best avoided in patients with low GFRs. There is no accepted treatment but some advocate PUVA and extracorporeal photopheresis. No spontaneous remissions have been recorded. Rapid correction of renal function generally stops the condition progressing.

Calciaphylaxis is discussed on page 630.

**Thyroid disease** (see also p. 985)

Hypothyroidism may cause dry firm gelatinous (myxedematous) skin with diffuse hair thinning and loss of the outer third of the eyebrows. Hyperthyroidism may be associated with warm sweaty skin and a diffuse alopecia. Graves’ disease is rarely associated with thyroid acropachy (‘clubbing’ with underlying bone changes) and pretibial myxedema (a red-brown mucinous infiltration of the shins which can become lumpy and tender).

**Cushing’s syndrome** (see also p. 1012)

Cushing’s syndrome may cause hirsutism, a moon face, a buffalo hump, stretchmarks (striae) and a pustular folliculitis (often called steroid acne) of the skin.

**Hyperlipidaemias** (see also p. 1063)

Hyperlipidaemias can present with xanthomas, which are abnormal collections of lipid in the skin. All patients with xanthomas should be investigated for hyperlipidaemia although the most common type, called xanthelasmas (yellow plaques around the eyes), are usually associated with normal lipids. There are a number of other clinical variants of xanthomas such as (i) tuberous xanthoma (firm orange-yellow nodules and plaques on extensor surfaces), (ii) tendon xanthoma (firm subcutaneous swellings attached to tendons), (iii) plane xanthoma (orange-yellow macules often affecting palmar creases), (iv) eruptive xanthoma (numerous small yellowish papules commonly on the buttocks).

**Amyloidosis**

*Macular amyloid* is a common purely cutaneous variant seen in Asians. It is characterized by itchy brown rippled macules on the upper back.

*Systemic amyloid* may be associated with reddish brown papules, nodules or plaques especially around the eyes, the flexural areas and mucosal surfaces. Distinctive periorbital bruising and macroGLOSSIA may also be present.
**Systemic malignant disease**

Certain rashes may be a non-metastatic manifestation of an underlying malignancy: paraneoplastic dermatoses (Table 23.11). Rarely tumours can metastasize to the skin where they normally present as papules or nodules which may proceed to ulcerate.

**BULLOUS DISEASE**

Primary blistering diseases of the skin are rare. A variety of skin proteins hold the skin together. Inherited abnormalities or immune damage of these proteins cause abnormal cell separation, inflammation, fluid accumulation and blistering.

(Fig. 23.27). The level of blistering determines the clinical picture as well as the prognosis. Therefore skin biopsy for light and electron microscopy together with immunofluorescence (IMF) studies is paramount in diagnosis. However, remember that the commonest causes of skin blistering are chickenpox, herpes, impetigo, pompholyx eczema and insect bite reactions, although these are often localized.

**IMMUNOBULLOUS DISEASE**

**Pemphigus vulgaris**

Pemphigus vulgaris is a potentially fatal blistering disease occurring in all races but commoner in Ashkenazi Jews and possibly in people from the Indian subcontinent. Onset is usually in middle age and both sexes are affected equally. The development of autoantibodies against the desmosomal protein desmoglein 3 is pathogenic in this disease and the autoantibodies can be measured experimentally as markers of disease activity. Desmoglein 3, an adhesion molecule, is expressed in skin and mucosal surfaces, so both will blister. Rarely the disease can be drug induced (e.g. penicillamine or captopril).

Skin biopsy shows a superficial intraepidermal split just above the basal layer with acantholysis (separation of individual cells). In the rarer variant, pemphigus foliaceus (characterized by anti-desmoglein 1 autoantibodies), the split is higher in the upper epidermis. As desmoglein 1 is not expressed in oral mucosa, only cutaneous blisters are seen in this subtype. Both direct IMF of skin (perilesional) and indirect IMF using patients’ serum show intercellular staining of IgG within the epidermis.

**Clinical features**

Mucosal involvement (especially oral ulceration) is common and is the presenting sign in up to 50% of cases. This may then be followed by the appearance of flaccid blisters, particularly involving the trunk. They tend to be sore rather than itchy. Blistering usually becomes widespread but they rapidly

---

**Fig. 23.27** Section of the basement membrane zone, showing the structural sites of damage in bullous disorders. LAD, linear IgA disease; EB, epidermolysis bullosa; K, Keratin.
Treatment

This is with very high-dose oral prednisolone (60–100 mg daily) or pulsed methylprednisolone and may need to be lifelong. Therefore other immunosuppressants such as azathioprine or mycophenolate mofetil (or occasionally cyclophosphamide or ciclosporin) are used as steroid-sparing agents. Intravenous immunoglobulin infusions may help gain quick control whilst waiting for these other drugs to work. The anti-B cell drug rituximab (anti-CD20 monoclonal antibody) helps multidrug-resistant cases and has been used in combination with immunoglobulin. It is expensive and has been associated with severe side-effects including sepsicaemia and death in some studies.

Whilst treatment is normally effective, perhaps up to 10% of patients may die either due to complications of the disease or more commonly from side-effects of the treatment.

Bullous pemphigoid

Bullous pemphigoid is more common than pemphigus. It presents in later life (usually over 60) and mucosal involvement is rarer. Autoantibodies against a 230 kDa or 180 kDa hemidesmosomal protein (‘bullous pemphigoid antigen 1’ and ‘type XVII collagen’) play an aetiological role.

Skin biopsy shows a deeper blister (than in pemphigus) due to a subepidermal split through the basement membrane. Direct and indirect IFM studies show linear staining of IgG along the basement membrane.

Clinical features

Large tense bullae appear anywhere on the skin (Fig. 23.28) but often involve limbs, hands and feet. They may be centred on an erythematous or urticated background and they can be haemorrhagic. Pemphigoid can be very itchy. Mucosal ulceration is uncommon but a variant of pemphigoid exists which predominantly affects mucosal surfaces with scarring (mucous membrane pemphigoid).

Treatment

This is with high-dose oral prednisolone (30–60 mg daily) and steroid-sparing agents such as azathioprine or mycopheno-

late mofetil. Weekly methotrexate is also occasionally used. In general, disease control is easier than with pemphigus. Often treatment can be withdrawn after 2–3 years. Treatment often causes side-effects, especially as most patients are elderly. Occasionally localized or mild disease can be controlled with superpotent topical steroids, oral dapsone or high-dose oral minocycline.

Dermatitis herpetiformis

(see also p. 279)

Dermatitis herpetiformis (DH) is a rare blistering disorder associated with gluten-sensitive enteropathy (coeliac disease). DH and coeliac disease are associated with other organ-specific autoimmune disorders. The HLA associations (B8, DR3, DQ2 in 80–90% of cases) and immunological findings (endomysial, tissue transglutaminase, reticulin and gliadin autoantibodies present in serum) are similar to coeliac disease.

Skin biopsy shows a subepidermal blister with neutrophil microabscesses in the dermal papillae. Direct immunofluorescent studies of uninvolved skin show IgA in the dermal papillae and patchy granular IgA along the basement membrane. The jejunal mucosa shows a partial villous atrophy.

Clinical features

Dermatitis herpetiformis is commoner in males and can present at any age but is most likely to appear for the first time in young adult life. It presents with small, intensely itchy blisters of the skin. The lesions have a predilection for the elbows, extensor forearms, scalp and buttocks. The tops of the blisters are usually scratched off thus crusted erosions are often seen at presentation. Remissions and exacerbations are common.

Treatment

This should always be with a gluten-free diet (GFD, p. 279). Control of the skin disease can be obtained with oral dapsone (50–200 mg daily) or sulphonamides. If a strict GFD is adhered to, oral medication can often be withdrawn after 2 years.

Use of dapsone. Dapsone frequently causes a mild dose-related haemolytic anaemia (which is usually well tolerated) but the haemolysis can be devastating if there is G6PD deficiency. Liver damage, peripheral neuropathy and aplastic anaemia can also rarely occur so regular monitoring of a blood count and liver function is needed.

Linear IgA disease (chronic bullous dermatosis of childhood)

Linear IgA disease is a subepidermal blistering disorder of adults and children. Pathogenic IgA autoantibodies bind to a variety of basement membrane proteins including type XVII collagen and laminin 5 (see Fig. 23.27). It is the most common immunobullous disease seen in children. Rarely it is induced by vancomycin.

Clinical features

Linear IgA disease can present with circular clusters of large blisters, a pemphigoid type of blistering or a dermatitis herpetiformis picture. Mucosal involvement of the mouth, vulva and eyes is not uncommon and can cause scarring. Direct

Fig. 23.28 Bullous pemphigoid.
IMF studies of skin show linear IgA deposition along the basement membrane.

**Treatment**

This is with oral dapsone (50–200 mg daily) or sulphonamides. Occasionally immunosuppression is needed. Many patients show spontaneous resolution after 3–6 years.

**MECHANOBULLOUS DISEASE**

**(EPIDERMOLYSIS BULLOSA, ‘EB’)**

These are due to inherited abnormalities in structural skin proteins which lead to ‘skin fragility’. The resultant blistering tends to arise secondary to trauma and often appears at or shortly after birth. These conditions can be a mild inconvenience, severely disabling or fatal but fortunately are very rare. There are three groups of disorders in which the fundamental gene/protein abnormalities have been characterized.

**Epidermolysis bullosa simplex** is a group of autosomal dominant genodermatoses characterized by ‘superficial’ blistering owing to mutations of cytoskeleton proteins within the basal layer of the epidermis, e.g. keratin 5 (chromosome 12q) or keratin 14 (chromosome 17q). Most forms of EB simplex show mild disease with intermittent blistering of the hands and feet, especially in hot weather. The teeth and nails are normal and scarring is absent.

**Epidermolysis bullosa dystrophica** is a group of genodermatoses characterized by ‘deeper’ blistering associated with scarring and milia formation. The level of split is deep within the basement membrane and is due to a mutation in the COL-7A1 gene ( locus at chromosome 3p21.1) which causes a loss of collagen VII in the anchoring fibrils. Nails, mucosae and even the larynx are often involved. The autosomal dominant variety is milder but the autosomal recessive type produces severe disease with disabling scarring, fusion of digits, joint contractures and dysphagia. Life expectancy is significantly reduced. Repeated scarring results in the development of multiple squamous cell carcinomas and most die from this complication in early adult life. The average life expectancy after the appearance of the first squamous cell carcinoma is 5 years.

**Junctional epidermolysis bullosa** is the most severe form. It is characterized by a split in the lamina lucida of the basement membrane and is due to mutations in various proteins, mainly laminin 5 but also $\alpha_6\beta_4$ integrin or the 180 kDa bullous pemphigoid-2 antigen. It presents at birth with widespread blistering and areas of absent skin. Erosions of the central face and hoarseness from laryngeal involvement are common. Nail and teeth abnormalities are also common. Both a lethal and a rarer non-lethal form of junctional EB exist and they show an autosomal recessive inheritance. The lethal form causes death in infancy or early childhood.

**Investigation and treatment**

Investigation and treatment of EB should be carried out in a specialist centre. Diagnosis at birth on clinical grounds is difficult and should be avoided. Exact diagnosis depends on ultrastructural analysis of induced blisters in the skin and immunohistochecmy, and these investigations can be further confirmed with genetic testing. Only then can prognosis and genetic counselling be given accurately to parents. Prenatal diagnosis is available for the more severe forms of EB.

**SKIN TUMOURS**

**BENIGN CUTANEOUS TUMOURS**

**Melanocytic naevi (moles)**

Moles are a benign overgrowth of melanocytes that are common in white-skinned people. They appear in childhood and increase in number and size during adolescence and early adult life. They often start as flat brown macules with proliferation of melanocytes at the dermoepidermal junction (junctional naevi). The melanocytes continue to proliferate and grow down into the dermis (compound naevi) which causes an elevation of the mole above the skin surface. The pigmentation is usually even and the border regular. They eventually mature into a dermal naevus (cellular naevus), often with a loss of pigment.

**Blue naevus** is an acquired asymptomatic blue-looking mole. It is due to a proliferation of melanocytes deep in the mid-dermis.

**Basal cell papilloma (seborrhoeic wart)**

This is a common benign overgrowth of the basal cell layer of the epidermis. The lesion can be flesh coloured, brown or even black and often has a greasy appearance. The surface is irregular and warty and the lesions appear very superficial as though stuck on to the skin (Fig. 23.29). Tiny keratin cysts may be seen on the surface. They can be treated with cryotherapy or curettage.

**Dermatofibroma (histiocytoma)**

Dermatofibromas appear as firm, elevated pigmented nodules which may feel like a button in the skin. A peripheral ring of pigmentation is sometimes seen. They are often found on the leg and are commoner in females. There may be a preceding history of trauma or insect bite. The lesion consists of histiocytes, blood vessels and varying degrees of fibrosis. If symptomatic, excision is required.

**Epidermoid cyst (previously ‘sebaceous cyst’)**

Epidermoid cysts present as cystic swellings of the skin with a central punctum. They contain ‘cheesy’ keratin rather than sebum; thus the old term ‘sebaceous cyst’ should be avoided. These cysts occasionally rupture causing significant dermal inflammation which is not infected.

**Pilar cyst (trichilemmal cyst)**

Pilar cysts are smooth cysts without a punctum usually found on the scalp. They may be multiple and familial.

---

**Fig. 23.29** Seborrhoeic warts (basal cell papillomas).
Keratoacanthoma
Keratoacanthomas are rapidly growing epidermal tumours which develop central necrosis and ulceration (Fig. 23.30). They occur on sun-exposed skin in later life and can grow up to 2–3 cm across. Whilst they may resolve spontaneously over a few months, they are best excised both to exclude squamous cell carcinoma (which they can mimic) and to improve the cosmetic outcome.

Pyogenic granuloma (granuloma telangiectaticum)
Pyogenic granulomas are a benign overgrowth of blood vessels. They present as rapidly growing pinkish red nodules which are friable and readily bleed. They may follow trauma and are often found on the fingers and lips. They are best excised to exclude an amelanotic malignant melanoma.

Cherry angiom (Campbell de Morgan spots)
These are benign angiokeratomas that appear as tiny pinpoint red papules, especially on the trunk, and increase with age. No treatment is required.

**POTENTIALLY PRE-MALIGNANT CUTANEOUS TUMOURS**

Solar keratoses (actinic keratoses)
These frequently develop later in life in white-skinned people who have had significant sun exposure. They appear on exposed skin as erythematous silver-scaly papules or patches with a conical surface and a red base (Fig. 23.31). The background skin is often inelastic, wrinkled and may show flat brown macules (‘liver spots’ or solar lentigines) reflecting diffuse solar damage. A small proportion of these keratoses can transform into squamous cell carcinoma but only after many years.

*Treatment* of lesions is with cryotherapy, topical 5-fluourouracil cream or 5% imiquimod cream.

Bowen’s disease
This is a form of intraepidermal carcinoma-in-situ which rarely can become invasive. It is thought to be due to long-term sun exposure. It presents on exposed skin, most commonly women’s legs, as an isolated scaly red patch or plaque looking rather like psoriasis although it has a rather irregular edge. The lesions do not clear but slowly increase in size with time.

Fig. 23.30 Keratoacanthoma.

Fig. 23.31 Solar keratoses with background actinic damage.

A variant which can show partial or full-thickness dysplasia can involve the epidermis of the mucosa or neighbouring skin. This can affect the vulva, the glans penis and perianal skin and is termed vulval (penile, or anal) intraepithelial dysplasia. Clinically it can present as non-specific erythema or as a warty thickening. These diseases have a stronger link with HPV and probably have a higher pre-malignant potential than Bowen’s disease. They are commoner in immunosuppressed individuals. The anal form is increasingly reported in HIV-positive patients (as indeed is anal carcinoma) and extension to the rectum may occur.

*Treatment* is with topical 5-fluourouracil, 5% imiquimod cream, cryotherapy, curettage, photodynamic therapy or a tissue-destructive laser.

Atypical mole syndrome (dysplastic naevus syndrome)
This is often familial. A large number of melanocytic naevi begin to appear in childhood even on unexposed sites. Individual lesions may be large with irregular pigmentation and border, and histologically they may show cytological and architectural atypia but no frank malignant change. Individuals with this condition have an increased risk of developing malignant melanoma. They should have their moles photographed and be regularly reviewed. Suspicious lesions should be excised.

Giant congenital melanocytic naevi
These are very large moles present at birth. Only the very large lesions (>20 cm across) show an increased risk of developing malignant melanoma and the risk has recently been downgraded: each lesion probably has a <5% risk of malignancy. Excision may be considered but is rarely possible without multiple operations and marked disfigurement so regular monitoring is advised. There have been a number of recent reports showing that a few of these lesions improve spontaneously and partially resolve during childhood.

Lentigo maligna
This is a slow-growing macular area of pigmentation seen in elderly people, commonly on the face. The border and pigmentation are often irregular. Some people regard this lesion as a melanoma-in-situ. There is an increased risk of developing invasive malignant melanoma. Treatment is by excision if possible but 5% imiquimod cream is currently...
being tried in the very large lesions where surgery would be disfiguring.

**MALIGNANT CUTANEOUS TUMOURS**

**Basal cell carcinoma (rodent ulcer)**

Basal cell carcinomas are the most common malignant skin tumour and most relate to excessive sun exposure. They are common later in life on exposed sites although rare on the ear. They are 10–20 times more common in the chronically immunosuppressed solid organ transplant population. They can present as a slow-growing papule or nodule (or rarely be cystic) which may go on to ulcerate (Fig. 23.32). Telangiectasia over the tumour or a skin-coloured jelly-like ‘pearly edge’ may be seen. A flat, diffuse superficial form exists as an ill-defined ‘morphoeic’ variant. Basal cell carcinomas will slowly grow and erode structures if untreated but these tumours almost never metastasize.

**Treatment**

Treatment is usually with surgical excision with a 3–5 mm border. Radiotherapy, photodynamic therapy, cryotherapy or 5% imiquimod cream can be useful for large superficial forms but follow-up for recurrence is required. Curettage may occasionally be used in older patients although not for central facial lesions as they often recur. Recurrent tumour or morphoeic basal cell carcinoma is best treated with Mohs’ micrographic surgery to ensure adequate clearance.

**Squamous cell carcinoma**

Squamous cell carcinoma (SCC) is a more aggressive tumour than basal cell carcinoma (BCC) as it can metastasize if left untreated. Most relate to sun exposure, and daily application of sun cream has been shown to reduce the incidence in Australia. SCC can arise in pre-existing solar keratoses or Bowen’s disease or be due to chronic inflammation such as in lupus vulgaris. Rarely multiple tumours may arise due to arsenic ingestion in early life. Multiple tumours also occur in people who have had prolonged periods of immunosuppression such as renal transplant patients where certain human papillomavirus subtypes may be involved in malignant transformation.

Clinically the lesions are often keratotic, rather ill-defined nodules which may ulcerate (Fig. 23.33). They can grow very rapidly. Examination of regional lymph nodes is essential. They are most common on sun-exposed sites in later life. Ulcerated lesions on the lower lip or ear are often more aggressive.

**Treatment** is with excision or occasionally radiotherapy. Curettage should be avoided.

**Malignant melanoma**

Malignant melanoma is the most serious form of skin cancer as metastasis can occur early and it causes a number of deaths even in young people. As with other types of skin cancer the incidence is continuing to increase, probably due to excessive exposure to sunlight. The history of childhood sun exposure and intermittent intense sun exposure appears to be necessary for the development of malignant melanoma. Other risk factors include pale skin, multiple melanocytic naevi (>50), sun sensitivity, immunosuppression, atypical mole syndrome, giant congenital melanocytic naevi, lentigo maligna and a positive family history of malignant melanoma. Malignant melanoma is commoner in later life but many young adults are also affected. A number of oncogenes and tumour suppressor proteins (CDK4, CDKN2a, B-Raf, PTEN, Ras, Rb, p53, p16) have been implicated in the pathogenesis of melanoma.

**Diagnosis** of melanoma is not always easy but the clinical signs listed in Table 23.12 help distinguish malignant from benign moles. Examination with a dermatoscope (a handheld polarized light source with magnification) can further help in detecting malignant lesions.

Four clinical types exist:

- **Lentigo maligna melanoma** is where a patch of lentigo maligna develops a papule or nodule signalling invasive tumour.
- **Superficial spreading malignant melanoma** is a large flat irregularly pigmented lesion which grows laterally before vertical invasion develops.

</tbody>
</table>

- **Nodular malignant melanoma** (Fig. 23.34) is the most aggressive type. It presents as a rapidly growing pigmented nodule which bleeds or ulcerates. Rarely they are amelanotic (non-pigmented) and can mimic pyogenic granuloma.
- **Acral lentiginous malignant melanomas** arise as pigmented lesions on the palm, sole or under the nail and they usually present late. They may not be related to sun exposure.

**Treatment**

In the UK all patients with melanoma > 1 mm thick should be referred to their regional multidisciplinary team (dermatology/plastic surgery/oncology/melanoma nurse) for expert management. Surgery is the only curative treatment and entails urgent wide excision: 1 cm margin for thin melanomas (<1 mm) increasing to 3 cm margin for thicker melanomas (>2 mm). Histological analysis will determine the depth of invasion (‘Clark’s level’) and the thickness of the tumour (‘Breslow thickness’). Patients with melanomas greater than 1 mm are staged according to the American AJCC criteria which look at tumour thickness, metastasis and lymph node status and this helps predict prognosis and 5-year survival rates. Sentinel node biopsy for patients with thicker lesions is currently under assessment as a tool for predicting prognosis and it may prove to be useful in determining therapy (e.g. lymph node dissection) and improving survival but this is only available in a few centres and it remains a research tool. Metastatic disease can involve surgery to lymph nodes, isolated limb perfusion, radiotherapy, immunotherapy and chemotherapy but none of these is currently very effective. Initial optimism for high-dose alpha-interferon therapy in advanced disease has recently been challenged with a systematic review suggesting no clear benefit. Other areas of therapeutic research involve immunization with the ganglioside GM2 (a molecule frequently expressed on melanoma cell surfaces), VEGF receptor tyrosine kinase inhibitors and VEGF inhibitors, but none of these is yet of proven benefit.

The role of governments and medical personnel in public health education to discourage sunbathing and encourage the use of sunscreens is of the utmost importance in skin cancer prevention.

**Cutaneous T cell lymphoma (mycosis fungoides)**

This is a rare type of skin tumour which often follows a relatively benign course. It presents insidiously with scaly patches and plaques which can look eczematous or psoriasiform. Lesions often appear initially on the buttocks. These lesions may come and go or remain persistent over many years. Patients may well die of unrelated causes. Skin biopsy confirms the diagnosis, showing invasion by atypical lymphocytes. T cell receptor gene rearrangement studies show that there is often a monoclonal expansion of lymphocytes in the skin.

Occasionally the disease can progress to a cutaneous nodular or tumour stage, which may be accompanied by systemic organ involvement. In elderly males the disease may progress rarely to an erythrodermic variant accompanied by lymphadenopathy and peripheral blood involvement (‘Sézary syndrome’, 483).

All patients should be staged at the time of diagnosis to assess for any systemic involvement.

**Treatment**

Early cutaneous disease can be left untreated or treated with topical steroids or PUVA. More advanced disease of the skin, or systemic involvement, may require radiotherapy, chemotherapy (e.g. methotrexate), immunotherapy or electron beam therapy. Bexarotene, a retinoid X receptor agonist, is a new therapy for more advanced disease.

**Kaposi’s sarcoma**

This is a tumour of vascular and lymphatic endothelium that presents as purplish nodules and plaques. There are three types:

- The ‘classic’ or ‘sporadic’ form (as described by Kaposi) occurs in elderly males, especially Jewish people from Eastern Europe. It presents as slow-growing purple tumours in the foot and lower leg which rarely cause any significant problem.
- The ‘endemic’ form occurs in males from central Africa and shows more widespread cutaneous involvement as well as lymph node (or occasionally systemic) involvement. Oedema is a prominent feature.
- The immunosuppression-related form is more severe and is most common in homosexual patients with HIV. Lesions are widespread and often affect the skin, bowel, oral cavity and lungs.
All three types have a strong association with herpes virus type 8 but other factors must be involved as herpes type 8 seroprevalence is up to 10% in the USA and 50% in some African countries. HAART (p. 191) has significantly reduced the incidence of Kaposi’s sarcoma in HIV although the prevalence has started to increase again over the last few years for as yet unexplained reasons.

Treatment

Treatment of advanced Kaposi’s sarcoma is with radiotherapy, immunotherapy or chemotherapy.

DISORDERS OF BLOOD VESSELS/LYMPHATICS

LEG ULCERS

Leg ulcers are common and can have many causes (Table 23.13). Venous ulcers are the most common type in developed countries.

Venous ulcers

Venous ulcers are the result of sustained venous hypertension in the superficial veins, owing to incompetent valves in the deep or perforating veins or to previous deep vein thrombosis. The increased pressure causes extravasation of fibrinogen through the capillary walls, giving rise to perivascular fibrin deposition, which leads to poor oxygenation of the surrounding skin.

Venous ulcers are common in later life and cause a significant drain on health-care budgets as they are often chronic and recurrent; they affect 1% of the population over the age of 70 years. They are most commonly found on the lower leg in a triangle above the ankles (Fig. 23.35), and may be associated with:

- oedema of the lower legs
- venous eczema (p. 1239)
- brown pigmentation from haemosiderin, which is derived from red blood cells that have extravasated through the capillary wall
- varicose veins, but not invariably
- lipodermatosclerosis (the combination of induration, reddish brown pigmentation and inflammation) – a fibrosing panniculitis of the subcutaneous tissue
- scarring white atrophy with telangiectasia (atrophie blanche).

Treatment is with high-compression bandaging (e.g. Unna boot or four-layer bandaging) and leg elevation to try to decrease the venous hypertension. Doppler studies should always be done before bandaging to exclude arterial disease. This treatment is best delivered in the community by appropriately trained nurses. ‘Four-layer bandaging’ is increasingly popular as this provides high levels of graduated compression (with pressures decreasing up the leg). Ulcer dressings are used to keep the ulcer moist and free of slough and exudates. Up to 80% of ulcers can be healed within 26 weeks. Slower healing rates occur in patients with decreased mobility and if the ulcers are very large, present for longer than 6 months or bilateral. Diuretics are sometimes helpful to reduce the oedema. Antibiotics are necessary only for overt bacterial infection. Unusual fungal infection (‘tinea incognito’) is increasingly reported under compression bandaging.

Venous leg ulcers can be very painful so adequate analgesia should be given, including opiates if required. Split-thickness skin grafting is used in resistant cases. Support stockings (individually fitted) should be worn lifelong after healing as this lessens recurrence.

Underlying venous disease is best investigated with duplex ultrasound or plethysmography. Surgery for purely superficial venous disease can occasionally be useful for ulcer healing but, in general, venous surgery is unhelpful.

Support stockings should be used for prophylaxis against ulcers.

Arterial ulcers

Arterial ulcers present as punched-out, painful ulcers higher up the leg or on the feet. There may be a history of claudication, hypertension, angina or smoking. Clinically the leg is cold and pale. Absent peripheral pulses, arterial bruits and loss of hair may be present. Doppler ultrasound studies will confirm arterial disease.

Treatment depends on keeping the ulcer clean and covered, adequate analgesia and vascular reconstruction if appropriate. Compression bandaging must not be used.

Neuropathic ulcers

Neuropathic ulcers tend to be seen over pressure areas of the feet, such as the metatarsal heads, owing to repeated trauma. These are most commonly seen in diabetics due to peripheral neuropathy. In some developing countries leprosy is a common cause.

Fig. 23.35 Venous leg ulcer.
Treatment depends on keeping the ulcer clean and removing pressure or trauma from the affected area. Diabetics should pay particular attention to foot care and correctly fitting shoes with the help of a specialist podiatrist (p. 1056).

PRESSURE SORES (DECUBITUS ULCERS, BEDSORES)

These occur in the elderly, immobile, unconscious or paralysed patients. They are due to skin ischaemia from sustained pressure over a bony prominence, most commonly the heel and sacrum. Normal individuals feel the pain of continued pressure, and even during sleep movement takes place to change position continually. Pressure sores may be graded:

- Stage I: non-blanchable erythema of intact skin
- Stage II: partial-thickness skin loss of epidermis/dermis (blister or shallow ulcer)
- Stage III: full-thickness skin loss involving subcutaneous tissue but not fascia
- Stage IV: full-thickness skin loss with involvement of muscle/bone/tendon/joint capsule

There are numerous risk factors for development of pressure sores (Table 23.14).

The majority of pressure sores occur in hospital. Seventy per cent appear in the first 2 weeks of hospitalization, and 70% are in orthopaedic patients, especially those on traction. Between 20% and 30% of pressure sores occur in the community.

Eighty per cent of patients with deep ulcers involving the subcutaneous tissue die in the first 4 months.

The early sign of red/blue discoloration of the skin can lead rapidly to ulcers in 1–2 hours. Leaving patients on hard emergency room trolleys, or sitting them in chairs for prolonged periods, must be avoided.

Management

Prevention

Prevention is better than cure. Specialist ‘tissue-viability nurses’ help identify at-risk patients and train other clinical staff. Several risk assessment tools have been devised for the immobile patient based on the known risk factors. The ‘Norton scale’ and Waterlow Pressure Sore Risk Assessment (Box 23.3) are two such validated systems which produce a

Treatment
- bed rest with pillows and fleeces to keep pressure off bony areas (e.g. sacrum and heels) and prevent friction
- air-filled cushions for patients in wheelchairs
- special pressure-relieving mattresses and beds
- regular turning but avoid pressure on hips
- ensure adequate nutrition
- non-irritant occlusive moist dressings (e.g. hydrocolloid)
- adequate analgesia (may need opiates)
- plastic surgery (debridement and grafting in selected cases)
- treatment of underlying condition

VASCULITIS (see also p. 548)
Vasculitis is the term applied to an inflammatory disorder of blood vessels which causes endothelial damage. Cutaneous vasculitis (confirmed by skin biopsy) may be an isolated problem but occasionally is associated with vasculitis in other organs. The most commonly used classification is based on the size of blood vessel involved (see Tables 10.18 and 10.19).

The cutaneous features are of haemorrhagic papules, pustules, nodules or plaques which may erode and ulcerate. These purpuric lesions do not blanch with pressure from a glass slide (‘diascopy’). Occasionally a fixed livedo reticularis pattern may appear which does not disappear on warming. Pyrexia and arthralgia are common associations even in the absence of significant systemic involvement. Other clinical features depend on the underlying cause.

Leucocytoclastic vasculitis (LCV) or angiitis is the most common cutaneous vasculitis affecting small vessels. This usually appears on the lower legs as a symmetrical palpable purpura. It is rarely associated with systemic involvement. It can be caused by drugs (15%), infection (15%), inflammatory disease (10%) or malignant disease (<5%) but often no cause is found (55–60%). Investigations are only necessary with persistent lesions or associated signs and symptoms. Whilst LCV often settles spontaneously, treatment with analgesia, support stockings, dapsone or prednisolone may be needed to control the pain and to heal up any ulceration. Urticarial vasculitis is discussed on page 1243.

Calciphylaxis (calcific uraemic arteriopathy) is described on page 630.

LYMPHATICS

Lymphoedema
Lymphoedema refers to a chronic non-pitting oedema due to lymphatic insufficiency. It is most commonly seen affecting the legs and tends to progress with age. The legs can become enormous and prevent wearing of normal shoes. Chronic disease may cause a secondary ‘cobblestone’ thickening of the skin. Lymphoedema can be primary (and present early in life) due to an inherited deficiency of lymphatic vessels (e.g. Milroy’s disease) or can be secondary due to obstruction of lymphatic vessels (e.g. filarial infection or malignant disease).

Treatment is with compression stockings and physical massage. If there is recurrent cellulitis, long-term antibiotics are advisable as each episode of cellulitis will further damage the lymph vessels. Surgery should be avoided.

Lymphangioma circumscriptum
This is a rare hamartoma of lymphatic tissue. It usually presents in childhood with multiple small vesicles in the skin which weep lymphatic fluid and sometimes blood. They reflect deeper vessel involvement so surgery should be avoided. Cryotherapy or CO₂ laser treatment may help the superficial lesions.

DISORDERS OF COLLAGEN AND ELASTIC TISSUE

Ehlers–Danlos syndrome (see also p. 568)
Ehlers–Danlos syndrome (EDS) can be subdivided into at least 10 variants. They are all inherited disorders causing abnormalities in collagen of the skin, joints and blood vessels. Clinically this causes increased elasticity of the skin, hypermobile joints and fragile blood vessels causing easy bruising or in some cases internal haemorrhage. The skin is hyperextensible but recoils normally after stretching. It is easily injured and heals slowly with scarring like tissue paper. Pseudotumours may occur at the sites of scarring (such as elbows and knees) consisting mainly of fat, but calcification can occur.

Pseudoxanthoma elasticum
Pseudoxanthoma elasticum is a rare group of disorders characterized by abnormalities in collagen and elastic tissue affecting the skin, eye and blood vessels. The skin may be loose, lax and wrinkled. It can look yellowish and papular (‘plucked chicken skin’) and tends to loose its elastic recoil when stretched. Skin changes are best seen in the flexures, especially the sides of the neck. Non-cutaneous features are not always present but they include recurrent gastrointestinal bleeding, early myocardial infarction, claudication and angioid streaks on the retina reflecting disruption of vascular elastic tissue.

Striae
Striae are visible linear scars due to dermal collagen damage and stretching. Histologically a thinned epidermis overlies parallel bundles of fine collagen. They occur commonly over the abdomen and breasts in pregnancy but also occur on the thighs and trunk in rapidly growing adolescents as well as on some obese individuals. They are also seen in Cushing’s syndrome and corticosteroid therapy. They are also rarely seen in Marfan’s syndrome (p. 780). Striae are initially reddish blue but fade to white atrophic marks. Puberty-related striae normally disappear completely.

Keloid scars
Keloid scars are characterized by smooth hard nodules (Fig. 23.36) due to excessive collagen production. They may occur spontaneously or follow skin trauma/surgery and they are often itchy. They tend to affect young adults and are much
commoner in black Africans. Sites of predilection include the shoulders, upper back and chest, earlobes and chin. Unlike hypertrophic scars (which fade within 12 months) keloids are persistent and may continue to enlarge.

Treatment is with triamcinolone injection, compression with silica gels or surgery, but surgery must be followed by steroid injection or superficial radiotherapy or it may make the problem worse.

**HYPOPIGMENTATION**

**Vitiligo**

Vitiligo is a common autoimmune disorder of depigmentation due to areas of melanocyte loss. Sufferers often have relatives with other organ-specific autoimmune disorders. It presents in childhood or early adult life with well-demarcated macules of complete pigment loss. There is no history of preceding inflammation. Patients are very susceptible to sunburn. Lesions are often symmetrical and frequently involve the face, hands and genitalia (Fig. 23.37). The hair can also depigment. Trauma may induce new lesions. Spontaneous repigmentation can occur and often starts around hair follicles, giving a speckled appearance. However repigmentation is rare if a lesion has persisted for more than 1 year or if the hair is depigmented. The psychological consequences of vitiligo can be devastating, especially in Asian or black African people.

Treatment is often unsatisfactory and has no impact on the long-term outcome. Sunblocks should be used to prevent burning. Potent topical steroids or phototherapy may help some individuals. Tacrolimus ointment (0.1%) is being assessed. If vitiligo is almost universal and fixed, depigmentation with monobenzone can be used. Finally, referral to a specialist camouflage clinic is often the most helpful ‘treatment’.

**Post-inflammatory hypopigmentation**

This is one of the most common causes of pale skin. It is much more common in people with pigmented skin. It may be seen as a consequence of eczema, acne or psoriasis and may even be the reason for individuals presenting to a doctor. Providing the skin disease is controlled the pigmentation will recover slowly after many months. Post-inflammatory hyperpigmentation can also occur.

**Oculocutaneous albinism**

This is a group of rare autosomal recessive disorders affecting the pigmentation of skin, hair and eyes. It can affect all races. Melanocytes are normal in number but have abnormal function. Clinically it presents with universal pale skin, white or yellow hair and a pinkish iris. Photophobia, nystagmus and a squint are also present in most cases.

Treatment involves obsessive protection against sunlight to avoid sun burning and development of skin cancer.

**Idiopathic guttate hypomelanosis**

This occurs most commonly in black African people and is of unknown aetiology. It presents with small (2–4 mm) asymptomatic porcelain-white macules, often on skin exposed to sunlight. The borders are often sharply defined and angular. There is no effective treatment.

**Leprosy** (see also p. 140)

Both tuberculoid leprosy and indeterminate leprosy can present with anaesthetic patches of depigmentation and should always be considered in people from endemic regions. Loss of hair and decreased sweating may also be present in the lesions.

**HYPERPIGMENTATION**

**Freckles (epheles)**

These appear in childhood as small brown macules after sun exposure. They fade in the winter months.

**Lentigos**

These are a more permanent macule of pigmentation similar to freckles but they tend to persist in the winter. Solar lentigos (also called ‘liver spots’) occur in older people on exposed skin due to actinic damage.
Chloasma (melasma)
These are brown macules often seen symmetrically over the cheeks and forehead and are most common in women. Chloasma can occur spontaneously but it is also associated with pregnancy and the oral contraceptive pill.

Metabolic/endocrine effects
A generalized skin darkening can occur with chronic liver disease, especially haemochromatosis. It also is seen sometimes in Cushing’s syndrome, Addison’s disease (more marked in palmar creases and buccal mucosa) and Nelson’s syndrome.

Peutz–Jeghers syndrome (p. 285)
This is an autosomal dominant condition which presents with brown macules of the lips and perioral region. It is associated with gastrointestinal polyposis.

Urticaria pigmentosa (cutaneous mastocytosis)
This presents most commonly with multiple pigmented macules in children. These lesions tend to become red, itchy and urticated if they are rubbed (Darier’s sign). Occasionally lesions may blister, and in the rare congenital, diffuse form of the disease the skin may become thickened and leathery. Occasionally systemic symptoms are present such as wheeze, flushing, syncope or diarrhea, reflecting extensive mast cell degranulation from the skin. Anaphylaxis occurs very rarely and may be precipitated by mast cell degranulators such as aspirin or opiates. The condition spontaneously resolves after some years in children but is persistent in adults.

Skin biopsy shows an excess of mast cells in the skin. A mutation in the proto-oncogene c-kit often underlies the condition resulting in mast cell proliferation and mast cell apotosis. Monoclonal antibodies against mast cell markers (tryptase and CD117) help confirm the cell type.

Rarely there may be infiltration of internal organs with mast cells (systemic mastocytosis), especially in adult disease or neonatal disease. This can involve any organ but especially the bone (where it can cause severe pain), gastrointestinal tract, liver and spleen. There is a small risk of developing leukaemia if the bone marrow is heavily infiltrated.

Treatment of the skin, if required, is with antihistamines, sodium cromoglicate or PUVA.

Other conditions with pigmentation
Café-au-lait macules are seen in neurofibromatosis types 1 and 2, tuberous sclerosis, ataxia telangiectasia, Fanconi’s anaemia, multiple endocrine neoplasia type 1 and McCune–Albright syndrome.

Multiple lentigines are seen in Peutz–Jeghers syndrome, xeroderma pigmentosum, LEOPARD syndrome (Lentigines, Electrocardiographic conduction abnormalities, Ocular hypertelorism, Pulmonary stenosis, Abnormalities of genitalia, Retardation of growth, Deafness) and Carney complex (lentiginosis, myxomas of heart and skin, endocrine overactivity.)

Acquired melanocytic naevi are seen in Turner’s syndrome (p. 1007) and atypical mole syndrome (dysplastic naevus syndrome, p. 1258).

### DRUG-INDUCED RASHES

Drugs can be toxic and teratogenic but they can also cause problems through allergic reactions. This frequently presents in the skin where just about any type of skin rash can arise (Table 23.15) although a widespread symmetrical maculopapular rash is the most common type (Fig. 23.38). ‘Fixed drug eruptions’ may occur where a rash evolves and resolves at a specific site. The rash is reproduced at exactly the same site after a repeated exposure.

The history is of great value in assessing drug reactions as a drug cause is very common. The use of prick testing and patch-testing is rarely helpful and not without risk. Drug allergy can only be proven by rechallenging but this is rarely justified as it carries some risks. Rechallenging is occasionally justified for antituberculosis drugs or antiretrovirals but this should be carried out under medical supervision as there is a risk of anaphylaxis. Certain individuals (e.g. those with HIV infections) are more susceptible to drug rashes (Fig. 23.39).

FURTHER READING

Fig. 23.39 Erythema nodosum in a patient with HIV on co-trimoxazole.

Most rashes will settle spontaneously once the offending agent is removed. The commonest culprits in a hospital setting are antibiotics and chemotherapy agents. The three most serious types of drug rashes are:

- erythroderma (p. 1249)
- toxic epidermal necrolysis
- drug-induced hypersensitivity syndrome.

Toxic epidermal necrolysis is characterized by widespread subepidermal blistering and sloughing of more than 30% of the skin and a high mortality (30–50%). A prodrug of cough, myalgia and anorexia may precede skin signs by 2–3 days. The skin may be itchy but typically takes on a burning quality. Fever and mucosal involvement are common. The internal epithelial surfaces (lung, bladder, gastrointestinal tract) are also involved. Multifocal failure and sepsis often occur. Toxic epidermal necrolysis can be fatal even after drug withdrawal and intensive care support. Patients should be managed in intensive care or a specialized burns unit. All drugs where possible should be withdrawn. Occlusive cutaneous dressings significantly reduce the pain, and an ophthalmological assessment and oral hygiene are necessary. Specific medical treatment with steroids or ciclosporin is controversial and rarely used. Intravenous immunoglobulin may be beneficial if given early in the disease and this is more commonly used.

A variant exists called Stevens–Johnson syndrome where the damage is restricted to the mucosal surfaces with milder bullous involvement of the skin (<10%). Both SJS and TEN are commoner in slow acetylators and very much commoner in those with HIV infection.

Drug-induced hypersensitivity syndrome (DHS, also called ‘anticonvulsant hypersensitivity syndrome’, ‘drug reaction with eosinophilia and systemic symptoms’) is a serious adverse systemic reaction to a drug typically occurring 3–6 weeks after initial exposure. It is characterized by a generalized mucocutaneous rash, fever and lymphadenopathy with variable arthralgia, pharyngitis, periorbital oedema and hepatosplenomegaly. Rarely postulation of the skin and conjunctivitis are present. The blood may show a peripheral eosinophilia, lymphocytosis with atypical lymphocytes, and a hematologic picture. It can progress to multiorgan failure.

The cause of DHS is unknown but it may in part be due to genetic deficiency of epoxide hydrolase, a hepatic enzyme that detoxifies the arene oxide metabolites of antiepileptic drugs. There have been a number of reports about reactivation of various herpes family viruses (HHV 6 and 7, CMV, EBV) associating with DHS, the significance of which remains unclear. DHS can occur with any drug but a common culprit is one of the aromatic anticonvulsants (carbamazepine, phenytoin, phenobarbitone, primidone and clonazepam) and as they can cross-react all these drugs must be avoided in the future. Sodium valproate is a suitable alternative. There is also potential for cross-reaction with the newer anticonvulsants vigabatrin and lamotrigine. Treatment is with drug withdrawal, systemic steroids and supportive care.

**DISORDERS OF NAILS**

Psoriasis and fungal nail infection are the commonest causes of nail dystrophy and are discussed on pages 1240 and 1232.

- Nail pitting can be caused by psoriasis, alopecia areata and atopic eczema. A few pits can be present due to trauma.
- Onycholysis (distal nail plate separation) is caused by psoriasis, thyrotoxicosis, following trauma and rarely due to a photosensitive reaction to drugs such as tetracyclines.
- Koilonychia (thin spoon-shaped nails) can be caused by iron deficiency anaemia or rarely be congenital.
- Leuconychia (white nails) is seen in hypobaluniaemia. A striate congenital leuconychia exists.
- Beau’s lines (transverse lines) appear as solitary depressions which grow out slowly over many months. They arise due to a severe illness or shock which causes a temporary arrest in nail growth.
- Yellow-nail syndrome is a rare disorder of lymphatic drainage. It presents with thickened, slow-growing, yellow nails which may be associated with pleural effusions, bronchiectasis and lymphoedema of the legs.
- Onychogryphosis is a gross thickening of the nail which is seen in later life, especially in the big toenail. There is often a history of preceding trauma. Both psoriasis and fungal infection can also cause nail thickening.
- Nail–patella syndrome is an autosomal dominant condition which presents with triangular rather than half-moon-shaped lunulae, especially of the thumb and forefingers. The nail plates may be small or dystrophic. The patellae are hypoplastic or absent. Other skeletal anomalies may be present and renal impairment (glomerulonephritis) occurs in up to 30% of individuals.
- Melanonychia (longitudinal brown streaks) may be seen as a normal variant in black-skinned patients. In a white patient it may reflect an underlying subungual melanoma, especially if the pigmentation progresses proximally onto the nail fold (‘Hutchinson’s sign’).
- Clubbing is discussed on page 820.

**DISORDERS OF HAIR**

**HAIR LOSS**

Hair loss can be due to a disorder of the hair follicle in which the scalp skin looks normal (non-scarring alopecia) or due to a disorder within the scalp skin that causes permanent loss.
of the follicle (scarring or cicatrical alopecia). This latter form causes shiny atrophic bald areas in the scalp which are devoid of follicular openings. There are many causes of alopecia (Table 23.16).

### Androgenic alopecia

Androgenic alopecia (male pattern baldness) is the most common type of non-scarring hair loss and depends on genetic factors and an abnormal sensitivity to androgens. It presents in young men with frontal recession followed by thinning of the crown, and there is often a positive family history. It also occurs in females but tends to occur at a later age, be milder and show little in the way of frontal recession. If acne and menstrual disturbance are also present, the cause may be polycystic ovary syndrome or another endocrine disorder of androgens.

_Treatment_ may not be required. Topical 5% minoxidil lotion or oral finasteride (1 mg daily) can help arrest progression and may cause a small amount of regrowth, providing it is used early in disease, but the treatment needs to be continued possibly lifelong. Approximately one-third of patients will not respond to either therapy. Finasteride is a selective inhibitor of 5α-reductase type II and it can cause side-effects in 1% of patients such as loss of libido. It should not be used in females as it can affect the sexual development of a male fetus. However, antiandrogen therapy (e.g. cyproterone acetate or spironolactone) may help some women.

### Alopecia areata

Alopecia areata may be regarded as an immune-mediated type of hair loss associated with other organ-specific autoimmune diseases. It presents in children or young adults with patches of baldness. These may regress to be followed by new patches of hair loss. The presence of broken exclamation mark hairs (narrow at the scalp and wider and more pigmented at the tip) at the edge of a bald area is diagnostic. Regrowth may initially be with white hairs and often occurs slowly over months. Occasionally all of the scalp hair is lost (alopecia totalis) and rarely all body hair is lost (alopecia universalis). The nails may be pitted or roughened.

_Treatment_ has no effect on the long-term progression. Potent topical or injected steroids may be of limited use. Topical immunotherapy with diphencyprone, PUVA or topical 5% minoxidil is occasionally tried but often does not help. Wigs can be provided for severe cases and patient support groups are often beneficial.

### Other disorders

#### Traction alopecia

This refers to the ‘mechanical damage’ type of hair loss that arises from pulling the hair back into a bun or tight plaiting. It is more common in black Africans.

#### Telogen effluvium

Telogen effluvium refers to the pattern of diffuse hair loss that occurs some 3 months after pregnancy or a severe illness. It occurs because ‘stress’ puts all the hairs into the telogen phase of hair shedding at the same time. The hair fully recovers and the normal staggered hair growth/hair shedding cycle resumes within a few months.

#### Dissecting cellulitis

This is a chronic folliculitis affecting predominantly young black males. It presents with papules and pustules over the occipital region of the scalp with hair loss. If severe, the back of the scalp becomes a boggy swelling (discharging pus) with areas of scarring alopecia. It can be complicated by keloid scar formation (‘acne keloidalis nuchae’).

_Treatment_ is difficult but prolonged courses of low-dose antibiotics are worth trying in early disease. Prolonged courses of isotretinoin can help a few individuals and deep surgical excision can be used in recalcitrant cases.

### INCREASED HAIR GROWTH

#### Hirsutism (p. 1003)

Hirsutism refers to the male pattern of hair growth seen in females. The racial variation in hair growth must be considered. Certain races (e.g. Mediterranean and Asian) have more male pattern hair growth than northern European females. This is not due to excess androgens but may reflect a genetically determined altered sensitivity to them. If virilizing features (deep voice, clitoromegaly, dysmenorrhoea, acne) are present, a full endocrine assessment is necessary. Hirsutism can cause severe psychological distress in some individuals.

_Treatment_ involves physical methods such as bleaching, waxing, electrolysis, photoepilation and laser therapy. Anti-androgen therapy is occasionally helpful.

### Hypertrichosis

Hypertrichosis refers to the state of excessive hair growth at any site and occurs in both sexes. It can be seen in anorexia nervosa, porphyria cutanea tarda and underlying malignancy, and is caused by certain drugs (e.g. ciclosporin, minoxidil).

### BIRTH MARKS/NEONATAL RASHES

#### Strawberry naevus (cavernous haemangioma)

Strawberry naevus affects up to 1% of infants. It presents at, or shortly after birth as a single red lumpy nodule (Fig. 23.40) that grows rapidly for the first few months. Multiple lesions...
can be present. They will spontaneously resolve with good cosmesis but may take up to 7 years for complete resolution. Occasionally plastic surgery is needed after resolution to remove residual slack skin. Reassurance of parents is usually all that is required.

Treatment is indicated if:
- the lesion interferes with feeding or vision
- the lesion ulcerates or bleeds frequently
- the lesion is associated with high-output cardiac failure from shunting of large volumes of blood
- the lesion consumes platelets and/or clotting factors causing potentially life-threatening haemorrhage (‘Kasabach–Merritt syndrome’).

The last two complications are very rare and only tend to occur in large lesions with significant deep vessel involvement.

Treatment modalities include intraleosional or oral corticosteroids, surgery (for selected lesions), and tunable dye laser (for treating ulceration). Alpha interferon injections, vincristine or embolization are only used for life-threatening events.

**Port-wine stain (naevus flammeus)**

Port-wine stain is also called a capillary haemangioma but strictly speaking it is not a haemangioma, just an abnormal dilation of dermal capillaries. It presents at birth as a flat red macular area and is commonly found on the face. It does not improve spontaneously and it may become thickened with time. If the lesion is found in the distribution of the first division of the trigeminal nerve it may be associated with ipsilateral meningeal vascular anomalies that can cause epilepsy and even hemiplegia (Sturge–Weber syndrome, p. 1169). If a port-wine stain involves the skin near the eye, glaucoma is a risk and ophthalmic assessment is mandatory.

Treatment of port-wine stains is ideally with the tunable dye (pulsed dye) laser. Facial lesions respond best but lesions can redarken after some years.

**Other conditions in the newborn**

**Milia**

‘Milk spots’ are small follicular epidermal cysts. They are small pinhead white papules commonly found on the face of infants. They resolve spontaneously, unlike in adults.

**Mongolian blue spot**

This appears in infants as a deep blue-grey bruise-like area, usually over the sacrum or back, and is occasionally mistaken as a sign of child abuse. It is due to deep dermal melanocytes. It is very common in Oriental children, less common in black Africans and rare in Caucasians. It has usually disappeared by the age of 7 years.

**Toxic erythema of the newborn (erythema neonatorum)**

Toxic erythema of the newborn is a term used to describe a common transient blotchy maculopapular rash in newborns. The rash is occasionally pustular but the child is not toxic or unwell. It disappears spontaneously within a few days.

**Nappy rash (‘diaper dermatitis’)**

This is an irritant eczema caused by occlusion of faeces and urine against the skin. It is almost universal in babies. The flexures are usually spared, which is a useful differentiating feature from seborrhoeic and atopic eczema. If satellite lesions are present around the edge it may indicate a superimposed *Candida* infection. This rash can also occur in the elderly incontinent.

Treatment involves frequent changing of the nappy and regular application of a barrier cream.

**Acrodermatitis enteropathica** (p. 225)

This is due to a rare inherited deficiency of zinc absorption. It presents 4–6 weeks after weaning or earlier in bottle-fed babies. There is an erythematous, sometimes blistering, rash around the perineum, mouth, hands and feet. It may be associated with photophobia, diarrhoea and alopecia.

Treatment is with lifelong oral zinc, which seems to override the poor absorption. The response is rapid.

**HUMAN IMMUNODEFICIENCY VIRUS AND THE SKIN** (p. 188)

HIV infection commonly causes significant dermatological problems. A rash may even be the presenting feature of underlying HIV infection. It is estimated that 90% of HIV-positive patients will suffer with a mucocutaneous disorder during the illness and that up to 30% of people with AIDS will suffer from three different dermatoses. These rashes can often be clinically atypical and difficult to diagnose, and skin biopsy and skin culture is sometimes required for diagnosis. Many of the skin problems are resistant to standard treatments, but HAART (p. 199) has decreased the prevalence.

Cutaneous infection and opportunistic infection are increased due to HIV-induced immune deficiency. *Molluscum contagiosum* is particularly common, especially on the face. Lesions are often multiple and of a ‘giant’ size measuring over 1 cm across. Molluscum is rarely seen in immunocompetent adults but can be the presenting feature of HIV. Other viral infections such as extensive ulcerative herpetic or widespread viral warts may be seen. Bacterial infections (e.g. staphylococcal boils) and fungal infections (e.g. ringworm and *Candida* are
also common. Recalcitrant and recurrent oropharyngeal candidiasis is a particular problem.

Opportunistic infections such as cutaneous cytomegalovirus (pustules or necrotic ulcers), sporotrichosis (linear nodules) or Cryptococcus (red papules, psoriasiform or molluscum-like lesions) can pose diagnostic difficulties, stressing the need for skin biopsy and culture.

Inflammatory dermatoses show an increased incidence with HIV infection, probably due to an immune dysfunction or imbalance rather than as a consequence of immune suppression. Severe, extensive seborrhoeic eczema is very common and may be a presenting sign of HIV. Other types of eczema, psoriasis, ichthyosis (dry scaly skin), nodular prurigo and pruritus are all common in HIV infection and can be very severe. Granuloma annulare and lichen planus are probably increased in incidence. The treatment of these conditions can be difficult in patients with low CD4 counts (<200 mm<sup>-2</sup>), and oral immunosuppressive therapies (e.g. prednisolone, ciclosporin) are best avoided. Topical therapies and phototherapy seem relatively safe and oral retinoids are a safe option for psoriasis.

‘Autoimmune dermatoses’ such as bullous pemphigoid, thrombocytopenic purpura and vitiligo seem to be increased in incidence. The aetiology is related to polyclonal stimulation of B lymphocytes by HIV with a resulting abnormal antibody production. Erythroderma is sometimes seen in HIV disease where skin biopsy suggests a ‘graft-versus-host disease’ mechanism. This presumably reflects a severe underlying immune dysfunction of T lymphocyte control.

Adverse drug rashes are much more common in HIV patients. Reactions to co-trimoxazole, dapsone (used in Pneumocystis prophylaxis) and antiretroviral drugs appear particularly common. Drug rashes may be severe (especially with nevirapine and efavirenz), resulting in erythroderma or toxic epidermal necrolysis. Other unusual rashes include a striking nail/mucosal pigmentation from zidovudine, paronychia from indinavir and facial lipodystrophy mostly from protease inhibitors.

Cutaneous tumours, e.g. Kaposi are sarcoma (p. 204), are much more common in homosexuals with HIV than other groups. Basal and squamous cell carcinomas and benign melano-cytic naevi are also a little increased in incidence, presumably reflecting a loss of immune surveillance.

‘Specific’ HIV dermatoses

‘Itchy folliculitis’ of HIV

Itchy folliculitis (also called papular pruritic eruption) is common in HIV as CD4 counts decline. The previously described staphylococcal folliculitis, eosinophilic folliculitis, pityrosporum folliculitis, and demodex mite folliculitis are probably all part of a spectrum and the term ‘itchy folliculitis’ is useful to encompass these. It presents with intensely itchy papules centred on hair follicles and occurring most commonly over the upper trunk and upper arms. The face is more commonly involved in black patients. Individual lesions frequently have the top scratched off, leaving a crateriform appearance. The aetiology is unknown but may reflect a hypersensitivity reaction as high IgE and eosinophil counts may be present.

Treatment with oral minocycline, potent topical steroids and emollients may help. Phototherapy or oral isotretinoin is useful in resistant cases.

Oral hairy leucoplaikia

This is characterized by white plaques with vertical ridging on the sides of the tongue. Unlike with oral Candida the lesions cannot be peeled off to leave raw areas underneath. It was first recognized in HIV disease but can rarely occur in other forms of immunosuppression. It is thought to be due to co-infection with Epstein–Barr virus.

Treatment with aciclovir, ganciclovir or foscarinet may help.

DERMATOSES OF PREGNANCY

There are a number of minor skin changes during pregnancy. There is an increase in spider naevi, melanocytic naevi, skin tags and chloasma. The abdomen shows mid-line pigmentation (linea nigra) and striae (stretch marks). There are four less common skin problems associated with pregnancy.

Polymorphic eruption of pregnancy (PEP, also called ‘pruritic urticarial papules and plaques of pregnancy’)

This rash tends to appear in the last trimester of a first pregnancy in 1 in 160 cases. It is of unknown aetiology and recurs only rarely in subsequent pregnancies. It presents with very itchy urticated papules and plaques and occasionally small vesicles. Lesions usually start on the abdomen and striae but may spread to the upper arms and thighs. The umbilicus may be spared. PEP is commoner in twin pregnancies. The rash is not associated with any maternal or fetal risk. PEP has recently been shown to be associated with low maternal serum cortisol levels.

Treatment is with reassurance, bland emollients and mild topical steroids. The rash disappears after childbirth.

Prurigo of pregnancy

Prurigo of pregnancy affects 1 in 300 pregnancies. It usually starts on the abdomen in the third trimester but may persist for some months after delivery. Clustered excoriated papules (prurigo-like lesions) occur on the abdomen and extensor surfaces of the limbs. The cause is unknown but pregnancy related itch (pruritus gravidarum) may be due to cholestasis (p. 362). Rarely liver biochemical tests are abnormal and urinary HCG levels may be elevated. It can recur in subsequent pregnancies. Some authors believe the condition is associated with an increase in fetal mortality but this remains controversial.

Treatment is with topical steroids and oral antihistamines.

Pruritic folliculitis of pregnancy

This occurs in the second or third trimester of pregnancy and is characterized by an itchy folliculitis which looks similar to steroid-induced ‘acne’. It is not associated with any increased maternal or fetal risk.

Treatment with topical benzoyl peroxide and hydrocortisone cream helps to relieve symptoms.

FURTHER READING

Pemphigoid gestationis (herpes gestationis)

This is the rarest of the pregnancy-related rashes (1 in 60,000). The immune changes of pregnancy appear to set off bullous pemphigoid. It is characterized by an itchy blistering urticated eruption that starts on the abdomen but may become widespread. Large bullae may be present. Unlike PEP, it can occur early, starting in the second or even first trimester of pregnancy, and the umbilicus is often involved. It tends to recur in subsequent pregnancies and at an earlier stage. Diagnosis is confirmed by immunofluorescence studies.

A transient bullous eruption occurs in 5% of infants, presumably due to transplacental passage of the offending antibody. There is no increase in fetal mortality but there is an increased incidence of prematurity and low birth weight which is probably due to the autoantibody causing placental insufficiency.

Treatment of mild cases is with potent topical steroids but most cases will require oral corticosteroids. The steroid dose may need to be increased after delivery as there is often a postpartum flare-up of the disease. The rash can be set off again by the oral contraceptive pill and this should be avoided.

PRINCIPLES OF TOPICAL THERAPY

Dermatology is unique in having such direct accessibility to the affected organ. This allows the use of topical treatments which can avoid certain systemic side-effects.

A topical therapy consists of an active ingredient, an appropriate vehicle or base to deliver this, and often a preservative or stabilizer to maintain the product’s shelf-life. A cosmetically acceptable product is necessary and must be accompanied by instructions to the patients about correct usage as without this compliance tends to be poor. Perfumed or scented products should be avoided.

Bases and their uses

- **Creams.** A cream is a semisolid mixture of oil and water held together by an emulsifying agent. They need to have added preservatives such as parabens. They are ‘lighter’ and rub in more easily than ointments. They have a high cosmetic acceptability and are useful for topical treatments of the face and hands. Aqueous cream is a particularly useful as a soap substitute.

- **Ointments.** These are semisolid and contain no water, being based usually on oils or greases such as polyethylene glycol (water soluble) or paraffin (fatty). They feel greasy or sticky to the touch. They are the best treatment for dry, flaky skin disorders as they are good at hydrating the stratum corneum and they deliver an active ingredient (e.g. a steroid) more effectively. If patients dislike the greasy nature of ointments a cream is better than no treatment at all, but creams are less effective and do have to be used more frequently. A compromise may be to use a cream on the face and an ointment elsewhere (Table 23.17).

*Trade names

- **Lotions.** These are based on a liquid vehicle such as water or alcohol. They are usually volatile and rapid evaporation promotes a cooling effect on the skin. They are useful for weeping skin conditions and are ideal for use on hairy skin (e.g. the scalp). The cooling effect can be a useful antipruritic. Alcohol-based lotions should be avoided on broken skin as they cause stinging.

- **Gels.** These are semisolid preparations of high molecular weight polymers. They are non-greasy and liquefy on contact with the skin. They are useful for treating hairy skin (e.g. the scalp).

- **Pastes.** Pastes contain a high percentage (>40%) of powder in an ointment base. They are thick and stiff and difficult to remove from the skin. They are useful when a treatment needs to be applied precisely to a skin lesion without it smearing on to surrounding normal skin. An example would be dithranol in Lassar’s paste (used on plaques of psoriasis) as dithranol will burn the surrounding normal skin.

Safety of topical steroids

Providing that preparations of appropriate strength are used for the body site being treated, these compounds can be used safely on a long-term intermittent basis (p. 1237). If potent steroids are misused they will cause skin atrophy manifest as striae, wrinkling, fragility and telangiectasia.

Problems with topical therapies

- **Systemic absorption** may occur but only if very large areas of inflamed skin are treated topically and especially if the treatment is occluded with bandages or polyurethane films. Neonates are particularly susceptible to this owing to the relative increase in body surface area to volume.

- **Contact allergy** to topical preparations is not uncommon and may be suspected by unusually resistant disease or by apparent worsening of a condition after application of a substance. It is more common with creams as it is often the result of allergy to the preservative or emulsifying agent. Allergy can also be due to the active ingredient itself (e.g. neomycin or hydrocortisone).

- **Folliculitis** can occur due to blockage of hair follicles. Creams and ointments should be applied to the skin in the same direction as hair growth to try and prevent this blockage. It is a particular problem with the use of ointments in hot weather (especially if under occlusive bandages) and a lighter cream may be more appropriate at this time.
