The fourth-largest company listed on the London Stock Exchange, GSK has roughly 100,000 employees and develops treatments and vaccines in major disease areas including mental health, infectious disease, gastrointestinal disease, asthma, diabetes, and cancer. Among its best sellers are the asthma/chronic obstructive pulmonary disease (COPD) treatment Advair, the generic of which has been delayed for five years and counting due to the Food and Drug Administration’s (FDA’s) lack of a set standard for the bioequivalence of inhaled steroids in multidose inhalers; the erectile dysfunction pill Avodart; the corticosteroid Flixotide, used primarily for asthma and allergic rhinitis but also prescribed for nasal polyps, skin disorders, and Crohn’s disease; Augmentin, a trade name of the antibiotic amoxicillin; the prescription dietary supplement Lovaza; and the anticonvulsant Lamictal, used to treat epilepsy, bipolar, and clinical depression. Its consumer health care division’s portfolio is also deep, including products like Aquafresh and Sensodyne toothpaste, Breathe Right nasal strips, Nicorette nicotine gum, and Boost health drinks.

GSK has had a checkered legal history. In 2012, it pled guilty to criminal charges for promoting Paxil and Wellbutrin for off-label uses, reporting false prices to Medicaid, and failing to report important safety information about Avandia, resulting in a $3 billion settlement, the largest paid by a drug company up to that point. It faced similar class action suits and criminal fines for marketing off-label uses of paroxetine for child patients; has faced charges of bribery in multiple countries, including being found guilty of systematic bribery by a Chinese court in 2014, resulting in a suspended prison sentence for the former head of GSK’s Chinese operations; and recent bribery investigations in the United Kingdom, United Arab Emirates, Lebanon, Jordan, Syria, and Iraq. Among other allegations in these investigations, GSK representatives are alleged to have made direct payments to health care professionals and institutions in order to assure their business.
At the end of 2013, amid several years of increasing complaints about pharmaceutical industry practices by consumer advocates and public health officials, GSK adopted new ethical standards in its practices, including no longer paying medical or health care professionals for speaking at medical conferences, no longer compensating doctors who prescribe their products, and no longer requiring prescription-related sales targets of its representatives. Doctors would continue to be compensated for GSK-sponsored clinical trials, market research, and advisory services, which the company defends as necessary to disease research. It has further shored up its reputation with a joint project with the Bill and Melinda Gates Foundation, developing a malaria vaccine that it submitted for approval in 2014, with the intention of selling it in developing countries at 5 percent over cost. In late 2014, amid fears of Ebola, GSK announced it had begun the first-ever human trials for an Ebola vaccine.

GSK had a long history of successes in oncological treatments, including recent approvals of Tafinlar and Mekinist to treat melanoma. In early 2014, it sold off most of its cancer portfolio to pharmaceutical company Novartis, with a deal to co-market future oncology products in return for a $16 billion cash payout. Though a leading pharmaceutical company, GSK’s ranking in cancer drugs was disproportionately low relative to its size, and selling off most of its cancer division allowed it to refocus on its strengths while also taking a needed cash injection. At the same time, it retained key elements of its cancer research and development programs with serious long-term potential, including epigenetics research and immunotherapy—programs that could not be sold today for a fraction of what they may someday be worth when that research has borne fruit.

Less than two months after the sale to Novartis, GSK entered into a $350 million, seven-year collaboration with Adaptimmune, a biotech company developing immunotherapy treatments for blood, skin, and ovary cancers. Adaptimmune is based in Oxford, England, part of the UK’s cancer research Golden Triangle (along with Cambridge and London).

Global Health Issues and Cancer

The concept of global health (GH) is relatively recent, and it encompasses diverse aspects of population and health in a world context. It covers areas such as epidemiology in a wide sense, public health, and demography. In fact, we cannot understand this concept without framing it in other conceptual elements related to measurement (statistical data, quality of life, life expectancy, mortality, or morbidity); health conditions (geographical, human, economic, sociocultural and political circumstances, and situations where access to wealth and basic services or resources, equality, or equity are involved); intervention (planning, prevention, impact, efficacy, and efficiency); and environment (sustainability). It is a concept whose reach goes beyond any border and that intends to fight disparities and to give global protection to all human groups regardless of their origin, status, or location. The concept of GH began to be used instead of international public health because there is a general concern about the state of health of every citizen of the world and a literal conviction that the commitment with health in a specific region of the world implies an involvement with the health of any person everywhere.

Because this topic is visibly interdisciplinary, it is essential to determine the limits and frames of some terms involved in it. One first step is to define what global means and if GH relates somehow to...
globalization and to what extent. A further step would be to specify what kind of disciplines deal directly with this matter.

The interest in global health coincides with the new millennium. In a few years, GH became a discipline in most departments and universities in the United States. It emerged from several perspectives and ways of understanding and interpreting health and its improvement and the different strategies to reduce, eradicate, or prevent some specific (infectious) diseases. Although it became a hegemonic term, many critical voices affirm that GH is a concept not totally new—in the 1950s, the World Health Organization (WHO) used it in its campaign for the eradication of malaria—and sometimes, it has been manipulated by that same institution for political reasons in order to concentrate power in its main role of coordinator and leader.

Currently, the concept of GH goes beyond the idea of health in itself in the sense that it also covers aspects like welfare and well-being. In addition, from the point of view of global health—where risk factors, measurements, analysis of determinants, and comparison of trends are main tools—cancer, both as a disease and as a social reality, has gained a central place, and it plays a relevant role.

Cancer Onto Global Health Agendas: Organization of Data

However, that relevance must be clarified because, while cancer has been raised onto GH agendas of high-income countries, it receives less attention in low-income countries, where according to statistics, cancer also has a big impact. In order to monitor cancer incidence and to have a proper identification of new cases, many countries have established a national registry, even though most registries are transnational, which is also an aspect related to the general idea of GH. For example, the International Association of Cancer Registries (IACR) has existed since 1966, and its fundamental mission is to collect data of quality and, eventually, to compare them. The European Network of Cancer Registries (ENCR) was created in 1990 with the purpose of facilitating exchange of data among the different national cancer agencies, monitoring cancer incidence, and making these incidence data available. On the other hand, umbrella institutions like WHO bring together global health topics, data, and analysis, highlighting the need of avoiding exposure to risk factors and the significant amount of cancers that can be cured. A database is an elemental tool to evaluate and understand the morbidity and mortality in several regions around the world. They are also common and reliable sources of information on cancer survival.

All the institutions linked somehow to cancer from the perspective of globalization keep in mind that their actual challenges are advanced research, good expertise, implementation and consolidation of clinical trials, and the creation of resources that allow reducing the incidence of cancer worldwide.

Cancer Control in the Framework of Global Health

From 11 million cases occurring annually worldwide, just 6 million are in low-income countries. More than 50 percent of those cases result in a patient’s death. It is clear that cancer is a global disease. But this affirmation deserves some consideration in terms of epidemiology and causality. Whereas in high-income countries, most cancer cases are related to lifestyle (like cancer of the colon, lung, or even breast), in low-income countries, infectious agents are usually involved in the incidence rate, impact, and development of that disease. Coordinated approaches and efforts in several fields had as an immediate result an effective control of some risk factors, following the successful example of what happened with noncommunicable diseases, especially infectious diseases, and the mitigation of their impact. Certainly although GH guidelines may not be applicable at a universal level, there are some care programs that include basic outlines, like prevention, early detection, and best treatment (adapted to each case). Prevention is a form of control, and it proved to be useful in the case of tobacco consumption (that factor is generally recognized as the most preventable cause of death), diet, alcohol use, and infections. Some organizations like the IARC, belonging to the WHO, insist on effective prevention measures more than on treatment to win the global battle against cancer. But the application of the three basic program clauses previously mentioned has to overcome substantial obstacles in terms of knowledge and awareness, culturally and socially different backgrounds, lack or deficiency of resources, and the limitations of access to them.
In spite of the differences in the ways of fighting cancer, there is also a growing awareness among the world population. On the other hand, public health systems provide possibilities of screening for the cases of breast, stomach, or colon cancer. One of the problems here is, however, that not every country has the proper equipment to provide specialized services for diagnosis or care resources for surgery, the treatment before and after that, and pain control. For that reason, many cancers that could be cured remain as causes of death among people worldwide.

Cancer Burden Worldwide
There is no doubt that cancer is one of the leading causes of death in the world. Population aging, particularly in Western societies, explains the fact that, every year, the number of cancer patients increases. Reliable statistical data let us know that about 11 million cases of cancer are diagnosed every year worldwide. Those data don’t include, however, cases of skin cancer. Of all these cases, 53.4 percent are male and 46.6 percent are female. Around 45 percent are cases diagnosed in Asia, 26 percent in Europe, 15 percent in North America, 7 percent in Latin America, and approximately 6 percent in Africa. For males and females, the most common cancer is lung; the second-most common is colon (with a stronger incidence in males than in females). Among females, the most common cancer is breast, followed by cervix and colon. Among men, the most common are lung, prostate, and stomach.

According to official data, in 2008, and in the context of Asia, more than 6 million new cases were detected. Most of them were males, although there is practically the same number of cases in males and females. About 60 percent of the cases supposed the death of the patient in both males and females. In the same period of time, the registered cases in Africa were approximately 750,000. From them, around 320,000 were male and the rest female. The cases resulting in the patient’s death were about 260,000 for men and 283,000 for women. The number of detected cases in North America in 2008 was 1,603,900, with the proportion of males a little higher than females. Among them, the number of deaths was 332,500 for males and 305,900 for women. Instead, in the rest of America (Central and South America and the Caribbean), the number of cases was 825,000, most of them registered in South America. The incidence of cancer is higher among the female population in the case of Central and South America and a little bit lower in the Caribbean. Instead, the number of deaths is higher among the male population (a total of 280,000 in the whole region) than among females (except in the case of Central America, where the number of women’s deaths overtakes the number of men’s deaths).

For the same period, the number of registered cases in Europe was 2,300,000. The highest incidence concentrates in western Europe (1,034,300) and the lowest in northern Europe. In the whole region, men are more affected by the disease than women, although in eastern and central Europe the number of cases for men and women are quite similar (around 490,000 cases in both groups). However in terms of deaths, in northern Europe, there is a balance in the cases of males and females, but the dominant factor in the whole region is that there are more men’s deaths than women’s. The total number of deaths reaches 1,800,000 people. In the austral region, the total amount of cases is 140,000, most of them in Australia. Although the dominant factor is a higher incidence in the case of males, in Melanesia and Micronesia, the number of women affected by cancer is notably higher (3,700 in Melanesia, as opposed to 3,300 men; and 400 in Micronesia, as opposed to 300 men). The total of deaths in the whole region is 56,000, of which 24,000 are women and the rest men.

With respect to main causes and risk factors, in the case of developed countries, diet and nutrition are implied in 30 percent of the cases, followed by tobacco, which represents about 16 percent; infections, which represent 8 percent; occupational exposures, which represent 5 percent, and environmental elements, which represent 2 percent. The rest of the cases have different causal backgrounds. In the context of developing countries, infections are in the first place, involved in 26 percent of the cases, followed by diet and nutritional factors, which represent 20 percent of the cases, and tobacco, which represents about 10 percent. The rest of the cases also have different causal backgrounds.

In respect to the kinds of cancer, lung is at the top, with a total of 1,800,000 new cases in 2012, which represents 13 percent of the total diagnosed cases. In second place is a cancer that affects basically the female population, breast cancer, with an incidence of 1,600,000 new cases, representing 11.6 percent of the total diagnosed cases. In third place is colorectal
cancer, with 1,361,000 annual new cases, representing 9.7 percent. In last place, with only 44,000 new cases (0.3 percent of the total) is Kaposi’s sarcoma. Actually, the most common cancers for men are lung, prostate, and colorectal, nearly 42 percent of all cancers, and liver or stomach, at about 5 percent. In the case of women, breast cancer leads to 25 percent of the total diagnosed cases every year. For women, breast, colorectal, and lung cancers represent more than 43 percent of all cancers. Cervical cancer represents about 8 percent of all cancers in women.

Cancer survival is measured taking into consideration the percentage of patients who are alive five years after the diagnosis. But that measurement is not absolute; it includes many other factors, like the type of cancer, the initial stage at the moment of the diagnosis, or even the availability of treatment for each case. For those cancers whose survival rates are high—like breast or colorectal cancer—the differences between developing and developed countries are enormous. For example, whereas in the United States, the survival rate for breast cancer after five years is 85 percent, in countries of northern Africa, it gets down to 39 percent.

**Toward Global Intervention: Prevention Policies and Analysis of Risk Factors**

As most studies suggest a direct link between cancer risk and lifestyle, prevention policies play a fundamental role in the eradication of cancer worldwide. Those policies could be indirect—campaigns in order to make the population everywhere aware of messages about eating healthy and getting active—or direct monitoring and (opportunistic or organized) screening of potential or actual patients or high-risk groups. Indirect strategies appeal to individual responsibility. Instead, direct intervention supposes organizational support and a public health system providing specialized services. In countries where a health infrastructure cannot be afforded, programs for raising awareness should be implemented so that populations can become more sensitive to signs and symptoms, a first step to early diagnosis of the disease, and report any change or abnormality.

According to recent data, about one-third of cases are preventable, and for that reason, prevention used to be considered the best long-term strategy of controlling such a disease. The global policy frameworks are described as follows.

**Tobacco.** Tobacco is the most common preventable risk for cancer mortality at the global level. It causes an estimated 22 percent of cancer deaths annually. Tobacco is not only behind cases of lung cancer but also esophagus, mouth, tongue, larynx, cervix, bladder, throat, kidney, pancreas, and stomach. It affects smokers and nonsmokers, and some cases are already detected in children. Chewing tobacco leaves, a custom of the native populations of both South and North America, increases the risk of mouth cancer. On the other hand, smokeless products like electronic cigarettes need further research in order to know their effects on a person’s health. In the United States, tobacco use is responsible for approximately one in five deaths. Tobacco consumption in Latin America is higher—perhaps even epidemic—and it will be the main killer in the continent in a few years. Smoking causes directly 270,000 cancers every year in Europe. Africa, where the incidence of lung cancer was relatively low, is experiencing an important increase of cases as the number of smokers has become four times higher in the last years due to the influence of Western habits. In Asia, lung cancer deaths attributable to smoking ranged from 0 to 40 percent in females and from 21 to 49 percent in males.

**Physical Inactivity.** Regular activity or sport practice mean some direct benefits for health because they allow keeping a healthy weight and prevent becoming obese or simply overweight (it is proven that there is a link between being overweight and the incidence of some cancers, like breast, esophagus, colorectal, endometrium, and kidney). The combination of activity with a balanced diet rich in vegetables and fruits supposes a powerful protective against cancer. On the other hand, it seems plausible that a high consumption of red meat increases the risk of colorectal cancer.

**Infections.** Infections are active agents in the incidence of cancer in developing countries (it is believed that they are the main cause in 22 percent of the cases as opposed to 6 percent in developed countries). Hepatitis B and C are behind liver cancer; infection by human papillomavirus behind cervical cancer, and *Helicobacter pylori* can produce cancer of the stomach, or at least it increases its risk. Nearly 18 percent of cancers worldwide are attributable to infections, but again, there are big differences between the regions. In Africa, it
reaches 25 percent of the cases, and in developed countries scarcely 10 percent.

**Occupational Cancer.** The exposure to some agents in the context of workplaces and what is worked with seems to be the main cause of some types of cancer, like lung, bladder, skin, and larynx or leukemia in documented cases. Actually, more than 40 carcinogenic occupational agents have been identified. For example, mesothelioma is a lung cancer produced by exposure to asbestos. Despite all evidence, it is estimated that, every 52 seconds, occupational cancer produces another victim (about 600,000 deaths annually worldwide)—it used to be a hidden cause of the disease. According to a report from the WHO, between 7 and 19 percent of all cases of cancer are directly attributable to toxic exposure to carcinogen elements. The highest incidence of occupational cancers occurs among workers of uranium mining, with 54 percent.

**Environmental Pollution.** According to WHO, the environment could be defined as all the physical, chemical, and biological factors external to the human host and all related behaviors but excluding those natural environments that cannot reasonably be modified. Human beings are exposed to many carcinogenic agents through inhalation, eating, drinking, and skin contact. Pollution affects water, air, and soil through chemical elements in a way that may cause about 1 to 5 percent of cancers. Arsenic or coal use is widespread in Asia. Arsenic is a direct agent related to a notable number of deaths in poor countries like Bangladesh, and coal use causes lung cancer in nonsmoking people. Among them, women have more possibilities of contracting that disease. Benzidine is linked to bladder cancer. Other toxic substances behind a vast majority of cancers attributed to environmental factors are asbestos, radon, and silica. Actually, humans do not live in contaminant-free surroundings, and it provokes a permanent interaction.
with their internal genetic makeups that may lead to a fatal mutation able to destabilize the organism. Even so, it is estimated that almost one-third of the cancers caused by environmental elements could be prevented by a simple modification of lifestyle.

**Alcohol Use.** Alcohol use is an important risk factor in several types of cancer, like liver, breast, stomach, larynx, pharynx, ovaries, oral cavity, or esophagus. Despite its high incidence in cancer, it affects men and women in different ways. In men, heavy consumption of alcohol becomes a risk factor for oral cavity, liver, and pharynx cancer in almost 22 percent of cases. Instead, in women, the incidence is smaller—only 6 percent—and 3.5 percent of cancers and deaths caused by cancer are attributable to alcohol use. The incidence is much higher in women than in men.

**Radiation.** Radiation as a risk is well known after strong evidence in epidemiological studies with Japanese survivors of atomic bombs. Ionizing radiation causes leukemia in young people and thyroid cancer (affecting the female more than the male population); radon gas is the second cause of lung cancer, after tobacco; and ultraviolet radiation is behind most skin cancers in the world. In this latest case, the solution seems to be quite simple, just by avoiding excessive exposure and by using proper sunscreen and clothes.

On the other hand, these specific fields of intervention need to be combined with other intervention policies that cover research, application of preventive treatments like vaccines (particularly useful in those countries affected by epidemic or generalized infections), clinical trials, and regular screening of potential patients and people belonging to groups at risk in order to guarantee an early detection and diagnosis of the disease. Early detection makes sense, in the last instance, only when it leads to a follow-up and effective treatment.

**Risk Factors and Genetics**

Lifestyle factors, geographical distribution, and incidence of infections are just elements that interact with genetic susceptibility. Inherited circumstances and conditions may raise a person’s risk of cancer of any kind. Some mutations can be predicted—approximately between 5 and 10 percent of cancers can be traced directly from genetic defects—but unfortunately sometimes anything can be changed.

Variant identification in cancer genomes has to be placed in a context of global challenges because the link between cancer and genetic mutations is a global concern. But there are many questions that remain, so far, with no answer, for example, if generalized mutational profiles could be identified in a determined type of cancer. Even in the case that mutational variables could be identified, there are specific personal variations that interfere with such identification of patterns, making it, and any further therapeutic strategy, extremely complex. One first step is to create a large database with information of a homogeneous population. Some sophisticated registries were already created about 20 years ago in Poland. On the other hand, the Cancer Genome Atlas project applied epigenetic assessment together with sequencing and classifying genomic definition of molecular subtypes, an indispensable tool with global range this is statistically valuable worldwide.

**Toward Global Care**

A diagnosed cancer means a coordinated response that involves experts, personalized treatment, and proper tools and information. An integral treatment should also include psychological help for the patient and his or her family. At the same time, in cases with no possibility of cure or total remission (no cancer signs), an adequate service of palliative care and control of pain (pain relief) must be offered. The principles of GH assume not only the application of those policies at home but also the possibility of exporting the know-how to less-privileged countries.

Although the steps to be taken are clear, it is an incontrovertible reality that the access to essential therapies is far from being global and that barriers to information and to treatment exist. A priority is, then, to create opportunities for improving global access to cancer therapies. One eventual solution that committed oncologists offer is the training of sanitary personal to deliver medical care, surgery, and radiation oncology in a resource-limited context as the best way to maximize their implementation and access to diagnostic facilities.

The greatest challenge is the differences between high-income countries and low- or middle-income countries. Whereas in high-income countries, services include the opportunity of an early diagnosis, proper treatment and surgery, and even
some extra services to reinforce the welfare and well-being of the patient and his or her family—for example, emotional support, practical information, community cancer programs, volunteers’ work, personal coaching, organized supportive care or follow-up care—in low- or middle-income countries, sometimes they need to import others’ experiences.

In Western countries, it is common that each patient receives an individualized survivorship plan, including guidelines to control his or her disease and maintain his or her health. In the last 25 years, the priority is patient’s quality of life.

In a vast majority of regions in the world, a great number of cancer cases are diagnosed in advanced stages. For these patients, there is no realistic treatment for cure, and the only possibility is to follow a pain relief treatment and palliative and supportive care. Most of those treatments are oral pills against pain, which usually are inexpensive, and they range from simple painkillers to powerful opiates, depending on patients’ needs. Opioid drugs are not easily available in developing countries, sometimes due to their price, the lack of knowledge about them, or—more often—because of regulatory policies that limit their access and use. Although WHO establishes a clear normative in regard to drug policies for scientific purposes, the reality is that, in many countries, there are barriers and false beliefs that cannot be overcome. Sometimes, chemotherapy or radiotherapy is prescribed as a part of the palliative treatment.

Government

The international cancer community drew attention for the responsibility of governments in developing effective programs, public policies, convenient legislation, and regulation setting with the focus on cancer management at different levels through policies implemented by the national health systems. But cancer is also affected by governmental decisions and practices that are far beyond the reach of medicine and the health systems, for example, when regulating the transportation, household and industrial energy, water and waste, housing, education, agriculture, and industry’s production.

Political initiatives such as the World Cancer Declaration outline a common strategy to reduce the global cancer burden by increasing cancer’s visibility on the international political agenda and setting a common strategy. Still, in many low- and middle-income countries, cancer is absent on the political agenda when compared to the visibility and resources given to other diseases such as human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS), even though enough evidence has demonstrated that low- and middle-income countries endure a double burden of communicable and noncommunicable chronic diseases.

Cancer is today one of the most common health problems in the world, with a burden that represents a crisis for public health for which governments
attempt to find responses, basically to cancer control. This strategic approach defines primary prevention, early diagnosis, treatment, palliative care, and surveillance as the arenas for current governments' interventions.

Prevention and Early Stages
Cancer primary prevention means identifying the risk determinants or causes of cancer among those factors that epidemiological studies have associated with the development of the disease. Many modifiable risk factors for cancer have been identified: tobacco smoking, alcohol consumption, excessive exposure to sunlight, lack of physical activity, overweight and obesity, dietary factors, occupational exposures, and chronic infections. For reducing tobacco smoking—the most important human carcinogen—governments include restrictions on advertising cigarette products and forbidding smoking in workplaces and public settings. Such restrictions on indoor smoking are effective strategies for reducing the prevalence of smoking.

Prevention programs can reduce the level of exposure of populations to the common modifiable risk factors for cancer as well as other noncommunicable diseases. However, the cancer-causing infections human papillomavirus (HPV) and hepatitis B (HBV) are still not covered by universal vaccination programs worldwide.

As Peter Boyle argues, the major issue in the low- and middle-income countries is the delivery of the prevention action in a way that is affordable for the countries' health systems. One of the main barriers of preventive programs pointed out by anthropologist George Foster is not including a combined basis of the programs offered: health programs based on externally defined health priorities. Another barrier is stigma associated with cancer and the lack of inclusion of people's conceptions in order to understand different perceptions of cancer within different populations. Juliet McMullin has said that only by taking local perspectives into account can changes proposed in social policies be incorporated.

The other arena of governmental intervention is secondary prevention, which includes early detection by cancer screening. Detecting cancers at an early, asymptomatic stage could lead to a decreased mortality rate in certain cancers, such as breast, cervical, prostate, and bowel. As Ichiro Kawachi argues, governments play a major role in financing and delivering cancer screening and treatment services. Nonetheless, population-based screening and early detection programs are still not universally implemented for some types of cancers (screening anyone within specific age-groups) nor selected screening for people who are known to be at a higher risk of developing cancer. Public education and awareness about important cancer warning signs and symptoms also need to be improved as another target for government action.

Cure, Care, or Alleviating Suffering
Known as tertiary prevention, national health systems offer cancer treatments that lead to cures for some. Governments are encouraged in the World Cancer Report to strengthen their health systems to ensure sustained delivery of comprehensive patient-centered cancer control programs across the life course, improving the accessibility of affordable, effective, and quality medicines and technologies.

In low- and middle-income countries, access to treatment is scarce and inequitable because most of the services are provided in health centers located in big cities, leaving a rural population with no access. The high cost of medicine and technologies almost makes these services inaccessible for the poor population. Other barriers to quality access to cancer treatments identified by Paul Farmer and colleagues is a shortage of oncologist specialists, treatment guidelines, and regulatory mechanisms; restrictions on importation of drugs, resulting in limited access to cancer medication; lack of affordable disease-control programs; advanced stages of diagnosis; and lack of availability and quality of cancer treatment centers.

With regard to palliative care, there are wide disparities in the capacity, resources, and infrastructure dedicated to the care of people with life-limiting illnesses. Most countries have neither formal palliative care policies nor integrated palliative care services; they do not meet basic international guidelines in the provision of palliative care and have legislation or policies whose effect restricts the availability of opioids for medical purposes.

Pain control is typically low cost and easily delivered, but there are still barriers that prevent the full implementation of palliative care within many sanitary systems, meaning many patients die with preventable suffering. These barriers are distribution
of resources, availability of opioids, insufficient professional training, morphine's myths among patients and professionals, substance controls that lead to blocking health care providers from supporting needs, and absence of specialists, facilities, and treatments.

**Research and Surveillance**

Governments also have a main role in defining debates about funding research for cancer and setting priorities within the cancer program, for example, the proportion allotted to basic biological research, clinical trials, and cancer prevention programs.

Strategies to control cancer need local data for adapting international guidelines to specific contexts. However, neither the number of new cases of cancer nor the number of deaths is available in many parts of the world. The World Cancer Report states that, in 2000, less than 20 percent of the world’s population was covered by cancer registration and 35 percent by vital statistics schemes based on medically certified cause of death, which gives greater priority to surveillance. According to the Cancer Declaration, population-based cancer registries and surveillance systems are needed to measure the global cancer burden and the impact of national cancer control programs. Governments are called to improve surveillance of cancer morbidity, mortality, and prevalence by establishing population-based cancer registries and for identifying priorities in public health. It can also contribute to programs aimed at reducing inequalities in health outcomes.

**Conclusion**

It was addressed that the primary role of governments in generating multi-sectoral public policies and action plans to control cancer are at different levels, but there are still important differences across and within nations in how they deal with this disease. As a result, a wide and unequal range of responses are being implemented.

These disparities among regions must be remarked upon, noting the inequalities in cancer incidence, mortality, quality of life, and survivorship. The lack of recognition of cancer as a major public health issue has been recognized as one of the main barriers. In that sense, governments' implementation of educational interventions to increase community understanding of cancer is promoting early detection and adherence to treatments. Many interventions to culturally diverse target audiences are being adapted to become more appropriate; considering the complexity of cancer, this requires a comprehensive approach. Further difficulties in cancer control in some low- and middle-income countries are compounded by inadequate government budgetary allocation to cancer management.

Finally, for successful strategies in cancer control, not only is the government necessary but also the engagement of the rest of society: nonprofit organizations, health voluntaries, and private-sector businesses, among others.

Greece

Ancient Greece played a very significant role in the development and evolution of medical history. Hippocrates is a renowned figure in medicine and had so much influence that medical providers today take the Hippocratic oath before they are allowed to serve their patients. One of the Greeks' strong points was that, while they explained away natural phenomena as the work of the Gods, they practiced secular medicine and attempted to find natural explanations for the ailments people faced. Not all of the ancient Greeks were so accepting, though, and preferred relying on the gods—Apollo in particular—to alleviate their conditions.

Hippocrates is so famous that even Plato and Aristotle wrote about him. He believed that the work of priests and doctors should be segregated and that doctors should observe their patients. This was the framework for what would be later known as clinical observation, and this insight is part of the reason that Hippocrates is considered the father of modern medicine. He suggested examining a patient and inquiring about his or her appetite and sleep, and he also kept a detailed book of symptoms and ailments so that doctors could forecast the turn a disease would take. This method spread throughout Greece and the eastern Mediterranean, and writings that survived have provided historians with excellent study resources.

In Hippocrates's day, hospitals did not exist in the way that they do now. The sick made their way to temples dedicated to the healing god Aesculapius, or Asclepieia, which functioned as places of worship as well as a place of healing. Hippocrates set forth the belief that all illnesses had a natural explanation and cure as opposed to a divine origin or curse.

The origin of the word cancer was Hippocrates using commonplace words like carcinos and carcinoma to describe tumors that respectively do not and do have tumors that can form ulcers. In Greek, these terms meant crab, which was likely named as such because of the fingerlike projections from cancer. Galen, another Greek physician, utilized the common word oncos, a Greek term to describe swelling. Hippocrates was a proponent of the humoral theory, which was that everybody had four humors. These were bodily fluids, namely blood, phlegm, yellow bile, and black bile. All of these were balanced in a healthy person, but too much or too little occurred in a person who was sick. Too much black bile was believed to cause cancer, a belief that was carried on by the Romans and continued on through the Middle Ages for more than 13 centuries.

In the days of Hippocrates, physicians knew that cancer could return even when it had been taken out surgically. A second-century Greek physician by the name of Galen, whose writings were kept for centuries, viewed cancer in the same way Hippocrates did: The afflicted were incurable. Cancer treatment barely progressed even as breakthroughs were made in other areas.

Because cancer was considered incurable, treatment went through a very slow evolution. Galen described surgically removing tumors in breast cancer and stated that it could be cured through removal if it could be caught in an early stage. Surgery was much more dangerous at this time because there was the potential for many more complications, including blood loss. This was a time when anesthesia was not available, so surgery was extremely painful for the patients. It was only in the 19th and early 20th centuries that surgical cancer treatment became more effective.

Before the discovery of anesthesia, doctors who could operate swiftly and precisely were in high demand. Once anesthesia was introduced in the mid-1800s, surgical knowledge and techniques advanced so quickly that the time came to be called the century of the surgeon.

The Greek beliefs about cancer carried on throughout the centuries and were expanded upon or debunked over the centuries. The evolution of cancer understanding and treatment ranged from the belief that cancer was contagious to the belief that it spread through the blood and only seeded in parts that could host it.

In 1830 until the close of the 19th century, less than 10 percent of the population of Greece had health care coverage. In 1922, the Ministry of Hygiene and Social Welfare was founded. The quality of health care service was primitive by comparison with other European countries. The first serious attempt by the government to provide better health care for the masses involved establishing the Social Security Organization in 1934. This gave health care and pension coverage to blue-collar and white-collar workers in urban areas as well as in industries with more than 70 employees. It resulted in
health care access for more than one-third of the population.

In 1941, temporary hospitals were set up for the war effort and remained afterward. The next plateau was 1953, when the government passed legislation to found a National Health Service. The aim was decentralizing health care competencies to the health regions and, through them, to the district health councils. Regional councils gave their insight on the health care needs by population, morbidity, and other factors and would get the required equipment and buildings. This marked the first time a needs-based approach to health care was used; however, the law was not implemented, and the chance was lost.

In the 1960s, a period of fast economic growth saw a number of institutions establishing their own insurance funds. These funds were mainly financed by employer contributions, and the funds provided high-quality insurance for their employees.

Farmers made up more than half of the Greek population at this time, and in 1961, legislation was passed to provide health care for them as well—the founding of the Agricultural Insurance Organization. This marked the first time that farmers ever had had access to health insurance.

Between 1967 and 1974, the dictatorship consolidated these health care services. It was during this period that the idea of a comprehensive health care system came about. In 1968, plans were made for an overhaul of the health care system. The Ministry of Health had many goals in this, not the least of which was improving health care for the rural population, instituting a family doctor system, improvements in psychiatric care, and more.

By the end of 1973, only a fraction of the health care policies had come into fruition. Public funding of health care had actually decreased, and the rest of the proposals on the establishment of a national health service died out. Once democracy was restored in 1974, public pressure and problems with the existing health care system were amplified, making this a heavy issue for the new government. Problems with health care continued on into the late 1990s and early 2000s.

Green, Adele

Applying sunscreen for extended time spent in the sun seems now to be common sense—parents at pools or beaches with their children, those over 55, and those simply wishing to prevent the effects of aging apply sunscreen almost automatically. But the extensive oncological research that went into first defining the effects of the sun's ultraviolet (UV) rays on the development of a variety of skin cancers and, in turn, first provided the scientific data that backed up the use of sunscreen is barely two decades old and initially faced doubts and skepticism even within the scientific community. Cancers, it was long held, are largely genetic, and environmental factors and even personal decisions were marginalized as risk factors. Australian cancer researcher Adele Green was among the most diligent and dedicated of that first generation of oncology researchers whose groundbreaking research led, in her case, to a lifetime of tireless promotion of sunscreen, a practice, Green and others argued, that made skin cancers not merely treatable but actually preventable. Born in the late 1950s, Green grew up in a generation in which cancer was a bugaboo, a hobgoblin to be feared for its apparent and evident randomness. To that point, save avoiding tobacco products, the scientific community was largely committed to cancer treatment studies. Green challenged that mind-set. Her work and her public advocacy of sunscreen as well as her message that personal decisions played a large role in cancer prevention led to much recognition and prestigious accolades in her native country, among them being named to the Companion of the Order of Australia and being short-listed in 2013 for Australian of the Year.

Australia was, oddly, a nearly perfect research laboratory environment for the study of melanomas.

See Also: Breast Cancer; History of Cancer; Insurance.
It is the world’s largest island with more than 16,000 continuous miles of coastline (the sixth-longest coastline in the world). Add to that an average six-month summer season where daily high temperatures can range between 75 and 95 degrees and a majority population of people with European ancestry and fine white skin. Adele Green, in 1979, then a graduate from the prestigious medical program at the University of Queensland and a practicing physician, treated case after case of melanomas that were far too established to provide much hope to her patients (later she would describe skin cancer as an epidemic in Australia). She began to believe that research would be far more valuable and help far more people than her work as a doctor treating, one by one, skin cancers after they had already been established. What caused the spike in skin cancers in Australia? She returned to complete her doctoral research in epidemiology, completing her degree from the University of Queensland in 1984. She studied tropical medicine and treatment abroad, first in England and then at Harvard before returning to her native country in 1996, certain now that the particular environmental conditions of Australia were key to melanoma prevention. She was appointed director of the University of Queensland’s Epidemiology and Population Health Unit, a forward-thinking facility that saw as its mission nothing less than the promotion of the general health of the state’s residents. Although her research would come to include work in ovarian cancer and in esophageal cancer in men, she pioneered research into the impact of the sun’s UV rays on melanomas.

Her groundbreaking work centered on a four-year study of a group of selected residents, all under the age of 55, in the southeast Queensland coastal town of Nambour, a thriving beach community at the heart of Australia’s so-called Sunshine Coast, a tourist paradise. Green eliminated narrowing the pool by race or general skin color, cancer history, weight, or gender—she even used smokers. It was a radical notion—Green wanted to test a random sampling of Australians. The results were stunning—residents who used sunscreen daily and broadly (i.e., all over the exposed body) not only preserved the natural smoothness of the skin lost in the process of aging but, far more important, actually avoided the onset of skin cancers. It was the first conclusive data linking exposure to the sun to melanomas; previous work had been limited to studying the effects of UV rays on hairless mice in controlled laboratory conditions. As the study’s lead author, Green began what would become a decades-long public campaign to get her fellow Australians to use sunscreen of sun protection factor (SPF) 15 daily and to reapply it throughout the day. Although cosmetic companies would attempt to take advantage of the public’s use of sunscreen by providing increasingly expensive sunscreen with higher SPF numbers, Green’s research definitively showed that the increase in protection beyond 15 was minimal.

Green’s message to her island country became clear—skin cancers and melanomas could be avoided. She took to any public forums to spread the message. Indeed, although her unconventional research methodologies are certainly part of her legacy, she has had far more impact as a public spokesperson and as a mentor of an entire generation of Australian oncology students, inspired by her message that skin cancer was impacted, of course, by genetics but that personal decisions and choices contributed to it. Green was a charismatic and engaging speaker—she never came across as scolding or judgmental. A regular on television programming and radio talk shows as well as appearances in public forums across her country, she became a kind of celebrity, the family doctor to her nation-continent (she is frequently compared to Dr. Mehmet Oz, or “Dr. Oz,” on American television). In addition to advocating sunscreen, Green also pioneered the relationship between leafy green vegetables and cancer prevention as well as regular exercise (she was particularly fond of dancing). Although other oncology researchers believed time would be better spent in researching the mechanisms of melanomas, Green argued that preventing skin cancer through a simple protocol of common-sense decisions made far more sense.

Gregoire, Christine

At the turn of the 20th century, cancer was among the most mysterious and terrifying diseases. Unlike tuberculosis or yellow fever, which had heroic narratives of medical research and survival stories among patients, because of the limited treatments developed, a cancer diagnosis was considered a death sentence, and those who had to deal with the agonizing dying process itself were viewed as victims, not patients. Families often kept the diagnosis a private matter or gave cancer elaborate euphemisms. With the exponential growth of cancer research and treatment options in the post–World War II boom in the biomedical field, with President Richard Nixon’s call for a war on cancer in 1973, and with a growing public awareness that cancer, if caught early enough, could actually be treated successfully, there has grown a subgenre of medical narratives and cancer survivor stories.

These people, whichever gender, whatever age, became inspiration models; their tales of courage and endurance, featured in magazines and talk shows and most recently in Internet videos, have lifted the spirits of those others who face similar diagnoses. Among the most prominent cancer survivors of this era is Christine Gregoire, a two-term governor of Washington, whose doctor, during a routine checkup in anticipation of Gregoire’s run for the governorship, detected early-stage breast cancer. Because the cancer was detected early enough, treatment was a viable option. Gregoire decided on a mastectomy and returned to full vigor and the public spotlight within a week. Over the next decade, as she dominated the state’s Democratic Party, she never forgot the importance of early detection and tirelessly championed the cause among women age 40 and above.

Born in 1947 in Michigan, Christine O’Grady grew up the only child of a single mom who worked as a line cook in a restaurant and never completed high school. Her mother relocated them to Washington before O’Grady was three. O’Grady was taught early on by her mother the importance of education, and she devoted herself to her studies. Graduating in speech and sociology from the University of Washington in Seattle, she initially wanted to teach public school. But finding no opportunities, she returned to school to study law and earned her Juris Doctorate from Seattle’s Gonzaga University in 1977. Inspired as so many of her generation by John Kennedy’s call for community involvement, Gregoire, now married, knew public service was her ambition.

After a brief stint as a typist-clerk in the parole and probation offices and then in the state’s Department of Ecology (she had grown up in love with the state’s wilderness), she moved to the state’s attorney general’s office, where she worked initially with social services in investigating and ultimately protecting children from abusive parents. She became known quickly as one of the Democratic Party’s rising stars. Energetic and charismatic, she spoke in a straightforward manner that gained wide voter trust. She decided in 1991 to run for attorney general. She was elected (the first woman to hold that position) and once again distinguished herself as a fighter and champion of populist causes, most notably successfully spearheading the state’s massive lawsuit against several tobacco companies for misinforming the public over the dangers of smoking. Reelected twice, she decided she would make a run for the governorship. In an effort to present the voters a clean bill of health, she underwent a standard set of physical examinations. In her early 50s and quite active and hands-on as attorney general, she felt fine and considered the tests as a mere formality.

It was her routine mammogram, however, that detected a ductal carcinoma in one of her breasts, undetectable by standard manual examinations. That the cancerous cells had gotten no further than the duct, that is, noninvasive, located just under the skin, gave doctors two treatment options: She could undergo intense radiation therapy that would take six grueling weeks and would leave Gregoire physically exhausted and, more problematically, it could not discount a return of the cancer, or she
Two-term Washington state governor Christine Gregoire became a famous anti-cancer advocate after her bout with breast cancer. (Washington State Office of the Governor)

could elect a mastectomy, a more radical option but one that had had far more promising long-term results. Gregoire did not dwell in self-pity or depression—rather she made a quick decision.

Doctors removed the breast and did standard reconstructive work in a single day, all under the relentless scrutiny of the state’s media. To doubters who thought a cancer survivor so soon after treatment would not be up for the campaign, much less the daily 16-hour grind of a governor, Gregoire demonstrated in her campaign a resilience and grace that convinced voters to vote on the basis of her politics, not her disease. When asked, she stressed that her recovery was thanks to early detection and the advances in cancer treatment, among the first public figures to make such public pronouncements about breast cancer.

She was elected after a difficult challenge (by a margin of just under 160 votes and that was resolved by a recount) and quickly established a national presence for her campaigns to address a variety of populist causes from education reform to welfare reorganization, from tax initiatives geared to help the poor and middle class to gay rights. But she also vigorously pushed for state support of stem cell research, citing such controversial biomedical research as the best promise not only in cancer treatment but in a variety of diseases, most prominently in treating dementia and catastrophic nervous system conditions. Her own cancer never returned, never interfered with her managing the responsibilities of the office—and she was reelected in 2008, becoming something of national figure when she endorsed Barack Obama rather than Hillary Clinton. Gregoire was reelected handily.

In May 2012, as her second term was ending (she had announced she would not seek a third term), she and her husband made a difficult public announcement that her husband, Mike, had been diagnosed with colon cancer during a routine checkup. He had been in no pain and had evidenced none of the symptoms. Surgery immediately removed the cancerous segment, and doctors predicted a full recovery. Once again, Gregoire emphasized the importance of early screening. Once out of office, although she was courted by the Obama administration for a cabinet-level job, Gregoire retired from public life to spend time with her family—however, she did accept a trusteeship on the board of the Fred Hutchinson Cancer Research Center, one of the state’s top-rated cancer research and treatment facilities.

Guatemala

The Central American Republic of Guatemala, independent since 1821, is home to 15 million people who have witnessed major changes in their disease profile. Whereas preventable upper respiratory tract and gastrointestinal infections were once the biggest health threats, Guatemalans now experience increasing rates of noncommunicable diseases, including many cancers. Much of Guatemala’s Maya population also suffers high rates of malnutrition and poverty, compounding their already difficult health picture. Mayas and others who live in marginal areas should an especially heavy cancer burden that centers on five types.

Major Cancers
Since at least 2005, more Guatemalans have died from stomach cancer than from any other cancer. Mortality from this disease has been especially marked among Guatemalan men, for whom it is the most frequently diagnosed cancer. Guatemalans as a whole, though, suffer heavily from this malignancy and were ranked fourth globally in its occurrence in 2012. But while stomach cancer remains the leading cancer cause of death among Guatemalan men and women, women are also very vulnerable to liver cancer. In fact, Guatemalan women had the third-highest rate of liver cancer in the world in 2012. Liver cancer is the second-most prevalent cancer in Guatemala, and though it affects men and women, its diagnosis has been uneven across these groups. Given the high rates of drinking and alcoholism among men, the underreporting of this cancer among men is cause for concern.

The cancer most frequently diagnosed among women, meanwhile, is cervical cancer. In Guatemala’s rural areas, where many women marry early and have short intervals between births, women face an increased overall risk of developing this cancer. To address this, in the 1980s, health workers began making the Pap test more widely available. Persisting problems with cytology lab work and patient follow-up visits, though, limited the test’s effectiveness. In 2002, then, the Pan American Health Organization (PAHO) and some nongovernmental organizations (NGOs) began promoting the VIA/Cryo diagnostic protocol, in which trained health personnel apply a 3 to 5 percent acetic acid solution to the cervix, which causes abnormal cells to temporarily turn white under bright light. Abnormal lesions can then be treated immediately by cryotherapy. The entire process is as reliable as cytology but much faster and more cost-effective. This process has limitations, though, because it relies on subjective visual reading and is not suitable for women over age 50. The Ministry of Public Health and Social Services (MSPAS) and other stakeholders are currently studying how to administer human papillomavirus (HPV) vaccines to the country’s most vulnerable women.

Research is also under way to limit the mortality tied to prostate cancer, considered the fourth-leading cause of all cancer deaths in 2011. Worth noting, though, is that, whereas most health agencies point to stomach cancer as the leading cancer cause of death, in Guatemala City’s public oncology hospital (INCAN), prostate cancer was detected more often in men than stomach cancer in 2012. This suggests that where screening and diagnostic resources are concentrated, more detection of prostate cancer occurs, despite national trends. The fewer screening opportunities in rural areas may be associated with how Guatemalan men had the fourth-highest rate of prostate cancer in the world in 2012.

Limited diagnostic resources in the countryside, together with other factors like smoking and wood smoke inhalation, have imperiled lung health and contributed to lung cancer prevalence. This cancer is now the fifth-leading cancer cause of death in Guatemala. With smoking on the increase, the high rates of upper respiratory tract infections are on track to worsen, along with overall vulnerability to cancers. Among Mayas, moreover, as tobacco use stems from ancestral practices, it is deeply entrenched in some quarters of community ritual life. And with the widespread visibility of cigarette smoking, including in TV advertising, smoking is attracting younger Guatemalans. Poor indoor environmental quality, especially in smoke-filled kitchens in rural homes, also threatens respiratory health and may contribute to rising rates of lung cancer.

System Challenges
Guatemalans face many challenges with cancer, but diagnostic screening remains a top issue. Many cancers in rural areas go undiagnosed, partly because many women are reluctant to reveal intimate parts of their bodies to screeners, and partly because many men resist getting medical attention at all, much less
screening. But in view of how Mayas make up half
the population, the MSPAS has long tried to reach
indigenous people, and especially women, through
Maya midwives, something it will likely continue
doing to broaden screening services. At the urging
of NGOs, more health personnel are also trying to
improve their outreach and service efforts. Part
of this requires addressing how health personnel
in rural areas seldom speak one of the country’s
22 Maya languages. This language divide dissuades
many Mayas, particularly women, from going to
clinics or from returning for follow-up care.

Some Western groups have been involved in can-
cer capacity building in conjunction with INCAN,
the only publicly operated oncology hospital. Their
work has included (1) helping update INCAN’s
record keeping system and cancer registry, which
until recently were paper based, (2) identifying trans-
mittance vectors of infectious agents linked to stom-
ach and cervical cancers, and (3) helping improve
the screening infrastructure. Mammography, for
example, is still not widely available in the public sec-
tor, and even at INCAN, it is expensive. A mammo-
gram there costs around $18, which is about twice the
average daily wage of $9.70, itself far more than most
rural people make in a day. Health centers and posts
throughout Guatemala remain poorly staffed and
underequipped, and with the state devoting less than
0.05 percent of gross domestic product (GDP) to can-
cer research, cancer mortality is expected to increase.

Affluent Guatemalans, meanwhile, have a wider
range of health choices, including private hospitals
and physicians trained in the United States or Europe.
Many seek treatment at U.S. centers like MD Ander-
son Cancer Center in Houston. Their situation, of
course, contrasts starkly with that of most Guatema-
lans, who wrestle with marginalization and whose
lives are more likely to be irreparably disrupted by a
cancer diagnosis. With cancer impeding the social
mobility of many poorer Guatemalans, the country as
a whole will continue feeling the effects of this disease.

Guinea

Guinea has been in the process of reorganizing
its health care system since the Bamako Initiative
in 1987. It formally endorsed community-based
activities to increase access to drugs and health care
services to the population, in part by implement-
ing fees. This strategy saw a spike in accessibility
through community-based health care. The services
provided experienced a boost in quality as well.

The Bamako Initiative aimed to resolve dif-

Guinea has joined a growing number of countries

In June 2011, the Guinean government instituted
a levy on all air traffic taking off from the country.
These funds were given to UNITAID to increase
the reach of programs to treat human immuno-
deficiency virus (HIV), acquired immune deficiency
syndrome (AIDS), tuberculosis, and malaria.
who are using transactional taxes and other such methods as vehicles for increasing health care to its people. In 2014, the life expectancy in Guinea reached 59.6 years.

Although Guinea has seen some improvement when it comes to health care access, Guinea also suffers from severe problems on the same front. Like many countries in Africa, many of Guinea’s people fall prey to HIV and AIDS. In 2001 and 2002, studies concluded that HIV was higher in urban areas, with prevalence in some cities as high as 7 percent of the population. Forty-two percent of commercial sex workers were afflicted as well as 6.6 percent of active military, 7.3 percent of truck and taxi drivers, 7.3 percent of miners, and 8.6 percent of adults who also suffered from tuberculosis. In 2004, it was estimated that more than 170,000 children and adults were afflicted with these diseases. HIV is spread primarily by way of heterosexual intercourse with multiple partners. Both genders are basically at the same risk, with young people between the ages of 15 and 24 most likely to become afflicted.

The epidemic of HIV is fueled by several different factors including unprotected sex, multiple sexual partners, poverty, illiteracy, unstable borders, lack of civic responsibility, refugee migration, and scarce access to medical care as well as public services.

Another serious problem plaguing Guinea’s population is malnutrition. In 2012, a study reported chronic malnutrition rates as high, with levels ranging from 34 to 40 percent according to region. Acute malnutrition rates in mining zones were reported as above 10 percent. About 139,200 children were suffering from acute malnutrition and 609,696 from chronic malnutrition, and another 1,592,892 were afflicted with anemia. The factors behind these high levels of malnutrition include limited medical access, degradation of care practices, poor hygiene practices, and low levels of food diversity.

In 2014, the Ebola virus broke out in the highly populated capital city of Guinea: Conakry. The health ministry prohibited sale and consumption of bats, which were thought to carry the pathogen, but the virus spread out from the rural areas in spite of this measure. With limited access to health care and a capital city with 2 million people, the emergence of Ebola is a thing of nightmares. Ebola is passed from person to person by close contact and has a mortality rate of between 25 and 90 percent.

The people most affected thus far have been living in rural areas. The victims are commonly impoverished people who have little to no access to any health care system. There is also very little in the way of incentives for major companies to make any sort of investment in medical solutions for these people when there would likely be no return on the investment.

Cancer has become a health problem in Africa. As screening has become more widespread, it has been reported that 715,000 new diagnoses were made, and 542,000 deaths as a result of cancer occurred in 2008. These numbers have been hypothesized as nearly doubling by 2030 simply due to population aging and growth. Despite these worrying figures, cancer is not as highly prioritized due to other public health concerns. The magnitude of this cancer burden is lost on many policy makers as well as the general public.

Most of the cancers in Africa are related to infectious agents. These include but are not limited to Kaposi’s sarcoma, urinary bladder cancer, and cervical cancer. Some areas are experiencing an increase in the cancers most common in North America as lifestyles change, such as taking up smoking, an increase in inactivity, and weight gain. The cancers cropping up include breast, colorectal, and prostate cancers.

Unfortunately, most cancers in Africa are diagnosed at a late stage. This is from many different factors such as lack of access to medical care, lack of knowledge or limited knowledge about the signs and symptoms of cancer, and a stigma associated with the cancer diagnosis in Africa. In addition to this lack of knowledge, most cancers are only found at an advanced stage because of nearly nonexistent screening or early detection services. As a result, the mortality rate of cancer is much higher than the rate for the same type of cancer would be in developed countries. The five-year survival rate for women suffering from breast cancer is less than half in Gambia, Algeria, and Uganda, as opposed to nearly 90 percent in the United States. This is, in part, because a late cancer diagnosis means that the cancer is in or nearing its final stages, and treatment options become severely limited.

While Guinea is making strides to create a health care system for its people, it is also afflicted with diseases and hunger, both of which are ravaging its citizens. Guinea has quarantined people known to have been exposed to the Ebola virus,
but the fruits of this effort will only be seen in the coming years. Still, Guinea has been working against obstacles to its citizens’ overall health for many years now, with marked improvements in the metrics of accessibility and quality. Hopefully in the years to come, Guinea will resolve its health care problems. With the public health crises in full effect, however, public exposure to cancer information may take a while.

H. Lundbeck (Denmark)

In the last generation of television medical dramas and in the small, but significant genre of antibusiness films, writers and directors, needing a clear and easy villain to generate drama, have often demonized without much subtlety pharmaceutical companies, faceless drug companies that cynically rush poorly tested drugs into the market, that care only about the bottom line, that dump potentially dangerous drugs into unsuspecting Third World markets, or that employ elaborate armies of legal counsel, conversant in legalese, to deflect any responsibility, legal or moral, away from pharmaceutical companies’ obvious agenda of making profits off the victims of sickness.

Given the paranoia and suspicion such mainstream productions inevitably generate, it is easy to forget that, in addition to university researchers and laboratory teams in high-profile cancer facilities, pharmaceutical companies are in fact often at the forefront of cutting-edge research. Certainly compelled by profit margins and shareholder interests, these companies nevertheless fund massive research efforts to bring to market revolutionary medicines that have in fact radically altered the approach to cancer treatment. H. Lundbeck, a global pharmaceutical conglomerate headquartered in Valby, just outside Copenhagen, is an example of just such a company, working with government agencies, university facilities, and even patients themselves to alter the public’s perception of drug companies. Over the last decade, Lundbeck has patented two revolutionary drugs that specifically target cancer treatment: Treanda and Trisenox. But more importantly, Lundbeck has used its global social media reach to begin a landmark effort on the part of a drug company to become involved with the psychological effects of disease: It has begun a major push to work with families, especially children, traumatically impacted when a member of the family has been diagnosed with cancer.

The story of H. Lundbeck is one of both savvy business evolution and the rich potential of globalization. Founded by Hans Lundbeck at the height of World War I, Lundbeck was initially conceived as a kind of old-school trading company to assist war-ravaged Denmark, trading in everything from aluminum foil to biscuit mix. With the end of the war, the company quickly expanded initially into beauty products. Research teams eventually began testing the lucrative market for newer and more effective painkillers, and by World War II, Lundbeck had established a national reputation as a pharmaceutical company. In the 1950s, the company pioneered research into drugs that would help in treating Alzheimer’s disease, although at the time it was known as dementia or senility, and by the late 1970s, with the introduction of the drug Truxal to diminish the effects of schizophrenia, Lundbeck
was an international pharmaceutical player, phasing out its other agencies to focus on drug research. Initially, the company became known for its major advances in drug protocols for a wide range of brain disorders, including incipient Alzheimer’s, depression, insomnia, bipolar disorder, schizophrenia, and even epilepsy. All the while, the business divisions oversaw the careful expansion of the company into new markets, establishing bridgeheads into most of Europe, the United States, and most revolutionary of all, the Peoples’ Republic of China. By 2013, H. Lundbeck was a $2 billion conglomerate that employed more than 6,000 researchers and technicians in 57 countries.

Beginning in the early 1990s, Lundbeck branched into funding major research into cancer treatment. Its initial success came with the drug Trisenox. The drug, which used a variant of the poison metal element arsenic (arsenic trioxide), was targeted to treat specifically acute promyelocytic leukemia (APL), a relatively rare type that affects adults after age 40, and then largely for APL patients who had experienced a radical relapse after a period of apparent remission. Anterior cruciate ligament (ACL) devastates the white blood cells in bone marrow and in the blood itself. Patients struggle with fatigue and frequently develop anemia and in extreme cases internal hemorrhaging. Although many variants of leukemia have become treatable, ACL has for the most part resisted treatment protocols. Licensing of Trisenox faced some resistance as the drug, with its extremely toxic arsenic base, despite its remarkable success in clinical tests, caused significant side effects—most centrally to the heart’s ability to maintain rhythmic beating and keep blood circulating. The reality was that the side effects of the treatment drug could themselves be fatal. But countries approved the drug for use but only under doctor’s direction because, as an injected drug, it eased the patient’s need to endure often difficult chemotherapy sessions, bringing not only hope, given the drug’s success, but also relief to thousands of cancer patients worldwide.

But in 2010, the remarkable success of bendamustine hydrochloride, its brand name Treanda, became Lundbeck's signature contribution to cancer treatment. Targeted to treat relapsed indolent B-cell non-Hodgkin's lymphoma and chronic lymphocytic leukemia (which together account for about 6 percent of all cancer deaths), Treanda, an injection, had proven effective in clinical trials involving both patients with an extended history of cancer treatments and those just diagnosed—in short, it held promise for virtually the entire range of patients with non-Hodgkin’s lymphoma and leukemia. What perhaps best indicates Lundbeck’s concern for intensive testing, the drug was introduced into a study involving 319 patients with leukemia, patients selected without regard to ethnicity, age, or gender. It was a random test—many drug companies routinely adjust their demographics for drug testing in an effort to earn drug licensing and approval to market. A remarkable 76 percent of patients treated with Treanda responded to the treatment, and even more promising, in follow-up studies, patients showed no signs of the disease in the bloodstream up to 21 months (previous drug protocols averaged nine). Patients could return to relatively normal life, although the drug had notable side effects, including prolonged nausea, headaches, and vomiting.

What made Treanda such a revolutionary cancer drug was how it killed infected cells—although researchers admitted they were not entirely sure how the drug did what it did. Cells can die two ways: (1) a process known as necrosis, a relatively unpleasant process in which some external trauma (infection, blunt force, as in a car accident, or the introduction of a poison) kills the cells or (2) a process known as apoptosis, in which the cell is actually told to die, to commit a kind of tidy cellular suicide in a controlled and directed fashion. Although it is the basis of radiation treatments and chemotherapy sessions, apoptosis in cancer treatments can often leave the patient physically exhausted. Like radiation or chemotherapy, an injection of Treanda, by short-circuiting the wiring of the DNA, sent a signal for diseased cells to die, leaving the patient with much milder side effects. Approved first in Europe and then in the United States and Canada, Treanda is now available virtually worldwide and has become a new and promising option for cancer patients.

Haemophilia Society (United Kingdom)

The UK Haemophilia Society was founded in 1950 to serve the needs of people with hemophilia and related bleeding disorders, including hemophilia A, hemophilia B, von Willebrand disease, and risk factors associated with the development of inhibitors against the treatment (depending on ethnicity and severity of the bleeding disorder). It is the only independent society with a presence across the United Kingdom. It is a charitable organization working toward providing the best medical care for patients with hemophilia. The Haemophilia Society is currently headed by President Baroness Molly Meacher, who has been active in the field of mental health and drug reform at the House of Lords. She has served as president of the society since March 2013. She has extensive expertise in issues related to health and social care, and involvement with UK National Health Service (NHS) supports.

It is estimated that hemophilia and related disorders affect around 15,000 people in the United Kingdom, who are drawn from all racial groups. Furthermore, von Willebrand’s is believed to affect up to 1 percent of the population, many of whom currently remain undiagnosed. The Haemophilia Society’s mission is to provide patients with necessary information and treatment options for hemophilia and other bleeding disorders, the freedom to choose medical interventions, and the ability to seize opportunities available to them. The society is led by people affected by hemophilia and works in close partnership with the NHS. The society has over 4,000 members, 60 percent of whom have bleeding disorders. The other 40 percent are primarily family members or friends of people with bleeding disorders.

The Haemophilia Society has worked hard to disseminate information through Web sites, magazines, pamphlets, and research. The society also has individual advocacy and support for patients in the form of consultation and advice through telephone helplines, enabling patient access to physiotherapy clinics, and the organization of community fundraising efforts. The society encourages patients to meet other people with bleeding disorders, and it helps in the organization of events for children and families of affected people, and people with human immunodeficiency virus (HIV) or hepatitis C, with support via a Facebook page. The society has been supporting a campaign to raise awareness about contaminated blood. One important agenda for the Haemophilia Society is to campaign for better societal treatment and care for people affected by blood disorders. Members of the Haemophilia Society regularly participate in meetings with the UK Department of Health.

Important activities of the Haemophilia Society include providing members with up-to-date information on hemophilia treatment and care; providing assistance with application procedures for Disability Living Allowance and other applicable social benefits; providing information on special travel arrangements, treatment centers, and documentation procedures for patients traveling abroad for treatment; and raising awareness among women regarding bleeding disorders. The Haemophilia Society also advises and supports patients with hepatitis C and HIV through its wide network of volunteers. Parents with newly diagnosed children are also counseled and informed regarding treatment options and management of the disorder. The Aventis Alert pager service of the Haemophilia Society enables parents to be contacted if their children suffer from bleeding disorders.

The Haemophilia Society started the innovative Get Involved, Get the Best (GIGTB) project in 2009, to support active involvement of people affected by bleeding disorders in improving options for care and treatment. The project aims to bring a patient perspective to three main arenas involving local commissioning, auditing of hemophilia centers every three years, and the establishment of a Pan-Thames Haemophilia Consortium and services reconfiguration. Long-term volunteers are actively involved in this program, and youth leaders
are encouraged. The society has a presence through local groups across the United Kingdom, with 17 local groups in England, 2 in Wales, 4 in Scotland, and 1 in Northern Ireland.

In May 2011, as an attempt to increase awareness in the society regarding the challenges faced by people with bleeding disorders, the Haemophilia Society launched its Buddy Award scheme, sponsored by Novo Nordisk. The event was inaugurated at a launch event held at the House of Commons in London. The annual awards recognize the pivotal support provided from family members, caregivers, friends, and teachers of children who suffer from bleeding disorders. Because there is a severe lack of public awareness for bleeding disorders, families and friends have immense responsibility for their sibling/friend, and the Buddy Award recognizes and appreciates the valuable contribution made by friends and family. In 2014, 70 nominations were received for the buddy awards from all across the United Kingdom, and the award function was held at the London Zoo, with more than 200 guests attending. The award ceremony was held on April 17, which is the World Haemophilia Day, and winners included friends and family of patients with bleeding disorders, teachers, and social workers, as well as nurses and caregivers for patients.

The Haemophilia Society initiated a program called Talking Red, in order to tackle the problem of poor understanding of bleeding disorders and to raise awareness about bleeding disorders among women who suffer from bleeding disorders without realizing it. The first Talking Red awareness week was held on June 21, 2014, and encouraged women to be aware of bleeding disorders manifesting as frequent and heavy periods, easy bruises, frequent or heavy nosebleeds, heavy bleeding after surgery or dental procedures, and abnormal bleeding after childbirth. Talking Red encourages people not to be embarrassed to talk about bleeding and to raise awareness.

Resources/CharitiesEvaluationServices/Documents/haemophiliassocie
have considerable public health implications. It is for this reason that hair dye represents one of the most researched cosmetic products, having been the subject of both longitudinal and experimental scientific investigation.

Following development of the *Salmonella typhimurium* mutagenicity assay in the mid-1970s, it was reported that just over 50 percent of the amine ingredients of oxidative hair dyes had mutagenic properties. This test, which uses several strains of the bacterium *Salmonella typhimurium* to assess the carcinogenic potential of various chemicals, is beneficial in that it is significantly less time and resource intensive than rodent studies, though there are instances in which false positives and false negatives result. Ultimately, it was determined that this assay was of limited predictive value for the rodent carcinogenicity of the ingredients of oxidative hair dyes as species-specific metabolic differences have been found to be major determinants of the carcinogenic properties of aromatic amines.

**Regulation**

Beginning in the mid-1970s, due to the recognition that oral administration of certain aromatic amines was linked to cancer in rodents, many industrialized countries introduced regulations to prevent the use of those ingredients found to be toxic in rodent studies from use in commercially available hair dyes. This historical shift is of key importance in understanding the links that may exist between use of hair dyes and the development of cancer, given that certain cancers such as urothelial cancers may have latency periods of two or more decades. Thus, studies examining cases of cancer diagnosis occurring in the 1990s and 2000s may, in fact, be detecting carcinogenicity associated with dye products that have become unavailable due to heightened regulatory restrictions.

Today, government regulation of hair dyes varies throughout the world. In the European Union (EU), the safety of hair dyes and their ingredients is reviewed by the Scientific Committee on Cosmetic Products and Non-Food Products Intended for Consumers (SCCNFP), an independent agency whose role is to advise EU member states on any safety concerns regarding cosmetic ingredients. Those ingredients found to pose confirmed or presumed carcinogenic or reproductive risk are prohibited from use in products marketed to EU consumers.

Under federal regulations in the United States, the Food and Drug Administration is responsible for evaluating the safety of cosmetics and hair dyes, though the safety of specific ingredients is largely self-regulated. In 1976, the independent Cosmetic Ingredient Review was established to evaluate the risks of cosmetic ingredients. Since its founding, this group has written safety assessments of more than 650 ingredients, nearly all of which have been identified as safe or acceptable for use within certain parameters.

In Japan, hair dyes and their ingredients are considered by the Ministry of Health, Labor, and Welfare to be quasi-drugs and are subject to approval, which may include evidence of their safety. Similar agencies and regulations also exist in other Asian countries.

**Research**

Research on the development of cancer in both professional and personal consumers of hair dye has not resulted in clear conclusions. While some large-scale epidemiological studies have found that cancer risk increased in association with hair dye use, other prospective investigations have not demonstrated this link.

**Personal Hair Dye Use**

A pooled analysis of four smaller studies examining hair dye use and the development of non-Hodgkin’s lymphoma in women found that women who used hair dye prior to 1980 demonstrated a 30 percent higher risk of developing non-Hodgkin’s lymphoma than did women who had never used hair dye. Women who used oxidative dyes beginning in 1980 or later were not found to exhibit this increased cancer risk, with one exception: Women who used darker-colored dyes after 1980 were found to have an increased risk of follicular lymphoma. When contrasted with nonhair dye users who developed cancer, women who used hair dye prior to 1980 were significantly more likely to develop follicular lymphoma and chronic lymphocytic leukemia or small lymphocytic lymphoma.

Studies examining the personal use of hair dye and the risk of leukemia development have also had unclear results. In one case-controlled study, a slight leukemia risk was associated with use of
Hair Dye

pre-regulated dyes, though the increase was not statistically significant. Of note, researchers found that this minimal increase in risk was associated with oxidative as well as semipermanent and temporary hair colorants. In contrast, a similar investigation conducted in Italy found that only users of black dyes exhibited an increased cancer risk. This study’s results must be considered cautiously, as the frequency and timing of use of hair dye products were not evaluated as a component of the study, despite other researchers having acknowledged the importance of considering these factors when assessing carcinogenicity in oxidative hair dye products.

Individual studies and meta-analyses examining personal hair dye use and the risk of bladder cancer have produced especially conflicting results. While some researchers have found evidence of an increase in rates of bladder cancer associated with personal hair dye use, other research has not.

The relationship between breast cancer development and use of hair dye in women has been examined frequently since the late 1970s, with no studies to date finding any association of increased breast cancer risk for women who use hair dyes relative to those who do not.

There is limited research examining whether hair dye use is related to other types of cancers, and it may be some time before samples and results from available studies can be pooled due to significant variations in study designs.

Professional Hair Dye Use

One recent meta-analysis concluded that professional hairdressers do experience an increased cancer risk for several anatomic sites. Specifically, researchers reported a 62 percent increase in the development of multiple myeloma, a 52 percent increase in rates of larynx cancers, a 30 percent increase in rates of bladder cancers, and a 27 percent increase in lung cancer. These postulated that this increase in rates across these various sites reflected the multiple pathways, including respiratory, dermatologic, and systemic exposure, whereby industrial hair colorists may be exposed to carcinogenic agents. This analysis additionally indicated that professional hairdressers’ risk is not significantly increased for Hodgkin’s disease, non-Hodgkin’s lymphoma, leukemia, or ovary, breast, kidney, or colon cancers.

In 1993, the International Agency for Research on Cancer (IARC) conducted a meta-analysis that indicated that, relative to nonhairdressers, the risk of bladder cancer development for professional hairdressers was 1.6 times greater for male hairdressers and 1.1 times greater in females. The agency cautioned against assuming a direct corollary relationship between professional oxidative hair dye application and the increased risk for bladder cancer development, noting that hairdressers experience professional exposure to thousands of chemicals, including volatile solvents, propellants, formaldehyde, and methacrylates in the routine tasks of their chosen profession.

Conclusion

Ultimately, several factors may explain the relative inconsistency of findings regarding hair dye and cancer risk. Some research has examined age cohorts that may have been too young to assess the risk for certain types of cancers. Other studies have not properly controlled for other potential
confounding factors, such as ventilation, smoking history, glove use, and dye strength, in the case of professional hairdressers, or frequency or length of hair dying in the case of consumers. The largest study examining this relationship to date found a decreased mortality due to bladder cancer in women who had used dyes compared to those who had not, a finding that other researchers have labeled implausible. It is clear that to question the relationship between ever using hair dye and death due to cancer may represent too broad a question, which is likely to be influenced by any number of confounds. In response to the admittedly limited available research on the topic, the IARC recently stated its position that professional exposure to hair dyes was likely carcinogenic to humans, while personal use of oxidative hair dyes could not be classified as carcinogenic.

Haiti

A Caribbean nation of close to 10 million people, Haiti shares the island of Hispaniola with the Dominican Republic. Unlike its neighbor, however, Haiti lacks the robust tourism and consistent gross domestic product (GDP) often associated with Caribbean countries and is the poorest country in the Western Hemisphere. The World Health Organization (WHO) reported in 2014 the life expectancy of Haitian men to be 61 and Haitian women 64.

National data on cancer incidence and mortality are difficult to ascertain. Haiti does not maintain a national cancer registry. E. J. Mitacek, D. St. Vaillieres, and A. P. Polednak reported in the International Journal of Cancer that the major types of cancer recorded from 1979 to 1984 were stomach, intestine, primary hepatic, cervix, penis, and Kaposi’s sarcoma. Although the American Cancer Society reported in 2007 that Haiti has the highest liver and cervical cancer incidence and mortality rates of any Caribbean country, it had the lowest incidence and mortality rate from breast cancer. Another recent study indicated that Haiti had a higher incidence rate of cervical cancer than any other country in the world; in fact, the World Health Organization (WHO) reported that the incidence of cervical cancer in Haiti is 12 times that of the United States.

The 2010 earthquake in Haiti destroyed a large portion of the health infrastructure, including the Ministry of Health building. An estimated 150 nurses were killed when a nursing school collapsed, further exacerbating an already poor public health environment. Multiple other hospitals, clinics, and public health facilities were destroyed. Following the event, government and aid agencies immediately focused resources on epidemic diseases such as cholera and other waterborne diseases. Cancer control and care initiatives received very little post-earthquake support. Following the earthquake, international funds flowed into Haiti for reconstruction along with experienced medical professionals and administrators. It remains to be understood or measured if this influx will provide, over time, new and improved health facilities and programs across the medical continuum, including cancer prevention and care.

According to the Global Task Force on Expanded Access to Cancer Care and Control in Developing
Countries Innovation (GTF.CCC), in 2011, Haiti had one national oncologist who was trained in Mexico. Like many physicians in Haiti, this clinician works in the private sector, and only the wealthiest can afford services. Haiti does have in-country resources for Pap smears with two pathology labs, one private and one public. Currently, cancer detection occurs late. Treatment regimens typical to First World countries are not available. Radiation and chemotherapy are financially out of reach for most. Surgical cancer treatment is most common but often inappropriate due to the advanced state of most diagnosed cancers. Due to the absence of detection and treatment options, outcomes are generally poor to mixed.

Prior to the 2010 earthquake, Haiti possessed the world’s second-highest concentration per capita of nongovernmental organizations (NGOs). Many of these NGOs have access to medical professionals and services from wealthier nations. Zanmi Lasante (ZL, Partners in Health in Haitian Kreyol) employs close to 5,000 doctors, nurses, and community health workers. They serve an estimated 3.4 million, primarily in the central plateau and lower Artibonite, and are the only consistent source of free oncological care in Haiti.

As the largest health care provider in Haiti, the primary ZL Sociomedical Complex is located in Cange and supports not only the complex but more than 15 public health facilities throughout the area. The Cange complex houses a 104-bed, full-service hospital with two operating rooms, adult and pediatric inpatient wards, an infectious disease center, an outpatient clinic, a women’s health clinic, ophthalmology and general medicine clinics, a laboratory, a pharmaceutical warehouse, a blood bank, and radiographic services. In 2013, Hospital Universitaire de Mirebalais (University Hospital) opened. This 205,000-square-foot facility with 300 beds not only serves the people of the central plateau and lower Artibonite but provides education and training for Haitian community health workers, physicians, and nurses. Oncology care at University Hospital includes cancer screening, education, oral and intravenous chemotherapy, and palliative care.

Palliation outside of hospital facilities is not an integrated or even accepted feature of care within the country. A cultural reticence to administering narcotics and government controls make access to pharmaceutical pain management difficult. Because of the lack of formal and diffuse oncology care, informal family caregivers are common and are often the only medical line of care experienced by a household. Many Haitians also rely heavily on spirituality and religion in medical care.

Critical to many cultures, the concept of God, as well as other forms of spirituality and the supernatural, plays an important role in cancer and other health narratives. Studies have shown that culture and religion can significantly influence a patient’s perception of illness and treatment, making Western-based cancer care treatment problematic due to stigmas, fears, and previous negative experiences with “modern” healers. These factors may prompt the patient to seek indigenous and traditional medical practices instead. Although Haitians primarily identify themselves as Roman Catholic, many continue to follow varying forms of voodoo or a combination of the two.

The Haitian health literacy rate is extremely low due to lack of contact with formal and trained medical practitioners, both in person and in the media. Haitians also have little access to technology, which significantly limits the available channels of intervention communication. While a majority of Haitian households possess a radio, which provides daily broadcasts, few own or watch television. Although well over half of the population is literate, Haitians have a low rate of newspaper readership. Few Haitians use a computer, and even fewer use the Internet. Therefore, any type of media communication intervention, community awareness or detection campaign, or public education regarding cancer is difficult, if not circumstantially impossible. This absence of media outreach has a deleterious effect on early intervention for oncology care, oncology outcomes, and survivorship.

Head and Neck Cancer

Head and neck cancer (HNC) usually refers to cancers arising within the upper aerodigestive tract, the paranasal sinuses, and the salivary glands. While the incidence of some subtypes of HNC is declining in the United States, rates within Europe and Asia have either remained stable or increased. Risk factors include substance use, social deprivation, and exposure to the human papillomavirus (HPV). Symptoms, treatment, and outcomes vary according to tumor type, stage, and a variety of demographic and biological factors.

Risk Factors

Differences in the use of substances such as tobacco and alcohol may account for the geographical variations described above. Tobacco use and alcohol consumption are the leading risk factors for HNC, and they have a synergistic effect when used together, accounting for around 75 percent of HNC globally. Head and neck cancer is linked to social deprivation with increased incidence and worse survival associated with more adverse social circumstances. The mechanisms for this are unclear but are thought to relate to tobacco and alcohol use, diets deficient in fresh fruit and vegetables, increased presence of comorbidities, and a tendency for later presentation with advanced disease. HPV is a known risk factor for oropharyngeal cancer, and it may be implicated at other associated sites. HPV-associated tumors are most likely found in males, those age 50 or under and from black and minority ethnic groups; these tumors are also strongly associated with risky sexual behavior. They are also associated with better individual outcomes after treatment: a reduced mortality risk compared to non-HPV cancers and an increased three-year survival rate.

Many approaches aimed at reducing the incidence of HNC are intended to reduce tobacco and alcohol consumption and improve detection of early-stage lesions and tumors. There is also interest in prophylactic vaccines used to treat cervical cancer.

The Physical and Psychosocial Impact of Head and Neck Cancer

Presentation of HNC may include facial swelling, nonhealing ulcers, change in voice, problems with swallowing, or persistent sore throat and earache. After diagnosis is confirmed, a treatment plan will be developed by a team of clinicians including surgeons, oncologists, radiologists, specialist nurses, dentists, and psychologists. The treatment plan is influenced by site, histology, stage, and extent of disease. It is likely to include surgery to the primary tumor site and lymph nodes in the neck as well as radiotherapy and chemotherapy. Some patients will require nutritional support provided via a percutaneous endoscopic gastrostomy (PEG), and others may require a potentially permanent tracheostomy.

The effects of treatment for HNC vary according to tumor characteristics and treatment modality and are ongoing after treatment has finished. They can include significant systemic upset, scarring and hair loss in visible areas, loss of teeth and taste, xerostomia, impaired swallowing, speech alteration or loss of voice, shoulder weakness, and osteoradionecrosis of the jaws. Consequently, there may be a considerable impact on quality of life (QoL).

QoL generally worsens after diagnosis of HNC, reaching a nadir around the end of treatment. Around 12 months after diagnosis, it returns to pretreatment levels, although symptoms such as dry mouth, sticky saliva, and altered taste may remain with continued negative impact on mouth opening, intimate relationships, and perceptions of role and function. There is evidence that those with pharyngeal cancer show greatest deterioration compared to other sites, and speech scores are worse in those with laryngeal tumors.

Single therapy treatment (surgery or radiotherapy) may reduce symptom burden compared to combination therapy: Treatment with surgery alone seems
to avoid symptoms of dry mouth and sticky saliva. The use of PEG tubes to support nutrition is widely established but reported to be the strongest independent predictor of poor QoL. This may be related to physical weakness associated with compromised nutrition, discomfort and systemic upset, or perceptions of the PEG as a reminder of the cancer and a barrier to intimate relationships.

The impact of demographic factors including age, gender, marital status, and employment on QoL is less clear, and studies report conflicting findings. Women with HNC are reported to have worse QoL outcomes than men, supporting findings elsewhere in the oncology literature. However, despite no impact of marital status on QoL, cohabiting is associated with earlier diagnosis, reduced risk of gastrostomy dependence, and improved survival. Conversely, continued substance use is associated with adverse outcomes: tobacco use is associated with reduced QoL, and continued alcohol consumption is associated with worse survival.

Anxiety and depression are associated with HNC and predicted by living alone, being male, lower educational attainment, younger age, and unemployment at diagnosis. They are associated with longer hospital stays, increased treatment complications, malnutrition, and increased mortality, with suicide rates four times higher in those with HNC than the general population. There is a relatively high risk of recurrence or new tumor development, and many people report anxiety due to fear of recurrence. Body image concerns are also frequently reported, especially by those with oral and oropharyngeal tumors.

Rates of HNC vary according to various social and physical factors as do individual outcomes, including persistence of symptoms and survival. While the personal costs of a diagnosis of HNC can be great, societal costs for treatment and aftercare are considerable. Although estimates of those returning to work after treatment vary, there is evidence that people with HNC are less likely to return to work than breast, colon, or prostate cancer patients. Further rigorous and good-quality research is required to improve the quality of our knowledge regarding this condition.

**Health Advocacy**

Health advocacy is the mobilization of people or organizations to address a specific health concern. Health advocacy often is political because it seeks to amend existing health-related policies or implement new ones. Therefore, health advocacy can be an important tool for indirectly helping people with cancer better manage their disease. For instance, a health advocacy effort may convince policy makers to implement a law that would grant cancer patients more affordable medical treatments through improved health insurance coverage. In this entry, an overview of health advocacy is presented and a recommendation for how health advocacy may be systematically performed is offered.

**Overview of Health Advocacy**

Historically, advocacy has been used in the legal profession to describe a lawyer representing a client and speaking on behalf of the client. Rhetoricians who study advocacy examine the art of negotiations, persuasions, and argumentations that occur in court-oriented dialogue. In this context, the term advocacy implies reasoned argument toward change rather than pleading for change. There are various forms of advocacy, such as citizen advocacy, environmental advocacy, and health advocacy, among others. In citizen advocacy, professionals represent
people within an institution to speak up for their rights. In environmental advocacy, professionals represent the environment to preserve and safeguard it. In health advocacy, professionals, caregivers, or community members represent clients or patients to advance better solutions to address the health-related problems they face. For example, one may advocate for cancer patients by persuading the government that more resources should be allocated for the construction of cancer-support facilities. Those who advocate are not limited to lawyers but include people with other occupational and community roles, such as social workers, academics, health care professionals, caregivers, and patients.

Because health advocacy may require much effort, it is often carried out by a group of people or an organization rather than an individual. Therefore, health advocacy often involves coordinated action to bring about change in health policies. For instance, organizations such as clinics and grassroots cancer organizations may unite to form a cancer coalition to advocate for greater affordability in cancer treatment. Group-level health advocacy started in the early 20th century in volunteer organizations and social movements. Early health advocates were activists in civic organizations, women’s associations (e.g., Young Women’s Christian Association), labor organizations (e.g., American Association for Labor Legislation), and nonprofit organizations (e.g., American Cancer Society).

Health Communication Advocacy Model
There are a variety of ways to approach health advocacy. This entry presents a revised version of Marifran Mattson’s Health Communication Advocacy Model as one framework that people or organizations may utilize to guide them through the health advocacy process. The model emphasizes the crafting of persuasive messages that communicate advocacy goals to audiences and incorporate a social marketing perspective in developing and implementing an effective health advocacy campaign. Crafting messages refers to the effective creation and dissemination of advocacy messages using communication theories. Social marketing refers to the use of marketing concepts to relay messages and generate responses in target audiences to calls for social action. When theories and concepts of communication and social marketing are fused together in this way, advocacy efforts are more effective in compelling audiences to support advocacy goals. There are three phases in the Health Communication Advocacy Model: the assemble team phase, the formative research and message development phase, and the implementation and evaluation phase. Advocacy practitioners who utilize the model should proceed systematically through each phase.

Practitioners utilizing this model begin their advocacy campaigns with the assemble team phase. In this phase, a team of people with relevant expertise is put together to work toward a shared advocacy goal. In the context of cancer-related advocacy, the team should be comprised of individuals with expertise regarding cancer. These experts have knowledge of or experience with cancer and may include physicians, cancer patients, and caregivers. The team also should include representatives from community partners, which may be clinics, grassroots organizations like cancer associations, or large, networked organizations such as cancer coalitions.

Community partners are important as they enable advocacy efforts to have more resources and further reach. The team also would benefit from recruiting public health and communication specialists as they are proficient in communicating health-related concerns efficaciously to small and large audiences. Last, a lobbyist is recommended to be part of the advocacy team. A lobbyist is a professional who provides advice on political strategies and has considerable political knowledge and network connections. A lobbyist may help an advocacy team weave through political complexities and be connected with policy makers to persuade them to support the advocacy goals. When the team is assembled, its members construct a position statement regarding the health issue that they wish to address. For instance, if lack of affordable care for cancer patients is the health issue, an advocacy team’s position statement may be “to persuade legislators to pass a law that requires health insurance companies to provide better coverage for cancer treatment.” After the position statement is constructed, the team proceeds to phase two of the model.

Phase two is the formative research and message development phase. In this phase, the advocacy team identifies the legislators, activists, media, and other audiences who may influence policy-making decisions and develops messages to persuade these audiences to be in favor of the advocacy goal. Grounded in communication theories, the messaging process
Health Advocacy

involves crafting messages that are stimulating and motivational. This may be achieved through emotional appeals, immersive audio and vivid imagery, and portraying the threat of the disease or illness. For example, a message may depict, through a patient’s testimonial, the difficulties of managing cancer and the deleterious consequences of not being able to afford managing cancer in order to persuade legislators to support policies that provide insurance coverage for cancer treatment. Messages also should address barriers that may hinder audiences from supporting the advocacy goal. For instance, if some audiences are not familiar enough with using the Internet to access and sign online petitions, then messages should include instructions on how to support the advocacy campaign in other ways, such as rallying at the statehouse. Messages also should be culturally consistent and relevant. In other words, messages should adopt the language and norms recognized by an audience of a specific culture. An advocacy team also should consider their resource capabilities in developing and disseminating messages, including time, money, and staffing.

The message design process also should take into account social marketing strategies. Philip Kotler and Gerald Zaltman posited four elements vital for successful social marketing: product, promotion, place, and price.

Product in the context of an advocacy campaign refers to the advocacy goal; the advocacy team needs to present their advocacy goal clearly to audiences.

Promotion refers to the method by which the goal is brought to the attention of audiences. An advocacy team may achieve promotion in several ways, including raising awareness of the goal online, through the radio, or through publicity events.

Place refers to the channels through which audiences translate motivation into action. An advocacy team needs to provide specific directions for audiences to know how to support the goal. For example, an advocacy team may need to provide a URL for signing online petitions supporting the goal.

Price refers to the costs that audience members may incur in supporting the advocacy goal. An advocacy team must take into consideration the psychological, monetary, energy, and opportunity costs that audiences may face in supporting the advocacy goal and address these concerns in the campaign messages. Draft messages should be pre-tested to determine what needs to be improved or added before disseminating the messages to target audiences.

The next phase in the model involves implementing and evaluating the advocacy messaging strategies. The advocacy team may assess the progress toward the advocacy goal through methods such as monitoring media coverage; recording the frequency of traffic on its Web site, blogs, or social media sites; and tracking the number of legislative votes in favor of the advocacy goal. If the result of the advocacy effort is considered successful by the team or if the advocacy goal is achieved, the advocacy team should disseminate information to patients and relevant others who may benefit from the campaign’s progress or policy change. For example, if resulting legislation mandates health care coverage for the majority of cancer treatment expenses, the advocacy team should attempt to inform cancer patients and their caregivers that the legislation has passed and how they can acquire the benefits. If the result of the advocacy effort is unsatisfactory for the advocacy team or if the advocacy goal is not achieved, the advocacy team may choose to return to the formative research and message development phase of the model to reattempt achieving the advocacy goal by improving their messages to persuade their target audiences. Alternatively, the advocacy team may withdraw from the campaign. However, even if the team abandons the advocacy campaign, they should inform patients and relevant others about the progress of the campaign.

Health advocacy is important as it may help people with cancer better manage their disease. Advocacy efforts may lead to policy changes that provide support for cancer patients or remove obstacles that cancer patients may face. Marifran Mattson’s Health Communication Advocacy Model is one framework that practitioners may use to guide them through the health advocacy process.

Further Readings
The Healthy People Initiative is a comprehensive, nationwide health promotion and disease prevention agenda set by the U.S. Department of Health and Human Services. The Healthy People Initiative began in 1979 with Healthy People: The Surgeon General’s Report on Health Promotion and Disease Prevention. This was followed by the Healthy People 1990, Healthy People 2000, Healthy People 2010, and most recently, Healthy People 2020. Each initiative is released at the dawn of the previous decade (i.e., the current 2020 initiative was released in the early 2010s) and provides a list of health promotion and disease prevention objectives the United States hopes to achieve before the next decade arrives.

The overarching vision of the initiative is “a society in which all people live long, healthy lives.” This vision is guided by two main goals. The first goal is to increase quality and years of healthy life without preventable disease, disability, and injury. Quality of life refers to how happy or fulfilled an individual is with his or her life and is often measured using self-report data, number of healthy days over a certain period of time, or the number of healthy years without chronic or acute health problems. Years of health life, or life expectancy, refers to the average number of years of life remaining at a given age. For example, the current life expectancy for a child born in the United States is nearly 79 years. However, females tend to live longer than males, and whites tend to live longer than minorities, which brings us to the second main goal of the Healthy People Initiative: to eliminate health disparities among all segments of the population (e.g., gender, race, ethnicity, socioeconomic status, etc.). One example of a health disparity concerns the fact that African American men have higher rates of cancer than men or women of any other race/ethnicity.

Healthy People 2020 includes more than 1,200 measurable objectives and evidence-based resources for 42 different topics ranging from access to health services to human immunodeficiency virus (HIV) to vision care. This has increased considerably since its inception in 1979, when there were just 226 objectives in 15 topic areas. Further, Healthy People 2000 contained 312 objectives in 22 areas, and Healthy People 2010 had 467 objectives in 28 areas. A few of the 12 new areas included in Healthy People 2020 include adolescent health; genomics; lesbian, gay, bisexual, and transgender health; preparedness; and social determinants of health. And while new topic areas and objectives are added every decade, it is worth noting that cancer has been an important focus of all Healthy People initiatives to date. This is not surprising given that cancer has been the second-leading cause of death—following heart disease—for more than 50 years.

The overarching goal of the cancer section is to “reduce the number of new cancer cases as well as the illness, disability, and death caused by cancer.” This section contains 27 objectives and sub-objectives. For example, the first objective (C-1) is to “reduce the overall cancer death rates.” Also for example, objectives C-2 through C-8 focus on
Hepatitis B

reducing death rates from specific types of cancer (i.e., lung, breast, cervical, colorectal, throat, prostate, and melanoma, respectively). To provide an example of an objective with multiple subobjectives, objective C-20 reads, “Increase the proportion of persons who participate in behaviors that reduce their exposure to harmful ultraviolet (UV) irradiation and avoid sunburn”; and one of its subobjectives (C-20.5) reads, “Increase the proportion of adolescents in grades nine through 12 who follow protective measures that may reduce the risk of skin cancer.”

In addition to the section on cancer, many of the other sections and objectives target modifiable health risk behaviors that have been linked to one or more types of cancer such as tobacco use, obesity, exposure to UV light, poor nutrition, and physical inactivity. For example, one of the 15 physical activity objectives (PA-2) aims to “increase the proportion of adults who meet current federal physical activity guidelines for aerobic physical activity and for muscle-strengthening activity.” Other objectives focus on vaccinations against diseases that cause cancer such as the human papillomavirus (which causes cervical and other types of cancer) and hepatitis B virus (which causes liver cancer). For example, one of the 33 immunization and infectious disease objectives (IID-15) aims to “increase hepatitis B vaccine coverage among high-risk populations.” On a related note, as screening and early diagnosis can reduce death rates for certain cancers, some objectives deal with increasing early detection via screenings for certain types of cancer, including breast cancer (i.e., mammography), cervical cancer (i.e., Pap test), and colorectal cancer (i.e., occult blood test, colonoscopy, etc.). For example, another of the 20 cancer objectives (C-16) aims to “increase the proportion of adults who receive a colorectal cancer screening based on the most recent guidelines.”

An early report released by the Centers for Disease Control and Prevention in 2013 indicates, since the 27 cancer objectives and subobjectives were released, two have been met (i.e., those dealing with adolescent and adult use of artificial light for tanning), 11 are moving in the desired direction, four have seen little to no change, and two have gotten worse (i.e., those dealing with melanoma deaths and cervical cancer screening). Four of the remaining eight were considered developmental (meaning no baseline data is available, so there is no point of reference to assess), and only baseline data exists for the other four (meaning it is not yet possible to assess if they are getting better or worse). In sum, the Healthy People Initiative sets an ambitious agenda for the nation’s health in a wide variety of areas including cancer prevention and detection. It also provides measurable benchmarks and ways to check changes in the nation’s health over time.

Hepatitis B

The liver is one of the largest and most important organs in the body. Among other things, the liver filters harmful chemicals from the blood, stores
vitamins and minerals, helps fight infection, and aids in the digestion of food. *Hepatitis* is a general term used to refer to an inflammation of the liver. Hepatitis can be caused by excessive alcohol consumption, an autoimmune disease where the body starts to attack the liver, or one of at least five different viruses (i.e., hepatitis A, B, C, D, and E) that can be contracted in a variety of different ways. For example, hepatitis A and E are contracted primarily through ingesting contaminated food or water, and hepatitis B, C, and D are contracted primarily through contact with infected blood and body fluids. This entry focuses on hepatitis B and the hepatitis B vaccine, which has the distinction of being the first vaccine that prevents both a sexually transmitted disease and a type of cancer. More recently, a vaccine was developed for the human papillomavirus (HPV), which is another sexually transmitted disease that causes cervical and several other types of cancers.

The hepatitis B virus (HBV, Hep B) can damage the liver and cause liver cancer. HBV is transmitted from person to person through contact with infected blood or body fluids (i.e., semen, vaginal fluid, etc.). Thus, HBV is most commonly transmitted through sexual contact, contact with contaminated injection drugs, tattooing, and body piercing needles, or from mother to child. HBV is not spread by animals or insects, through food, water, or air, or via casual contact like holding hands, kissing, or hugging (though it can be transmitted by sharing toothbrushes and razors contaminated with infected blood). Because HBV is a communicable disease that can be spread from person to person, it is one of more than 80 diseases that must be reported to government authorities so public health officials can monitor the occurrence and spread of diseases (i.e., it is a nationally notifiable disease).

HBV is a fairly resilient virus. It can survive on an untreated surface for more than seven days and is 50 to 100 times more contagious than human immunodeficiency virus (HIV, the virus that can lead to acquired immunodeficiency syndrome [AIDS]). According to the Centers for Disease Control and Prevention's (CDC's) most recent fact sheet, more than 1 million individuals in the United States have chronic HBV, and approximately 40,000 new people become infected with HBV every year. Further, each year HBV-related liver disease results in approximately 3,000 deaths in the United States (and more than 600,000 deaths worldwide).

HBV may be either acute or chronic. Acute HBV (lasting less than six months) includes new infections with more mild symptoms such as jaundice (yellow skin and eyes), fever, fatigue, loss of appetite, nausea, and so on, that your immune system is able to cure after a few weeks or months. Chronic HBV (lasting more than six months) occurs when your immune system cannot fight off the virus, so it never goes away completely and can be accompanied by more severe symptoms such as cirrhosis (scaring) of the liver, liver failure, and liver cancer. Acute HBV is not usually treated unless it becomes chronic. Chronic HBV is treated with medicines that help manage or treat the disease by slowing or stopping the virus from damaging the liver. When the liver has deteriorated to the point that it is no longer adequate to sustain life, a liver transplant will become necessary.

People with acute or chronic HBV are often asymptomatic and may not be aware that they are infected. In fact, it is not uncommon for those with chronic HBV to be symptom free for many years or even decades. For this reason, HBV is sometimes referred to as a silent killer because it can progress to a very severe state over time with little to no warning. However, it is important to note that, while many people with HBV may appear healthy, they are still capable of spreading the disease to others.

There is also a simple blood test that a health care provider can order if a patient thinks he or she is at risk or may have been exposed to HBV. The HBV blood panel uses a single blood sample but actually includes three different tests, all of which are needed for proper diagnosis. HBV typically takes a month or more before it can be detected in the blood, so it may be necessary to conduct a second blood test to confirm the status if possible infection may have occurred recently. It is also important to note that the sooner a person gets tested, the sooner he or she can start treatment (which gives the best chance of treating the disease and preventing damage to the liver).

**The HBV Vaccine**

HBV is a preventable disease. Risk of contracting HBV can be reduced by avoiding the main sources
of infection such as unprotected sex and contaminated needles. However, the best way to prevent HBV is to get vaccinated (making it one of 27 vaccine-preventable diseases according to the CDC). The three-dose HBV vaccine is typically administered over a six-month period. The first injection can be administered any time, the second injection should be administered at least one month after the first dose, and the third injection should be administered six months after the first dose. All three doses of the vaccine are necessary to provide the best protection. The vaccine has proven to be both safe and efficacious. The most common side effect is soreness and redness at the injection site. Approximately 95 percent of individuals who receive the vaccine develop effective protection against HBV. To illustrate, the steep declines in HBV rates in the United States over the last two decades are attributed largely to the increase in HBV vaccine rates over this same time period.

The CDC recommends the HBV vaccine for all infants at birth, older children who did not receive the vaccine at birth, and adults in high-risk situations. This latter group includes, but is not limited to, health care and public safety workers, people living with someone who has HBV, men who have sex with men, individuals with multiple sexual partners, injection drug users, and those traveling to countries with higher HBV rates. While the HBV vaccine typically costs up to $150 per dose, it is often available for free or at a significantly reduced price via most insurance plans or at public health clinics.

The Global Vaccine Action Plan (GVAP), a framework approved by the World Health Organization (WHO) in May 2012, aims to improve global health by providing universal access to vaccination. The HBV vaccine is included among the recommended vaccinations, and the WHO works in partnership with Gavi: The Vaccine Alliance, an international organization founded in 2000, to increase access to new and underused vaccines for children in low-income countries. Gavi support of the HBV vaccine began in 2001, when the vaccine was administered to over one million children in Mozambique, and by 2004, half of the world’s low-income countries included the HBV vaccine in their routine immunization programs. As of 2013, the HBV vaccine was included on the national immunization schedule of 179 countries. However, the vaccine is not always delivered, and the WHO estimates that 5.3 to 6.0 million deaths (8.3 deaths per 1,000 persons vaccinated) could be prevented in the years 2011–2020 if the HBV vaccine were routinely provided (against a counterfactual of no HBV vaccination). One goal of the GVAP is to increase coverage with the pentavalent vaccine (providing protections against diphtheria, tetanus, pertussis, hepatitis B, and Hib) in 94 primarily low- and middle-income countries; coverage is projected to increase from 50 percent in 2011 to over 90 percent by 2020.

Hepatitis C

Hepatitis C is an infectious disease caused by the hepatitis C virus (HCV). HCV predominantly affects the liver but can also affect the brain,
Hepatitis C

This blood-borne virus causes inflammation and damage to the liver, preventing it from performing its essential functions within the body. An HCV infection is insidious and can eventually result in cirrhosis (scarring of the liver), liver failure, or hepatocellular (liver) carcinoma. Most people are asymptomatic.

In 2011, worldwide cases of the chronically HCV infected were estimated to be between 130 and 170 million. Annually, there are about 3 to 4 million new infections and 350,000 HCV-related deaths. Globally, HCV prevalence rates are estimated at around 2 to 3 percent, with rates being over 3.5 percent in north Africa, the Middle East, and central and east Asia. Some populations in the Middle East have very high rates, such as Pakistan (4.8 percent) and Egypt (22 percent). Egypt's elevated rate is attributed to parenteral therapy for schistosomiasis (also called Bilharzia). Countries with rates around 2.5 percent include most populations in Africa, Europe, southwest Asia, and the Americas. July 28 of every year is World Hepatitis Day.

Having a chronic HCV infection for decades can develop into cirrhosis. HCV patients with cirrhosis have an increased chance (about one in five) of developing hepatocellular cancer, liver failure (acute and chronic), or esophageal or gastric varices, which are life-threatening conditions. Overall, up to about 4 percent of the HCV infected will develop hepatocellular cancer, and 2.5 percent will experience liver failure, although developing cirrhosis is more common in patients with hepatitis B, blood flukes (schistosoma), and human immunodeficiency virus (HIV), as well as in chronic alcoholics. Excessive alcohol intake increases the risk of developing cirrhosis as does having a coinfection with hepatitis B. Globally, HCV causes about one-third of cirrhosis cases and one-quarter of the cases of hepatocellular cancer. In multiple countries worldwide, HCV is the primary reason for liver transplants. Other HCV-caused or associated conditions not related to the liver include: cryoglobulinemia, diabetes, lichen planus, necrolytic acral erythema, pancreatic cancer, thrombopenia, and Sjögren's syndrome.

Classification

The Centers for Disease Control and Prevention classifies HCV as a biosafety level two, considered a medium potential hazard to the environment and persons. HCV is listed under the World Health Organization International Classification of Diseases (ICD) as 10 B17.1. HCV is a small (55–65 nanometers), enveloped RNA virus that belongs to the genus *Hepacivirus* in the *Flaviviridae* family. There are at least two members of the genus *Hepacivirus*, which are HCV and canine *hepacivirus*, and other viruses that infect horses, bats, and rodents. There are seven major genotypes of HCV, with several subtypes.

Since the 1970s, HCV was suspected to be a different type of hepatitis than either A or B. When found, it was identified as a non-A non-B hepatitis (NANBH). It was confirmed in 1989, and a screening test was developed, resulting in blood transfusion-derived HCV infections being reduced to almost zero by 2000. Hepatitis C infects only humans but has been experimentally transmitted to chimpanzees. Humans’ immune response to an HCV infection does not prevent chronicity in the majority of cases, nor does the immune system response prevent reinfection. An HCV-infected person can acquire the other hepatitis types, such as A and B.

There are two phases of HCV: acute and chronic. HCV starts as an acute infection that can last up to six months, and if not resolved, the virus stays in the body, becoming a long-term condition (chronic), and can cause lasting liver complications. Chronic HCV is associated with persistently elevated or fluctuating liver enzymes in many patients. Approximately 60 to 85 percent of the acute HCV-infected adults advance to the chronic phase. Some patients, typically younger or female, are more likely to clear the virus spontaneously.

Symptoms

The majority (about 80 percent) of HCV patients are asymptomatic. When symptoms do present, they are nonspecific and may include anorexia, polyarthritis, vague abdominal discomfort, malaise, emesis (vomiting), fever (greater than or equal to 100 degrees F [38 degrees C]), rash, and fatigue. These symptoms can last about a week (range of 3–10 days). Symptoms in the chronic stage may include depression, mild cognitive problems (troubles with concentrating and short-term memory), behavior (mood swings), pain (headaches and joint [arthralgia] and muscle aches and pains [myalgia]), pain in the abdominal and liver region, digestive
problems, itching, and fatigue. In the chronic stage, the onset of jaundice (yellowing of the skin and eyes) is possible. Chronic HCV infection is a major risk factor for serious liver complications (e.g., cirrhosis or hepatocellular cancer).

**Transmission**

HCV is transmitted primarily parenterally (e.g., intranevous, intra-arterial, intraosseous, intramuscular, or intrathecal). The foremost sources of HCV infection include intravenous drug use (IDU); anyone who received blood from an unscreened donor, such as a blood transfusion (pre-1992 in particular) or clotting factor concentrates (pre-1987 in particular); anyone who received or is receiving hemodialysis; anyone who works at a job that exposes them to blood from medical-associated needles (needle-stick injuries), blood transfusions, organ transplants, or infected or improperly sterilized instruments; and persons exposed to unsterilized items used in rituals (e.g., scarification or circumcisions [male and female]), traditional medicine (e.g., bloodletting), or other means of piercing the skin barrier, such as tattooing or ear and body piercings.

Prison inmates are a group with elevated HCV infection rates compared to the general population due to the high-risk behaviors of prison life, such as IDU and nonsterilized instruments used for tattooing. Another group with higher-than-normal prevalence rates are those with HIV, people with abnormally low levels of immunoglobulins (e.g., hypogammaglobulinemia), and persons who have had an organ transplant. This risk group is associated with a rapid progression to cirrhosis.

Household exposures that involve sharing personal care items, such as a toothbrush or razor, or casual contact, such as hugging, kissing, or sharing eating utensils, are not considered risk factors for acquiring HCV. Sexual contact with an HCV-infected person and vertical transmission (mother-to-child) transmissions have been documented but are either not conclusive or are rare. Breast-feeding is not considered a transmission route; however, caution is advised with any exposure to blood from an HCV-infected person, such as from cuts, sores, or if breast-feeding, cracked or bleeding nipples.

The transmission route changes from the developed to developing world. In the developed world, the primary route of transmission is IDU, while in the developing world, it is from unhygienic medical practices and blood transfusions. Risk groups for HCV infection include IV drug users (past and present). IDU is considered a major risk factor throughout the world for acquiring HCV. It is estimated that 60 to 80 percent of intravenous drug users are infected with HCV, accounting for approximately 10 million cases in the developed countries, such as China, the United States, and Russia.

**Diagnosis, Treatment, and Prevention**

Diagnosis is initially based on blood tests that detect antibodies against HCV (anti-HCV) but do not make a distinction between acute, chronic, or resolved infection. There are a number of diagnostic and monitoring tests for HCV, such as enzyme-linked immunoassay (ELISA or EIA), protein immunoblot, and RNA polymerase chain reaction (PCR). Tests that detect and measure antibodies in blood are ELISA or EIA and immunoblot assays. If antibodies are detected, a confirmatory test (e.g., HCV RNA or PCR) is performed to establish the infected person's viral load.

If there is no RNA and the immunoblot is positive, it is assumed that the person has a resolved infection; however, if the immunoblot is negative, it is assumed that the ELISA or EIA was a false positive. Some patients appear to have a resolved infection but continue to be infected. These patients have elevated liver enzymes, but conventional testing is unable to detect the presence of HCV antibodies. This is called a cryptogenic occult infection. If the person has HCV, there are several blood tests to determine the degree of hepatic fibrosis. If these tests are inconclusive, a liver biopsy can be used to determine the amount of liver damage.

Treatment for HCV is not always necessary and depends on the extent of liver disease as well as HCV genotype and whether the genotype will be responsive to treatment. Genotypes 2 and 3 are generally considered treatable. The diagnostic tests will aid in determining the best treatment options. When warranted, a common treatment will be a combination of the antiviral drug ribavirin (pill) and interferon (injection). HCV genotype 1 is treated with either protease inhibitors (Simeprevir, Victrrelis, or VX-950) or a nucleoside
inhibitor (ribavirin) in pill form with an antiviral drug (peginterferon alfa-2b and 2a).

Recently approved medication called sofosbuvir (pill) inhibits HCV from replicating its RNA. The treatment with sofosbuvir is 12 weeks for HCV genotypes 1, 2, and 4 and treats genotype 3 in 24 weeks, with a cure rate up to 90 percent. Other HCV combination treatments last between 24 and 48 weeks, depending on the infecting genotype. These treatments have cure rates for HCV genotype 2 and 3 at 70 to 80 percent, while other genotypes range from under half up to 70 percent. A combination treatment of ribavirin and pegylated interferon for genotype 6 has a cure rate ranging from 60 to 90 percent. The newer medications are less reliant on interferons, making it so most patients will only need to take ribavirin and an oral protease inhibitor.

The goal of treatment is to have a sustained virological response (SVR), which is defined as HCV being absent from the blood for six months after treatment. Treatment for patients with cirrhosis or hepatocellular cancer is limited, with many requiring a liver transplant. Alternative medicine of milk thistle, licorice root, ginseng, schisandra, St. John's wort, colloidal silver, and thymus extract are inconclusive or there is no evidence these therapies are effective against HCV.

Prevention

Presently, there is no vaccine for HCV like there is for Hepatitis A and B. In health care settings, universal precautions for preventing transmission of blood-borne infections are the best strategy for reducing HCV infections. These precautions include avoiding contact with bodily fluids or patients (in particular, blood) with medical gloves, face shields, and eye protection. Other HCV-prevention strategies include screening blood and donors, implementing safe injection practices, such as needle-exchange programs for intravenous drug users as well as substance abuse treatment, and medications administered in pill form if syringes are limited or will be reused (if possible).

Further Readings

Hepatocellular (Liver) Cancer, Adult (Primary)

Hepatocellular carcinoma (HCC), commonly referred to as liver cancer, is the most common primary cancer that occurs in the liver (primary meaning it originates from the affected organ). HCC is one of the leading causes of cancer-related death worldwide. While HCC is common throughout the world and has a poor prognosis overall, the risk of HCC can be lowered through prevention (through both education and the use of vaccination). New antiviral medications show significant promise in reducing the number of patients with chronic hepatitis B or hepatitis C, which are the most common causes of cirrhosis leading to HCC worldwide.

Prevalence and Outcomes

Worldwide, HCC is one of the most common and deadly cancers diagnosed due to the poor prognosis and late diagnoses common in HCC. The rate of HCC is increasing worldwide, with the fastest increases in developing countries with high rates of hepatitis B or C infection. Approximately 600,000 deaths worldwide per year are attributed to HCC. In the United States, HCC was responsible for more than 20,000 deaths in 2013, and approximately 30,000 new cases are diagnosed annually. HCC is more common in men than in women, though this varies by geographical region.
Causes
HCC develops as a result of cirrhosis, or scarring, of the liver. Cirrhosis is often caused by the hepatitis B virus, hepatitis C virus, alcohol abuse, and autoimmune disease. The rate of cancer worldwide correlates directly with the rates of hepatitis B and C.

In spite of the fact that cirrhosis is known to be the biggest factor in developing HCC, only a small number of those with cirrhosis, including cirrhosis from alcohol use and from hepatitis B and C virus, go on to develop HCC. Chronic (long-term) infection with hepatitis B and C viruses are known to cause cirrhosis (scarring), which can lead to HCC. About 15 to 25 percent of individuals with chronic hepatitis B or C develop HCC, and an individual is often infected for between 20 and 30 years prior to the onset of cancer. Worldwide, hepatitis B virus is the most common cause of cirrhosis leading to HCC and is responsible for between 50 and 80 percent of HCC cases. Hepatitis C infection is responsible for 10 to 25 percent of all HCC cases worldwide. Developing countries, especially those in Asia and Africa, have the highest rates of HCC as well as the highest rates of hepatitis B virus. In the United States, chronic hepatitis C virus infection is the most common cause of cirrhosis leading to HCC.

Excessive or prolonged use of alcohol is also a cause of cirrhosis of the liver. Because of this, individuals with excessive or prolonged alcohol use leading to cirrhosis of the liver are at a higher risk for HCC. Alcohol-related cirrhosis is the third-most common cause of HCC in the United States. Other causes of HCC have been identified. These include autoimmune disease and nonalcoholic fatty liver disease (NAFLD).

Symptoms and Detection
Symptoms of HCC may be nonspecific and can result in late diagnosis. Symptoms include unintentional weight loss, loss of appetite, upper abdominal swelling and pain, nausea and vomiting, general weakness and fatigue, white chalky stools, and jaundice.

HCC is diagnosed through imaging, such as X-rays, ultrasounds, computerized tomography (CT) scans, or magnetic resonance imaging (MRI) followed by biopsy to determine the nature of the mass. Blood tests, such as liver function tests, are also used during investigation of potential liver cancer.

Outcomes and Treatment
Left untreated, patients with HCC rarely live past one year, with many patients succumbing to HCC within six months. HCC has a low survival rate overall, with the best outcomes (five-year survival rates) for those who are able to have the portion of the liver that is affected by HCC removed.

There are a number of available treatments for HCC, and treatment varies depending on the liver’s condition, location and size of the tumors, and the individual’s health and age.

Surgery is the traditional method of dealing with cancer. Surgery is possible either when the cancer is limited in size with significant amounts of healthy liver available or when the cancer is limited only to the liver and the individual is a candidate for liver transplant. Liver transplant is not common due to scarcity of livers for transplant and, in the cases of hepatitis, the risk of infection of the donor liver.

Other treatments have been used with various rates of success. These include chemotherapy (the use of chemicals introduced to the bloodstream to destroy cancer cells), radiation therapy (the use of targeted, high-intensity energy from outside the
body through the skin to the location of the tumor to kill cancer cells), cryosurgery (the use of extreme cold to freeze and destroy tumor cells), radiofrequency ablation (the use of heat to destroy tumor cells), and ethanol injection (injection of alcohol into the tumor to destroy tumor cells).

Prevention of Hepatocellular Carcinoma
Prevention and treatment can lower the rate of HCC. Vaccination is possible for hepatitis B virus, though no vaccines are available for hepatitis C. Proper hygiene to prevent transmission through bodily fluids is important in preventing hepatitis, though new antivirals hold the most promise of reducing the number of chronic hepatitis cases. Education on proper hygiene, proper screening of blood products, and early intervention with those with heavy alcohol use, autoimmune disease, and other risk factors are also important in terms of reducing the number of HCC cases.

Antiviral medications show promise in treating hepatitis. Effective antiviral medications have the ability to prevent cirrhosis, leading to fewer cases of HCC, and will be helpful in preventing re-infection in transplant scenarios.

Conclusion
HCC is a primary cancer that usually results from cirrhosis of the liver, most often from chronic hepatitis B or C virus infection. There are a number of treatments available for HCC, and prevention is a key in lowering the number of HCC cases. Vaccination and new antiviral medications hold promise in lowering the number of HCC cases and deaths.

Further Readings

Hepatocellular (Liver) Cancer, Childhood (Primary)

Hepatocellular carcinoma (HCC), commonly referred to as liver cancer, is a very rare form of liver cancer in children. HCC is a primary cancer that occurs in the liver, primary meaning it originates from the affected organ and is able to metastasize (or spread) to other organs. HCC is one of the leading causes of cancer-related death in adults worldwide; however, HCC is very rarely diagnosed in children, and when found in children, the causes are often different than those in adult cases.

Prevalence and Outcomes
HCC is a very rare cancer in children, with most cases diagnosed in older children and adolescents. Current estimates regarding the prevalence of hepatocellular carcinoma in children and adolescents is approximately 0.5 cases per million.

The prognosis for children with hepatocellular carcinoma is poor due to both tendency toward late diagnosis and the complications due to underlying medical conditions or disease. Surgery is the most effective of treatments, with full remission most likely to be possible in those who have small tumors and successful removal of either the tumor or entire liver followed by a liver transplant.

Causes and Risk Factors
In adults, HCC commonly develops as a result of cirrhosis, or scarring, of the liver. In children and teens, however, HCC is often due to other conditions. Childhood risk factors for developing hepatocellular liver cancer include genetic conditions, liver abnormalities, and disease, as well as infection with the hepatitis B or C virus.

Genetics, specifically inborn errors of metabolism, increase the risk of HCC. Inborn errors of metabolism are conditions, present from birth, where an individual is not able to break down components
of food (usually due to an enzyme deficiency), leading to a buildup of that component, which affects the liver. Some inborn errors of metabolism that increase the risk of HCC include alpha-1 antitrypsin deficiency, hereditary tyrosimia, Gaucher’s disease, and urea cycle defects. Liver abnormalities and diseases, including biliary atresia (a malformation of the bile ducts, which leads to liver damage), also increase the risk of hepatocellular carcinoma.

Conditions that cause severe iron overload or require frequent blood transfusion may also contribute to the development of HCC. Exposure to the hepatitis B virus or hepatitis C virus at a very early age is related to the development of HCC. Hepatitis B is more likely to be related to development of HCC in children than hepatitis C, which typically takes a longer time frame for HCC to develop. Although the hepatitis virus usually progresses slowly in individuals with chronic infection, the earlier that a person is infected, the higher the risk is of developing HCC. Children who contract hepatitis B or C virus at extremely young ages are more likely to develop chronic hepatitis B or C and HCC in childhood or adulthood.

Symptoms and Detection
Symptoms of HCC may be nonspecific and can result in late diagnosis. Symptoms include unintentional weight loss, loss of appetite, upper abdominal swelling and pain, nausea and vomiting, general weakness and fatigue, white chalky stools, and jaundice. HCC is diagnosed through imaging, such as X-rays, ultrasounds, computerized tomography (CT) scans, or magnetic resonance imaging (MRI) followed by biopsy to determine the nature of the mass. Blood tests, such as liver function tests, are also used during investigation of potential liver cancer.

Treatment
Left untreated, patients with HCC rarely live past one year, with many patients succumbing to HCC within six months. HCC has a low survival rate overall, with the best outcomes (five-year survival rates) for those who are able to have the portion of the liver that is affected by HCC removed. Many cases of HCC require treatment before surgery in order to limit the size of the tumors in order to have the best chance at removal.

There are a number of available treatments for HCC, though surgery is standard for children with HCC, typically in combination with other methods. Surgery is possible either when the cancer is limited in size with significant amounts of healthy liver available or when the cancer is limited only to the liver and the individual is a candidate for liver transplant.

Other treatments have been used with various rates of success. These include chemotherapy (the use of chemicals, introduced to the bloodstream to destroy cancer cells), radiation therapy (the use of targeted, high-intensity energy from outside the body through the skin to the location of the tumor to kill cancer cells), cryosurgery (the use of extreme cold to freeze and destroy tumor cells), radiofrequency ablation (the use of heat to destroy tumor cells), and ethanol injection (injection of alcohol into the tumor to destroy tumor cells).

Early Detection of Hepatocellular Carcinoma
Frequent screening of high-risk children is key for early detection and treatment of HCC in children. Children who are at high risk of developing hepatocellular carcinoma due to chronic disease that affects the liver, liver abnormalities, or genetic issues such as inborn errors of metabolism require frequently monitoring and screening to ensure early diagnosis and proper treatment.

Vaccination against the hepatitis B virus is suggested for children in order to lower the chances of contracting it. There is no vaccine currently available for the hepatitis C virus; however, new antiviral medication shows promise in lowering the number of children who contract chronic hepatitis C virus.

Conclusion
Childhood HCC is a very rare primary cancer that can result from genetic issues (most commonly inborn errors of metabolism), liver abnormalities and diseases, or infections that affect the liver such as the hepatitis B or C virus. Surgery is the typical treatment for children with HCC. HCC in children differs from adults in that most cases arise from conditions other than cirrhosis (scarring) of the liver. Vaccination and antiviral therapy have shown promise in reducing the number of children with HCC due to the hepatitis B or C virus.

Herbert Irving Comprehensive Cancer Center

The Herbert Irving Comprehensive Cancer Center (HICCC) was created in 1911. It was initially named the Institute for Cancer Research. The center at Columbia University was designated as a National Cancer Institute (NCI) cancer center in 1972, and it was upgraded to the status of comprehensive in 1979. HICCC conducts basic research, clinical research, and research based on population demographics as well as providing patient care.

The center’s main objective is to better comprehend the biology of cancer, how it spreads, and what preventative measures might be used to lessen the occurrence of the disease. This research is then put into practice by designing procedures, therapies, and prevention education. Their aim is to reduce the incidence of cancer progression as well as making the quality of life better for cancer sufferers. The HICCC helps to alleviate some of the problems related to cancer and cancer treatment through scientifically improving methods and collaborating with multiple disciplines.

HICCC’s research is split between three main divisions: the Basic Science Division, the Disease-Specific Division, and the Population Science Division. These different divisions focus on different facets of cancer, from its cellular construction to its prevalence among different demographics. In addition to this, the HICCC has taken measures to include underrepresented ethnicities and races in its research.

The Basic Science Division houses research into topics such as cancer genetics and cancer regulatory networks. Essentially, this division seeks to understand the molecular and cellular reactions that cause cancer to develop and spread. Research in this division delves into genetics and epigenetics of cell division and the biological reactions that occur in it, the stability of genes, and what part genetics plays in cancer.

The Disease-Specific Division includes programs researching breast cancer, malignancy and development of lymphoid cancer, neuro-oncology, and prostate cancer. Cancers in each system of the body have different characteristics that require different treatment and different challenges in diagnosis. This division takes a look at the individual cancers and researches them in depth.

The Population Science Division looks into cancer epidemiology alongside prevention, disparities, and control. This division explores cancer as it relates to populations and finding patterns that indicate cause-and-effect relationships. They apply statistics to find these correlations. When the relationships are found, more knowledge about prevention can be gleaned from the data.

Currently, HICCC works with the Clinical Protocol & Data Management (CPDM) Office. The CPDM serves a managerial function. It coordinates and reports on the clinical trials of the center, wherever the study is taking place. They have the infrastructure and the ability to oversee HICCC’s clinical research program. The services this office performs include prioritization of clinical trials, screening and following up with patients, identifying individuals for the study, and regulating other clinical research items.

HICCC is in the Washington Heights area of New York City. This area has more people of differing racial and ethnic genealogy than most places in the city. This positioning allowed the center to add three additional programs to their offerings. The Research Recruitment and Minority Outreach program brought people into the trial who have been underrepresented in research. The Columbia University Screening and the Women at Risk programs were both founded and used to educate and provide services related to breast cancer to populations who were statistically more at high risk of developing the disease.
The center also provides training programs in a partnership with the university. The curriculum includes basic lab research, epidemiology, clinical science, and public health. The focuses of these programs are cancer biology, pediatric and adult oncology and hematology, and environmental health and epidemiology. As the HICCC provides support for cancer research, the infrastructure already exists for the university students to utilize.

Membership with HICCC is reviewed and renewed each year based on the required characteristics of membership. Members are expected to benefit the center through the following: collaborating with the center's other investigators; offering support in achieving the center's main mission, goals, and priorities; and providing the center with an annual report of research activity. In exchange for this, members are able to utilize the center's shared resources; apply for research funding and developmental aid; and participate in member seminars, special events, and retreats. To date, the HICCC has more than 200 members across six different schools.

The HICCC provides access to shared resources for use by its members to facilitate cancer research. These shared resources include everything from biostatistics and genomics technology to small animal imaging and transgenic mice. Biostatistics is paramount in cancer investigating, and the HICCC provides the infrastructure to do so with the help of a biostatistician. They provide statistical consulting and collaboration in the design, procedures, and interpretation of experiments. Genomics technology provides the infrastructure and knowledge to compare genetic sequences, and transgenic mice are genetically modified for testing.

Some doctors in Columbia Urology are also faculty with the HICCC. Here, they are able to design and complete research related to prostate cancer treatment. This includes clinical trials on new and potentially life-saving treatments for both aggressive and less-aggressive types of cancer. These doctors generally collaborate with other departments and other cancer centers nationwide. The ultimate goal is the improvement of diagnostic accuracy and effectiveness of treatment.

There are more than 200 researchers working with the HICCC. The NCI's funding for members is more than $33 million, but researchers at the cancer center have been awarded more than $95 million in cancer research funding from their peers. Their activity focuses on various facets of cancer research, from cellular mechanisms and interaction with tissue to the statistics of cancer occurrence across different population demographics. The researchers may work with vastly different aspects of cancer, but they all have the common goals of reducing the occurrence of cancer, reducing the progression of tumors, and creating a better quality of treatment and life for cancer patients.

The Herbert Irving Comprehensive Cancer Center facilitates research into cancer on the genetic as well as the social front. Every different facet of the disease that the center researches or provides the means for other organizations to research brings more innovation, new techniques and therapies, and overall improvement in the quality of treatment and quality of life of the patients. From genetically modified lab mice to exploring the structure of genes, the HICCC supports cancer research as well as cancer researchers.

Herbicide

An herbicide is a type of pesticide used for preventing, reducing, or destroying unwanted weeds and plants. Approximately 10 percent of all plant species are weeds; of these, nearly 10 percent plague cultivated crops worldwide. Herbicides are some of the most commonly used pesticides in the world and account for billions of dollars in pesticide sales.
Glyphosate, atrazine, and 2,4-dichlorophenoxyacetic acid (2,4-D) are the top three most frequently applied herbicides on agricultural land in the United States. This entry provides an overview of the history of herbicide development and ways that these substances have been used in agriculture; sources and routes of human exposure; environmental and human health effects; and regulatory strategies to prevent exposure.

**History of Herbicide Development and Uses**

Weed control was initially conducted by mechanical or manual means such as cultivation, hoeing, and hand pulling. These labor-intensive methods were gradually replaced by simple chemicals used as general herbicides, including inorganic compounds such as brine and a mixture of salt and ashes. In the late 1800s, copper sulfate was used specifically to kill weeds in grain fields. Sodium arsenite solutions were also developed and used as the standard herbicide until 1960. Although some inorganic herbicides continue to be used, most were eventually restricted by the U.S. Environmental Protection Agency because of their persistence in soil. This contributed to the development of organic, synthetic herbicides that are now heavily used where intensive and highly mechanized agriculture is practiced (e.g., North America, western Europe, Latin America, Japan, and Australia).

Herbicides can be classified several ways. In general, selective herbicides kill weeds without harming the crop or plant of interest. Truly selective herbicides are active only against a certain species of plants but not against others. On the other hand, nonselective herbicides kill all vegetation. The placement, dosage, and timing of herbicide application are important determinants of selectivity. Herbicides can also be characterized on the basis of contact (surfaces) versus translocation (distant plant tissues), timing (preplanting, preemergence, and postemergence), area covered (band, broadcast, spot treatments, or directed spraying), and chemical groups.

There are more than a dozen major chemical classes of herbicides including phenoxyxs, organophosphates, triazines, carbamates, and arsenicals. The first of the phenoxy herbicides was 2,4-D, which was introduced in 1944 as a selective agent that could be translocated throughout the plant. In agriculture, 2,4-D is applied on cereal, grain crops, and sugarcane. Other phenoxy herbicides include 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and 2-methyl-4-chlorophenoxyacetic acid (MCPA). Some nonagricultural uses of phenoxy herbicides are for clearing weeds on rights-of-way, on turf and lawns, and in forest conservation programs. 2,4-D and 2,4,5-T were also used in the Vietnam War as defoliants. Glyphosate, a phosphorous-based herbicide, is the most widely used pesticide in the United States and in the world. Atrazine, a common triazine herbicide, is mainly applied on corn, sorghum, and sugarcane to control broadleaf and grassy weeds in the United States. Carbaryl is a type of carbamate herbicide that is popular in Canada for lawn use. Organic arsenical agents, such as monosodium methanearsonate (MSMA) and disodium methanearsonate (DSMA), were used for many purposes but are gradually being phased out, eliminated, or prohibited as they transform over time to a more toxic, inorganic form of arsenic in soil that can migrate to drinking water sources.

In the mid-1990s, genetically modified or biologically engineered seeds were designed to be tolerant to certain herbicides. The purpose of this development was to allow for broad, over-the-top application of herbicides while minimizing damage to crops of interest. For example, crops tolerant to glyphosate are able to be sprayed with this chemical. Soy was the first type of crop to be grown in this manner, followed by alfalfa, corn, cotton, spring canola, sugar beets, rice, wheat, and winter canola.

**Sources and Routes of Human Exposure**

Herbicides are used extensively in agriculture and outside of farms. Occupational exposure to herbicides in agricultural environments may occur from loading, mixing, spraying, applying, and harvesting treated crops. Herbicides may be sprayed on foliage or applied directly into soil, among other application methods. Other important occupationally exposed populations are golf course workers who spray large areas of grassy turf as well as pesticide applicators who clear rights-of-way, roadsides, or train track brush. Herbicide manufacturing workers may also be exposed to chemicals individually and in combination, their by-products, contaminants, and inert agents that are part of herbicide formulations.

Environmental herbicide exposure can occur in public, home and garden settings, and daily
activities. Children may be exposed from playing in schools, parks, and home lawns and gardens. Children and youth who are part of farm families may also be exposed to herbicides. This type of exposure, called para-occupational exposure, is defined as exposure that occurs to people living in households where occupationally exposed workers reside but who are not themselves occupationally exposed. Exposure can also arise through drift of pesticide mists among those who live in close proximity to agricultural areas, golf courses, or other large areas where herbicides are sprayed.

As with all pesticide exposures, human contact with herbicides may occur through skin, inhalation, or oral ingestion. Workers can encounter dermal exposure and inhale fine mist particles from spraying. Children's high level of hand-to-mouth activity increases the likelihood of oral ingestion of residues, and both children and adults can consume herbicides through dietary sources. Herbicides can also leech or run off from soil into ground and drinking water.

**Environmental and Human Health Effects**

The health impacts of herbicides have been studied for several decades and remain an area of active research. Environmental effects vary and depend on factors such as degree of toxicity in different species, persistence or half-life, volatility and the potential for runoff or leaching, and the dose and number of applications usually required for the pesticide to be effective against target species. Herbicides may damage more than just weeds, especially for nonselective agents that are applied in close proximity to nontarget vegetation. Generally, insecticides are more toxic to wildlife than herbicides. However, some forms of herbicides (like certain 2,4-D esters) can be toxic to different organisms (e.g., fish and other aquatic life).

Herbicide resistance is a challenging issue that has emerged in recent years. According to the Ontario Ministry of Food, Agriculture, and Rural Affairs, herbicide resistance is “the genetic capacity of a weed population to survive an herbicide treatment that, under normal conditions, would effectively control that weed population.” There are almost 250 herbicide-resistant weedy biotypes in 47 countries worldwide, and these numbers are steadily growing. Resistance can be reduced, but not prevented entirely, by practices such as using herbicides only when necessary and rotating herbicides among herbicide groups.

In the province of Ontario, Canada, the Ontario Independent Fact Finding Panel on 2,4,5-T conducted a comprehensive study of 2,4,5-T uses by Ontario government ministries and agencies and if exposure may have impacts on workers’ health. The panel found that exposures exceeded the benchmark level for some individual employees involved in ground, backpack, and aerial mixing or loading and application or flagging. Workers whose exposures were much higher than the benchmark were almost all occupationally exposed groups, with the highest levels of exposure to 2,3,7,8-TCDD, a 2,4,5-T contaminant. The panel concluded that workers’ health could be affected but that the risk of developing diseases as a result of 2,4,5-T or 2,3,7,8-TCDD exposure for an individual would likely be very low. Studies of Vietnam War veterans exposed to herbicides and their contaminants

Nearly 50 percent of the world’s labor force is engaged in agriculture and most are exposed to herbicides. As with all pesticide exposures, human contact with herbicides may occur through skin, inhalation, or oral ingestion. (Photos.com)
Herbicides demonstrated associations with heart disease, Parkinson's disease, and numerous cancers, including soft tissue sarcoma, non-Hodgkin's lymphoma, and chronic lymphocytic leukemia.

The International Agency for Research on Cancer (IARC) has thoroughly evaluated the human and animal evidence of carcinogenicity for some herbicides, including 2,4-D, 2,4,5-T, dicamba, MCPA, MCPB, dichlorprop, and mecoprop. These were all classified by the IARC as Group 2B, possibly carcinogenic to humans. However, these assessments were done in the late 1980s and early 1990s. Epidemiological studies published since then add valuable information to these evaluations. For instance, licensed pesticide applicators exposed to glyphosate in the U.S. Agricultural Health Study did not have associations with cancer incidence overall or most cancer subtypes studied; however, there was a suggestive link to multiple myeloma. A Canadian study found a significantly elevated risk of non-Hodgkin's lymphoma among men who reported ever using 2,4-D. These population-based studies are often hampered by small numbers of cancer cases. Follow-up in larger groups of exposed cases is warranted.

Regulations and Exposure Prevention
Concerns about the known or potentially harmful health effects of herbicides in the environment and humans (specifically, children) have prompted numerous jurisdictions worldwide to introduce cosmetic pesticide bans with varying levels of protection on public and private property. In Canada, ornamental pesticide bans began in the early 1990s and now exist in more than 170 cities and towns. For instance, in 2009, the province of Ontario followed the city of Toronto's lead and passed the Cosmetic Pesticides Ban, which prohibits the use of pesticides for aesthetic weed control on lawns across the province.

The city of Toronto evaluated the effectiveness of their pesticide bylaw and found that it improved health and environmental protection by reducing pesticide use and motivating many residents and companies to take more sustainable approaches to lawn and garden care. Its success may be due to an implementation strategy based on public education and enforcement, phased-in penalties, and ongoing review and adaptation.

Strong collaboration with other city divisions was also crucial. In the United States, the city of Takoma Park, Maryland, recently passed a law that generally restricts the use of cosmetic lawn pesticides on private and public property. Pesticides have been banned on school and day care center grounds in New York and Connecticut, and other states have adopted or are considering adopting similar measures to protect children's health.

Alternatives to synthetic herbicides can be used to prevent and control weeds with different degrees of effectiveness. Manual weed removal may be possible in small areas. Natural chemicals and plant-based oils can act as contact herbicides. Larger plots of land could benefit from wholly or partially exercising other options such as integrated pest management and organic agriculture. These and other methods may also reduce crop damage caused by synthetic herbicides, prevent leaching and runoff, and help avert resistance.

Conclusion
Herbicides and associated technologies to prevent and control weeds have evolved greatly over time. Beginning with manual removal, today's methods of weed management integrate innovations in chemistry and genetic engineering with long-standing traditions such as integrated pest management. Nevertheless, herbicide exposure is associated with numerous known and suspected ecological and human health effects. Exposure prevention is a key guiding principle in herbicide bans and related legislation. Further research is needed to fully understand herbicide health effects and the best measures for reducing exposure.

History of Cancer

The history of cancer is a story of theories about the causes and effects of the disease as well as of the continuing specific discoveries regarding the disease’s structure, treatments, and methods for diagnosis. Furthermore, this history is also embedded in the more general advances within medicine, such as new methods concerning surgery and discoveries regarding new techniques and instruments. In such a broad sense, the history of cancer may be subdivided into distinct periods, where the first covers the relatively long ancient and medieval periods based on what we by now consider as incorrect theories about the nature of cancer.

A transitional period of theories trying to replace the ancient theories followed but was quickly replaced by a period based on the cellular theory, proposing that both normal and cancerous cells come from cells of common origin. There were a series of new techniques for diagnosis and treatments from the mid-19th century and onward. More recently, further advances within this prolonged cellular period have been made based on new insights into genetics and other scientific fields.

Cancer Before the 19th Century

Archaeologists have found human remains dating several thousand years back from which specimens have been interpreted as consistent with cancer. Such is the case of a female skull from the Bronze Age (1900–1600 B.C.E.) and Peruvian Inca skeletons from ca. 2,400 years ago. When it comes to written evidence, however, the oldest existing cases date from Egyptian papyri, such as the so-called Edwin Smith Papyrus from the 16th century B.C.E. or even earlier. It contains descriptions of eight cases of breast tumors or ulcers. These were removed using a cauterization technique; however, the writing also says that the disease had no actual treatment. Another papyrus describes that the removal of a thigh tumor should be avoided because it could be fatal for the patient in question.

More detailed descriptions exist from the Greek and Roman civilizations. The doctor Hippocrates (460–370 B.C.E.) left a number of detailed descriptions of various diseases, including descriptions of lesions that had affected skin, breasts, stomach, cervix, and rectum. He also classified these into cancers that were in an early stage and others that were “occult.” As for treating early-stage cancers, the options were to cauterize and to apply several ointments. Hippocrates is also credited with the word cancer because he used the term karknoma to describe ulcers or growths that appeared to be malignant tumors. The word means crab in the Greek language, and one interpretation is that Hippocrates might have associated the spreading forms of cancers with the shape of crab claws. Hippocrates’s theory about cancer was to persist for more than 1,300 years and was based on his overall theory of the four types of body fluid, or humors, that a human body had. These were blood, phlegm, yellow bile, and black bile. A person was healthy when the humors were balanced. An excess of the black bile humor, however, was the cause of cancer. The Roman doctor Aulus Cornelius Celsus (25 B.C.E.–50 C.E.) elaborated on the Hippocrates theory and divided cancers into different stages. He called the first stage cacoethes (malignant), and only this stage was receptive to treatment. The doctor and philosopher Claudius Galenus (130–200) introduced the Greek word onkos, meaning a bulk or a mass, for referring to a growth or a tumor that appeared to be malignant, and is thus credited as the originator of the term oncology. Within Arab medicine, there were also a series of doctors who made observations and recommendations regarding cancer, including Avicenna of Baghdad (980–1037), who observed that cancer may destroy neighboring tissues.

Approaching the 17th century, there were a number of theories contesting the humor theory, including hypotheses proposed by Zacetus
Lusitani (1575–1642) and Nicholas Tulp (1593–1674), who published their hypotheses in 1649 and 1652, respectively, that cancer was contagious based on observations of breast cancer cases within the same household. John Hunter (1728–1793) was the first to suggest possible predispositions to cancer like, for example, age, heredity, and even perhaps the climate. Xavier Bichat (1771–1802) contributed to scientific progress in a number of ways but is also known for his misleading theory published in 1800 proposing that blastema, a substance that he thought was formed from blood and lymphatic fluid, was the primary source of all cellular tissues. His view persevered as a universal theory on cancer during several subsequent decades.

One probable cause behind the lack of any significant progress regarding the treatment of cancer during especially the medieval period was that postmortem autopsies had been practiced on a very limited scale, mainly due to religious obstacles. Autopsies were, however, becoming more frequent by the 16th century and were part of the basis for the William Harvey (1578–1657) epoch-making treatise on blood circulation (1628). Later, the doctor and professor Giovanni Morgagni (1682–1771) focused for the first time in his 1769 treatise on the potential of systematic approaches toward pathology.

Nineteenth-Century and Early-20th-Century Breakthroughs

During the 19th century, research took advantage of the findings made possible through the use of the modern microscope. Rudolf Virchow (1821–1902) has often been called the founder of cellular pathology and contributed to the understanding of tumors through a work titled *Cellular Pathology* (1858) as well as three comprehensive, albeit unfinished, illustrated volumes published between 1863 and 1867. According to Virchow’s method, tissues that were removed by the surgeon could be examined thoroughly and a precise diagnosis of the cancer could be made. The pathological method thus provided a scientific basis for the study of cancer, and hospital staff and researchers could understand in a better way the damage that had happened to the patient as well as the options for more precise cancer surgery. This breakthrough meant in addition that a pathologist by way of using a microscope could inform about whether an operation had completely removed the tumor or not. Virchow’s cellular theory is the basis of how cancer overall is understood today, but he built his treatise in part upon some of his immediate predecessors, such as Johannes Müller. Müller developed the blastema theory regarding the origin of cancer in 1838 by way of arguing that blastemas were budding cells and not lymph. He thus showed in part the way toward the understanding that cancer is made up of cells.

Incidentally, significant progress occurred within the field of general surgery techniques from about the same time as these new cellular insights became widely known. Removal of tumors had been an option from ancient times, and continued to be so, but this approach faced a crucial dilemma. During surgery, the patient might die due to loss of blood or of excruciating pain, and the simple means of anesthesia that had been available, such as opium, were of limited reliability. In 1846, John Collins Warren (1778–1856) and William T. G. Morton (1819–1868) used ether as a general anesthetic and performed a public demonstration of its effects when they removed a tumor from the jaw of a patient. Incidentally, the Japanese doctor Seishū Hanaoka (1760–1835) had performed more than 150 breast cancer operations from 1804 onward using a general anesthetic based on herbs, but this was unknown to the West due to Japan’s closure policy of the times. The Warren and Morton operation, however, became quickly known and heralded the age of modern anesthetic techniques. Furthermore, Joseph Lister (1827–1912) in Scotland applied the theories regarding germs proposed by Louis Pasteur (1822–1895) and announced in 1867 the practice of using disinfection during operations. One of the legendary surgeons of the times was William Stewart Halsted, who started to perform a radical form of operation for breast cancer in 1891. Attempting to remove all tracks of the cancer in order to avoid recurrence, Halsted removed the breast and its underlying muscles as well as the lymph nodes under the arm during his operations.

Some time after Virchow’s publications, Stephen Paget (1814–1899) proposed in 1889 a new theory, called the seed and soil theory, regarding the spreading of cancer. It was similar to theories proposed by Karl Thiersch (1822–1895), showing that cancer spreading is due to the spread of the malignant cells and not the work of some kind of unidentified fluid, and by Ernst Fuchs (1851–1930) in 1882, regarding the predisposition of an organ to
be the recipient of specific growths. Paget, however, constructed a more comprehensive theory, and it eventually turned out to constitute the foundation for theories regarding how cancers spread from one organ to another, the process of metastasis. Paget thought that metastatic tumor cells were like a kind of seed that spread throughout the body by way of the bloodstream but settled only in a "soil," an organ, which it finds compatible. Virchow himself incidentally thought, incorrectly, that some kind of chronic irritation was the cause of cancer and that cancers spread like a liquid.

The late 19th and early 20th centuries were also a period of several technological breakthroughs regarding the diagnosis and treatment of cancers. In 1895, the physicist Wilhelm Conrad Röntgen (1845–1923) discovered electromagnetic rays later known as X-rays or Röntgen rays. The first technical manual of X-ray radiology was published, and the first diagnostic radiology units were installed in European and U.S. hospitals already in 1896. Shortly thereafter, two different research groups, including Marie Sklodowska Curie (1867–1934), Pierre Curie (1859–1906), and Antoine H. Becquerel (1852–1908) discovered the radioactivity of uranium. Marie Sklodowska Curie is credited with the isolation of the highly potent radioactive substance that got the name *radium*, and the Curies used the term *radio-active* for the first time in a paper published in 1898.

Radium was thereafter introduced as a treatment for cancers, with skin cancer being the first type. In the first years and decades of therapeutic radiation, the approach was referred to as brachytherapy, meaning that radioactive material was implanted inside or next to tumors. Cancer cells thereby received radiation from a very close range. Later, the approach became refined in a number of ways, including the first electron linear accelerator designed for radiation therapy in 1943, capable of more precise targeting of tumor cells at the same time, so healthy tissue had a better chance of being left unharmed.

**Insights Into Environmental Influences Causing Cancer**

There also have been numerous developments regarding possible external factors influencing cancer in parallel with the research and experiences focusing on clinical diagnosis and treatment of patients. In a book published in 1700, Bernardino Ramazzini (1633–1714) listed a series of possible occupation-related diseases, including a virtual absence of cervical cancer, but relatively high incidence of breast cancer, among nuns. In 1761, John Hill (1716–1775) published “Cautions Against the Immoderate Use of Snuff.” Percivall Pott (1714–1788) described in 1775 how chimney sweeps suffered illness caused by soot, and Katsusaburo Yamagiwa (1863–1930) and Koichi Ichikawa (1888–1948) published in 1915 how they induced cancer in laboratory animals by applying tar to rabbit skin.

During the 1930s, clinicians began to suspect in earnest that there was a linkage between smoking and several types of cancer, and this was subsequently confirmed in 1950. Thereafter, other substances added to the list of carcinogenic substances included asbestos. Its use started to become banned in an increasing number of settings starting in the 1980s. Benzene, a chemical widely used as a solvent and once an ingredient in an after shave lotion, was discovered to be carcinogenic and became classified as such in 1987. In addition, a growing number of studies indicated a link between melanoma and excessive sun exposure (1970s–1990s), and a 2000 study linked excessive household radon exposure to lung cancer. Starting in 1998, the National Health Institute issued treatment guidelines highlighting the obesity–cancer link.

**Some Further Advances in the Treatment and Diagnosis of Cancer**

The first experimental usage of chemicals within cancer treatment used nitrogen mustard, based on wartime observations of the potential effects of the gas. Nitrogen mustard was approved by the Food and Drug Administration (FDA) on March 15, 1949, as the first chemotherapy drug approved for cancer because it was found that it kills cancer cells. It was temporarily effective in managing some cancers, but another avenue of research from about the same time proved to be a broader venture into chemotherapy. Sidney Farber (1903–1973), who was a pediatric doctor, used the substance aminopterin, based on folic acid, a kind of vitamin B. As vividly described in Siddhartha Mukherjee’s 2010 book, aminopterin was synthesized by Farber and Yellapragada Subbarow (1895–1948), and Farber subsequently used it from 1947 onward for children...
with leukemia with remarkable results. From the 1960s onward, it became common to combine two or more drugs within a combination chemotherapy approach. Furthermore, so-called adjuvant therapy, in which both chemotherapy and surgery were used in treatment, was gradually being developed as chemotherapy was expected to function in the most effective way in the cases where tumors were small. Most commonly, surgery would occur first and chemotherapy second, but chemotherapy given before surgery could also be an option in order to shrink down the tumor and allow for easier surgical removal. During the 1980s, several new types of antinausea drugs were marketed in order to alleviate the side effects of chemotherapy.

When it comes to diagnosis, Otto H. Warburg (1883–1970) had discovered already in 1929 that cancer cells use glucose at a higher rate than normal tissues. This principle lies behind the positron emission tomography (PET) scanning technique developed from the 1950s onward. The first and relatively simple version of a PET scanning device was invented in 1950, whereas the first complete scanner was invented as recently as 2001. Building on ultrasound technology developed during World War II, the University of Minnesota reported in 1952 that ultrasonic echography made it possible to distinguish between benign and malignant breast tumors. The first scanner for routine usage started operation in 1958. Geoffrey N. Hounsfield (1919–2004) developed during the 1960s several prototypes of the computed tomography (CT) scanner. CT scanning made it possible to differentiate very subtle differences in tissue densities.

The publication of the structure of DNA in 1953 had a profound impact on both the treatment and diagnosis of cancer. Renato Dulbecco (1914–2012) discovered the interaction between tumor viruses and the genetic material of cells, and he received the 1975 Nobel Prize together with Howard M. Temin (1934–1994), David Baltimore (1938–), who had shown that information in the synthesis of proteins essential to such oncogenesis could be transmitted from RNA, the nucleic acid synthesizing protein within a cell, to DNA. During the 1970s, methods for sequencing DNA were developed and laid the foundation for identifying and targeting mutated genes and DNA damage that causes cancer. Subsequently, in 1976, Michael Bishop and Harold E. Varmus discovered that different forms of cancer all arise from a common genetic mechanism involving specific genes present in normal cells, the cellular origin of the retroviral oncogenes mechanism. A series of discoveries followed, including the discovery of p53, the most frequently mutated gene in connection with cancer, in 1979, and the discovery of the C-erbB2 cancer-causing gene in mice in 1981, followed by discovery of HER2, the human version of this gene, in 1985.

In 1975, Georges J. F. Köhler (1946–1995) and César Milstein (1927–2002) discovered a technique for producing monoclonal antibodies for use against defined proteins. The first commercially available such monoclonal antibody drug was approved by the FDA in 1997 (rituximab, for treating non-Hodgkin's lymphoma). The following year, the first humanized antibody targeting a cancer-related molecular marker received FDA approval. This antibody was for the treatment of HER2-positive metastatic breast cancer. Shortly thereafter, the first drug specifically developed to target the molecular problem that causes a particular type of cancer was approved by the FDA: the 2001 approval of imatinib used in treatment of chronic myeloid leukemia. Still another important event was the 2004 approval of bevacizumab, used for the treatment of metastatic colorectal cancer. Bevacizumab is unique in that it targets the vascular endothelial growth factor (VEGF). VEGF is a factor that causes the growth or proliferation of blood vessels. The drug thereby became the first antiangiogenic agent ever approved by the FDA and is also counted as the first of a new generation of targeted drugs. It was later approved for use in the treatment of, for example, non–small cell lung cancer and breast cancer.

There are some cases where there may be a known genetic predisposition toward certain types of cancer. These include the 1990s discovery of the BRCA1 and BRCA2 genes, genes that cause some breast cancers. The first evidence that the BRCA1 gene existed was provided by the University of California Berkeley in 1990, and it was cloned by scientists at the University of Utah in 1994. The BRCA2 gene was discovered in 1994 at the Institute of Cancer Research in the UK. Other genes linked to cancers that run in families include genes related to cancers of the colon, rectum, kidney, ovary, thyroid, and pancreas and skin melanoma. Such familial cancers are far less common than spontaneous cancers, but the knowledge may be
used to identify, through genetic screening, people who have a higher risk of developing particular forms of cancer.

Holden Comprehensive Cancer Center at the University of Iowa

The Holden Cancer Center at the University of Iowa was established in 1980. It became the National Cancer Institute (NCI)–designated Holden Comprehensive Cancer Center in 2000 and is the only NCI-recognized cancer center in the state of Iowa. The Holden Comprehensive Cancer Center encompasses interlinking clinical services, cancer research, and cancer education. The Holden Comprehensive Cancer Center involves more than 300 faculty and physicians from more than 36 departments and six colleges across the University of Iowa campus and the University of Iowa hospitals and clinics. Research in the Holden Comprehensive Cancer Center is split broadly into six programs that include (1) Cancer Signaling and Experimental Therapeutics, (2) Cancer Immunology and Immunotherapy, (3) Free Radical Cancer Biology, (4) Tumor Imaging, (5) Cancer Epidemiology, and (6) Cancer Genomics and Cell Growth. Cancer prevention and cancer and aging represent other areas of focus for researchers in the Holden Comprehensive Cancer Center.

Each of the six programs includes faculty across many colleges and has a strong emphasis on translational research. This research is supported by significant shared resources and core facilities that include (1) Bioinformatics Core, (2) Biostatistics Core, (3) Cancer Center Support Grant, (4) Central Microscopy Research Facility, (5) Clinical Trials Support Core, (6) DNA Core, (7) Flow Cytometry Core, (8) Gene Transfer Vector Core, (9) Population Research Core, (10) Radiation and Free Radical Research Core, (11) Small Animal Imaging, (12) Tissue Procurement Core, (13) Lymphoma SPORE Grant, (14) Biospecimens, (15) Biostatistics and Bioinformatics, (16) Clinical Research, (17) High Throughput Screening Facility, (18) Large-Scale Digital Cell Analysis System, and (19) the Proteomics Core. The Holden Comprehensive Cancer Center specifically promotes interdisciplinary cancer research; provides health care related to the prevention, detection, and treatment of cancer; and educates cancer professionals and the citizens of Iowa about cancer.

As a result of this, outreach is a major component of the Holden Comprehensive Cancer Center’s activities. This includes providing cancer information to patients, families of patients, and physicians and other health care professionals. The Holden Comprehensive Cancer Center has many cancer center support groups that meet in local communities. The Holden Comprehensive Cancer Center has a strong focus on translating research advances in the laboratory to advances in patient care. One way in which the Holden Comprehensive Cancer Center achieves this is through clinical trials. The Holden Comprehensive Cancer Center offers more than 300 active clinical trials. Each trial is carefully monitored and controlled to ensure patient safety and privacy and to ensure data integrity. The Holden Comprehensive Cancer Center also incorporates significant numbers of patients in its active portfolio of phase I and phase II clinical trials.

Honduras

The Central American country of Honduras is bordered by the Caribbean Sea and north Pacific Ocean as well as Nicaragua, El Salvador, and Guatemala. The terrain is diverse, ranging from desert-like regions to tropical rain forest with fluctuations in climate from extreme dry and hot weather to torrential rains and flooding with cooler temperatures.

Historically, the land once was inhabited by the Mayan and Lenca tribes until the discovery of Honduras by Christopher Columbus in 1502. Spain began conquest of the territory in 1525 and succeeded in complete takeover from the native population in 1539. The Spanish empire ruled until 1821, when Honduras gained independence from Spain and became part of the Mexican empire. Honduras gained full independence in 1840.

With the original groups consisting of native tribes and the movement of the Spanish empire into the land, the mixing of people created a new heritage of native and European known as Mestizo. Currently, 90 percent of the 7.9 million population is Mestizo, with the remaining population of 2 percent black and 1 percent white.

Of the population, 60 percent live in poverty, making Honduras one of the poorest countries in Latin America. The extreme poverty can be highly attributed to Hurricane Mitch, which devastated Honduras in 1998. More than 5,000 people lost their lives, and damage ranged in the billions of dollars. This disaster placed a major burden on government funds, which led to limited health care resources. This in turn created lack of appropriate means to provide health care and poor quality of care for Hondurans.

In regard to health care in Honduras, a national public health system was established in 1959. During the first decades of the public health system, the capital city of Tegucigalpa was the sole location in which services were provided. Access to care was extremely limited for those who did not have the means or ability to travel. In the 1970s, the government extended care to San Pedro Sula; however, with the locations of both Tegucigalpa and San Pedro Sula in the northwestern part of the country, access to care was still difficult for those living in the east or south. Over the decades, the government has attempted to increase access to care; however, as of 2013, 15 percent of the population does not have access to care.

In considering the state of the health care system, a particular aspect of health care that is at a considerable deficit is that of cancer-related care. Honduras lacks the appropriate resources for the population in regard to cancer awareness, prevention strategies and programs, screening protocols and procedures, means to make a prompt diagnosis, and treatments.

In the Honduran population, cancer rates have been researched but are difficult to determine due to the lack of care and therefore lack of diagnosis. It is understood that stomach, liver, prostate, and cervical cancer have the greatest prevalence in the population. For females, cervical cancer is the leading cause of cancer-related death, while for males prostate cancer is the leading cause. The overall leading cause of cancer-related deaths in Honduras is stomach cancer.

In Honduras, the cancer survival rate is extremely low, with a five-year survival rate below 2 percent. This low survival rate most likely is due to poor awareness, lack of screening, and deficiency in early detection as well as insufficiency of funds to receive appropriate care and poor quality of treatment.

In regard to preventative measures, research of current preventative tactics demonstrates that there are some prevention policies in place. In regard to tobacco smoke, Honduras has created policies to ensure that all public places are smoke free, and health warning labels are in place on all packaging. While these policies are in place, other high-risk behaviors such as obesity and alcohol abuse do not have policies.

Currently in Honduras, there are cancer screening guidelines in place for some types of cancer. There are cervical cancer guidelines in place that recommend Pap tests every three years starting at age 30 years old. Screening coverage of the population is estimated at around 40 percent. For breast cancer, no guidelines are currently recommended,
with limited availability of mammography. For gastrointestinal cancers, no guidelines currently are in place with lack of availability to endoscopy screening. As with most aspects in health care in Honduras, much of the population does not have access to screening resources.

In regard to treatment for cancer in Honduras, as with other health care resources, treatment is difficult to access due to availability and cost. Currently, chemotherapy and radiation therapy are offered; however, affordability of these expensive treatments makes them accessible only to those with financial resources. Additionally, it is estimated that there are as few as five treatment centers in Honduras. This makes access to care difficult for those in rural and remote places.

Due to the lack of resources and poor access to care, Honduran and international organizations have recognized the ongoing deficits in cancer care and have set in place numerous initiatives with the goals of improvement in awareness, prevention programs, screening initiatives, diagnosis, and treatment.

A current Honduran organization involved in cancer initiatives is the Liga Contra el Cáncer, also known as the League Against Cancer. The League Against Cancer is composed of medical professionals and volunteers that provide care free of charge or at low cost. The organization supports a medical center located in San Pedro Sula that provides services including surgery, chemotherapy, and radiation therapy as well as psychological support for patients and families.

On an international level, the American Society of Clinical Oncology has sponsored an international initiative called Health Volunteers Overseas that facilitates cancer care to the Honduran population. Health care providers in the Health Volunteers Overseas include nurses, physicians, and treatment experts who are specialized in oncology care. These specialty professionals work alongside Honduran health care providers to train and facilitate the provision of up-to-date and quality care for patients.

Hong Kong Anti-Cancer Society

The Hong Kong Anti-Cancer Society (HKACS) is a charitable organization that was established to assist in the prevention and treatment of cancer in the southern region of China. In the era of its founding, many Hong Kong–area hospitals lacked the infrastructure to support fully those suffering from cancer and their families. Supported by private donations, as well as by the Hong Kong Council of Social Service, the Community Chest of Hong Kong, and the Union for International Cancer Control, which has its headquarters in Geneva, Switzerland, the HKACS has undertaken to increase the available medical facilities to treat cancer; to support research on cancer treatments and education about the disease’s prevention; and to provide services for cancer survivors and their families.
The Early Years of the Hong Kong Anti-Cancer Society

The HKACS was founded in March 1961 by John Hung-chiu Ho, a highly respected radiologist in the city’s medical community. Ho received his medical training at the University of Hong Kong; after graduating in 1940, he pursued additional study in diagnostic and therapeutic radiology in the United Kingdom, as radiological and oncological sciences were not well developed in Asia at this time. During the 1950s, Ho was active in Hong Kong’s philanthropic circles, raising funds for the cancer wing at Queen Mary Hospital and launching the Queen Elizabeth Hospital’s Institute of Radiology and Oncology. His research evinced that cancer was the leading cause of death in Hong Kong and placed heavy burdens on the region’s medical centers.

Leading the charge against the spread of cancer, Ho, along with a group of cancer sufferers and Hongkongers who shared his concern about community health, established the HKACS. The concerns of the HKACS encompassed the emotional and physical well-being of those afflicted with the disease. Since its early years, the HKACS has sponsored workshops, exhibitions, talks, and other activities to educate the citizenry of Hong Kong on cancer prevention. In addition, it has disseminated information in the form of printed literature, electronic media, and public talks on lifestyle choices that minimize the risk of cancer. Given the link between common forms of cancer in southern China and the consuming of preserved, salted fish, much of the HKACS’s work has centered on nutrition and dietary habits.

In 1966, the HKACS began raising funds for the region’s first medical center devoted specifically to cancer treatments; with the charity’s gift of HK$2.65 million and the political support of Sir David Trench, who was the colonial governor of Hong Kong from 1964 to 1971, Nam Long Hospital opened with 120 beds in 1967. By 1978, the society had increased the number of beds by 33 percent. The HKACS continued to raise money for Nam Long Hospital through the 2010s, even after the Hong Kong government assumed administrative control over the formerly private medical center.

Ho’s contribution to the field of radiology continued after his tenure at the helm of the HKACS began; during the late 1970s, he published a series of journal articles on the causal relationship between infants’ diets and nasopharyngeal carcinoma, which was especially predominant in that part of Asia. The society applied Ho’s research and made combating nasopharyngeal carcinoma part of its platform.

The Hong Kong Jockey Club Charities, which have played a role in the city’s philanthropic community since 1884, have partnered closely with the HKACS since its founding, providing financial support for outreach activities to cancer survivors. Since the 1960s, the HKACS has received more than HK$110 million from the Hong Kong Jockey Club Charities in support of Nam Long Hospital alone. In addition, the Hong Kong Jockey Club Charities have sponsored the integration of Chinese and Western medical treatments for sufferers of cancer.

The Hong Kong Anti-Cancer Society in the 21st Century

Ho led the organization from its founding until his retirement in 2000. Subsequent senior leadership of the HKACS also had close ties to the medical or social welfare fields: Dr. Y. F. Poon, a noted radiologist who has published numerous journal articles on nasopharyngeal carcinoma, served as chairman for the year after Ho’s retirement; Dr. Leong Che Hung, who had helped establish the Hong Kong Academy of Medicine and chaired the Hong Kong AIDS Foundation, the Advisory Committee on Nursing for Hong Kong, and the Hong Kong Hepatitis Research Foundation, was Poon’s immediate successor; and Patricia Chu Yeung Pak-Yu, who became chairperson in 2012, previously had served as deputy director of Hong Kong’s Social Welfare Department as well as the chairperson of the Social Workers Registration Board.

The HKACS has partnered closely with other community organizations that share its mission of eradicating cancer, including the Hong Kong Cancer Fund, the Children’s Cancer Foundation, the Hong Kong Bone Marrow Donor Registry, and the Cancer Crusade Angel’s Service Society of Hong Kong. In 2009, in collaboration with the Hong Kong Baptist University, the HKACS opened the Cancer Rehabilitation Center, which was designed for both inpatient and outpatient care.

By 2014, the HKACS was headquartered in the Wong Chuk Hang district of the city. Under its administrative structure, the responsibilities for programmatic activities have been subdivided among four different committees: the betterment fund subcommittee, which directly supplies cancer...
patients with financial assistance; the detection and prevention subcommittee, which assesses risks of developing cancer and offers consultations; the cancer research subcommittee, which administers more than HK$350,000 annually for competitive research grants on nasopharyngeal carcinoma and female lung cancer; and the cancer education subcommittee, which offers programming on both the prevention and management of the disease.

Hospice Care

Over the past 40 years, hospice care has become an integral part of the cancer continuum by improving the quality of life of patients and their families living with advanced cancer. This entry provides a succinct overview of hospice services, a brief history of the development of hospice care, an explanation of the relationship between hospice and palliative care, and a description of hospice care in the context of oncology; this entry concludes with comments on pervasive misconceptions about hospice care.

Hospice can be thought of as both a philosophy of care and a defined component of the health care delivery system. Understood as a philosophy, hospice holds paramount concepts of patient autonomy, enriched quality of life, respect, dignity and compassion for the dying, and effective bereavement. Moreover, hospice is a holistic approach to caring for the dying addressing the biological, psychological, social, and spiritual needs of the patient and family in order to promote living fully through the final stage of life.

As a defined component of the health care delivery system, hospice programs are designed for patients with a life-limiting illness whose physicians have determined life expectancy is less than six months if the disease takes its expected course. Patients who meet the eligibility criteria for admission to hospice also choose to forgo curative or life-prolonging treatments in order to focus on maximizing comfort and enhancing quality of life. Hospice programs must provide services from an interdisciplinary team of specially trained medical professionals, medications, medical equipment, and supplies needed for the care of the terminal diagnosis and bereavement support to the surviving family. Surveys indicate that people prefer to die at home, surrounded by friends and family, free of pain, and with as much control as possible. Hospice programs respond to those wishes.

Hospice services are provided wherever a patient resides, which can include private residences, nursing homes, assisted-living facilities, hospitals, and hospice in-patient units used for acute symptom management and respite care. Most hospice care occurs at a patient’s residence.

In the United States, hospice services are covered by Medicare, Medicaid in most states, and many private insurance companies. Any person can make a referral to a hospice program. While this is typical of a physician or hospital, referrals also can come from a patient, the family, a friend, or a spiritual care provider.

Core Hospice Services

Hospice services include support by a team of specially trained medical professionals who work with a patient and the family to discuss values, identify goals of medical care, and then design treatments, therapies, and interventions to maximize the patient’s quality of life. Because there are many sources of suffering or distress for an individual with a terminal illness, hospice care requires expertise from an interdisciplinary team. The hospice team includes but is not limited to the following.

Physicians. Hospice physicians bring expertise and specialization in pain and symptom management, in educating around disease progression, and in
facilitating goals of care conversations. Hospice medical directors are responsible for decisions around eligibility for hospice services as well as management of the plan of care for each patient. The American Board of Medical Specialties approved hospice and palliative medicine as a recognized subspecialty in 2006. Much as an oncologist brings specialization in the understanding and treatment of individuals with cancer, hospice and palliative medicine physicians bring expertise and specialization in pain and symptom management to individuals living with serious illness.

Nurses. Hospice nurses serve multiple roles for patients and families. Nurses work to implement the plan of care and work with physicians to ensure patients receive adequate relief of pain and suffering. Nurses provide education to the patient and caregiver on disease progression, medications management, supplies, medical equipment, and patient care issues. A patient and family will have access to hospice nurses by phone at all times. The hospice nurse will provide ongoing medical and physical assessments to ensure all the patient's needs are being met. Most hospice nurses have advanced certification in hospice and palliative care.

Social Workers. Hospice social workers oversee the psychosocial support needed by the patient and family. This support can take many forms, including but not limited to counseling, connection to available community resources, assistance with goals of care conversations, procuring volunteer support, assisting patients and families in navigating the health care delivery system, and education on grief and bereavement for the family. Social workers also can assist patients with health care insurance questions and funeral planning.

Spiritual Care Providers. There is variability among hospice providers on the level of spiritual care support provided to patients and families. Most hospice providers employ health care chaplains who assist patients in exploring the spiritual dimensions of their lives, facilitate discussions about connectedness with the transcendent, and address sources of spiritual distress. Hospice chaplains also can pray with patients, read sacred texts to patients, connect patients to a faith community, and officiate funerals. Chaplains do not represent any particular faith tradition or denomination while working in their professional role. Some hospice programs provide spiritual care with the use of volunteer chaplains or ministers.

Certified Nursing Assistants. Certified nursing assistants provide assistance with activities of daily living for hospice patients such as bathing, changing, and dressing. Additionally, certified nursing assistants are specially trained to assist patients in a way that preserves respect and dignity.

Bereavement Support. Hospice providers are required to offer bereavement support to the surviving family for the first 13 months after a patient dies. There is variability among hospice providers in the scope of bereavement services available. While all hospice providers offer grief education, some hospice organizations employ bereavement counselors who provide individual and group counseling services. Bereavement counselors may begin supporting the patient and family prior to death if any members of the family are experiencing anticipatory grief.

Volunteers. Volunteers are a mandated component of hospice care. Hospice providers train community volunteers to provide practical support to patients and families. Volunteer services typically include respite care for the caregiver, companionship visits for the patient, and transportation services. Volunteers also provide administrative support to hospice programs.

Other Providers. Pharmacists, speech therapists, physical therapists, occupational therapists, and dieticians may also be involved in the care of the patient should the patient's condition or goals of care require them.

The hospice team is designed to address all potential sources of pain and distress a patient and family may experience. This team of highly trained medical professionals works with the patient and family to identify goals for care and to develop a comprehensive end-of-life plan of care. Provision of services and presence of each discipline in the home depends on patient and family needs and preferences. The hospice team will update the plan of care as the patient's condition changes and meet every 15 days to formally discuss the plan of care.
In addition to the interdisciplinary team, hospice services also include provision of all medications, medical supplies, and medical equipment related to the terminal diagnosis. In short, hospice providers are experts at providing quality physical, psychosocial, and spiritual care to individuals and their families in the late stage of serious illness.

The hospice approach to caring for individuals with terminal illness has improved end-of-life care. There is a large body of evidence that demonstrates the hospice approach to caring for individuals with a terminal illness results in better pain and symptom management, enhanced quality of life, and improved caregiver well-being.

A Brief History of Hospice Care
Dame Cicely Saunders, a nurse, social worker, and physician in London, England, is widely recognized as the founder of modern-day hospice. Saunders started work to improve care for the terminally ill in 1948 because she believed the medical orthodoxy at the time was doing an inadequate job caring for the dying. Saunders witnessed patients dying in hospitals in both pain and isolation. Saunders's prescription for a better death was specialized medical care from an interdisciplinary team whose members could address a patient's total pain. She started St. Christopher's hospice in the United Kingdom in 1967, caring for almost exclusively patients with cancer diagnoses. For Saunders, it was individuals with advanced cancer diagnoses who could benefit most from the services of a hospice team.

The hospice approach to caring for the dying spread from Europe to Canada and then to the United States, with Connecticut Hospice opening in 1974. From 1974 to 1982, hospice programs developed around the United States. Many programs during this time were started by community volunteers, and the sustainability of the programs relied on donations. During this time, almost all patients served by hospice programs had diagnoses of cancer. In 1982, the United States Congress created the Medicare Hospice Benefit. This benefit established coverage for hospice services, and for the first time, hospice providers had a reliable revenue stream. Since the creation of the Medicare Hospice Benefit, hospice has grown steadily. In 2012, there were an estimated 5,500 hospice programs in the United States caring for approximately 1.6 million hospice patients. As hospice has grown to serve all individuals with a terminal diagnosis, the proportion of patients with a primary diagnosis has declined to approximately 40 percent.

Hospice Care and Palliative Care: What Is the Relationship?
It is often said that all hospice care is palliative care, but not all palliative care is hospice care. While this is true, the saying does little to clarify the distinction.

Palliative care is best understood as specialized medical care for individuals with one or more serious illnesses. Palliative care is active, interdisciplinary care that aims to relieve suffering and improve quality of life for patients and their families with advanced illness.

While the descriptions of hospice and palliative care appear similar, there are important distinctions. Unlike hospice care, palliative care services are available to anyone with a serious illness in need of pain and symptom management without the hospice necessity of having a terminal prognosis. Moreover, palliative care services can be provided concurrently with curative treatments.

While there is some variability in palliative care services based on geography and setting, palliative care is a team approach, which can include a physician, nurse practitioner, nurse, social worker, and chaplain. Palliative care teams are specially trained to manage intractable pain and other bothersome symptoms that include but are not limited to physical pain, dyspnea, nausea, delirium, restlessness, and constipation. Additionally, palliative care teams bring expertise in addressing emotional and spiritual distress. Palliative care providers are experts in communicating effectively with patients and families about prognosis and facilitating family meetings aimed at defining quality of life and goals to ensure that additional treatments are concordant with a patient's values and preferences.

Most palliative care services are provided to patients while in the hospital; however, palliative care may also be available in long-term care facilities, outpatient clinics, and an individual's home. It is important for caregivers of individuals living with serious illness to ask health care providers about available palliative care services in the area.

Similar to hospice care, palliative care services have grown rapidly over the past decade. According to the Center for the Advancement for Palliative Care, more than 65 percent of hospitals had palliative care programs in 2010, a 148.5 percent increase.
over the decade. With an aging population, the need for hospice and palliative care services is expected to grow significantly.

**Hospice Care and Oncology**

Hospice has been widely demonstrated to improve the quality of life for patients living with cancer as well as the well-being of caregivers supporting individuals with cancer. Not only has hospice been shown to be excellent at pain and symptom management, but surprisingly in some instances, hospice and palliative care extend life expectancy. Most notably, Jennifer Temel, M.D., and her research team conducted a randomized, controlled trial of patients with newly diagnosed non–small cell lung cancer. One cohort received standard oncologic care, while the other cohort received standard oncologic care and support from a palliative care team. The group of patients who received support from the palliative care team had better quality of life scores, fewer depressive symptoms, and prolonged survival when compared to the group who received only the standard oncologic care. This research is one example of a large body of research that shows that hospice and palliative care improve the quality of life of the patient, enhance caregiver well-being, reduce pain and bothersome symptoms, and in some cases extend life.

Because of the compelling evidence demonstrating the value of hospice and palliative care for individuals with advanced cancer, many reputable organizations have endorsed a broader utilization of hospice and palliative care. The American Society for Clinical Oncology (ASCO) is encouraging providers working with cancer patients to engage in discussions about palliative care and treatment options. Similarly, ASCO, as part of the Choosing Wisely campaign, recommends that patients with advanced cancer for whom treatment is unlikely to provide benefit avoid anticancer therapy and focus on symptom relief and palliative care. ASCO issued a clinical opinion emphasizing the use of palliative and supportive care at the time of diagnosis of metastatic or advanced cancer, which evidence has shown can increase quality of life and, in some cases, increase survival.

In addition to ASCO’s recommendations to increase palliative care services, the Institute of Medicine identified the need to ensure individuals with advanced cancer receive end-of-life care consistent with needs, values, and preferences as a key part of high-quality care delivery.

**Misconceptions About Hospice Care**

While hospice and palliative medicine have begun to bring end-of-life care into the medical mainstream, some pervasive misconceptions around end-of-life care persist.

*Hospice is only for the last hours to days of life.* While hospice is a benefit designed for the last six months of life, the average length of stay for hospice patients in the United States is approximately 70 days. Half of patients electing the hospice benefit will only receive services for approximately two weeks, potentially limiting the patient’s and family’s ability to take full advantage of the scope of hospice services. Surveys consistently show patients and families often wish they had known about hospice services sooner.

*Hospice is a place.* While hospice can be a place in the form of a stand-alone inpatient unit, most hospice care occurs in a patient’s residence. Hospice services are available in homes, nursing homes,
Hospice care has grown dramatically in the last 40 years, and the result has been an appreciable improvement in the quality of end-of-life care. Research has demonstrated that the hospice approach to terminal illness with an interdisciplinary team supporting patient and family and addressing total pain has multiple benefits including but not limited to better pain and symptom management, increased patient quality of life, improved caregiver well-being, and important support for the bereaved. Because of the multiple benefits of the hospice approach, numerous professional medical societies have recommended a broader utilization of hospice and palliative care services for individuals with advanced cancer. With an aging population, the demand for high-quality hospice and palliative care services is expected to increase.

Hospitals

Although the function of the hospital as an institution for health care or as a physical place to confine marginal populations has changed throughout time, its history and tradition has about 2,500 years. We cannot approach its function ignoring the role of religion in society, the hegemonic ideas about illness and disease, or the main purposes for its existence (healing, welfare, recovery, etc.), and the degree of responsibility involved in it. The etymological origin of the word hospital is the Latin term hospes, meaning foreigner, and therefore “guest,” a person who has to be taken in in the context of a hospitable reception. It has the same origin, then, as hospitality. Hospitality concerns both host and guest. It is important to take this into consideration in order to see how this aspect has evolved, depending on historical periods or cultural scenarios.

The Origins of the Hospital: From Ancient Times to the Middle Ages

Probably the generic hospital is an abstraction, and important nuances like location, religious nature, mission, and so on need to be approached. There is no doubt that the launching of hospitals is a response to the presumed needs of a given population. Originally, there was a clear fusion between religion and medicine. For that reason, in ancient cultures, clinics were founded within the temples. That was the case in Greece—dedicated to the god Asclepius—or Egypt. People went there to find medical advice and eventual healing. In other cultures, for example, Indian, institutions for care of the ill were created about the year 400. But the most evident link between religion and medicine appears in medieval Europe, when nuns and monks from religious communities, who followed a model of monastic discipline, provided care to the ill. Hospitals were charitable guesthouses. As some authors critically point out, those institutions were instruments of hope and pious benevolence. They gave care support not only to the ill but also to the homeless, poor, vagrants, prostitutes, disabled, or presumed lunatics. As a matter of fact, traditionally stigmatized groups play a main role in medieval asylums or hospices. People did not go there to look for healing, but sometimes they were captured to be confined. Healing was not a main goal.

Modern Times

In the 16th and 17th centuries, that concept changed, and medical institutions were, if not totally, at least partially secularized in most European countries. And, definitely, from the Enlightenment on, most hospitals were considered as places for science. The high incidence of infections within hospitals, however, extended the common belief that it was a place to die. The Enlightenment meant the implementation of some new rules, for example, the rite of visiting hours for relatives and the existence of reports and mandatory prescriptions. In summary, there is a progressive professionalization of medical caregivers. Surgery is not an open spectacle for large audiences anymore but rather a part of the whole treatment process of a patient. At the same time, voluntary hospital movements began, and many medical institutions were supported by private subscriptions. It was the first step to becoming centers of innovation and teaching and not only places to provide care to the ill and to marginal populations in general.

Throughout the 19th century, it is particularly relevant because new technologies were discovered and because most hospitals were also centers of training for future professionals. Early in the 19th century in England, for instance, it was mandatory that, before becoming a doctor, the future professional had at least half a year of experience in some asylum, dispensary, or infirmary. For that reason, it was important that hospitals could offer not only a room and treatment for the patient but
also good training for doctors and nurses. Thanks to this fact, hospitals transformed into centers of study of anatomy and of experimentation. At the same time, pharmacology was totally implemented at the end of the century. Nevertheless, substances like morphine, quinine, or codeine were discovered before 1840. Treatment used to rely on a change of air together with purgation and bleeding, with the idea of clearing impurities from the body. Hospitals, at that time, were also spas or retirement houses where a combination of care and some light activity was provided. After all, the main cause of morbidity was infection; tuberculosis was endemic, and cholera, in the last decades of the century, was epidemic.

**Toward a Current Concept of Hospital**

As a consequence of all this, hospitals began to generate epidemiological mapping and measurement, especially at the end of the 19th century. Concurrently, new knowledge in histology, pathology, and microbiology, even in hygiene, was developed. The improvement of the microscope and the invention of the ophthalmoscope aided diagnosis, and surgery notably improved thanks to the application of anesthesia and antiseptic procedures. In the first years of the 20th century, after X-ray discovery, many hospitals were better equipped—this does not mean, however, that they were modern in a modern sense. All those factors simply made medical institutions less unpleasant for the ill. People with mental illnesses had their own specialized institutions for confinement and isolation. In most European countries, hospitals were built and paid for with public funds. In the United States, hospitals were operated by different administrations (federal, state, and city) but also by both for-profit and nonprofit enterprises.

At the turn of the century—and the beginning of the 20th—hospitals became more complex in their organization and also in their staff, including trained persons with technical responsibilities. The introduction of the X-ray machine meant a big step forward, but it also introduced an economic variable because radiologists had to be paid for their services. It was expensive technology. Besides, if in the first decade of the century many patients belonged to low social classes, about 20 or 25 years later, middle classes began to be patients in hospitals with the idea that medical institutions not only offered a room to stay in but were also centers for research and, somehow, for scientific advancement. From an epidemiological point of view, the most common diseases at that time, as in earlier decades, were infections of all kinds. From the point of view of clinical patterns, one of the first tests applied in most hospitals in the first two decades of the century was a urine test. Blood counts were implemented much later in common medical practice.

In the 1930s, chronic diseases, such diabetes and dental problems, were not covered by the public health system (in Western countries, including the United States), and costs had to be assumed by the patient him- or herself. The 1950s was an era of expansion, and in the 1960s most intensive care units were completely established. From that point on, the concept of hospital—and its structure—was quite similar to the hospitals of today. Now highly advanced health information systems require a highly qualified sanitary personnel, and allow accessing millions of data points and choosing the optimal (and personalized) treatment for each patient.

**Cancer Hospitals in History**

The first hospital specializing in cancer was founded in Rheims in the 18th century. It remained active for about 20 years. After that, it was forced to close because there was a general conviction that cancer could be contagious. In the mid-19th century, hospitals for cancer patients were very common in England. The first cancer hospital in New York was set up in 1884. Many of those hospitals from the end of 19th century were inspired by philanthropic motivations—more than by a real interest in the patient’s improvement or survival. X-rays and radium (both discovered at the end of the century) increased the enthusiasm of surgeons, who saw the possibility of fewer surgeries and more alternative treatment. Those factors caused a true explosion of cancer institutions at the time of World War I.

From the 1950s on, when the concept of quality of life was established, most hospitals, first in developing countries but now also a large number of hospitals in low-income regions, share a main concern about an integral treatment for cancer patients, ranging from an accurate diagnosis to systematic follow-ups or painless palliative care, including emotional support for patients and their families.

HPV Vaccination

The human papillomavirus (HPV) vaccination is the first primary prevention method in the fight against cervical and other cancers. The vaccine is given in three doses over six months, and it is recommended that children receive the vaccine around 11 or 12 years old. The introduction of the vaccine came with controversy over its timing and appropriateness and produced barriers to adoption. Yet, evidence is growing that it is a successful method for preventing the spread of certain kinds of HPV that cause cancer.

Background of HPV Vaccinations

Research on developing an HPV vaccine began soon after it was discovered that a significant majority of cervical cancers (and, later, penile, anal, vagina, vulva, and head and throat cancers) can be attributed to certain strands of persistent HPV infection. In fact, about 26,000 new cases of cancer each year are attributed to HPV. Specifically, researchers began focusing on the development of a vaccine against HPV types 16 and 18; about 75 percent of cervical cancer diagnoses can be attributed to persistent infections with these types of HPV.

Two HPV vaccines are currently approved for use in the United States. In 2006, the pharmaceutical company Merck received Food and Drug Administration (FDA) approval for Gardasil, the quadrivalent vaccine that targets not only HPV types 16 and 18 but also types 6 and 11, which are known to cause about 90 percent of genital warts cases. The vaccine was, at that time, licensed for use in females ages 9 to 26 years. In 2010, the FDA approved Cervarix from the pharmaceutical company GlaxoSmithKline; this vaccine was licensed for use in females ages 10 to 25. Cervarix is a bivalent vaccine and targets HPV types 16 and 18. Since that time, both Gardasil and Cervarix have been licensed for use in males ages 9 to 26 years old. Both vaccines are given in a three-dose schedule; the second dose is given two months after the first dose, and the third dose is given six months after the first dose. Despite Cervarix being available to patients, about 99 percent of the doses distributed in the United States are the quadrivalent Gardasil vaccine.

For both vaccines, the Advisory Committee on Immunization Practices, a Centers for Disease Control and Prevention (CDC)-sponsored group of medical and public health experts who offer recommendations on vaccinations in the United States, advises that the optimum age for girls and boys to receive the vaccine is at 11 or 12 years old. Early immunization is desirable so that adolescents may develop immunity before they become sexually active and exposed to HPV.

HPV vaccination is considered safe relative to other adolescent vaccines, with similar levels of adverse reactions. Common side effects reported are pain, swelling, itching, and redness at the site of the injection; nausea; dizziness; syncope; headache; and fever—these are considered nonserious adverse events. According to clinical trial and post-licensure monitoring data collected by the Vaccine Adverse Event Reporting System (VAERS), about 92 percent of the adverse events reported by those patients who received the HPV vaccine were classified as nonserious.

Barriers to Vaccination and Behavioral Barriers

Behavioral barriers and controversy over vaccination limited the early diffusion of HPV vaccination in the U.S. population.

There are several reasons why the HPV vaccine has not been adopted quickly. First, many people think young people do not need the vaccine if they are not sexually active, misunderstanding the
need to vaccinate before being exposed to HPV through sexual contact. This leads to low uptake rates (i.e., dose 1). Second, the three-dose schedule of the vaccine complicates adherence. While many people will get the first dose, it can be a challenge to get patients to return for doses two and three at the appropriate time. Third, the vaccine is relatively expensive, with each dose costing about $130 ($390 for all three doses). The vaccine is covered by health insurance, but for those who do not have coverage or who have a deductible, cost is a significant barrier. Various health education and health communication campaigns have been developed to address these barriers, including focusing on education about HPV and the need to vaccinate early and receive all three doses on time and raising awareness about low-cost or free vaccine opportunities through local health departments or through the CDC’s Vaccines for Children (VFC) program.

Public Controversy
Negative publicity about the HPV vaccine’s development and its maker’s lobbying has fueled the public’s perception that the vaccine was approved too rapidly and it might not be safe. In fact, the HPV vaccines went through the same clinical trials and licensing process as all vaccines, and it is continuously monitored for safety by VAERS. Another area of controversy concerns the disease itself—HPV is a sexually transmitted disease, so despite the benefit of preventing cancers, the vaccine is still targeting a disease that is spread through sexual contact. With the recommendation to vaccinate children as young as nine, this has led many religious and political groups to make public comments objecting to policies to require HPV vaccination for school attendance or to give children this vaccine at all. Unfortunately, this controversy has contributed to low uptake rates of the HPV vaccine.

Evidence of Effectiveness
Despite these barriers, epidemiological evidence suggests that the HPV vaccination is successful. Since its 2006 approval, the CDC reports that more than 57 million doses of the HPV vaccine have been distributed, more than 50 percent of adolescents 13 to 17 years old have received dose 1, and more than 35 percent of adolescents 13 to 17 have received all three doses. Despite these relatively low rates of vaccination, the HPV vaccination has already made a difference in HPV infection rates. Researchers with the CDC published findings that, since the introduction of the quadrivalent HPV vaccine in 2006, HPV infection (for types 16, 18, 6, and 11) has dropped by more than half in females age 14 to 19 years. Further research will most likely show rates continuing to drop, given more widespread adoption of the vaccine and with males now being vaccinated as well.

Conclusion
The HPV vaccine represents a real step in the fight against cervical and other cancers caused by certain types of HPV. Within the next few decades, the combination of HPV vaccine combined with regular Pap and HPV testing may make cervical cancer mortality extremely rare. The quadrivalent HPV vaccine also has the potential to prevent 90 percent of genital warts cases, which can cause discomfort and embarrassment to millions of Americans. The Advisory Committee on Immunization Practices (ACIP) recommendations are clear, and despite several barriers to uptake and adherence to the three-dose vaccine schedule, recent research reveals the HPV vaccine is making a difference in not only HPV infections but also cases of cancer and genital warts. Continued HPV vaccination education and promotion is needed to ensure maximum success of this prophylactic innovation.

The President’s Cancer Panel. “Accelerating HPV Vaccine Uptake: Urgency for Action to Prevent
Cancer treatment in Hungary began in the Middle Ages (5th–15th centuries). After the fall of the Roman Empire, medical knowledge was primarily preserved and practiced from existing Greek and Roman texts in monasteries. However, the medicine practiced relied on a combination of Christianity, astrology, folk remedies, and other nonempirical sources. Civilians stricken with cancer or other diseases often traveled to monasteries from surrounding towns for medical assistance.

Under Ottoman rule (1541–1699), 77 madrasas operated from the dominion’s 39 major towns, where the Koran and Islam, as well as secular subjects like medicine, were taught. The Crusades and subsequent Ottoman rule spread Eastern advances in cancer treatment through Hungary into the Renaissance period, when ancient Greek and Islamic medical texts were translated from Arabic, including Avicenna’s *The Canon of Medicine*.

The regions of Hungary under Habsburg rule (1526–1804) also continued to advance in medical treatments with the rest of central and western Europe. Several institutions of higher learning were founded, including the Jesuit Academy in Kolozsvár in 1581 and the Calvinist College of Debrecen (now the University of Debrecen) in 1531. The first medical work in Hungarian was written ca. 1577 by György Váradi Lencsés, titled *A Complete Guide to Medicine* (*Ars Medica*).

The sunset of Ottoman’s rule and the rise of the Austro-Hungarian empire brought a large multi-ethnic population under its dominion, with tensions between nationalism and cultural supremacism on one hand and ethnic diversity and a robust political environment on the other. Lectures on the history of medicine were intermittently taught in Budapest beginning from 1835. In 1753, Holy Roman Empress Maria Theresa founded what soon became the Hungarian Royal University (now University of Szeged)—including the faculty of medicine and surgery (est. 1775)—where teaching was conducted in German. Semmelweis University, the oldest medical school in Hungary, was founded in 1796.

Austrian and Hungarian physicians performed surgical procedures on cancer patients using anatomical methods and provided state-supported medical education to a multiethnic student body. This approach contrasted sharply with the Prussian approach—partially adopted in the 1870s after the Austro-Prussian War—where surgery was grounded in a more physiological paradigm (including the administration of anticancer agents), a science-oriented medical education system for the elite, and a university that functioned independently from the state.

University- and hospital-centralized treatment has remained the primary approach to comprehensive cancer care in Hungary to this day. In 1952, the National Institute of Oncology (NIO) was established by the Hungarian Ministry of Health through expansion of the Eötvös Loránd Radium and Roentgen Institute, signaling a transition from radiological to comprehensive oncology care. Working in conjunction with the on-site Oncopathological Research Institute, NIO is considered Hungary’s premier center of oncology treatment and research. NIO director-generals have held positions of prestige at the World Health Organization and Union for International Cancer Control, including Drs. János Vikol (1959–1970), Sándor Eckhardt (1971–1992), and Miklós Kásler (1992–present), who led Hungarian participation in the 2004 European Code Against Cancer.

Internationally renowned Hungarians responsible for advances in oncology medicine and research
include Ignaz Philipp Semmelweis (1818–1865, an early pioneer of antisepctic procedures), and Nobel Laureates Drs. George Charles de Hevesy (1885–1966, an early pioneer in the use of radioactive tracers to study metabolic processes) and Albert Szent-Györgyi de Nagyrápolt (1893–1986, discoverer of vitamin C). In the United States, Dr. Szent-Györgyi developed research interests in applying quantum mechanical theories to cancer biochemistry and founded the nonprofit National Foundation for Cancer Research.

Despite its modern health care system, Hungary's cancer-related mortality rate remains the poorest in Europe, with a 2012 annual mortality rate of 458 people out of 100,000 people (followed by 347 per 100,000 in Russia and Ukraine). Hungary has the world's highest mortality rate for lung cancer at 135 per 100,000 people (followed by Poland at 90 per 100,000), primarily because of heavy smoking. Semmelweis University data suggest that breast cancer, which is observed in every seventh Hungarian woman, is diagnosed at advanced stages in 35 to 40 percent of cases at first treatment.

In 2005, Hungary's leading national daily newspaper ran an award-winning article by Viktória Kun highlighting the weaknesses in Hungary's oncology services. Cancer outcomes were reportedly dependent on treatment site, with admission to these sites dependent on personal connections or "gratitude money" payments. While cancer surgeries were performed in hospitals nationwide, patients were sent home postoperatively 65 to 70 percent of the time without follow-up referral to an oncologist and were subsequently lost from the system.

Alternative oncology therapies have been advanced in Hungary. One of only two clinics licensed to perform Gerson Therapy worldwide is located near Budapest. In the 1950s, Dr. Alexander Ferenczi treated post-chemotherapy cancer patients using one kilogram of beetroot a day (now available in freeze-dried powdered form) to successfully support tumor regression. Anthocyanin is reportedly the active ingredient in this remedy. In the early 1990s, Hungarian chemist Mate Hidvegi and his colleagues developed fermented wheat germ extract (FWGE), which is fermented with baker's yeast to concentrate bioactive benzoquinones. Dr. Hidvegi later developed and patented an industrial fermentation process for large-scale production of the FWGE extract, which is now marketed by his company Biropharma Ltd. in granulate and tablet form.

Huntsman Cancer Institute

Huntsman Cancer Institute (HCI) was established in 1995 through an endowment from Jon M. Huntsman, chairman and founder of Huntsman Corporation, Salt Lake City, Utah. HCI is part of the University of Utah Health Care system and is located in Salt Lake City on the University of Utah campus. Although HCI serves Utah residents primarily, this institution also serves residents of parts of Idaho, Montana, Nevada, and Wyoming in an area referred to as the Intermountain West. HCI utilizes a three-pronged approach to assist, directly or indirectly, people with cancer through research, education, and state-of-the-art patient care.

HCI was one of the first cancer centers to establish high-risk cancer clinics, providing families with unusually high rates of cancer with resources and strategies for risk management. To support their research goals, HCI has a significant amount of research facility space. HCI has 231,118 square feet of on-site research space with an additional 12,746 square feet of research space at their satellite locations, 442,000 square feet of state-of-the-art clinical space, and a new space of 220,000 square feet designated as the Primary Children's and Families' Cancer Research Center. HCI’s affiliations with larger regional and national cancer programs such as Intermountain Healthcare, National Cancer Institute (NCI), and the National Comprehensive Cancer Network (NCCN) enables their patients to participate in larger clinical trials and receive the most advanced medicines and treatment protocols.

HCI has access to unique assets such as the Utah Population Database (UPDB), a collection of millions of genealogic, birth, death, and marriage records linked to health data. HCI has managed the UPDB for nearly two decades, providing critical information helping to advancing the understanding of cancer biology, prevention, and early detection.

In January 2005, the HCI joined with Intermountain Healthcare to create the Huntsman–Intermountain Cancer Care Program. This program combined HCI’s leadership in laboratory, population sciences, and clinical research with Intermountain’s expertise in clinical quality improvement and program development, thus allowing HCI researchers to use data about cancer care and outcomes from throughout the mountain states region. Through this alliance, the spectrum for cancer research from causes, delivery of care, at-risk populations, and prevention is diversified. HCI is designated as an NCI-designated cancer center. Being an NCI-designated cancer center reflects HCI’s high standards for cancer care and research and demonstrates its support for scientific endeavors through investment of significant resources into the development of high-quality research programs, faculty, and facilities dedicated to the prevention, diagnosis, and treatment of cancer. As of this date, there are 68 NCI-designated centers, making HCI part of a unique national network. Membership in this community of NCI-designated cancer centers allows HCI to participate in future NCI strategic plans and initiatives as well as representing its own community in the national dialogue about cancer treatment. HCI is one of 25 institutional members of the NCCN, a nonprofit group of cancer centers whose sole focus is the improvement of the quality, effectiveness, and efficiency of cancer care. Membership in the NCCN gives HCI partnership opportunities with other NCCN member institutions for sharing resources such as clinical content, research, and educational programs.

Education

HCI established the cancer learning center (CLC) as a part of its commitment to provide information about cancer risk, prevention, and care, not only to patients with cancer but to the general public as well. CLC provides reliable cancer information with the goal of reducing patients’ fears about cancer, helping them become informed decision makers, and educating members of the public about cancer risk reduction. Since the establishment of the CLC, it has been recognized as a model program for cancer education, serving patients from almost every state in
the United States. The information is provided free of charge to HCI patients and to the general public. Information requests are accepted via telephone, via e-mail, or in person. Trained health educators have print and online materials as well as HCI doctors and nurses to assist in answering individual questions.

Utah is home to seven Native American tribes or nations, and HCI dedicates special programming designed to meet the needs of Native Americans for cancer education, screening, and care. As a culture that has been greatly affected by cancer, this HCI community outreach program demonstrates respect for Native American culture and tradition while working to assist and educate members of this culture about cancer. To further public awareness and education within the community, HCI presents the Inaugural Cancer Awareness Expo. This exposition is a free-to-the-public event featuring talks by cancer care providers, with booths staffed by lab researchers and free cancer screenings. To date, HCI has offered more than 100 health conferences and hundreds of presentations to schools and community groups.

State-of-the-Art Patient Care
HCI employs almost 1,500 health care providers and staff as well as having a substantial group of volunteers. The University of Utah Health Care System, which includes the HCI, has been ranked in the top 10 percent for three years in a row. HCI offers an extensive number of specialized cancer treatments and a new program, Supportive Oncology Service, which provides additional support for not only the cancer patients but their friends and families as well. HCI’s commitment to quality extends to their research, with the research branch housing 170 faculty researchers. HCI has been awarded $57.5 million in grant funding, and at any given time has more than 200 cancer clinical trials ongoing. Their research has been recognized with awards from The V Foundation for Cancer Research V Scholar Award, the Samuel Waxman Cancer Research Foundation Award, and the Damon Runyon Foundation for Cancer Research Award. HCI also demonstrates a high level of commitment to future generations of cancer researchers and care providers through their postdoctoral fellows, clinical fellows, masters and doctoral cancer-focused programs, and specialized oncology training for nurses.

Hypopharyngeal Cancer

The hypopharynx is the area of the neck where the larynx and esophagus meet. The hypopharynx is the bottom part of the pharynx, or throat, which is a hollow tube that is about five inches long. This acts as a passageway for food and air on their way to the esophagus. Hypopharyngeal cancer is a malignant tumor of this portion of the aerodigestive tract. Since the lining of the pharyngeal mucous membrane is primarily composed of squamous cells, more than 95 percent of malignant tumors in this area are squamous cell carcinoma. This type of
Hypopharyngeal Cancer

Cancer poses a high risk of metastasis via the lymphatic system. Hypopharyngeal cancer is relatively rare in comparison to other more common malignancies. Only approximately 2,500 cases are diagnosed in the United States each year, representing about 7 percent of all cancers of the upper aerodigestive tract. The relative male to female incidence in the United States is 3:1. Incidence of the disease is rare in patients younger than 30 years old, and rises after 40 years old. The mean age at diagnosis is 65 years. Because of its rarity and the absence of early symptoms, hypopharyngeal cancer is not usually detected in its initial stages. Most cases are diagnosed in the end stage, in which there is metastasis to other regions of the body. For this reason, this malignancy exhibits one of the highest mortality rates of any head and neck cancer. The prognosis for the end-stage patient is poor, with only 10 percent surviving for five or more years.

There are a number of symptoms that may be indicative of the presence of this cancer. Swollen lymph nodes in the neck are seen as the first sign in about one-half of presenting patients. A persistent localized sore throat that resists treatment, with pain that radiates up to the ears, is suspicious. The specific sore throat pain symptom for cancer is unilateral, rather than the generalized pain from an infectious inflammatory sore throat. In the late stage, blood streaked saliva, difficulty in swallowing, resultant weight loss, or voice changes may be observed. This morbidity is from the intrusive tumor causing pain, bleeding, and, in very advanced stages, airway obstruction from growth into the larynx.

Contributory factors to the development of this malignancy include smoking, chewing tobacco, heavy alcohol intake, and nutritional deficiencies of iron and certain vitamins. Tobacco smoke contains carcinogens, and similar to its causative effect in lung cancer, it alters the RNA or DNA during cell division. This can produce an oncogene, a gene that causes malignancy because of exposure to a carcinogen. Chewing tobacco can cause similar effects in that saliva partially digests the carcinogenic component, and when swallowed, it passes through the hypopharynx. Alcohol damages the lining of the hypopharynx, allowing toxic chemicals to penetrate the underlying membranes. A genetic disorder called Plummer-Vinson syndrome may contribute to this cancer because it causes long-term iron deficiency. Poor nutrition and resultant vitamin deficiencies can be contributory.

There are several ways in which the physician may arrive at a diagnosis of hypopharyngeal cancer. First is physical examination to detect swollen lymph nodes, and direct observation of the inside of the throat with a long-handled mirror. A more thorough modality of direct observation is endoscopy. Here, a lighted tube is inserted through the nose or mouth, allowing observation further down the throat into the esophagus or trachea. A small tissue sample may be excised for biopsy, to be analyzed for the presence of malignant cells. The physician may call for a computed tomography (CT) scan or magnetic resonance imaging (MRI) to gain a more definitive picture of any abnormalities in the body of the patient.

Once the positive diagnosis is made, there are a variety of treatment options, depending on the stage of the disease, comorbidities, and the general health status of the patient. One or more of the triumvirate of surgery, radiation therapy, or chemotherapy may be employed. Traditionally, surgery and radiotherapy were the primary treatment modalities. In recent years, chemotherapy has been added to the mix. In the early stages of the disease, surgery or radiotherapy is usually the treatment of choice, with the goal of eradicating the malignancy and preserving organ function. However, most patients present with advanced disease, including regional or distant metastases. In those cases, initial surgery followed by postoperative radiotherapy and chemotherapy are the preferred options. In some advanced cases, neoadjuvant chemotherapy, that is, chemotherapy administered to reduce the malignancy prior to surgery and radiotherapy, may be employed. Treatment goals include control of the disease, prolongation of survival, or simply to allow the patient to talk, eat, and breathe in as normal a fashion as possible. In summary, treatment may consist of radiation therapy prior to or following surgery, in some cases with chemotherapy. Or the treatment team may elect chemotherapy followed by surgery and/or radiation therapy; chemotherapy given at the same time as radiation therapy; or surgery followed by chemotherapy given at the same time as radiation therapy. Treatment may also include reconstructive surgery to restore eating, breathing, or talking if all or part of the hypopharynx is removed.

Management of this disease can present a vexing challenge to the physician because of its aggressive nature.
nature and its location in proximity to other critical structures, especially the proximity of several large lymphatic vessels that can spread malignant cells to other regions of the body. Because of the low incidence of this malignancy, a preponderance of clinical data on the ideal combination of therapeutic modalities is somewhat limited, although significant progress has been observed in recent years.

Hypothalamic and Visual Pathway Glioma, Childhood

Optic pathway hypothalamic glioma (OPHG) is a rare type of brain cancer representing 2 to 7 percent of all pediatric intracranial tumors, with 65 percent of tumors presenting in children less than 5 years of age. These tumors occur anywhere along the visual pathway, including the optic nerve or optic chiasm, and may also be found in the hypothalamus, the area of the brain responsible for controlling body temperature, hunger, and thirst. The term *glioma* refers to a tumor with similar microscopic cellular features to normal glial cells, including astrocytes (*astrocytoma*), oligodendrocytes (*oligodendroglioma*), and ependymal cells (*ependymoma*). Further classification of the glioma can be made based on the World Health Organization (WHO) grading system ranging from low grade (I, II) to high grade (III, IV), providing the basis for diagnosis and prognosis as well as treatment options for those patients who possess a specific glioma. OPHG are nearly always low-grade tumors, the majority of which are pilocytic astrocytomas (WHO grade I), although a small proportion are pilomyxoid astrocytomas and rarely grade II tumors. A significant percentage of OPHGs (10–70 percent) occur alongside the genetic disease neurofibromatosis type 1 (NF-1).

Association to NF-1
There is a marked increase in risk of developing an OPHG for children with neurofibromatosis type 1. This rare genetic condition presents with brown spots and tumor growth on the skin, freckling in places on the body (like the armpit) that are not exposed to sunlight, and tumor growth on nerves.

Symptoms
The symptoms of OPHGs generally manifest over months to years and vary depending on the location of the tumor. Those tumors found behind the eye demonstrate a forward protrusion of the eye known as proptosis. Vision loss is relatively uncommon, most likely due to the young age of the patients at presentation. Examination of the eye may demonstrate fluid accumulation, known as edema of the optic disk, or a pale color due to cell death (atrophy) at the optic disk.

OPHGs located at the optic chiasm and the hypothalamus present as large masses, although they are most commonly low-grade gliomas. Those with tumors at the optic chiasm often present with impaired vision and obstructive hydrocephalus, in which the cerebrospinal fluid accumulates due to the inability of cerebrospinal fluid (CSF) to flow into the subarachnoid space. Due to the resultant increase in intracranial pressure, infants may suffer
from symptoms such as vomiting, drowsiness, irritability, constant downward gaze, or seizures.

Those patients with hypothalamic gliomas may also present with a rare condition known as diencephalic syndrome, where the affected infants present with symptoms that include failure to gain weight and grow as would be expected upon age and gender, and they may also display progressive thinness and weakness known as emaciation. These patients may display a cheerful, alert external demeanor that is in stark contrast to their outward appearance.

Dysfunction of the endocrine hormones due to extension of the tumor into the hypothalamus occurs in 10 to 20 percent of patients with OPHGs. The most common problem is precocious puberty, where the patient undergoes puberty far sooner (before the age of 7 or 8) than would be expected. This is due to the disruption in the signaling among the hypothalamus, pituitary glands, and gonads, occurring in 39 percent of children with NF-1 and tumors of the optic chiasm.

The symptoms of patients with OPHGs differ between those with NF-1 and those without. Primarily, patients without NF-1 more commonly present with signs of increased intracranial pressure and hydrocephalus, while those with NF-1 associated OPHGs are more likely to present with precocious puberty.

**Diagnosis**

The use of magnetic resonance imaging (MRI) provides the best diagnosis of OPHG, allowing for full visualization of the entire optic pathway as well as potential involvement of the tumor into the hypothalamus. Computed tomography (CT) imaging is superior for bone detail and the detection of calcification within the tumor, a sign suggestive of a low-grade tumor.

Three typical patterns seen during imaging studies are thickening of the optic nerve and optic chiasm, tumor in close proximity to the hypothalamus contiguous with optic nerve involvement, and tumor in close proximity to the hypothalamus contiguous with optic tract involvement.

A biopsy is a surgical procedure to remove a small sample of brain tissue for examination under a microscope in order to determine the type and severity (malignancy) of the tumor present. Many children with OPHGs do not undergo biopsy in order to preserve the function of the patient’s optic nerve, and this is especially the case if the patient has had a prior diagnosis of NF-1.

**Clinical Course and Prognosis**

The behavior of OPHGs is unpredictable, ranging from spontaneous regression of tumor, aggressive malignant progression, and metastasis or spread of the tumor to other regions of the brain. Due to the fact that most OPHGs in children are generally benign, low-grade tumors, the variation in clinical course is generally a product of the location of the tumor rather than the specific cellular features.

For those tumors of the optic nerve located within the skull or the orbit of the eye, the median survival is greater than 15 years. There is a small risk (5 percent) of optic nerve tumors invading the optic chiasm, and recurrence of tumor may also develop following complete surgical removal of the tumor. The risk of recurrence, however, for those children with NF-1 is twice that of patients without NF-1 following complete surgical removal of the tumor.

**Treatment**

Current standard treatment strategies are controversial, challenging pediatric oncologists, due to the central site of involvement, the variation in clinical course, and the disease modifying effect of NF-1. The initial course of treatment is generally MRI imaging accompanied with ophthalmologic examinations. More active treatment is generally reserved for those patients with progressive decline in vision or significant changes in the nature of the tumor as seen on MRI imaging. Surgical removal of the tumors is rare as the risks of visual deficits, endocrine hormone dysregulation, and vascular complications of the brain increase.

Radiation therapy remains the mainstay of treatment. However, in recent years, the use of chemotherapy has become prevalent for those patients less than 10 years of age. The utilization of chemotherapy to shrink the size of the tumor works to avoid or at least postpone the use of radiation, which is often detrimental to development of a child’s immature brain.

Immigrant Populations

Immigrant populations face language, financial, and cultural barriers to obtaining cancer care. Americans show progress in their cancer survival rates in recent years, but foreign-born individuals display more diversity in their rates of cancer survivorship. Other developed countries demonstrate similar diversity with foreign-born populations. This entry addresses the current research on immigrants and cancer.

Patterns of Cancer Trends

P. S. Pinheiro and colleagues reviewed cancer rates of Hispanics and Latinos according to geographic origin (e.g., Mexico, Puerto Rico, and Cuba) in Florida. A Hispanic male cancer rate of 537 per 100,000 came out at a lower rate than the white male cancer rate of 601 per 100,000, whereas the female rates compared similarly and showed a Hispanic female cancer rate of 376 per 100,000 and a white female rate of 460 per 100,000, respectively. Among Florida Hispanics, Puerto Ricans showed the highest rates followed by Cubans and then Mexicans with the lowest rates.

According to I. Olver, F. Marine, and P. Grogan in 2011, the immigrants to Australia come from diverse backgrounds and show a reduced incidence of common cancers (colon, breast, prostate, and melanoma) and less overall mortality in these common cancers. The immigrant population represents 24 percent of the Australian population. However, the immigrant population displays higher rates of lung, stomach, liver, cervix, thyroid, and bladder cancer. These immigrants exhibit a distinct spectrum of cancer with more liver cancer from exposure to hepatitis B and C infections.

In 2012 R. Siegel, D. Naishadham, and A. Jemal demonstrated a lower incidence of cancer in Hispanics for breast, prostate, lung, and colorectal cancer; however, the researchers found an elevated incidence and mortality rate for stomach, liver, uterine, cervix, and gallbladder cancers in the Hispanic population. These higher rates possibly relate to cancer-causing infectious agents, reduced screening for cervical cancer, differences in lifestyle or food intake, and genetic factors. Implementing screening, vaccines, and proven interventions for obesity, smoking, and alcohol intake could reduce the incidence of the higher rates of cancers in Hispanics.

Breast cancer incidence continues to rise globally as it is the leading cause of cancer mortality in low- and middle-income countries. In 2012 O. Beiki and colleagues employed the Swedish nationwide registers to look at socioeconomic and immigration patterns in Sweden. The database encompassed a cohort of women between 1961 and 2007. The incidence in the immigrants produced a low result with an incidence rate ratio (IRR) of 0.88 (95 percent confidence interval [CI] = 0.86 to 0.90) but not for the daughters of the immigrants, who
Immigrant Populations

showed an IRR of 0.97 (95 percent CI = 0.94 to 1.01) in comparison to native Swedes. A further thought-provoking statistic found the case fatality rate of breast cancer to be 14 percent higher if diagnosed after age 50 in the immigrant population compared to native Swedes. The lower risk of breast cancer in the immigrant women compared to their daughters calls for further research on lifestyle factors to ascertain the differences in the two groups.

A cross-sectional survey in a Danish study by G. P. Kurita, P. Sjogren, K. Juel, J. Hojsted, and O. Ekholm found that individuals with non-Western backgrounds described an elevated pain prevalence, higher pain intensities, and more widespread body pain over individuals of Danish background; however, native Danes consumed more opioids at a higher rate than foreign-born individuals. These results indicate diversity exists in treatment of pain in cancer between the immigrant population and Danish population despite higher pain in the immigrant individuals.

A Canadian study by G. M. Carriere, C. Sanmartin, H. Bryant, and G. Lockwood in 2013 found areas of high concentration of foreign-born individuals demonstrating an all-cause cancer rate of 388 per 100,000 compared to individuals in low concentrations of foreign-born of 493 per 100,000. This pattern ensued for lung, colorectal, prostate, and breast cancer but did not emerge for liver, nasopharynx, and thyroid cancers. These results contain evidence suggesting lower cancer risk in foreign-born populations for a majority of cancers except nasopharynx, liver, and thyroid cancers.

D. K. Nguyen and M. Maggard-Gibbons reviewed incidence of gastric cancer in 2013 using the Surveillance, Epidemiology, and End Results (SEER) registry. Analysis of 42,187 patients from 1980 to 2009 in the SEER registry found individuals residing in high-immigration areas and foreign-born patients both demonstrated low rates of mortality, 0.74 and 0.87, respectively. So high-immigration areas and foreign born receive no disparity in cancer-directed therapies and survival after resection, as shown by the SEER registry results.

Research by K. Richardson, S. Jatrana, M. Tobias, and T. Blakely in 2013 found Pacific immigrants in New Zealand demonstrated lower all-cause cancer mortality. The lower rates existed in the group living in New Zealand for less than 25 years compared to a higher rate for immigrants living there more than 25 years. No difference was found for mortality between overseas born and New Zealand born for Pacific immigrants living in New Zealand.

Genetic studies by E. Corona and colleagues in 2013 found that patterns of disease changed with human migration. The researchers studied 102 diseases across 51 populations using the Human Genome Diversity Panel. A genetic-associated risk for pancreatic cancer decreased as individuals migrated toward East Asia. These studies pave the way for further investigation of migration effects on the genetic foundation of disease.

Research in the Netherlands by M. Arnold and colleagues in 2013 uncovered a higher rate of nasopharyngeal carcinoma due to differentiated, nonkeratinizing tumors. This increase of cancer appears to be related to Epstein-Barr virus infection and to an increase in immigration of people from China and North Africa. At the same time, the incidence of nasopharyngeal carcinoma due to keratinizing tumors decreased over the 20 years in nonforeign-born individuals.

S. M. Mousavi, A. Forsti, J. Sundquist, and K. Hemminki in 2013 employed the Swedish Family-Cancer Database to review death from female breast cancer in 12,505 and 137,547 subjects (immigrants in Sweden and Swedes, respectively) diagnosed with breast cancer. This study indicated that immigrant Turks, Southeast Asians, and Chileans displayed the lowest breast cancer risk, at a 0.44 incidence ratio, and immigrant Iraqis had the most-elevated risk of 1.19, compared to the Swedish subjects.

Cervical cancer screening and risk behaviors differ between U.S.- and foreign-born Hispanic women. J. R. Montalegre, R. Zhou, E. S. Amirian, and M. E. Scheurer found that Hispanics represent a heterogeneous group, with many members of the Hispanic group being nonforeign born using SEER data. Their results showed foreign-born Hispanic women with significantly elevated late-stage diagnosis of cervical cancer. The study also demonstrated differences in nativity (birth location) and survival by stage of diagnosis. Foreign born with early stage diagnosis showed poorer survival, with a hazard ratio (HR) of 1.31, whereas foreign born with late-stage diagnosis depicted better survival, with an HR of 0.81. The researchers believe it is inappropriate to lump Hispanics into one single group for cervical cancer studies.
Montealegre and colleagues in 2014 again used the SEER data file to look at missing data on birthplace of foreign-born individuals. Their results showed data missing for cervical, prostate, and colorectal cancer subjects. The researchers used multiple imputations of variables (e.g., diagnosis, treatment, and survival) in the SEER data file to accurately determine foreign-born status. Using the strategy developed by Montealegre and colleagues, nativity-related cancer disparities can be corrected for analysis of vulnerable populations like the foreign born.

Using the California Cancer Registry from 1995 to 2008, C. W. Schupp, D. J. Press, and S. L. Gomez in 2014 evaluated the impact of nativity (birth location) and neighborhood-level enclave (living in a community of Hispanics) on prostate cancer survival in Hispanics in California. The researchers studied 35,427 Hispanic males with invasive prostate cancer. The foreign-born Hispanics demonstrated a significantly lower risk of prostate cancer survival with an HR of 0.82 (95 percent CI, 0.75–0.87); in addition, if the foreign-born Hispanics lived in their ethnic enclave, the survival HR improved even more, with an HR of 0.79 (95 percent CI, 0.71–0.86) compared to U.S.-born Hispanics. These results indicate a better survival in Hispanic immigrants over U.S.-born Hispanics for prostate cancer.

Conclusion

Reviewing the current research in the cancer of immigrants demonstrates some diverse results in risk and screening profiles. Research on immigration populations in multiple countries indicates the need to study subgroups separately. An example is Hispanics from Cuba, Mexico, and Puerto Rico, who represent very heterogeneous groups. Many other developed countries demonstrate similar diversity in their incidence and mortality rates in different types of cancer. Foreign-born individuals frequently demonstrated significantly lower rates of common cancers (colon, breast, and prostate) but frequently significantly higher rates of stomach, liver, cervix, thyroid, and bladder cancer. These studies provide a starting point to study characteristics of the immigrant population to determine what attributes reduce their risk of common cancers.

India

India, a country inhabited by more than 1.2 billion people, is facing a tremendous challenge in rising cancer rates, the second-most common disease and one of 10 leading causes of death in India, accounting for the maximum mortality with about 0.4 million deaths per annum. The cancer deaths add up to about 6 percent of all adult deaths in India. The current 2.5 million cancer cases are increasing at the rate of 0.8 million new cancer cases per year. Along with the current high prevalence, cancer mortality is projected to increase to 1.2 million by 2035. India has taken some concrete steps in establishing a robust infrastructure and is a member of many global alliances to curb cancer, but it still needs to allocate significantly more resources to deal with this emerging challenge.

Causes

Apart from the globally prevalent general causes of cancer, some specific reasons are salient in the Indian context. The national cancer registry data indicated that oral cavity, lungs, esophagus, and stomach among men and cervix, breast, and oral cavity among women were the leading cancer sites. Researchers identified tobacco as the most important cause, and its use accounted for about two-fifths of all cancers in India, responsible for 40 to 50 percent of cancers in men and 20 percent of cancers in women. The mainly smokeless tobacco users in India number about 275 million, constituting 35 percent of the adults and 14.1 percent of children in the age-group of 13 to 15 years. In addition, changing dietary habits, increasing carcinogens in the environment, increased alcohol consumption, radiation exposure, and harmful lifestyles constitute the other contributory factors to the increasing cancer incidence. This is underlined by the effect of social factors, like inequalities and inequities that form some major determinants of the Indian cancer burden, with the poor more likely to die from cancer than the rich.

Impact

Apart from the health mortality and morbidity impact, cancer has severe emotional and economic effects on individuals and families. According to 2002 and 2003 estimates, the economic costs of cancer in India add up to nearly $5 billion in direct and indirect costs. Researchers noted that the tobacco consumption costs in India exceed the total budgeted expenditure estimates by the Indian government on essentials like public health, sanitation, and water supply. These economic inequities result in further disparities down the line, where the poor and vulnerable are the most affected by different forms of cancer; for example, the rural poor constitute 90 percent of the oral cancer patients, and women with breast cancer have been mostly detected in low socioeconomic strata. Further, the families of cancer patients incurred increased, unsustainable expenses on detection, treatment, and management of the disease, and 2010 estimates put a quarter of such families in an impoverished condition. These costs also eat away at the family and social capital, thus putting the entire health and social system at risk.

Policies and Interventions

India’s response to cancer is mainly through its National Cancer Control Program (NCCP), launched in 1975 with the triple aims of early detection, primary prevention, and prompt treatment. The NCCP, followed by the subsequent National Program for Prevention and Control of Cancer, Diabetes, Cardiovascular Diseases, and Stroke in 2010 and National Rural Health Mission in 2005, has positively impacted cancer health care services and human resources but with poor awareness, detection, and survival outcomes. The program has been drafting and implementing strategies linked to
the Indian five-year plans leading to the establishment of regional cancer centers, oncology wings in select government medical colleges, infrastructure development, and the initiation of a cancer program at the district governance level. India is also one of the first signatories and members from developing countries in the International Agency for Research on Cancer (IARC) that has ratified the World Health Organization tobacco control framework.

But none of the activities of the NCCP have been sustainable or leveraged into long-term results. As of now, the Indian government has revised the NCCP with five new schemes, which recognize new regional cancer centers (RCCs) by providing a one-time grant of $0.8 million, strengthening of existing RCCs with a $500,000 grant and development of oncology wings in government medical installations, increasing district cancer control programs, and involving nongovernmental organizations (NGOs) and civil society in information education and communication (IEC) activities. The current program is a part of the National Program for Prevention and Control of Cancer, Diabetes, Cardiovascular Diseases and Stroke, which lumps cancer with all the other noncommunicable diseases. The figures show the minuscule funding and resources pointing at the need for significant funding and policy attention to combat cancer in India. The population-based registries only cover about 7 percent of patients with cancer. The per-capita government cancer spending in India is a scant $641, compared to $2,202 in China and $86,758 in the United States. In addition to increased allocations for strengthening the health system and infrastructure on cancer prevention, diagnosis, and treatment services, protection systems must be developed to help individuals and families cope with adverse financial consequences, social support needs, and other expectations.

Other Challenges
One significant challenge is to map the cancer incidences in the vast population groups and areas in India and increase the coverage of people under the population-based cancer registries. India, with its ancient past and diversity, also poses a complex social environment, attitudes, and beliefs for cancer prevention and other communication strategies. Gender relationships, caste, social hierarchy, and stigma add to the complexities. Other challenges include low health service effectiveness, lack of trust in health service providers, and low medical service use. The large numbers of poor and rural people and health and socioeconomic disparities create further challenges and also underline the affordability of care.

Conclusion
India needs significantly more resources and programs to address the increasing cancer incidences and outcomes in its population. A fundamental need is to recognize cancer as a serious public health challenge and demonstrate strong political and bureaucratic commitment and action. The links of cancer with the socioeconomic fault lines and disparities in India need to be recognized and addressed. A crucial determinant would be how India negotiates the entrenched social inequalities and allocation and distribution of resources. Public health initiatives; legislation; convergent health policies; increased public health spending; leadership at national, district, and block levels; and
communication campaigns focusing on major social determinants of health are key to the strategy.

Indonesia

This southeastern Asian nation, officially termed the Republic of Indonesia, was created in 1949 after the citizens of the country established their independence from Dutch colonial rule. In the ensuing decades, Indonesia was the site of political turmoil concerning governance. However, the nation has stabilized considerably in the past 15 years. Currently, Indonesia is the fifth-most populated country on Earth, with nearly 240 million citizens. Indonesia is a unique nation as it is an archipelago comprised of more than 13,000 individual islands. Researchers presently estimate that cancer is the second-leading cause of death in the country.

Cancer control efforts in the territory of Indonesia date back to 1920, when Dutch administrators of the chain of islands enacted cancer treatment programs there. Various cancer control efforts in the country were spawned from this initial Dutch effort until 1942, when Japanese military forces occupied Indonesia and shut the programs down. After Indonesia gained its independence in the ensuing years, it took until 1962 for the next domestic cancer control program to be initiated in the nation in the form of the Indian Foundation for Cancer Control. Since then, many organizations have been formed with the goal of battling Indonesia’s domestic cancer incidences, such as the creation of the Indonesian Cancer Society in 1977 and the Jakarta Cancer Center Hospital in 1993.

There are currently no nationwide cancer registries in use in the country as the government has not procured the finances or the staff to manage cancer data deriving from the more than 13,000 islands of the Indonesian state. As the country is composed of 27 provinces, 241 districts, 55 municipalities, 3,501 subdistricts, and 66,979 villages, it would be a uniquely monumental effort to compile an accurate and effective national cancer registry. Instead, information regarding Indonesian cancer incidences and trends are garnered from regional hospitals and universities, where most Indonesian cancer patients are referred for treatment. Research and registration efforts in the country are regarded as relatively rudimentary, though cancer treatment facilities in the country have been hailed as proficient and strengthening.

Tobacco usage is currently uniquely high within the male Indonesian population, with nearly 70 percent of all Indonesian males being smokers. Such high usage rates have created the conditions for a robust lung cancer problem in the nation. Furthermore, on average, Indonesian lung cancer patients have been shown to be diagnosed with lung cancer when the disease is in its latest stages, making treatment options poor. As an Indonesian lung cancer patient’s chance of surviving the disease is estimated currently at being around 15 percent, there is much work that needs to be done in order to stem the tide against domestic incidences of lung cancer. Fortunately, the Indonesian government is now taking steps to enact extensive antitobacco legislation as well as to mandate that domestic tobacco companies use less toxic elements in their products. All in all, there is hope that the targeted efforts of the Indonesian government will bring down the incidences of lung cancer in the country.

While it is difficult to estimate the exact amounts of cancer incidences in Indonesia because the nation lacks a national cancer registry, in recent years, researchers estimate that the most prevalent forms
of cancer in Indonesia are bowel cancer, breast cancer, liver cancer, lung cancer, lymphomas, and oral cancer. Lung, bowel, and liver cancers are the most predominant forms of cancer incidences in males in the nation, while cervical, breast, and bowel cancers are the most common types of incidences of cancer in females there. Nationwide, incidences of esophageal cancer have been decreasing over the past several years, and incidences of soft tissue cancer have been steadily declining.

Regarding cancer, the future is positive for Indonesia. The country presently has more than 20 cancer treatment centers where the nation’s nearly 300 oncologists provide their highly specialized services. On top of this, new cancer treatment centers are being created, and new domestic oncologists are being trained every year. As treatment options for Indonesian cancer patients improve, more steps will need to be taken by the Indonesian government in order to further combat the disease, such as by creating an effective national cancer registry.

Infection

There is a strong association between sexually transmitted infections (STIs) and cancers. Specifically, STIs such as human papillomavirus (HPV) and human immunodeficiency virus (HIV) place individuals at increased risk for the development of cancers, researchers say, including cervical cancer, anal cancer, Hodgkin’s lymphoma, liver cancer, leukemia, and lung cancer. A malignancy increases risk of recurrence or second malignancy as compared to those without a history of cancer, according to the National Cancer Institute (NCI). STIs and cancer account for a substantial amount of national health care expenses and lost wages due to illness and represent two of the largest public health burdens in the United States, reports the Centers for Disease Control and Prevention (CDC). Therefore, the link between STIs and cancer is extremely important to the public health and economic health of the nation.

One of the most serious threats to public health in the United States is the HIV epidemic. Approximately 1.1 million people in the United States are infected with HIV. Individuals living with HIV have a higher risk of certain cancers than uninfected individuals due to the deleterious impact that this disease has on the immune system. In fact, the development of cancers such as Kaposi’s sarcoma,
non-Hodgkin’s lymphoma, and cervical cancer denotes a transition from HIV infection to acquired immune deficiency syndrome (AIDS). In addition to these AIDS-defining cancers, those with HIV are at increased risk for anal, liver, and lung cancer, which may be due to individual-level risk behaviors such as smoking and alcohol consumption.

Two of the most common cancers among people living with HIV are Kaposi’s sarcoma and non-Hodgkin’s lymphoma. Kaposi’s sarcomas that develop as a result of progressive HIV are called epidemic Kaposi’s sarcoma. Kaposi’s sarcoma is life threatening because of its potential to affect the lymph nodes and other organs, such as the digestive tract, lung, liver, and spleen. All lesions caused by Kaposi’s sarcoma contain human herpes virus-8 (HHV-8). However, individuals who are infected with HHV-8 may not necessarily develop Kaposi’s sarcoma. People with compromised immune systems are at increased risk of developing Kaposi’s sarcoma. Therefore, people living with HIV are more likely to have HHV-8, which can develop into epidemic Kaposi’s sarcoma.

Non-Hodgkin’s lymphoma impacts the white blood cells and lymph nodes and, as a result, impairs the body’s immune system. Non-Hodgkin’s lymphoma can cause seizures, facial paralysis, confusion, memory loss, and fatigue. There are two types of non-Hodgkin’s lymphomas: aggressive (i.e., fast growing) and indolent lymphomas. Each type of lymphoma can be comprised of either B-cells or T-cells. People living with HIV are more likely to develop an aggressive non-Hodgkin’s lymphoma than an indolent type. Non-Hodgkin’s lymphoma that develops as a result of immune-compromise related to HIV is called AIDS-related lymphoma. Diffuse large B-cell lymphoma, B-cell immuno-blastic lymphoma, and small, non-cleaved cell lymphoma are the main types of AIDS-related lymphomas. These types of lymphoma are considered AIDS defining because their development is a sign of a significantly weakened immune system as indicated by extremely low CD4 cell counts (i.e., white blood cell count lower than 200), which is considered the threshold for an AIDS diagnosis.

Fortunately, both Kaposi’s sarcoma and non-Hodgkin’s lymphoma are treatable. The standard of care for Kaposi’s sarcoma includes radiation therapy, chemotherapy, surgery, and biologic therapy. Radiation therapy usually uses photon or electron beams to kill or stop the growth of cancer cells. Chemotherapy uses a variety of drugs to stop the growth of cancer cells. Usually, chemotherapy drugs are administered orally, intravenously, or intramuscularly. In the case of Kaposi’s sarcoma located in the mouth, chemotherapy agents may be injected directly into the lesion, which is called intralesional chemotherapy. Alternatively, Kaposi’s sarcoma of the skin may be treated with a topical chemotherapy agent such as a gel or lotion. Another type of chemotherapy that is used to treat Kaposi’s sarcoma is liposomal chemotherapy. Liposomal chemotherapy uses fat particles to carry anticancer drugs, such as doxorubicin, to the site of the lesion. When the fat particles build up in the lesion, they excrete the doxorubicin. The method maximizes the effects of the doxorubicin while minimizing damage to healthy tissue. Surgery may also be used to remove the tumor or surrounding lesions, reports the American Society of Clinical Oncology (ASCO).

Local excision, curettage, electrodessication, and cryosurgery are the most common surgical options to treat Kaposi’s sarcoma. Local excision involves cutting cancerous cells and a small amount of normal tissue from the skin. Curettage and electrodessication involves cutting a tumor or lesion from the skin with a sharp tool and then using an electrode to treat the area to stop bleeding and destroy any cancerous cells on the edge of the surgical wound. Cryosurgery uses liquid nitrogen to freeze and kill cancerous cells. Biologic therapy uses the patient’s own immune system to fight cancerous cells. This type of therapy uses substances made by the patient’s body or artificial substances produced in a laboratory to boost, direct, or restore the patient’s immune system in the service of building a defense against cancer. Palliative care, which includes medication, nutritional changes, and other therapies, is used to treat HIV/AIDS-related Kaposi’s sarcoma. Although this does not cure the cancer, it helps relieve pain and other symptoms.

The standard of care for non-Hodgkin’s lymphoma is similar to the treatment for Kaposi’s sarcoma. Treatment usually involves monotherapy or combination therapy, including radiation therapy, chemotherapy, targeted therapy, plasmapheresis, biologic therapy, and watchful waiting. As described, radiation therapy involves the
elimination of cancerous cells through the administration of either high-energy X-rays or radioactive substances to the patient. The site and method of radiation depend on the type of lymphoma. Chemotherapy can also be used to treat non-Hodgkin's lymphoma. Some types of non-Hodgkin's lymphoma may spread to the brain and require central nervous system prophylaxis, which is chemotherapy that kills cancer in the brain or spinal cord. Target therapy uses drugs to identify and kill specific cancerous cells without damaging healthy cells. Two common drugs used in targeted therapy to treat non-Hodgkin’s lymphoma are a monoclonal antibody and a proteasome inhibitor. Monoclonal antibodies identify substances and kill cancerous cells by blocking their growth or keeping the cancerous cells from spreading to healthy cells and tissue. Protease inhibitors block the action of the proteasomes of cancerous cells, impairing their ability to replicate. Plasmapheresis involves removing extra plasma and antibody proteins from the blood when the blood becomes thick due to the excess of plasma and affects circulation. During the procedure, blood is removed from the patient, the blood cells and plasma are separated, and the blood cells are returned to the bloodstream without the plasma. A specific type of biologic therapy called interferon is used to treat non-Hodgkin’s lymphoma. This substance interferes with the division of the cancerous cells and slows cancer growth. Last, watchful waiting closely monitors a patient’s condition without direct intervention. Intervention may be recommended when the patient’s symptoms appear to change or worsen.

Although these treatments are efficacious, they are not without their challenges. There are complexities associated with simultaneous HIV and cancer treatments due to the debilitating nature of HIV infection and chemotherapy on the immune system. The treatment for individuals who are infected with HIV with a comorbid cancer diagnosis depends on the type and stage of cancer but often consists of standard cancer treatments coupled with highly active antiretroviral therapy.

Preparation of a human papillomavirus (HPV) vaccination. HPV is the most common sexually transmitted infection and plays a causal role in several types of cancers, although cervical and anal cancer are the two most common cancers associated with HPV. Recent efforts to reduce cervical cancer led to the development of vaccines protecting against specific types of HPV. (Flickr/PAHO/WHO)
Infection

(HAART) for HIV. However, HAART medications may interact with medications used to treat cancer, which necessitates a need for the management of both diseases and treatments by a doctor who has experience with these diseases.

HAART is used in conjunction with cancer treatments and afterward for people living with HIV. The use of HAART allows for the effective control of the HIV virus, which is advantageous because it decreases the side effects of cancer treatments, decreases the chances of recurrence, and improves the odds of recovery from cancer. Other cancer treatments for individuals living with HIV infection include radiation therapy, chemotherapy, immunotherapy, and target-related therapy. The selected treatment for cancer in individuals with HIV infection will be determined by a skilled and experienced physician who must take into consideration the stage of HIV infection and the severity and type of cancer for which a person has been diagnosed.

HPV is the most common sexually transmitted infection. Prevalence rates range from 40 to 49 percent in the general population. HPV plays a causal role in cervical, vaginal, vulvar, penis, anal, and oral cancers. However, the two most common cancers associated with HPV are cervical cancer and anal cancer. In fact, researchers have found that HPV accounts for all cases of cervical cancers and 85 percent of all anal cancers. Cervical cancer is the second-most common cancer among women worldwide, according to the World Health Organization (WHO), and left untreated, cervical cancer can be fatal. However, due to the increase in the use of Pap tests, the number of cervical-cancer-related deaths has declined by 70 percent. Anal cancer is less common than cervical cancer. Approximately 7,210 new cases have been diagnosed in 2014; however, prevalence rates have increased in past years. Other cancers such as vaginal, vulvar, penile, and oropharyngeal cancers are associated with HPV. It is estimated that HPV accounts for 50 percent of vaginal, vulvar, oropharyngeal, and penile cancers. While these cancers are not as life threatening as cervical cancer, they can result in significant impairments in daily functioning and quality of life, including loss of sexual functioning, fertility, and self-image.

Cervical cancer develops when external and internal tissues of the cervix develop cancerous cells. Cervical cancers first present as precancerous cells called cervical intraepithelial neoplasia, squamous intraepithelial lesion, or dysplasia. These precancerous cells can be detected by a Pap test and treated to prevent the development of cervical cancer. If these precancerous cells go undetected and untreated, they may develop into cervical cancer. There are two main types of cervical cancers: squamous cell carcinoma and adenocarcinoma. Some cervical cancers have properties of both squamous cell carcinomas and adenocarcinomas and are called mixed carcinomas. The majority of cervical cancers are classified as squamous cell carcinomas. Squamous cell carcinomas originate in the cells that cover the surface of the exocervix. Cervical adenocarcinomas start in the endocervix of the cervix and develop from mucus-producing gland cells.

Anal cancer is also closely related to HPV infection. There are several types of anal cancer cells, including carcinoma in situ, squamous cell carcinomas, adenocarcinomas, basal cell carcinomas, and gastrointestinal stromal tumors. Cells that are carcinoma in situ are cells that appear to be cancerous but have not grown into any of the deeper layers of the anus. These cells are analogous to the precancer cells found on the cervix during a Pap test. Squamous cell carcinomas are the most common type of anal cancer and originate in the cells of the lower part of the anus and the anal canal. As the cancerous cells spread to the deeper layers of the anus, they are considered invasive. Adenocarcinomas start in the cells that line the upper part of the anus and rectum. Basal cell carcinomas are found on the skin of the anus and are considered a type of skin cancer. Gastrointestinal stromal tumors are rare and usually found in the stomach or small intestine but can spread to the anus.

Recent efforts to reduce cervical cancer led to the development of vaccines protecting against specific types of HPV associated with cervical, anal, and other HPV-related cancers. These vaccines are currently available and are safe and clinically effective. The Advisory Committee on Immunization Practices (ACIP) recommends that all adolescent females between the ages of 11 and 12 years be vaccinated for HPV and that the vaccines are approved for females. ACIP recommends that males between the ages of nine and 26 years be vaccinated for HPV. However, vaccination rates among the general population and survivors of cancer are unacceptably low.
STI-related cancers pose a health challenge to patients and health care professionals. However, recent medical advancements such as the HPV vaccine and developing cancer treatments are promising. Future research agendas should continue to pursue treatment development and also identify factors that promote STI- and cancer-prevention behaviors. Specifically, research should focus on increasing HPV vaccine uptake to prevent cervical, anal, and other HPV-related cancers. In addition, research should investigate the impact of HAART adherence on AIDS-related lymphomas and sarcomas.

Insecticides

An insecticide is a substance that is used to kill, repel, or control insects. More than 1 million insect species worldwide can be found in habitats ranging from forests and swamps to deserts and cities. They are extremely adaptable, multiply in numbers rapidly, and are resilient to harsh environmental conditions. Approximately 10,000 species consume agricultural crops. Of these, nearly 700 are responsible for most insect damage to field and stored crops. In 2001, insecticides accounted for 12 percent of all pesticides applied to surveyed crops in the United States, with corn and cotton making up the largest shares of insecticide use. This entry outlines major chemical classes, human exposure, environmental and human health risks, and regulations and exposure prevention.

Major Chemical Classes

Many different insecticides with varying levels of sophistication have been developed since the existence of ancient civilizations. One of the first recorded was sulfur (brimstone), which was burned for use as a fumigant. Other agents included extracts of pepper and tobacco, soapy water, white-wash, vinegar, turpentine, fish oil, brine, lye, and
various readily available ingredients. Some of these substances were more effective than others; for instance, soapy water is still used today as a spray on household plants.

Dichlorodiphenyltrichloroethane (DDT), an organochlorine and once one of the most commonly used agents of this chemical type, was a synthetic agent developed in 1939 as an insecticide and chemical to control vector-borne diseases such as malaria and yellow fever. Organochlorine insecticides are generally characterized by an organic compound containing at least one covalently bonded chlorine atom. These stable structures persist in soil and sediment, can travel long distances in the upper atmosphere, and move slowly into groundwater. They deposit in plants and concentrate in the fatty tissues of fish, birds, and animals. Evidence of DDT’s toxicological effects became apparent shortly after its peak usage, and it subsequently was banned by the U.S. Environmental Protection Agency (EPA).

The most frequently used chemical groups today in the United States are organophosphates, carbamates, and pyrethroids, which primarily elicit neurotoxic insecticidal effects. Although less common, the following chemical classes are among many designed for specific organisms, environments, or circumstances: botanicals (toxicants derived from plants), fumigants (small, volatile, organic molecules used in confined spaces), inorganics (carbon-free compounds, e.g., sulfur), and repellants (usually applied to human skin or building surfaces, e.g., N,N-Diethyl-meta-Toluamide [DEET]). The variety of insecticides reflects the diversity of target species and their habitats as well as attempts to address negative health effects and insecticide resistance.

Transgenic plants were recently developed to incorporate pest-resistant genes from other species into plant genes. For example, the naturally occurring soil bacterium *Bacillus thuringiensis* (Bt) produces Bt toxin, a protein that is toxic to certain herbivorous insects. On its own, Bt is considered to be a biopesticide; when the gene that produces Bt toxin is introduced into crops such as corn, cotton, and potatoes, these crops can then synthesize their own bacterial protein to kill pests. While their use is controversial, biopesticides and transgenic plants are of increasing interest to governments, industry, and communities that are seeking innovative ways to cope with insects in food crops.

**Human Exposure**

Humans can be exposed to insecticides from natural sources, in occupational settings, as part of public health interventions, and from household and commercial uses. Exposure may happen via dermal contact and inhalation, even from historical or current uses in other countries. Contact may also arise from consumption of residues in human breast milk and on food products.

In occupational settings, farmers and farm workers can be exposed from insecticide mixing, loading, and transfer to application equipment. Forestry workers routinely apply insecticides on tree farms. Pentachlorophenol, an organochlorine and fungicide, was commonly applied to lumber as a wood preservative. Workers at wood treatment facilities and lumber mills were exposed along with those who then handled treated lumber. Insecticide-manufacturing workers can come into contact with chemicals during production and transfer to storage facilities.

Public health uses of insecticides remain in parts of the world where the prevalence of insects carrying diseases and the risks of becoming infected and seriously ill are both high. DDT and pyrethroids are sprayed indoors and used to treat bed nets in malaria-endemic regions.

Insecticides and their mixtures are widely available in stores for home, garden, and commercial uses. Examples include products containing carbaryl, malathion, boric acid, and pyrethrum. Topical head lice and scabies treatments containing the synthetic organochlorine lindane were commonly used and are still available by prescription; however, usage has declined since safer alternatives have become available.

The amount or level of exposure to insecticides from any source depends on the route of exposure, as well as the frequency, duration, and intensity of use at either a single point, an interval of time (e.g., growing season), or over a lifetime. Exposure may be averaged or calculated on a cumulative basis. There are various methods to measure human exposure, and the selection of methods depends on numerous factors: chiefly, feasibility and cost.

**Environmental and Human Health Effects**

Insecticides are the most common method of preventing and controlling insects. They have conferred numerous benefits for their ability to protect
food crops and supplies, control vector-borne disease, and mitigate bodily and household pests. However, widespread and long-standing use of these chemicals has had adverse consequences for environmental and human health. DDT exposure has been associated with eggshell thinning in birds, causing substantial declines in certain bird populations in the United States. Lindane has been associated with hormone disruption, nervous system effects, and cancer in humans.

Organophosphates are not as persistent as organochlorines; for example, the half-life of malathion in soil is one to 17 days, compared to two to 15 years for DDT. They do not tend to deposit and accumulate in fatty tissues of living organisms. Nevertheless, they are toxic to humans because they act by inhibiting the enzyme cholinesterase. Short-term exposure is associated with cholinergic effects such as headache, respiratory symptoms, convulsions, and coma. Chronic effects of exposure to low levels of organophosphates may include increased risks of neurological disorders in children in agricultural areas exposed prenatally and in early childhood. Carbamate insecticides have a similar anti-cholinesterase mode of action. The EPA has found that permethrin, a type of pyrethroid, is likely to be carcinogenic to humans by oral ingestion based on evidence in laboratory mammals and supporting structural activity relationship data.

Some individual agents have been evaluated in association with cancer. Canadian men who reported previous exposure to the insecticides malathion, DDT, carbaryl, aldrin, and lindane had significantly elevated risks of non-Hodgkin's lymphoma. Similar results were found in case-control studies conducted in the United States, with increased risks associated with greater numbers of days per year of use of DDT. Significantly higher risks were also observed for carbamate and organophosphate insecticides as groups. Canadian men who reportedly used carbaryl had a nearly 2.7-fold higher risk of being diagnosed with multiple myeloma. An increasing exposure–response trend based on days per year of use was also observed.

Insecticide resistance, including to Bt crops, is a major challenge, and multiple generations of insecticides have been developed in efforts to stay ahead of resistance. Additionally, Bt corn pollen may have unintended adverse effects on nontarget organisms (e.g., monarch butterflies). The human health effects of newer compounds (e.g., transgenic plants) are an area of ongoing research.

Regulations and Exposure Prevention
In 1991, the International Agency for Research on Cancer evaluated the carcinogenicity of aldicarb, chlordane, heptachlor, DDT, deltamethrin, dichlorvos, fenvalerate, and permethrin. Chlordane, heptachlor, DDT, and dichlorvos were classified as Group 2B (possible) human carcinogens based on inadequate evidence in humans and sufficient evidence of liver cancer in animal studies. Aldicarb, deltamethrin, fenvalerate, and permethrin were classified as Group 3 (not classifiable as to its carcinogenicity to humans) based on no human data and inadequate animal evidence. Occupational exposures in spraying and application of nonarsenical insecticides were deemed to be Group 2A (probable) human carcinogens based on limited evidence for lung cancer in humans.

DDT is still used in regions that lack effective pesticide regulation, enforcement, exposure controls, and safe handling practices. The Stockholm Convention on persistent organic pollutants bans DDT for all uses except for malaria control. In September 2006, the World Health Organization declared support for indoor use of DDT in African countries where malaria is endemic. Agricultural uses of lindane were banned by the EPA in 2007 and globally under the Stockholm Convention in 2009.

Reducing workplace exposure can be achieved through setting and enforcing occupational exposure limits, with the use of personal protective equipment as a last resort. Alternative approaches to pest control can be used at work and in other contexts. According to the EPA, integrated pest management (IPM) is “the coordinated use of pest and environmental information with available pest control methods to prevent unacceptable levels of pest damage by the most economical means and with the least possible hazard to people, property, and the environment.” It includes activities such as using mechanical trapping devices, natural insect predators and biopesticides, and monitoring crops for damage.

Conclusion
Insecticides have been used for millennia as agents to prevent and mitigate a diverse array of insect species. The merits of these chemicals need to be
carefully weighed with the known and potential harms to the environment and humans. Carcinogenic effects have been observed for numerous individual chemicals. The development of biotechnologies for creating genetically modified organisms, advancements in IPM, and regulatory actions are some of the important directions for the future of insecticides.

Insurance

Health insurance is an arrangement in which individuals pay an up-front premium in exchange for guaranteed full or partial compensation for health care costs resulting from sickness or injury. Health insurance in the United States includes both private and public insurance programs, including Medicare and Medicaid, that provide health care assistance for people who are unable to afford health care coverage. Health insurance organizations determine the cost of an insurance policy by estimating the overall risk of disease and health care expenses among targeted groups or individuals. Organizations then develop a health insurance policy structure, including the monthly or annual premium, deductibles, co-payments, or payroll deductions that will ensure funds are available to pay for health care benefits for individuals or groups as agreed on in the associated health insurance policy. In recent years, supplemental cancer insurance has emerged within the health insurance industry. Cancer insurance was developed in order to mitigate the high costs of cancer treatments and offer the individuals with cancer insurance policies financial assistance.

History of Health Insurance in the United States

Health insurance in the United States began as a quasi-indemnity policy as most people paid a fixed amount per day in the hospital. Just before the Great Depression, Blue Cross became one of the first companies to offer Americans private health insurance. The Blue Cross system originated as an agreement between hospitals and schoolteachers in Dallas, Texas. These early insurance agreements offered individuals reimbursement of a preset amount of hospitalization costs in exchange for a flat monthly premium. Early health insurance policies were run by hospitals; however, following World War II and partially driven by the favorable treatment from federal tax policies, life insurance companies entered into the health insurance market, and the popularity of private health insurance began to grow.
Interest in universal health coverage has consistently remained a subject of American politics; however, the goal to provide Americans with universal health coverage was not within reach until the passing of the Patient Protection and Affordable Care Act (PPACA) by President Barack Obama and the U.S. Congress in 2010. In association with the Health Care and Education Reconciliation Act, the PPACA has been the most significant overhaul of the U.S. health care system since the passage of Medicare and Medicaid in 1965. The goal of the PPACA is to increase the quality and affordability of health insurance and expand the number of Americans with public and private insurance coverage.

Today, health insurance plans are available to groups and individuals or may be obtained through public programs, such as Medicare and Medicaid. Group health insurance plans may then be further divided into either fee-for-service or managed care. Group health plans are offered through employers, educational institutions, professional associations, religious organizations, or other types of groups. Employer-sponsored health insurance plans are the most common form of individual health insurance. Employer-sponsored health insurance is paid for by businesses for employees as part of the employee’s benefit package. Typically, the employer makes a substantial contribution toward the cost of insurance coverage, while the employee is responsible for the remaining cost of the insurance premium, usually paid for with pre-tax or tax-exempt earnings.

Fee-for-Service and Preferred Provider Organization Plans
Fee-for-service health insurance operates under the traditional health insurance agreement in which the insurance company reimburses the care provider or hospital for all or part of the incurred patient fees. Preferred provider organization (PPO) health insurance is the primary type of health insurance in the United States that utilizes this traditional fee-for-service system. In these types of fee-for-service plans, individuals are granted the freedom to choose a care provider or site for health care services. A PPO will contract with individual health care providers in order to create a network of providers, including specialists and hospitals, available to patients. Individuals are granted the freedom to choose their care provider or site for health care services; however, if they choose a provider that is part of their PPO network, their co-payments are fixed at a predetermined amount and are significantly reduced. This system incentivizes individuals to choose providers within the network.

Managed Care and Health Maintenance Organization Plans
Managed care is a term used to describe strategies employed by health insurance organizations that are intended to improve the quality of health care while reducing its cost. These strategies were pioneered by health maintenance organizations (HMOs) but may also be used by other insurance organizations also seeking to reduce health care costs. The traditional fee-for-service and PPO health insurance plans thrived well into the 1970s until the U.S. Congress passed the HMO Act of 1973 in response to the rising costs of health care across the country. HMOs trace their origins to prepaid group health care practices that began in California during the Great Depression. HMOs are designed to implement tight restrictions on provider authorizations for treatments and patient choice of providers as a way to manage treatment utilization and quality. In recent years, the United States has witnessed dramatic growth in the number of HMO companies and plans as the private insurance market has struggled with cost containment.

HMO health insurance plans place the patient’s health care within the management of the insurance company. Patients usually select a primary care physician (PCP) from a list of providers approved by the insurance organization. The PCP then coordinates the patient’s care and is responsible for referrals to specialist physicians and approvals for diagnostic tests and procedures. People with managed care insurance coverage pay an annual or monthly premium and a co-payment when they receive health care services.

Government-Sponsored Health Insurance Plans
In an address on November 19, 1945, President Harry Truman proposed a system of U.S. public health insurance to include a national system, similar to those that were, at the time, common in many European countries. Truman’s proposal garnered wide public support; yet, the U.S. Chamber of Commerce, the American Medical Association (AMA), and the American Hospital Association (AHA)
fiercely opposed it. Truman saw that the battle for a national health care system would be long and costly, and many labor unions chose to support employer-sponsored coverage instead. Therefore, the national insurance system lost momentum and ultimately failed to pass.

Regardless, private insurance still remained unaffordable or unavailable to many U.S. citizens such as the poor, the unemployed, and the elderly. Therefore, many politicians and private citizens continued to express interest in the creation of a form of federally sponsored insurance for individuals in the population who were unable to afford private health insurance coverage. The 1960 Kerr–Mills Act was the first step toward the formation of public health insurance options; the law provided matching funds to states that assisted individuals with health care costs. In 1965, President Lyndon B. Johnson signed the Medicare and Medicaid programs into law through the Social Security Act, creating the first publicly run insurance program for the elderly and the poor; in 1972, Medicare was later expanded to cover individuals with disabilities, end-stage renal disease, and amyotrophic lateral sclerosis (ALS).

Medicare is the U.S. federal social insurance program that was created under Title 18 of the 1965 Social Security Act for people who meet certain age and disability criteria. Primary eligibility requirements include individuals who are 65 years of age and older, some younger individuals with disabilities, and people with end-stage renal disease or ALS. Medicaid was also created as part of the 1965 Social Security Act under Title 19. Medicaid was designed to serve as a social welfare program as opposed to a social insurance program. The program is for individuals with low income and resources and those who receive federal government aid. Medicaid recipients must be U.S. citizens or legal permanent residents, and poverty alone does not necessarily qualify an individual for Medicaid.

Supplementary Cancer Insurance
Cancer insurance is a relatively new phenomenon within the health insurance industry. Cancer insurance is beneficial for policyholders if they are diagnosed with cancer because it helps to mitigate the costs of cancer treatment and provides some financial assistance. This type of insurance is not meant to replace conventional health insurance but instead is meant to augment individuals’ existing health insurance plans covering the high out-of-pocket costs that are often associated with cancer treatment and care. Even more recently, supplemental cancer insurance has become available for specific forms of cancer, including breast and colorectal cancers. These specific types of cancer insurance are most appropriate for individuals who have a family history of a particular type of cancer and, thus, may be at higher risk.

International Agency for Research on Cancer

The International Agency for Research on Cancer (IARC) is an intergovernmental agency constituting the specialized cancer agency as part of the World Health Organization (WHO) of the United Nations (UN). The mission of the IARC is to coordinate and conduct research on the causes of human cancer and the mechanisms of carcinogenesis, and to develop scientific methodologies for cancer control.
It conducts epidemiological and laboratory studies into the circumstance of cancer worldwide. It disseminates scientific knowledge through publications, conferences, fellowships, and meetings. The agency also maintains a series of monographs on the carcinogenic risks to humans posed by various forms of agents, mixtures, and exposures. The IARC devotes particular attention to conducting research in low- and middle-income countries through collaborations and partnerships with researchers in these regions.

The development and establishment of the IARC can be traced to the many years of efforts that were devoted to the registration of persons suffering from cancer. Historical accounts show that early efforts to create a cancer census took place in London in 1728. These early, unsuccessful attempts were aimed at establishing reliable and comparable mortality or morbidity statistics. For more than 100 years until around 1900, nevertheless, demands in England and Germany persisted for improved statistical investigations on the promulgation of the cancer population as an imperative basis for etiological research. In 1900, an undertaking was again made to register cancer patients who were receiving medical treatment in Germany, based on the results of a general survey on cancer in Hamburg. Although the German approach was repeated between 1902 and 1908 in the Netherlands, Spain, Portugal, Hungary, Sweden, Denmark, and Iceland, the attempt to improve cancer registration continued to produce unsatisfactory results because of low participation in all the surveys.

Meanwhile, a cancer registration project had started in the United States, with ideas and recommendations that required compulsory registration of all cancer cases. Yet, the cancer registration that was piloted in the state of Massachusetts in 1927 was unsuccessful as only about one-third of the cancer cases were reported. The registration scheme that began in Mecklenburg in 1937, recording individuals, yielded better outcomes than the institutional approach. Between 1937 and 1938, the Mecklenburg registration format worked fairly well, as indicated by a recorded rate of about 200 new cancer patients per 100,000. Regional political developments caused a discontinuation of similar registration initiatives instituted in Saxony-Anhalt, in Saarland, and in Vienna in 1939. In the United States, similar encouraging outcomes were recorded, as all cases of cancer were documented in 10 urban areas during a calendar year in 1937 and 1938 and again in 1947 and 1948. From the mid-1940s, many individual countries participated in some form in the development of cancer registries.

Perhaps the most paramount momentum for the global establishment of cancer registries resulted from a conference that was held in Copenhagen in 1946 under the leadership initiative of the then director of the Danish cancer registry, Dr. Clemmesen. Following the conference, a group of 12 international leading authorities in the field of cancer control provided the interim commission for the WHO with recommendations for the worldwide establishment of cancer registries. Those recommendations suggested the following:

1. Great benefits would follow the collection of data about cancer patients from as many different countries as possible.
Such data should be recorded on an agreed-upon plan so as to be comparable.

Each nation should have a central registry to arrange for the recording and collection of such data.

There should be an international body whose duty it should be to correlate the data and statistics obtained in each country.

In May 1965, the IARC was established as a specialized cancer research center through a resolution of the 18th World Health Assembly (WHA) as an extension of the WHO. The founding nation members of the IARC were the Federal Republic of Germany, France, Italy, the United Kingdom, and the United States. France provided the building for the agency’s headquarters, located in Lyon, France. Recent member nations joining the IARC include Australia, Austria, Belgium, Brazil, Canada, Denmark, Finland, India, Ireland, Japan, Norway, the Netherlands, Qatar, Korea, Russia, Spain, Sweden, Switzerland, and Turkey.

In the area of governance, the IARC follows the same general rules as all other UN organizations. Particularly, it is governed by a governing council (GC), composed of the representatives of participating states, the director-general of the WHO, and the scientific council (SC). The GC elects the IARC’s director, who usually serves for a five-year term. The director reports to the IARC GC and is responsible for the overall leadership of the agency. The FC membership consists of highly qualified scientists who are appointed for four-year terms by the GC. In 2014, the IARC’s SC was headed by Dr. C. Ulrich as the chairperson, with Dr. J. F. Bishop as the vice chairperson. The Office of the Governing Council had Dr. M. Palmer as the chairperson, with Dr. A. Buzyn as the vice chairperson. The WHO’s director-general was Dr. M. Chan.

IARC activities are principally funded by the regular budget contributions paid by its participating states. The GC approved the biennium 2014 to 2015 budget in May 2013, at a level of 40,424,491 euros. Among the major funding sources for the IARC operations are the European Commission, the United States National Institutes of Health, the World Cancer Research Fund International, and the Bill and Melinda Gates Foundation. Also, the agency receives significant funding support from both governmental and charitable sources in France.

International Association for the Study of Lung Cancer

In 1972, the First International Workshop for the Therapy of Lung Cancer was sponsored by the National Cancer Institute. The international group of people enthusiastically supported Dr. David T. Carr’s suggestion that an international organization be founded. An organizational committee, including Dr. Carr, Dr. Oleg S. Selawry, Dr. Lawrence Broder, and Dr. George Higgins began to develop the association. The International Association for the Study of Lung Cancer (IASLC) was founded in 1974. Initially, 250 individuals accepted membership. Today 4,000 lung cancer specialists are among its members from 80 countries. Worldwide management is the responsibility of IASLC’s Council of Regents, a network of professionals around the world who are responsible for a country or group of countries within a geographical area to ensure effective communication among members and potential members. IASLC works to increase understanding of lung cancer with scientists, the public, and the medical community.
IASLC’s mission is comprised of three key concepts: (1) to embrace all aspects of lung cancer and other thoracic malignancies through the study of their etiology, epidemiology, prevention, diagnosis, and treatment; (2) to provide information and education about thoracic malignancies and lung cancer to IASLC members, the medical community, and the public; and (3) to use all means to eliminate thoracic malignancies and lung cancer as a threat to the individual patient and throughout the world.

The IASLC’s *Journal of Thoracic Oncology* (JTO) was first published in January of 2006. Initially publishing nine issues per year, the journal is now published monthly with multiple supplements. It is a multidisciplinary approach that includes original research, reviews, and opinions. Its audience includes all those involved in the treatment and research of thoracic malignancies and lung cancer, including pathologists, researchers, oncologists, pulmonologists, surgeons, radiologists, and epidemiologists.

The newest strategic plan approved by the IASLC board of directors includes seven mission goals: (1) embrace the study of lung cancer and thoracic malignancies; (2) provide education and information to the public, the medical community, and IASLC members; (3) advance research to reduce the incidence of thoracic malignancies worldwide; (4) commit to long-term, global growth; (5) value the work of volunteers; (6) solicit philanthropic funding to support research and education; and (7) commit to fiscal responsibility and operational excellence.

IASLC is significantly active in creating and maintaining 17 committees. The Awards Committee determines IASLC award recipients. The Career Development Committee recruits mentors to help members progress through their careers. The Communications Committee seeks to increase awareness of IASLC and educate the public. Education programs are planned and initiated by the Education Committee. The enforcement of ethical conduct and rulings on ethical issues are the responsibility of the Ethics Committee. Regular business of the association is monitored and completed by the Executive Committee. The Fellowship Committee selects recipients for the IASLC Lung Cancer Fellowship Award and Young Investigators Award. Fiscal management and risk management is monitored by the Finance Committee. The Membership Committee recommends and reviews levels of membership and strategizes to increase and maintain membership. The Nominating Committee develops a pool of members as candidates for elected positions. The Nurses and Allied Professionals Committee ensures IASLC is meeting nursing and allied health-related needs. Review of lung and thoracic malignancies is the responsibility of the Pathology Committee. The educational and related needs of the public are met by the Patient Advocates Committee. Cancer prevention activities are the responsibility of the Prevention, Screening, and Early Detection Committee. The Publications Committee manages all IASLC publications, including the JTO. The Staging Committee studies and improves patient information and research to improve the cancer staging system. The Tobacco Control and Smoking Cessation Committee aims to reduce the use of tobacco worldwide.

Some of the benefits associated with membership in the IASLC include access to the JTO, free continuing education opportunities, discounted registrations at workshops, eligibility for fellowship and travel awards, a monthly newsletter, and access to the member directory. Regular membership is for all researchers and clinicians at a rate of $250 per year. Allied health professional membership is discounted at a rate of $50 per year for nurses, therapists, patient advocates, statisticians, and pharmacists. Developing country membership also has a rate of $50 per year. Fellows, residents, and trainees may apply for a complimentary, nonvoting membership. IASLC also offers joint membership at discounted annual rates to the Pulmonary Pathology Society ($125) and the International Thoracic Oncology Nurses Forum and National Lung Cancer Forum for Nurses ($30).

Every year, IASLC supports young researchers to encourage innovative research. Three researchers who represent North America, Asia, and Europe are awarded funding for one year. The Prevent Cancer Foundation jointly sponsors the research with grants from Eli Lilly. Additionally, in collaboration with Boehringer Ingelheim, the Chinese Lung Cancer Fellowship Award enables one researcher to come to the United States for one year to research a project. The Lung Cancer Foundation of America also collaborates with IASLC with the Lung Cancer Research Grant, awarded every two years.

IASLC has also partnered with Patient Resource Publishing to produce the *Patient Resource Lung Cancer Guide*. The guide provides details to families
and patients with the information they need upon diagnosis. The information provided includes financial resources, symptom and side effect management, treatment options, and staging and pathology. IASLC also supports a variety of materials published by the American College of Chest Physicians, who in part provide smoking cessation information to practitioners and physicians.

**International Association of Cancer Registries**

The International Association of Cancer Registries (IACR) was established in 1966 in Tokyo as a global professional body to address both preventive and treatment dimensions of cancer. It aimed to develop standardized measures to estimate the prevalence and incidence of cancer globally to generate comparable data.

**History**

The earliest attempts to estimate the number of cancer cases were made in European countries at the turn of the century. In the United Kingdom, initial attempts to measure cancer prevalence based on mortality and morbidity statistics were undertaken in London, though these attempts were unsuccessful. In 1900, under the auspices of Katz, Germany was the first country to register all cancer patients undergoing treatment. On October 15, 1900, all physicians in the country were sent out questionnaires through the Prussian Ministry of Culture to record the details on prevalence of cancer. Between 1902 and 1908, several European countries, such as Denmark, Hungary, Iceland, the Netherlands, Portugal, Spain, and Sweden, made attempts to collect similar information but, however, were met with limited success owing to poor response and lack of collaboration among physicians. The first population-based cancer registry was set up in Hamburg, Germany, in 1926, and the main thought underlying this registry was not only to address medical dimensions of cancer but also to take into account public health dimensions. As a part of this work, three nurses visited hospitals and medical practitioners at regular intervals in Hamburg and recorded the names of the new cancer patients in the hospitals that were then transferred to the central index in the health department. This data was later compared to the official death certificates. By 1955, the country had 55 cancer registries. In the United States, around 1930, Wood indicated that cancer should be a notified illness and registration of cancer cases should be mandatory. In 1927, the state of Massachusetts started registering cancer cases, and it was a failure as only one-third of cases were registered.

The global importance of cancer registries came after a conference in Copenhagen in 1946 under the initiative of Dr. Clemmesen, the director of the Danish cancer registry in 1946. Twelve international experts recommended establishment of cancer registries to facilitate cancer control to the interim commission for the World Health Organization (WHO). They recommended collection of information on cancer patients across the world; that information should be collected in a uniform fashion to be comparable, and centralized cancer registries should be established in all countries of the world along with an international body that will correlate data and statistics from various registries in each country. The WHO established a subcommittee to work on the registration of cases of cancer and the statistical presentation of these cases. The International Union Against Cancer (UICC) in 1950 organized an International Symposium on Geographical Pathology and Demography of Cancer, which reiterated the importance of enumerating the prevalence
of cancer. In 1965, the IACR was established to standardize data collection methods across all the registries in the world. It was established as a specialized cancer research center under the WHO to generate comparable data globally.

Today, it serves as an organization that has membership of all cancer registries that collect and analyze data on the prevalence and incidence of cancer and study its implications for treatment in defined population groups. There are 200 cancer registries across the world, which cover around 5 percent of the world’s population, with more cancer registries located in developed countries. In developing countries, these registries are located in urban areas, which have more facilities for diagnosis and treatment. Population-based cancer registries cover only a small part of the population and are located in Colombia, India, Italy, and the United States. Few specialized registries for particular age-groups, such as the one on childhood cancer located in Oxford, United Kingdom, exist, and there are specific cancer sites such as the one in Dijon, France, for gastrointestinal cancers.

Role of Cancer Registry
Cancer registries play vital roles in cancer control as they periodically register and record all cancer cases that occur in the population, with specific details of cancer patients along with their clinical and pathological characteristics of cancers collected continuously and systematically from various data sources. Each registry analyzes and interprets the data to discern the information on the incidences and characteristics of cancer prevailing in population groups and variations across time in the occurrence of cancer. Population-based registries are vital in planning, monitoring, and evaluating various health services for the prevention, diagnosis, and treatment of the disease. Hospital-based registries could potentially assist health care providers in following up cases and generate data on the impacts of therapy.

Currently, the IARC series Cancer Incidence in Five Continents estimates that most of the registries are located in North America and Europe and there is a need to establish more registries in developing countries. In spite of variations in the data due to local needs and availability of information, the use of common nomenclature enhances the international comparability of the data.

Another important contribution made by cancer registries is to study disparities among and within nations. Through internationally comparable studies, it is possible to ascertain the dominant forms of cancer in certain spatial areas along with their risk factors and therefore design preventive and treatment pathways.

Within nations, it is possible to study prevalence of cancer among socially and economically deprived sections of the population and address issues of gender, race, ethnicity, and class in the planning of health services. The data collected by registries provide the most important tool for monitoring and evaluating the effectiveness of public health policies to mitigate cancer.

International Cancer Alliance for Research and Education

The International Cancer Alliance for Research and Education, or ICARE, is a nonprofit organization. The group was founded in 1981 in Bethesda,
Maryland, by renowned cancer scientists from all over the globe. The organization was intended to serve cancer think tanks that looked to identify obstructions to innovation in cancer research laboratories.

It is nearly impossible for one physician to care for any number of patients and simultaneously stay on top of every innovative treatment or promising trial that could benefit his or her patients. That's where ICARE comes in. The goal of this organization is to facilitate the communication of cutting-edge, life-saving information about cancer treatment among researchers, physicians, and patients. ICARE supports researchers in attempting to transition research from the lab to the patients through clinical trials. According to the ICARE mission statement, the organization wants to have the best minds in medicine to create the best chance of survival for cancer patients.

ICARE provides information geared toward people suffering with cancer and the physicians who treat those people on a person-to-person basis. Cancer is used broadly, meaning it includes any group of diseases whose characteristics include uncontrolled, rapid growth of cells that may invade and metastasize to other tissues or organs.

Cancer may be categorized by the organ or type of cell involved, whether or not it is malignant, and the course the disease most often takes. ICARE sponsors several programs geared toward patients through collecting, evaluating, and providing information and putting affected patients into contact with doctors and scientists worldwide. The alliance is composed of a network of scientists, physicians, staff, and volunteers, many of whom have felt the effects of cancer on a personal level. The alliance maintains a registry, which is a confidential membership list that allows for continued communication between ICARE and its members.

ICARE has been responsible for initiating many information and research programs that had the potential to up patient survival rates by increasing the flow of information on therapy advances to doctors and patients.

Over the past few years, ICARE has begun to change its scope from a solely informational entity to identifying, starting, and funding cutting-edge research projects aiming to treat tumors in individual patients. Research projects such as these have the potential to hasten the development of new therapies with fewer side effects. This change of scope was kick-started in 2010, when a group of ICARE scientists accepted the challenge of working with individual patients and their physicians to attempt to find treatments as swiftly as possible for clinical problems facing both patients and their doctors.

From 2010 to 2013, ICARE received funding to establish customized medical projects for three individual patients who were suffering from advanced stages of cancer. One was suffering from a rare form of cancer affecting the liver, and both of the others suffered from variations of metastatic melanoma. The project led to the development and consideration of more than 30 new medications or techniques to be used by the doctors of these three individuals.

Currently, ICARE is serving its mission by working with individuals in an investigative program that begins with one patient, one physician, and one researcher. The investigative teams, or I-Teams, participate with patients and their doctors in real-time academic research projects that are personalized to the cancer patient and his or her needs. I-Teams now constitute the majority of ICARE's efforts to achieve its mission.

On the official ICARE Web site, one can find a myriad of links to research for everything from bladder cancer to sarcoma. In addition to providing information on specific types of cancer, ICARE participates in a clinical trial-matching program. ICARE currently provides clinical trial information through its think tanks and symposiums, both of which have full participation from patients, leading physicians in the field, and cancer scientists.

In addition to sharing clinical trial information, ICARE also provides cancer therapy reviews (CTRs). These are published for many different kinds of cancer with the goal of housing all therapy information pertinent to the diseases in one central source. These CTRs contain much more than general descriptions and brochures that patients often receive from other sources. Each CTR provides an overview of the disease, information on staging procedures, the most current treatments and diagnostic tests, and a list of ongoing clinical trials and second-opinion centers, among other things.

ICARE is dedicated to forming a partnership of education and study involving cancer patients,
doctors, and researchers. Knowledge and the sharing of knowledge are key to ICARE’s mission. The objectives of ICARE are to create I-Teams to investigate each type of cancer among the medical, scientific, and patient communities; to provide support for the movement of research from lab to patient; and to facilitate creativity and innovation in cancer research. Patients and their physicians are given easy-to-use, comprehensive information regarding options for treatment and the most cutting-edge medical advances. ICARE is getting involved in the community by reaching out to local high schools, organizations, and small businesses.

ICARE is funded by donations from individuals who believe that targeted research will eventually lead to cures for these diseases. Already, a lot of good has been accomplished. Through ICARE, patients and doctors can research diagnoses and make the most informed decision for treatment based on the trials and research for a myriad of cancer types. Knowledge can be survival in this case, and ICARE provides that knowledge to patients and physicians alike. Through individual treatment studies, matching patients with clinical trials, and facilitating research into these subjects, ICARE makes a large impact on behalf of cancer patients worldwide.

For more information on how to get involved as a volunteer for ICARE or to make a donation, the ICARE Web site is http://www.icare.org. For more information about volunteering, visit http://volunteer.truist.com.

International Committee of the Red Cross

The International Committee of the Red Cross (ICRC) is an international humanitarian organization based in Geneva, Switzerland, founded by Swiss businessman Henri Dunant. In 1859, Dunant witnessed the suffering and dismal medical care received by wounded soldiers during the battle of Solferino, which pitted the Franco–Sardinian Alliance against the Austrian Army. Dunant, with the help of the local community, offered what help and assistance to injured soldiers and civilians he could, regardless of on which side of the conflict they were. Dunant understood that organizing in order to provide appropriate medical attention and humanitarian intervention could save and help heal many of the injured. He began to advocate internationally for a better system in order to achieve this. Today, 189 individual National Red Cross and Red Crescent societies form the International Federation of the Red Cross and Red Crescent Societies, which are associated with the ICRC. Worldwide, the ICRC has more than 10,000 staff in 80 countries. The organization has helped in war conflicts throughout the two world wars and in other modern battleground and war-induced crises as well as in natural catastrophes worldwide.

The ICRC has always aimed to offer protection and assistance to people suffering from crises and catastrophes around the world. In 1862, Henri Dunant published his book Memories of Solferino, which he sent to leaders worldwide. It soon impacted European society. He proposed the idea of developing a network of organizations in all nations capable of helping the injured and other victims in times of war.

Four Swiss citizens joined forces in order to achieve this goal: General Guillaume-Henry Dufour, lawyer Gustave Moynier, and two doctors: Louis Appia and Théodore Maunoir. In 1863, they founded an international aid society to help injured soldiers, which in time would become known as the ICRC. During that same year, the ICRC organized the first international conference in Geneva, in which 16 nations participated, with the end result of providing for the amelioration of the conditions of those injured at war. It was at that point that its emblem of a red cross over a white background was
adopted. The emblem covers situations of armed conflict, medical and religious personnel, military as well as civilians, who may use it to provide the injured with medical attention, equipment, and transportation. This marked the inception of the field of contemporary humanitarian human rights and the Geneva Convention of 1864.

The ICRC of the 1920s, after World War I, moved to implement additional rules to the provisions of the Hague Conventions of 1899 and 1907, which proved insufficient to protect civilian populations in enemy and occupied territories. The Geneva Conventions include four treaties: 1854, 1906, 1920, and 1949. The latter was ratified by 196 countries and proved seminal in setting international standards for humanitarian treatment of people during war. In 1949, after the horrors of the Holocaust had come to light, states agreed to the idea of protecting civilians under enemy control. Additional protocols were added in 1977 and 2005, which extend the ICRC’s mandate to international as well as internal armed conflicts. Among many awards won during its trajectory, the ICRC has been awarded the Nobel Peace Prize in 1917, 1944, and 1963.

The International Red Cross Committee Today
Since its inception, the ICRC’s goal has extended its mandates to provide protection and help not only to soldiers but also to victims of armed conflict, war, and catastrophe. Victims of war include noncombatant people who have been wounded or become prisoners and refugees. During World War I, the ICRC began implementing systems to connect military prisoners with their families. It also began to visit prisoners of war and political prisoners to ensure they were treated humanely and to call for the end of weapons of mass destruction such as mustard gas. Today, the mandate and mission of the ICRC follows the Geneva Conventions of 1949 and its additional protocols, and the original system has extended to help bring together people who have been displaced by catastrophes.

By World War II, the ICRC had persuaded more governments to adopt the Geneva Convention of 1929, which amplified the protections for prisoners of war. The ICRC, however, had not managed to get all countries to agree on international legislation to protect civilians in war-affected areas or under enemy control and thus had been unable to protect the millions of victims of the Holocaust.

Since the post–World War II years, the ICRC continued its mediating and humanitarian labor, working to persuade governments and leaders to support and respect international humanitarian legislation. It also has worked to help with the consequences of armed conflicts on populations, such as helping people in refugee camps, among others. The protection and aid mandates of the ICRC cover four types of population: the injured and sick in battlegrounds, injured and sick at sea, prisoners of war, and civilians under enemy control. Given the disasters that occurred against unarmed civilians during World War II, specifically the bombings of Hiroshima and Nagasaki, the ICRC has long advocated for nuclear disarmament as a humanitarian imperative. It also has been instrumental in bringing war-torn families together and in creating safe refugee camps for those displaced by wars. The Red Cross today is a standard-bearer respected by states and armed combatants worldwide and continues its mission to advocate for peace and for respect of humanitarian and international law.

International Myeloma Foundation

The International Myeloma Foundation (IMF) is a nonprofit organization based in North Hollywood, California. The primary aim of the foundation is focused toward finding a cure for multiple myeloma, a rare and incurable cancer of the plasma cells. The IMF works collaboratively with patients diagnosed with myeloma, families, myeloma specialists, and researchers at local, national, and global levels to meet this goal. However, the discussion about IMF cannot be appreciated unless myeloma is discussed.

Myeloma: A Rare and Incurable Cancer

Myeloma, also known as multiple myeloma, stems from the plasma cells, which are formed within the bone marrow. There are many individual variations in terms of symptoms, prognosis, and treatment options associated with myeloma; however, a diagnosis of multiple myeloma can potentially lead to a range of symptoms, depending on the severity of the disease process, which can include fatigue, pain, bone fractures, weight loss, and kidney problems. The term *multiple myeloma* is used as there are many areas of the body that can potentially be impacted by the disease process due to the fact that it stems from the bone marrow sites. It is also a disease that potentially can have a significant psychological impact on the person affected as well as his or her surrounding family and friends.

There are a number of treatment regimens available at different stages of the disease, all with varying side effects, and the treatment options available for myeloma have increased over the years and have extended the lives of many people living with myeloma. Such treatments can offer hope and a level of optimism in the face of a disease that may trigger uncertainty about the future.

Origins and Key Functions

According to the IMF Annual Report of 2013, the IMF has, since its founding, developed collaborative networks with approximately 350,000 members in 120 countries worldwide. The IMF originated in 1990 when a patient diagnosed with myeloma, Brian Novis, his partner, Susie Novis, and the hematologist providing their care and support, Dr. Brian G. M. Durie, decided to set up the foundation in recognition that there were gaps in the provision of information and support for people affected by myeloma.

Following an impressive and productive commitment to the founding and development of the IMF, Brian Novis died in 1992. Since then, Susie Novis and Dr. Durie have continued to advance the mission of the foundation in their respective roles as president and chairman and IMF board of directors to develop it into the flourishing and influential organization that exists today.

The IMF, in its mission statement and award-winning multilingual Web site, highlights a number of key areas that are central to their work, which include research, education, support, and advocacy.

Patient and Family Support

Given the significant impact of receiving a diagnosis of myeloma on the patient and his or her family members, there is a need for timely and accessible information and support. The IMF plays a key role in delivering such support through the provision of patient and family support seminars, which take place around the world. As of 2013, the IMF supports 245 support groups worldwide. Patients and family members have opportunities to attend seminars and hear about the latest, cutting-edge research and treatment interventions from highly skilled researchers and specialists working in the field of multiple myeloma. The seminars aim to educate and support people affected by myeloma so that they can increase their understanding of the disease and treatment options.

In addition to seminars, being a member of the IMF provides both patients and their families support through a toll-free information line when the need arises to clarify questions and obtain crucial information throughout the different stages of the disease process.

The IMF Web site provides comprehensive, current information about a variety of topics relevant
to myeloma and explains the key roles and functions of the IMF. Recognizing the importance of technology for disseminating information, the IMF has also developed a Myeloma Post app, which offers a further medium for provision of information and support. Beyond the efforts already identified, the IMF has a presence on social media, including Facebook and Twitter. These social media channels of communication have proved particularly effective during myeloma awareness week, observed in March each year, to both provide support and raise awareness.

The opportunities to access information relating to developments around myeloma and potential treatment options through seminars, the website, the app, Facebook, and Twitter or via the information line can potentially empower patients and their families and enable them to take active roles in their treatment through informed decision making.

**Research**

Working collaboratively worldwide and capitalizing on the cutting-edge technology that is available, there are a number of research initiatives in which the IMF has been involved. These have ranged from supporting research through funding to engaging in relevant research with partners around the world. The IMF has been involved in funding research initiatives since 1994 and, according to its 2013 annual report, has awarded 115 research project grants since 1994.

**Bank on a Cure**

Working internationally with key partners, the IMF has been involved in research called Bank on a Cure aimed at gaining a deeper understanding of the link between different DNA patterns and myeloma. It is anticipated that obtaining and analyzing samples of DNA from patients with myeloma will provide important information about potential causes of myeloma and provide specific information about which treatments can be tailored to individuals depending on their genetic analysis.

**The Black Swan Research Initiative**

The Black Swan Research Initiative (BSRI) focuses on research aimed at identifying a cure for myeloma. The name of the initiative originates from the discovery of the black swan in 1697, where up until that point in time, it was assumed that only white swans existed. Similarly, although there is currently no cure for myeloma, it is envisioned that there could be a cure in the future. According to the IMF, the BSRI is the signature project of the IMF and is a multipronged research project based on the growing understanding of how myeloma develops in the body as well as the ability to assess, measure, and quantify the disease development in the body and to measure and quantify the response to treatments. The BSRI is also dedicated to using treatments that will leave patients with the most minimal level of residual disease. The ultimate goal is to reach no residual disease, which should lead to a cure. Currently, the BSRI is working to define a cure as MRD-Zero, the eradication of minimal residual disease. This is important research as myeloma is currently a relapsing and remitting disease.

**Advocacy**

The IMF plays an important role in advocating for people with myeloma and their families and has also set up a number of advocacy initiatives focusing on raising awareness of multiple myeloma. The IMF has set up the first and only existing international
cohort of patients and people working in the area of myeloma in an attempt to work toward ending insurance coverage disparities, which ultimately lead to unequal access to treatment.

The setting up of the Myeloma Action Team, founded in 2013, builds on strengthening community networks and empowering advocates to influence policy development and federal legislation, particularly in relation to lobbying for access to treatment for people with myeloma who need it.

Conclusion

As has been discussed, the IMF plays crucial roles in driving the agenda for action and reflection on myeloma. Over the time of its existence, it has made great strides to improve the nature and quality of services for myeloma patients and their families. The collaborative relationships between myeloma patients, their families, myeloma specialists, researchers, the IMF, and service providers are perhaps some of the most innovative and unique types of collaborative relationships that can be found within medical and health contexts. Thus, it cannot be disputed that the foundation has achieved significant milestones. It must be acknowledged, however, that the future lies in such efforts being harnessed and sustained through financial, academic, and other human resources and from within communities and beyond. Having started from humble beginnings, the IMF has emerged as a global entity that plays a crucial role in empowering patients and their families and in providing a sense of hope in the face of an uncertain disease process.

International Psycho-Oncology Society

There is more to oncology than just treating cancer. There is a spiritual and emotional response to this by both the patients and their families. Patients have a higher chance of improvement and healing if these needs are also met. That is what the International Psycho-Oncology Society (IPOS) tries to foster by providing education and serving as an advocate for the goal of providing psycho-oncology to cancer patients.

In terms of education, IPOS sponsors the Psychosocial Academy. The lessons are provided by leaders in the field, and several workshops are offered throughout the year to address the most important issues faced both in research and in practice. The Psychosocial Academy provides numerous different courses: research methods, demonstrations of hypnotic and mind–body regulation for symptom management, the genetics of cancer, helping children cope with a parent that has the illness, end-of-life and palliative care, and more.

Among the goals of IPOS are educating doctors, patients, and families of patients. They press for further research and education in the emotional and mental effects of cancer on individuals and their families. They also seek to bring about more understanding of the importance of psychosocial resources to victims of cancer. Two main realms of the psychosocial view of cancer are the reaction of patients, families, and staff to the cancer diagnosis and treatment in all stages as well as the social and behavioral patterns that have an impact on tumor progression and the survival rates of patients. The ultimate goal is to provide cancer patients and their families all over the world with the best psychosocial care at every stage of the disease.

Cancer patients who learned relaxation coping skills before going through treatment had an easier time dealing with symptoms of treatment such as nausea and pain. The relaxation techniques used in the study included hypnosis and muscle-toning treatments. These techniques also are used to reduce problems in the body. If these techniques were learned before treatment, they also served to lower the anxiety of patients undergoing more
potent treatments to slow or destroy cancer. Individuals going through cancer treatment often feel out of control and hopeless, so these techniques give them something they can control and may help them to feel more connected to their treatment.

Some of the most common maladies caused by cancer treatment include nausea, pain, blood pressure, and pulse rate. The emotional needs of the patient can entail the need to control hostility, mood, and other common behavioral threats that can get in the way of a healthy lifestyle. The relaxation techniques patients were taught did more for anxiety than any other side effect regardless of the type of treatment the patient was undergoing. Counseling was also shown to be beneficial in terms of reducing distress, self-image, locus of control, tiredness, and sexual dysfunction. Structured counseling also showed benefits with depression and distress. Behavioral exercises and hypnosis were effective with symptoms such as anxiety, pain, nausea, and vomiting.

In a study of women with breast cancer, an experimental group was included in sessions aimed at reducing stress, helping with mood, changing health behaviors, and encouraging maintaining the cancer treatment and care. The results of the experimental group showed significant progress. Patients were more likely to improve behaviors such as smoking cessation, dietary habits, and social support. Their immune responses were also improved markedly just like their psychological and behavioral progress. The improvements were physiological as well as psychological.

Other studies have implied that these group therapies may not prolong life but argue that the quality of patients’ lives were improved. Patients had better moods and were better with pain management, showing the greatest results in women who had psychological distress or poor pain management skills at the time they entered the study. According to some studies, women with metastatic breast cancer that regularly attended an intensive support group lived 18 months longer on average than the control group. Those findings encouraged use of psychosocial treatment, but they have been criticized in tests that could not replicate such a trend.

There are concerns that the medical community will not acknowledge these results and use such treatments in the care of cancer patients. Quality-of-life results have been ignored in the past in cases where there was no physically measurable improvement in health. According to one researcher, the treatment should not be invalidated because it does help cancer patients. Even if it does not prolong life, it was instrumental in helping patients deal with pain, depression, and other quality-of-life improving metrics. Whether or not such psychosocial techniques prolong the lives of patients has been debated by different studies, but the benefits in pain management, depression, anxiety, and social support are clear.

One trend that these studies consistently show is that highly distressed breast cancer patients who go through these group therapies show positive changes. These highly distressed patients develop coping skills that alleviate their emotional and psychological symptoms. These studies alone suggest that doctors should give this methodology more consideration, especially in the treatment of highly distressed patients.

According to other studies, connected to written treatment manuals for leading these groups of breast cancer patients, a difference should be made between first-time cancer patients and women whose cancer is recurrent. It was more beneficial for these women to be in the respective groups that they belonged to. First-time cancer patients are dealing with different emotions and different struggles than women who have battled cancer already.

There are other forms of psychosocial treatments that are being researched, including individual therapy, acupuncture, meditation, and yoga. As these alternative therapies are being explored, physicians and counselors are keeping the needs of the patients in mind. These treatments give them a place to express their fears and stress, connect with other women who relate to them, and provide other intangible benefits that the patients consider important or encouraging. These metrics keep such alternative treatments from being ruled out as lacking any benefit, although spiritual and emotional benefits may be more difficult to discern.

International Society for Cutaneous Lymphomas

The International Society for Cutaneous Lymphomas (ISCL) is a nonprofit association with worldwide operations. It was founded in December 1992 at the World Congress of Dermatology in New York. The association is headquartered in Geneva, Illinois. The founding members of the association were Perter Heald from Yale Dermatologists Associates, New Haven, Connecticut; Gunter Burg from the University of Zurich, Switzerland; and Eric Vonderheid from Johns Hopkins University, Baltimore, Maryland. The objectives of ISCL are to increase knowledge of lymphoproliferative and related disorders of the skin and to foster collaboration among clinicians, scientists, and regional or national groups by sponsoring a database of different lymphoma problems and other common issues relating to the diagnosis and control of lymphoma as it develops. In summary, these objectives of the association can be stated as to foster communication and stimulate interactions among regional and national groups and individuals interested in cutaneous lymphomas. ISCL was formed after the realization that there were several regional groups that worked toward improving health care for persons with cutaneous lymphomas. ISCL was meant to create a global central point for coordination of the activities of the various groups.

Today, the association still works toward the realization of these objectives. The leadership of ISCL has been made up of Youn Kim, MD, from Stanford University Medical Center California, United States, as the president; Maarteen Vermeer, MD, PhD, from Leiden University Medical Center, The Netherlands, as the secretary; and Larisa Geskin, MD, of the University of Pittsburgh Medical Center, Department of Dermatology, Pittsburg, Pennsylvania, United States, as the treasurer. Under the executive arm of ISCL is the board of directors, which is made up of 18 members. The current members of the board are Marie Beylot-Barry of France; Kwang Hyun Cho of Seoul, Korea; Francine Foss of New Haven, Connecticut; Robert Gniadecki of Copenhagen, Denmark; Joan Guitart of Chicago, Illinois; Emmilia Hodak of Petah Tiqva, Israel; Richard Hoppe from Stanford, California; Werner Kempf from Zürich, Switzerland; Thomas Kupper from Boston, Massachusetts; Pablo L. Ortiz-Romero from Madrid, Spain; Pierluigi Porcu from Columbus, Ohio; H. Miles Prince from Melbourne, Australia; Pietro Quaglino from Torino, Italy; José Antonio Sanches, Jr., from São Paulo, Brazil; Professor Rudolf Stadler from Minden, Germany; Makoto Sugaya from Tokyo, Japan; John A. Zic from Nashville, Tennessee; and the Web site chair, which has been occupied by Elise A. Olsen from Durham, North Carolina.

To reach its global consumers, ISCL has a Web site through which interested persons can register as members. The majority of those who register are persons who are suffering from cutaneous lymphomas, persons looking for information about the diseases, or persons who wish to provide useful information about the disease. As a result, there are four membership categories:

General membership is available or can be granted to any physician or scientist actively involved in the care of patients with lymphoproliferative skin disorders or who are engaged in research in this or a related area. Associate membership can be granted to an allied health care professional, an individual, or an entity that grants financial support to the society or an individual involved in a cutaneous lymphoma patient support group who is interested in, and supports, the purposes of the society. Honorary membership is sought as a privilege position in the ISCL and is granted to any individual, who, as determined by the board of directors, has made an outstanding contribution to the society and to the field of cutaneous lymphoproliferative disorders.
As such, this membership is more of an appreciation for exceptional work in the field of cutaneous lymphoma. Resident membership may be granted to any physician in good standing who is in a residency program or postresidency fellowship and is interested in the field of cutaneous lymphoproliferative disorders.

Applications to become a member of the association are reviewed by the executive committee of the ISCL. As a member of the ISCL, one is entitled to serve on committees and attend the meetings of the association. However, it is only general and honorary members who have the power to vote as well as hold offices. The society holds meetings often as well as invites its members to attend meetings related to dermatology and cutaneous lymphoma.

To achieve its objectives of disseminating information to the various groups and individuals interested in cutaneous lymphoma, the ISCL publishes materials that are useful to its members. These will be from the members and researchers of the ISCL or from third-party sources. In addition to these publications, the meetings that ISCL members are eligible to attend contribute greatly toward the realization of the association’s objectives. ISCL also works in association with other cutaneous societies, for example, the Cutaneous Lymphoma Task Force (EORTC), the Japanese Association for Cutaneous Lymphomas, and the Latin American Cutaneous Lymphoma Group. The operations of the association are mainly through members’ contributions or donor contributions.

For improved care of cutaneous lymphoma patients, research is important for the establishment of new, better, and innovative care as well as management strategies for the disease. To realize this, the ISCL has several research projects as well as clinical trials in the United States. Some of these include the phase I dose-finding and preliminary efficacy study of Istodax in combination with Doxil for the treatment of adults with relapsed or refractory cutaneous T-cell lymphoma and analysis of cutaneous and hematologic disorders by high-throughput nucleic acid sequencing, among others that are ongoing.

International Society for Experimental Hematology

The International Society for Experimental Hematology (ISEH) was established in 1959 by a group of scientists who wanted to create a forum for the presentation and discussion of preclinical data in experimental hematology. Over time, ISEH remains committed to the promotion of the scientific knowledge and clinical application of basic hematology and immunological disorders. This society works through scientific programs, research, and publications. ISEH was incorporated in the United States in 1972. Currently, it has 800 active members, and it has operations in more than 40 countries spread
all over the globe. The society has an annual scientific meeting, and this attracts more than 500 participants within the four days in which the meeting runs. Through this annual meeting and an official monthly journal—Experimental Hematology—ISEH provides essential delivery of quality education, training programs, and discussion forums and promotes basic research in the field of hematology.

The members of the society present their significant breakthroughs in research through the forum. This has seen the presentation of high-profile research, such as on cloning and characterization of many new hematopoietic growth factors or the initial presentation on the work of Dr. Don Thomas that led to his award of the Nobel Prize in Medicine. The ISEH was the first to successfully describe a number of in vitro controls and to study the use of stem cells as needed; in vitro LTC-IC, CFU-C, CAFC, CFU-S assays; and in vivo transplant functions. Others work with the means of purifying cells in the body for managing several of the different health-related functions that the human body may have when certain treatments are to be managed. In recent times, studies have been made with the intention of managing different solutions for signals within blood cells, protein problems, and other commonplace issues. This all can work to see how well different solutions are to be managed in the best possible cases.

The mission of ISEH is the promotion of scientific knowledge and clinical application of basic hematology, stem cell research, immunology, cell and gene therapy, and all the related aspects through research, discussions, publications, support of investigators, and organization of scientific meetings. To achieve this objective, ISEH undertakes the following: sponsoring of international meetings while emphasizing the highest-quality science, sponsoring fellowships and awards to promote education and training, publication of a first-rate scientific journal, and any other activity that might be approved by the board.

ISEH leadership is the board of directors and has included Paul Frenette, M.D., from the Ruth L. and David S. Gottesman Institute for Stem Cell and Regenerative Medicine Research, United States, as the president; David Traver, Ph.D., from University of California San Diego Division of Biological Sciences, United States, as the president elect for 2017; Timm Schroeder, Ph.D., from the Swiss Federal Institute of Technology, Zurich, Switzerland, as the vice president; Jean-Pierre Levesque, Ph.D., from Mater Medical Research Institute, Australia, as the treasurer; R. Keith Humphries, M.D., Ph.D., from the British Columbia Cancer Research Center, University of British Columbia, Canada, as the editor; Margaret Goodell, Ph.D., from Erasmus Medical Center Cell Biology Department, United States, as the immediate past president; and the following directors—Andrew Elefanty of Monash University, Jonas Larsson of Lund University, Sarah Ellis of Peter MacCallum Cancer Centre, Hartmut Geiger of Ulm University, Trista North of Beth Israel Deaconess Medical Center, Emery Bresnick of University of Wisconsin, Conny Bonifer of University of Birmingham, Koichi Akashi of Kyushu University School of Medicine, and Patricia Ernst of Dartmouth Medical School.

ISEH activities range from a number of activities, among them knowledge, innovation, and exchange. To promote knowledge, ISEH offers comprehensive programs and publications in training and education. The members of the society provide the tools for expansive understanding and cutting-edge methodologies from around the globe. To enhance innovation, the society provides the latest scientific information. Its members are at the forefront of advances in experimental hematology with regard to the study of commonplace problems relating to hematologic functions and stem cell issues as well as gene problems that may come about. Transplant and gene therapy procedures are also studied in most cases. Last, ISEH does exchange programs to connect clinicians and researchers from around the world. This is best done through ISEH membership within an inclusive, international forum, which creates many opportunities for conversations between young scientists and leaders in the research field and industry.

The members of ISEH are professionals in varying positions; scientists—42.6 percent, students—19.4 percent, clinicians—16.5 percent, postdoctoral fellows—16 percent, and industry representatives—5.5 percent. The membership plans include active members who pay an annual fee of $175, which has the option of a two-year subscription at $329. This membership plan is for scientists engaged in the study of hematology and stem cell research. The other is the associate or member in training, which requires an annual fee of $65. This plan is open for students in universities or colleges as well as postdoctoral fellows.
ISEH has two major publications: *Experimental Hematology* and *Connections Newsletter*. *Experimental Hematology* is the society's official journal. It is committed to publishing the latest research reports, reviews, letters to the editor, and abstracts of the annual meeting of the ISEH. *Connections Newsletter* covers details on new developments in the field at large.

As a mark of success and achievement for not only the society but also its members, ISEH has a number of awards that are meant to recognize distinguished scientists in the field through their exemplary work. The awards available are the Donald Metcalf Award, McCulloch and Till Award, New Investigator Awards, and travel grants for young investigators.

**International Society for Preventive Oncology**

The International Society for Preventive Oncology (ISPO) is a World Health Organization (WHO)-associated group that has been in operation for nearly 50 years. ISPO is the forum of an international membership, and it studies interactive etiologic factors in cancer development and their impact on prevention, detection, and management of neoplastic diseases.

The ISPO mission statement is made up of scientific objectives and activities. The scientific objectives are to foster primary prevention of cancer through identification and control of cancer causes and to identify high-risk individuals and secondary prevention through detection and management of occult cancer and precursor lesions. In addition, ISPO seeks to promote continuing education in areas of the role of lifestyle, including sexual practices, nutrition, and tobacco, as cancer-causing factors and their impact as well as genetic influences, predictive markers, novel therapies, and other commonplace points that could be utilized in many forms.

In addition to the scientific objectives, ISPO has activities in which it seeks to disseminate information on a global scale on the latest advances in basic and clinical oncology. This is done through the society’s continuing education programs and educational initiatives, which include publications and international meetings and workshops. ISPO publications include the bimonthly, multidisciplinary journal *Cancer Detection and Prevention*, which publishes reviews on oncology and how to treat conditions while preventing serious complications from developing. International meetings and workshops foster education in oncology through investigators exchanging information on the newest approaches for identification of the multiple interacting factors in the etiology, prevention, detection, and management of serious issues.

Some of the international meetings and workshops that have been held by the society include the Seventh International Symposium on Biotechnology in Preventive Oncology in 2004 in Nice, France, with the topic predictive oncology and intervention strategies, the Sixth International Symposium on Biotechnology in Preventive Oncology on February 9, 2002, in Paris, France, and the Fifth International Symposium on Biotechnology in Preventive Oncology, held from October 28 to 31, 2000, in Geneva, Switzerland, with the topic on prognostic indicators for managing oncology and other commonplace solutions for taking care of patients who may be struggling with issues relating to cancer.

The past president of the society has been H. E. Nieburgs, M.D., who was the founder of ISPO. ISPO has Nieburgs's address as the society's mailing address. L. Santi, M.D., from Genoa, Italy, has been president, with G. de Thé, M.D., from Paris, France, as
Persons interested in oncology can apply and become members of the society. Such persons include primary care physicians, hematologists, immunologists, pathologists, epidemiologists, experimental oncologists, social scientists, and educators as ISPO supports the needs for health care professionals who need assistance with managing cancer prevention while educating people about how such solutions are to be utilized. Active members of the society are eligible to hold offices, vote in the biennial elections of the society, and serve in the various standing committees. To ensure members are well informed and up-to-date with information on cancer, the society provides continuing education through the society’s scientific activities, and members can attend the ISPO's workshops, international meetings, and regional symposia at a reduced fee. For one to be a member, a membership fee is required, which includes a yearly subscription to the "Cancer Detection and Prevention" journal and free online access to the journal.

The membership of ISPO consists of active, associate, junior, life, and honorary members. An applicant wishing to become a member of the society should be sponsored by two members of the society or by two individuals who are accepted to the society. Recommendation letters are required and can be sent accompanied with the application or separately to the secretary general. Also, the application should be sent with the initial fee, and it is considered to be the annual fee for the first calendar year. Active members are limited to physicians and other professionals at the doctoral level. Associate membership includes those persons of unusual proficiency and scientific attainment without a doctorate degree. Junior membership includes physicians and scientists in training.

"Cancer Detection and Prevention" is the journal founded by ISPO. The journal reflects the society's viewpoint that human cancer is a preventable disease and use of the information that has accumulated over time has the potential to eradicate morbidity and mortality of patients with neoplastic diseases. However, in 2008, the ownership of the journal was transferred to Elsevier Science, Ltd. Even with the ownership transfer, the publication of the journal has remained bimonthly.

The society is managed through membership fees, which are submitted annually. In addition, donor contributions are used, even though they are not common. ISPO has been presented with an award for outstanding contributions to the understanding of cancer that may provide practical applications for improved cancer control.

International Society of Nurses in Cancer Care

The International Society of Nurses in Cancer Care (ISNCC) was founded in 1984. According to its Web site, it is comprised of more than 60,000 cancer nursing members, which include national and regional societies and oncology institutions in addition to individual cancer nurse practitioners, researchers, and educators. The ISNCC “is a nongovernmental member of the World Health Organization (WHO) and is affiliated with the International Council of Nurses (ICN) and the Union for International Cancer Control (UICC).”

The ISNCC mission, as professed on its Web site, is to “maximize the influence of nursing to reduce the global burden of care,” and its vision is to “lead the global nursing community in cancer
control.” The ISNCC employs “strategic directions,” according to Kathryn Godfrey, for the purpose of obtaining its vision by “building and sustaining stakeholder relationships, influencing health policy, advancing and applying knowledge, developing and engaging cancer nurse leaders.” It is well regarded as an international institution that has a positive influence on the health care field through developing the “knowledge and skills of international cancer nurses.”

Three types of memberships are available: individual, association, and full membership. Individual memberships are available to nurses and other healthcare professionals who have an interest in cancer nursing. On the association member level, national specialist nursing groups, institutions, and organizations in the field of cancer nursing are eligible for membership. According to the ISNCC Web site, “This network is an invaluable international resource of nurses working in clinical practice, education, research and management to advise them on cancer nursing and the nurse’s role in cancer care. Oncology institutions, charities and related organizations are eligible to be associate members.” Full membership is available to oncology nursing societies providing resources for “working in clinical practice, education, research and management to advise them on cancer nursing and the nurse’s role in cancer care.”

Aims of the Society
The ISNCC focuses on the specific areas of charity, education, and science and enacts specific strategies to aid in all areas. Toward that end, the ISNCC provides a forum so that cancer nurses can improve care through discussion of strategies and innovations that advance clinical practice. The ISNCC also offers support for increasing the role of cancer nurses as leaders in the field internationally. Finally, the organization also emphasizes enhancement of health and well-being of people at risk for or living with cancer.

Through an array of committees developed and supported by ISNCC, members are encouraged to participate in the society in various capacities that advance ISNCC’s efforts to promote charity, education, and science. For example, ISNCC embraces its charitable focus within the organization through an International Conference on Cancer Nursing (ICCN) scholarship that ensures nurses from low- and middle-income countries are able to participate in the conference. Additionally, according to ISNCC’s position statement on Cancer Nursing Education, “investing in cancer nursing education is crucial to prepare adequate numbers of nurses to address the growing global burden of non-communicable diseases.” Furthermore, ISNCC takes a position that nursing is responsible for its own knowledge base and works to achieve its scientific goals through its annual conferences as well as through its Scientific Planning Committee, whose purpose is to “develop the overall conference program for the biennial International Conference on Cancer Nursing (ICCN) requiring international input and collaboration.”

Conferences
ISNCC holds the biennial International Conference on Cancer Nursing (ICCN). Recent hosts include Toronto, Canada; Singapore; Atlanta, Georgia; and Prague, Czech Republic.

At the 15th International Conference on Cancer Nursing in 2011, then president of ISNCC Professor Sanchia Arnada told delegates, “ISNCC is the voice of cancer nurses in the international arena. This conference is a unique experience where we learn from our colleagues in many different countries where sometimes the most remarkable innovations are those that are borne of the ingenuity of nurses with little support but great commitment.”

Developing Global Partnerships
A central goal of the ISNCC is to collaborate with other associations globally in order to develop mutually beneficial relationships. With each of its associates, Godfrey describes, the ISNCC “develops a Memorandum of Understanding (MOU)” for the purpose of “collaboration, mutual recognition, and shared, culturally sensitive approaches to the work of both organizations.” Collaborations are aimed at developing “communication with each other about eventual strategies to develop and promote oncology nursing and multidisciplinary cancer care.” Presently, the ISNCC “has MOU agreements with three international organizations—the Multinational Association of Supportive Care in Cancer (MASCC), the European Oncology Nursing Society (EONS), and the Oncology Nursing Society (ONS) USA.” ISNCC disseminates information to its cancer nursing members through the official Web site
and The International Cancer Nursing News, the quarterly publication that is available in both print and digital formats. Newsletters typically feature a message from the president, a research column, and an education column. More than 11,000 individuals and organizations subscribe worldwide.

International Society of Paediatric Oncology

The International Society of Paediatric Oncology (SIOP), founded in the late 1960s, has grown into a worldwide organization with more than 1,000 members from allied health professions, scientists, and other researchers. Members aim to improve treatment for childhood cancers with a vision that no child should ever die from cancer. SIOP’s visional goals include providing access to state-of-the-art treatment for pediatric patients; ensuring that all persons involved in childhood cancer have access to information through continued professional development, networking, and meetings; supporting caretakers of children with cancer with the best palliative and curative therapies; and advocating for long-term follow-up care for survivors. SIOP sponsors continental and regional meetings to promote good practice and the exchange of information, including an annual congress.

SIOP has six continental branches, and each addresses particular issues relevant to its specific region of the world. The regions include North America, Latin America, Europe, Africa, Asia, and Oceania. SIOP encourages all health care professionals to join their organization, to attend meetings and the annual congress, and to use the organization to develop regional networks.

The management and development of strategies and policies fall within the responsibility of the board of directors. The board of directors are elected by members of SIOP. SIOP has six primary committees: scientific committee (SC), psychosocial committee, publication committee, pediatric-psycho oncology committee (PPO), nurses committee, and the committee on developing countries (PODC).

The primary task of the SC is to organize the scientific program for the annual SIOP meeting. The annual meeting consists of two and one-half days of meetings: the expert sessions, eight keynote lectures, 10 symposia, 24 oral paper presentations, and one large poster session. Nurses, parents, and survivors have their own programs, while other programs are combined. Annually, the Schweig Guth prize is awarded to a young investigator for the best original scientific work and for the three best abstracts presented in clinical studies, studies in developing countries, and basic or translational studies. The official committee, scientific program advisory committee (SPAC) invites experts to speak and proposes topics for the annual meeting. The SC subcommittee groups include the following: pathology, basic science, radiation oncology, epidemiology, nursing, psychosocial, surgical, and psycho-oncology.

The psychosocial committee was formed in 1991 based on directives from the SIOP board, who recognized the importance of psychosocial issues in the care of children with cancer.
The committee has published 11 journal articles addressing psychosocial interventions as a part of pediatric oncology and therapeutic trials. The topics have included critical commentary, school and education, care of long-term survivors, communication of the diagnosis, therapeutic alliance, terminally ill children, siblings, burnout, refusal and noncompliance, informed consent, and alternative therapies. These 11 articles have been translated from English into Japanese, Greek, Portuguese, Spanish, and Italian.

The publication committee was created to review manuscripts prior to publication if they use the SIOP logo or SIOP data, originate from the board or committees, sanction SIOP treatment or management guidelines, or publish SIOP’s position on advocacy or policy. The committee determines if the article is appropriate to use the SIOP name, if the content is accurate and draws appropriate conclusions, and if it is a duplication of other articles. The committee can also offer a full editorial and scientific review if the authors request it.

The PPO, established in 2007, educates and provides support about the impact of childhood cancer on the children’s well-being and their families from a developmental perspective. The PPO strongly advocates for the inclusion of psycho-oncology in pediatric cancer treatment, rehabilitation, and counseling. The purposes of the PPO include support of the exchange of research data on psycho-oncology pediatric issues; support of the integration of data into practice; and integration of data into current research and theory.

The nursing committee promotes information exchange among nurses who care for pediatric oncology patients and their families. The committee promotes and develops standards of care that are globally relevant and initiates research in pediatric nursing oncology.

The PODC committee, established in 1998, has the goal to develop pediatric oncology in developing
countries. The committee has 12 core members and more than 60 consultants. The primary activities of the PODC committee are symposia and workshops, sponsorship of local meetings, educational programs, scholarships, exchange programs, clinical trials, and collaborative research.

SIOP created a “Standards of Care and Training” document in 2002. The purpose of the document was to outline that every child has a basic right to life and that parents should be supported in obtaining these rights for their children. The document sets guidelines for parents that outline what they should expect in terms of care and treatment. The document is intended to provide guidance for any professional in the position to advocate, provide care, or improve standards of care. It is also intended for patients and their families. A key source of information for the “Standards of Care and Training” document is the United Nations Convention on the Rights of the Child. In part, the convention concludes that access to information is available that promotes health, health care should conform to established standards, working parents should benefit from child-care facilities, children have the right to the highest standard of health and to treatment facilities that support this, every child has the right to social insurance, and every child has the right to education.

International Society on Thrombosis and Haemostasis

The International Society on Thrombosis and Haemostasis (ISTH) is a worldwide nonprofit organization to encourage the understanding, prevention, diagnosis, and treatment of thrombotic disorders and other commonplace problems that entail bleeding. ISTH was established in 1954, when a small group of investigators used seed money from the National Heart, Lung, and Blood Institute to form the International Committee on Thrombosis and Haemostasis (ICTH). The members of the group were well-known in the world of blood studies and the overall analysis of how the bloodstream functions. With time, interests in the group grew, and ICTH began consideration to expand the scope of the mission. Attendance to the yearly meeting of the ICTH grew, and they no longer could accommodate the meeting in the small, meant-for-committee rooms.

All through the 1960s, members of ICTH delved into expansion plans by clarifying and planning the mission, structure, and function and amending the leadership of a larger group. The vision behind the plans was to have a society that would be open to all researchers, clinicians, educators, and others who are in the fields of vascular biology. ICTH was built primarily on blood coagulation and hemorrhagic disorders. The new organization was designed not only to focus on the primary area as ICTH but also to include fields relating to platelet studies and understanding many problems that relate to serious issues all around the body. At the turn of the decade in 1969, in the 15th annual meeting in Bath, UK, members of ICTH finally came to vote, unanimously approving the creation of the ISTH.

Currently, the impact and contributions of ISTH are dedicated toward the understanding, prevention, diagnosis, and treatment of thrombotic and bleeding disorders. These activities are available in six continents with more than 3,800 members in more than 94 countries; the organization is now the leading thrombosis- and haemostasis-related professional organization in the world.

The governing body of ISTH is the council. The functions of the council are authorization and
exercising all corporate powers of the society and overseeing all of its activities. The executive committee is a subset of the ISTH council, and its function is to provide executive direction to the activities of the society in between council meetings. These governing bodies, just like every other organization, are guided by set laws and bylaws. ISTH bylaws empower the council to establish committees that recommend to the council policies, programs, and actions related to their areas of expertise and responsibility. The committees also implement recommendations that the council approves. Any ISTH member can be added to the council if consulted properly. Council members serve six-year terms and may serve up to two nonconsecutive terms with at least two years elapsing in between those said terms.

Every two years, members of the ISTH society elect five of their peers to the council. This replaces about a third of the elected members of the council. The Council also has ex-officio voting members who are members by virtue of holding another office with the ISTH, as mandated by the society’s bylaws. Office bearers have been Nigel Key from the United States as the chair, Nuala Booth from the UK as the treasurer, and Ingrid Pabinger from Austria as the secretary, who is also the chair elect.

ISTH is the leading global community of specialists in bleeding and clotting disorders. Given this fact, the society offers benefits that inspire, drive, and connect researchers in the translation of science to advance clinical practice to improve the lives of millions of people worldwide. As a member of ISTH, one is guaranteed to stay up-to-date on the latest scientific advances and emerging trends in thrombosis and haemostasis. This ensures every member of the society deepens and broadens in expertise.

One of the missions of ISTH is to ensure its members as well as any other persons interested in thrombosis and haemostasis have advanced knowledge and understanding through effective and consistent provision of quality information. To realize this, the organization has a number of publications. The Journal of Thrombosis and Haemostasis (JTH) is a key guide that is used in this field. Its authors, reviewers, and editors volunteer their time and expertise to contribute and disseminate important scientific information to the international research community. The society’s Scientific and Standardization Committee (SSC) prepares reports on the field to determine how well they are able to function as needed. As a service to the scientific community, these official SSC communications are made available as open-access documents: They are available on the society’s Web site. Most of the standards developed by SCC are adopted by the World Health Organization as international standards. ISTH’s quarterly e-newsletter highlights global thrombosis and haemostasis news, reports on the work of the society’s committees, and publishes other information that helps facilitate the participation of members in the many activities in the field. The other sources of information from ISTH include registries and databases, meeting materials, monographs, and member obituaries.

ISTH meetings include the ISTH congress, which meets every two years, and SCC meetings, held annually. The SCC and the congress are held jointly. All people associated with the field can attend these meetings in order to get a better idea of how the industry is working and what is being done in order to treat such problems as they come about.

Intraocular Melanoma

Eye-related cancers can develop on the eyelids, on the ocular surface, or inside of the eye. Melanoma is the most common intraocular malignant tumor in adults and can significantly affect vision-related quality of life and survival. This entry discusses the pathogenesis, epidemiology and risk factors, diagnostic methods, and treatment options for intraocular melanoma.

Melanomas arise from melanocytes, which are cells responsible for tissue pigmentation. These tumors are therefore often pigmented in appearance. Within the eye, melanocytes are most abundant in the uvea. The uvea is a layer of highly vascular and pigmented tissue that is located underneath the sclera, the white portion of the eye. The iris is the most anterior segment of the uvea. Moving toward the back of the eye, it continues as the ciliary body, which is responsible for movement of the lens and production of intraocular fluid (aqueous humor). The majority of the uveal tract is posterior to the ciliary body, called the choroid. The choroid has the highest blood flow in the entire body and plays an important role in sustaining the functions of the retina. Intraocular melanomas can arise from any of these tissues, but the most common are choroidal melanomas. Iris and ciliary body melanomas are relatively rare and have the better and worse prognoses, respectively.

Uveal melanomas represent approximately 3 percent of all melanomas, and the incidence in the United States is about five per million per year. It predominantly affects adult Caucasians: approximately 98 percent of cases occur in white patients, and the average age of diagnosis is about 60 years. It appears to affect both men and women equally. Uveal melanoma is generally a sporadic event, but rare cases of familial uveal melanomas have been reported. Diet and smoking do not appear to be risk factors, but those with light skin color, light eye color, and propensity to sunburn may be at higher risk.

Patients are diagnosed either on routine eye examination or when they present with visual symptoms, such as blurry vision, flashing lights, and visual field defects. Vision loss can also occur if the tumor involves the center of the retina or if there is associated retinal detachment. The most important step in the management of intraocular melanomas is an examination by an ophthalmologist with experience in ocular oncology. Uveal melanomas usually appear as pigmented masses, but some may contain minimal or no pigmentation, and some may be diffuse with minimal elevation. Small tumors can be difficult to distinguish from benign lesions, and close observation is a reasonable option for indeterminate lesions. Other diagnoses that may mimic choroidal melanomas include nevi, hyperplasia of the retinal pigment epithelium, hemorrhage, choroidal hemangioma, choroidal osteoma, and choroidal metastasis.

An important ancillary imaging study is ultrasonography, which can characterize the tumor and measure its dimensions. Ultrasound measurements are routinely used to track the growth or regression of intraocular tumors. Fluorescein angiography also may aid in diagnosis. Fluorescein is a synthetic dye that is injected into a vein, and photographs are taken using special filters that allow visualization of retinal and choroidal vasculature and associated lesions.

Management of intraocular melanoma used to be limited to enucleation (removal of the eye), but most patients are now treated with radiation therapy in order to preserve the eye and vision as much as possible. Eyes with large melanomas are
Intraocular Melanoma

at high risk for complications after radiation and have a poor visual prognosis; therefore they may still be managed by enucleation. Enucleations are performed under general anesthesia by ophthalmologists. Implants are placed into the orbit (eye socket), and prostheses are designed and fitted several weeks after the surgery. Many advances have been made in optimizing the cosmetic appearance and movement of prostheses.

The Collaborative Ocular Melanoma Study was a seminal clinical trial in the 1980s and 1990s that randomized patients with medium-sized choroidal melanomas to either enucleation or radiation therapy using I-125 brachytherapy. The study showed that survival rates did not differ significantly between the two groups. Brachytherapy is a form of radiation treatment where a short-range radiation source is implanted in close proximity to the target. Ophthalmic application of brachytherapy involves a plaque embedded with radioisotope seeds. The exact location, size, and shape of the melanoma are first determined by an ocular oncologist, and plaques are chosen to most effectively treat the tumor. The plaques are implanted in the operating room, and the patient wears a lead shield during the treatment period. The plaque is then removed in the operating room after several days. Brachytherapy is currently the most commonly used treatment modality due to its wide availability.

Proton beam irradiation is another type of radiation treatment that is offered at several specialized centers. Unlike conventional external beam irradiation, proton therapy uses charged particles that allow precise targeting of tumors while minimizing radiation exposure of adjacent tissues. A property of proton therapy called the Bragg peak results in a sudden drop-off of radiation after a highly concentrated, uniform dose is delivered to the target, thereby sparing any distal tissues, such as the optic nerve or other areas of the retina. In preparation for proton therapy, radiopaque rings are sutured onto the eye in the operating room to allow accurate tumor localization. Individualized face masks and bite blocks are created, and patients are asked to gaze at a fixation light during the treatment. Most tumors show regression in a few months and continue to regress thereafter.

Tumors that involve or are close to the optic disc (part of the optic nerve that exists inside the eye) or fovea (part of the retina responsible for central vision) carry poor visual prognosis due to damage by the tumor as well as by the radiation that needs to be directed at these vital structures. Approximately half of patients treated with either brachytherapy or proton therapy will develop radiation retinopathy, and about a quarter will develop radiation optic neuropathy. Radiation retinopathy is a slowly progressive condition caused by vascular damage from radiation. Retinal hemorrhage, swelling, exudation, and growth of abnormal vessels can occur, which may worsen vision. Depending on the manifestation and severity, laser treatments or injections into the eye may be helpful. Radiation optic neuropathy is caused by radiation damage to the optic nerve. The nerve can appear swollen or pale and have hemorrhages. There are no established treatments for radiation optic neuropathy.

Choroidal melanomas can metastasize through blood vessels, most commonly to the liver. Tumors that are large, involve the ciliary body, have certain appearances under the microscope, or carry specific genetic alterations are more likely to metastasize. Recent advances have allowed for profile needle biopsy samples based on analysis of DNA or RNA to categorize the tumors into those high and low risk for metastasis. Unfortunately, advances have not yet been made in the treatment of eye-related cancers can develop on the eyelids, on the ocular surface, or inside of the eye. Melanoma is the most common intraocular malignant tumor in adults. (Flickr/Dan Foy)
of metastatic disease. Up to half of patients with uveal melanoma will die from metastasis. However, genetic testing can now identify high-risk patients for clinical trials that may lead to effective therapies in the future.

Further Readings

Iran

The western Asian nation officially termed the Islamic Republic of Iran was created in 1979 as a result of the Iranian Revolution. Historically, the territory that makes up the modern state of Iran has been the site of numerous civilizations, empires, and cultures. Currently, Iran has a population of nearly 80 million citizens. The national language is Persian, while the national tender is the rial. In the past 50 years, the country has instituted the domestic infrastructure to meet the cancer challenges of its citizens resolutely.

Data regarding cancer incidences in Iran was first compiled in 1960 by Professor Abdollah Habibi, and contemporary researchers in the country now consider Professor Habibi’s reporting to have provided a prototype for the domestic cancer registries that were to arise within the country in the years to come. The first true national cancer registry in Iran was established in 1969 as the collaborative effort of Tehran University and the International Agency for Research on Cancer because researchers wanted to analyze the seemingly unusually high amount of esophageal cancer incidences in the nation's Mazandaran territory. Since the initiation of the national registry in 1969, domestic and international researchers have been able to accurately analyze incidence trends in the country.

Cancer is presently estimated to be the second-leading cause of death in Iran. While the nation has a robust cancer registry system in place to track cancer incidence rates, the country does not have a system in place to accurately track the mortality rates related to specific cancers. Researchers believe that more than 50,000 new incidences of cancer are occurring in Iran each year. In recent years, increased levels of obesity in the country have correlated with higher rates of intestinal cancers, while researchers have found lung cancer rates to be relatively low when compared to the population of domestic smokers in Iran.

Cancer care in Iran is regarded as well structured and effective. If an Iranian is diagnosed with cancer there, he or she is referred to local health centers, where they are further referred to advanced regional treatment facilities. Treatment is free of charge up until a patient is referred a third time, at which point personal health insurance is enacted. At present, there are efforts by the Iranian government to provide insurance to all nonurban Iranian citizens who would otherwise likely struggle to pay for more advanced levels of treatment. Somewhat ironically, cancer treatment in urban Iranian areas can be regarded as slightly chaotic, though the levels of treatment capabilities at the urban facilities are some of the best in the nation.

Currently, the most prevalent forms of cancer in Iran are breast, bladder, lung, ovary, and prostate cancer. Bladder, lung, prostate, and stomach cancers are the most common forms of cancer incidences in males in the nation, while breast, ovary, and stomach cancers are the most prevalent incidences of cancer in females there. Nationally, incidences of lymphomas, nasopharynx, and skin cancer have been consistently trending upward over the past several years, while incidences of bladder, bowel, and lung cancer have been consistently increasing.

Unfortunately, many citizens of Iran have had cancer throughout the nation’s history. The famous Iranian pop musician Toofan Ataee passed away as a result of lung cancer in 2012. Mahasti, another popular Iranian pop musician, succumbed to her fight with lung cancer after battling the disease for
several years. Moreover, the critically acclaimed Iranian playwright Ostad Mohammad died in 2013 from complications arising from liver cancer.

With regard to cancer, Iran’s future is bright. The nation is home to several facilities capable of excellent cancer care such as the Cancer Institute of the Islamic Republic of Iran, which was first established in Tehran in 1949. Since then, the institute has become one of Iran’s leading cancer research and treatment facilities as it is fully equipped to deal with the nation’s cancer incidences, having departments dedicated to chemotherapy, experimental research, genetic studies, pathology, radiology, and surgery. Not only is the facility capable of world-class cancer care, but it is also the site of Iran’s nationwide cancer registry center. This facility, among the many other capable cancer treatment centers in Iran, is a positive indication signaling that the nation has the proper means to adequately tackle domestic cancer incidences in the coming decades.

Further Readings

Iraq

Iraq is located in southwest Asia, bordered by the Islamic Republic of Iran on the east, Kuwait on the south, Saudi Arabia on the southwest, Jordan and Syria on the west, and Turkey on the north. The population as of 2012 was just over 32 million living in an area of 168,754 square miles (437,072 square kilometers). Iraq has two major ethnic groups: Arabs and Kurds. The history of health services in Iraq was not well documented until the beginning of the 20th century; however, it was likely to have been similar to other Middle Eastern countries, with limitations in terms of up-to-date medical services and a basic reliance on herbal medicine. Iraq has seen major advances in health care systems and preventative measures in the 20th century, and by the 1980s, the health system in Iraq was considered one of the best in the Middle East. However, since then, continuous unrest has led to a level of deterioration in all sectors in Iraq, including health care.

Iraq established a population-based cancer registry in 1976. The last registry was issued in 2011 and includes updated reports up to 2009 (according to the official Ministry of Health [MOH] Web site). Iraq has four pediatric oncology centers: two in Baghdad,
one in Basrah, and one in Mosul. Iraq also has five radiotherapy centers in service; two in Baghdad, the other three centers in three different governorates, and three more that are yet to start administering services to patients. Additionally, there are 23 oncology centers distributed in 18 governorates that provide chemotherapy for cancer patients. All these public oncology and radiotherapy centers are part of the free central health care system in Iraq.

In spite of the continuous effort to improve the quality and size of services available, these might not be sufficient to accommodate the number of cancer patients in Iraq. According to the last report by the Iraqi MOH, there were 15,251 new cancer cases reported in 2009, representing an incidence rate of 46.16 per 100,000 people and increasing from 44.46 in 2008. The most prevalent types of cancer reported among Iraqi patients were breast cancer, lung cancer, brain and central nervous system carcinoma, bladder carcinoma, and leukemia.

An important factor in controlling cancer globally is providing means for early diagnosis of cancer and for palliative therapy for cancer patients. A program for early detection and downstaging of breast cancer was established in Iraq in 2000 in collaboration with the World Health Organization (WHO). The program involved approximately 20 centers and clinics distributed in all Iraqi governorates. Mobile mammography units have been implemented to perform breast cancer screening services in Baghdad, Basrah, and Mosul. More are planned to be employed in other Iraqi cities and governorates. Palliative therapy, however, does not meet the current requirements for the increasing number of reported cancer patients.

Several studies have been conducted recently by Iraqi researchers looking at the rate of specific types of cancer or incidence among specific populations or cities. Overall, the studies have concluded that the incidence rates of the types of cancer studied are in general comparable to those reported for other Middle Eastern countries.

A recent study reported that the incidence of cancer was increasing in the city of Fallujah, Al Anbar governorate, and was higher than other cities during the year of 2011. This increase is claimed to be caused by depleted uranium used in armor-piercing munitions dropped in the war of 1991 and of 2003. Iraqi studies have shown that the level of this material is higher in regions where cancer incidences are high. However, other studies have argued against this hypothesis and reported acceptable levels of depleted uranium to be present in Iraqi soil.

Given the current state of increased exposure of the Iraqi people to hazardous pollution and the increased rate of tobacco smoking, cancer incidences are expected to rise.

### Ireland Republic of

Ireland is an island in the Atlantic Ocean found to the west of the island of Britain. Ireland’s human occupation stretches back at least to the Mesolithic, and Stone Age monuments and mounds still are widely scattered across the landscape. The island of Ireland is divided into 32 counties. The Republic of Ireland is a political unit that is constituted of 26 of the counties; the remaining six counties are part of the United Kingdom of England, Scotland, Wales, and Northern Ireland. Prior to the 20th century, the 26 counties also were part of the United Kingdom of
Britain and Ireland, but a bloody War for Independence concluded in 1922 with a treaty that granted home rule for most of the island. Medical care in the Republic has tended to follow a British model for the last two centuries. Medical care, including cancer treatments, has been controversial for decades, although charitable funding and research into cancer treatments has been outstanding.

Ancient Times
In ancient times Ireland was home to tribal people who generally are known today as Celts or Gaels; included among their gods was Dian Cecht, the god of medicine and herbs. The first recorded mortal physician in Ireland was Maelodar O’Tinnri, who died in 860 C.E. Cancer was known in ancient times as tuthle, aile, teine-buirr (fiery swelling), or úrphasiú. Ancient Celtic medicine in Ireland was based upon a combination of herbal medicines, such as bilberry (fraochán), which contains the antioxidant anthocyanidin (which blocks cell proliferation), and other anti-cancer constituents. Bilberry still is used in some modern anti-cancer remedies. Druids, Celtic priests, were reported to harvest mistletoe (drualas), which is toxic in large quantities, to make a hallucinogenic drink. Mistletoe also has been used for a cancer treatment, and some modern drugs, such as Iscador, Plenosol, Helixor, and Isorel, have contained mistletoe extracts.

The Middle Ages
In the middle ages noble Irish families would have hereditary personal physicians attached to their houses, who would possess their own medical books, for example the Book of the O’Lees, from 1443, the Book of the O’Hickeys, or the Book of the O’Shiels. These books were compendia of the medical knowledge of their days in both Latin and Irish (Gaeilge). According to Belfast-based archaeologist Robert M. Chapple’s blog from March 26, 2014, an American student named Lauren Jean is investigating The Culture of Medicine in Late Medieval Ireland in the original medieval Irish, and it promises to reveal exciting information about medieval Irish medicine, including cancer treatments.

Folk Beliefs
Herbal remedies for cancer still figure in modern folk medicine, as does the belief in holy wells. In 2014 the Irish language television channel, TG4, ran a series of programs titled Garraí Glas (Green Garden), hosted by Síle Nic Chonaonaigh, on the modern usage of herbal medicines, including their use by GPs such as Frieda Ní Chatháin, who supplements her pharmaceuticals with herbs from her “physic garden,” and herbalist Darach O’Murchú, who recommends sorrel for its anti-cancer properties.

Other folk beliefs in cures for cancer and other diseases have a pre-Christian provenance. Nonetheless, such practices as visits to sacred wells, followed by leaving personal objects behind, persist to this day. Lawrence J. Taylor reports that pilgrimages to holy sites such as Lourdes, Medjugorje, or local shrines were considered to be especially powerful. Taylor also reports that blessings by alcoholic priests were sought for cancer cures in rural County Donegal (sober priests’ cures were considered less powerful). Cancer cures also were sought from lay women, known as “healers,” at prayer meetings.

Cancer Statistics
Since 1994, the Republic of Ireland has maintained a National Cancer Registry, which uses
information gathered from hospitals, health care centers, cases reported by medical personnel and laboratories, and death certificates as its sources. According to Cancer in Ireland 2013, which is the National Cancer Registry's latest annual report, cancer cases show a 3 percent annual increase, with most diagnoses occurring in those over 65 years of age. Cancer deaths are increasing at an annual rate of 1 percent. Whether this increase is because more people are living beyond the age of 65 today than in the past is not discussed in the report.

Female breast cancer is the most common type of cancer reported, perhaps because of the Breast-Check screening program, at 32 percent of cases, closely followed by prostate cancer at 31 percent of cases reported to the Registry. Much less common are colorectal/bowel cancer at 13 percent, and lung cancer with an 11 percent incidence rate. Nonetheless, lung cancer is the most common cause of death by cancer in Ireland, at 20 percent of all deaths. The National Cancer Registry reports that this is 50 percent above the European average.

Even so, the five-year long-term survival rates have improved considerably (now at more than 100,000) since 1994, when the National Cancer Registry was started: up from 42 percent to 60 percent in men and up from 52 percent to 62 percent in women. This may be credited, in part, to the 2004 government-issued ban on smoking in enclosed work spaces, such as public houses, taxis, retail establishments, or offices. The five-year long-term survival rates for testicular, prostate, and thyroid cancer now top 90 percent. This may be credited to an increase in treatment rates: chemotherapy (medical oncology or haemato-oncology) rates have increased by 13 percent since 2000, radiation treatments (radiation oncology) have increased by 4 percent, and surgical intervention, known as surgical oncology, has risen by 2 percent.

The Republic of Ireland's Health Services Executive (HSE), which replaced the Regional Health Boards, operates a National Cancer Control Programme (NCCP) with eight self-sufficient Regional Cancer Centres joined together in a network that consists of two centers within each of the four HSE regions. The East Dublin North East region contains Beaumont and Mater University Hospitals; the East Dublin Mid Leinster region holds Saint James's Hospital and Saint Vincent's University Hospital. Cork University Hospital and Waterford regional Hospital are in the NCCP South region, while Galway University Hospital and Mid-Western Regional Hospital are in the NCCP West region. Each of the Centres is set up to serve more than 500,000 people. The executive board of NCCP consists of Susan O'Reilly, Director, Mary Hynes, Deputy Director, Arnold Hill, Maccon Keane, Jerome Coffey, Marie Laffoy, Deirdre Murray, and Majella Byrne. Their goal is to prevent cancer, increase survival rates, and improve the quality of life for patients. NCCP reports that 20,000 people contract cancer each year, of which 7,500 die.

**Charities and Community Services**

CROSS (Cancer Research of the Oesophagus and Stomach) at Saint James's Hospital not only funds cancer research through Trinity College, but also funds the education and training of researchers, for example scholarships for Masters of Science degrees in translational oncology. Another charity, ARC, founded at the Mater Hospital in Dublin in 1994, offers psychological counseling as well as holistic and complementary treatment methods free of charge in ARC Houses. Throughout Ireland cancer support services may be accessed by telephone or online. Some of these services include transportation to medical centers or appointments, drop-in centers where anyone may come for information or counseling, social work or at-home nursing caretakers, and a variety of other support systems, including hospice for terminal patients.

Ireland (Ohio) Cancer Center

The Ireland Cancer Center was the first cancer-focused medical center at the University Hospitals Cleveland in Cleveland, Ohio, a multidisciplinary hospital facility founded in partnership with the city’s Case Western Reserve University. In 2011, a major university-led fund-raising drive led to renovations and new facilities construction that resulted in the center’s reopening as the newly named University Hospitals Seidman Cancer Center.

History

The genesis of Cleveland’s University Hospitals cancer center dates back to 1940, when its original cancer-focused treatment centers were founded as a faction of the Cleveland Cancer Consortium.

Advanced patient facilities were first constructed at the center in the 1970s, when the Ohio state legislature granted $14 million toward plans for their design and development. The state legislature was set in motion to secure funding for the center’s initial construction thanks in large part to the political efforts of then-Ohio Governor James Rhodes. Rhodes worked in concert with prominent Cleveland-based businessman, philanthropist, and University Hospitals Case Medical Center board member R. Livingston Ireland. Ireland’s efforts helped expand numerous arts-based programs throughout the city.

Governor Rhodes was convinced the city should move ahead with the project when he received an impassioned letter from Ireland regarding the necessity of such a facility for the residents of Cleveland and future generations of Ohioans touched by the disease. Ireland himself was stricken by bone cancer at the time he penned his letter. He ultimately succumbed to the illness in 1982. The center was renamed in Ireland’s memory in 1984.

It was in that same year the Ireland Cancer Center underwent a long-proposed merger between Cleveland’s University Hospitals Case Medical Center and Case Western Reserve University. The alliance created one of the most expansive clinical and laboratory research facilities in the American Midwest.

Reopening as Seidman Cancer Center

The Ireland Cancer center received national accolades on numerous occasions for its pioneering efforts in cancer treatment, patient care, and research. The center was recognized as Northern Ohio’s first officially designated clinical cancer center in 1987 by the National Cancer Institute (NCI.)

In 1996, the Ireland Cancer Center received a $500,000 grant from the National Institute of Health to commence the United States’ first major research program dedicated to Kaposi’s sarcoma, a form of cancer often associated with acquired immune disease syndrome (AIDS). By 1998, the seven-building facility’s success in both research and patient care had earned it the NCI’s highest designation, that of comprehensive cancer care center.

In 2011, the grand opening of the University Hospitals brand-new Seidman Cancer Center encompassed the 120-bed Ireland Cancer Center into a
state-of-the-art 150 bed facility. The 375,000-square-foot facility was completed at a cost of $240 million. The new institute was named in honor of Ohio philanthropists Jane and Lee Seidman, who donated more than $40 million to the new center’s construction as part of the university’s strategic fund-raising drive known as University Hospitals Vision: 2010.

**Facility Highlights**

The 375,000-square-foot facility conducts clinical cancer research while simultaneously providing patients and families with the latest in advanced diagnostic and therapeutic care techniques. The Seidman Center’s breadth of technological advances includes gamma knife radiosurgery and intraoperative radiation therapy technologies.

The center is also just the fourth in the world to utilize specialized scanners that combine positron emission tomography (PET) and magnetic resonance imaging (MRI) for clinical purposes, a technology that exposes patients to considerably lower amounts of harmful radiation than previously used methods.

In addition to its advanced MRI technology, the University Hospital Seidman Cancer Center is also home to a cellular therapy laboratory that allows doctors and specialists to conduct immediate evaluation and analysis of samples derived from patients undergoing treatment for leukemia and other blood cancers as well as bone marrow transplants.

In July 2014, the Seidman Cancer Center was awarded more than $4 million in support across a three-year grant from the U.S. Department of Health and Human Services (HHS) to create a new national care standard dedicated to improving clinical care for patients in the late stages of complex cancer. The program was founded in an attempt to provide in-depth insight to patients regarding their methods and options for treatment in less-technical, nonmedical terminology. Such information is relayed to patients via individually assigned health care professionals known as navigators.

The Seidman Cancer Center is also home to an expansive Clinical Trials Unit, which offers more than 300 programs offering cancer patients the latest in experimental treatments.

The facility’s clinical trials unit is also dedicated to a myriad of studies concentrating on cancer prevention and control as well as to investigations focused on the genetic traits of the disease. Much of the Seidman Center’s clinical work is carried out in conjunction with the Case Western Reserve University School of Medicine.

**Other Innovations**

The Seidman Center’s Cleveland headquarters also houses the Mary and Al Schneider Healing Garden. The garden, which is located on a one-third acre parcel of land at the hospital’s center, is a four-season garden custom designed to promote feelings of relaxation and well-being among both patients of the hospital and the general public. The garden’s labyrinth path features expansive water sculptures and displays meant to represent earth, air, fire, and water.

In addition to an expansive garden, the Seidman Center is also home to an expansive collection of contemporary art. The collection, which is comprised of more than 300 paintings, drawings, and pieces of sculpture, is also meant to comfort and uplift both the hospital staff and its patients. Among the facility’s most prominent works are paintings by the Spanish painter Joan Miró.

Irish Cancer Society

The Irish Cancer Society is a registered charity that was founded in the Republic of Ireland in 1963 by Professor Austin Darragh to provide information about treatments and cures for cancers after he learned that 100 Irish people died each year from a wholly curable form of skin cancer. Since that time, the Irish Cancer Society, located at 43-45 Northumberland Road, Dublin 4, Ireland, with local offices throughout the country, has become the leading disseminator of information regarding cancer cures and treatments as well as a major contributor to research, treatments, and support for patients and student physicians in the field of oncology on the order of 30 million euros since its beginnings (adjusted from the pre-21st-century currency, the Punt).

Ninety-four percent of the Irish Cancer Society's funding comes from the public, and special events to raise funds are national events that are supported on radio, television, and in print media. Among these fund-raising events since 1988 are Daffodil Day (influenced by Daffodil Day in Canada), which has Dell Computer Company as a major partner and supporter and involves buying daffodils and Daffodil Day merchandise on March 28 to raise funds. Daffodil Day brings in about 12 percent of the funds raised by the society. In 2014, the Irish Cancer Society and Today FM radio sponsored a Shave or Dye event that encouraged shaving or dying hair in support of chemotherapy patients and to raise funds. In October 2013, Irish senator and former presidential candidate David Norris shaved his beard for the first time in 40 years in support of the charitable fund-raiser. The Irish Cancer Society also held fund-raisers called Get the Girls to support breast cancer awareness and treatment; Relay for Life, a 24-hour walking fund-raiser; and Movember, a moustache-growing contest to help in the fight against prostate cancer.

Criticisms of the Irish Cancer Society are difficult to come across, although on January 23, 2014, it was revealed that a fund-raising lottery held by the society had lost 420,000 euros between 2009 and 2013. Nonetheless, the society continued to hold the lottery because the government of the Republic of Ireland had compensated the organization 1,200,000 euros from the Department of Justice's charitable lotteries scheme, according to an Irish Times report.

Sponsored Programs

Fund-raisers help the Irish Cancer Society to endow research scholarships, fellowships, and other programs. As of 2012, the Irish Cancer Society provided more than 1 million euros (5 percent of their annual budget) to patients who were in need of financial help, according to Kathleen O’Meara on Radio Télfís Éireann's (RTÉ) Morning Ireland program. Collaborative cancer research centers are the first of their kind in the world, according to the society. Their first project, the largest the Irish Cancer Society has ever funded, is a 7.5 million euros venture called BREAST-PREDICT, and it will collect tumor samples from every breast cancer patient in Ireland as part of a five-year study to determine how best to treat individual patients, based upon their responses to various treatments, and to predict if drugs taken before the patients’ cancer diagnoses may affect their treatments. Most of the funding is predicted to come from the Get the Girls campaign. The principal investigators on this project are William Gallagher of University College Dublin, John Crown of Dublin City College, University College Dublin, Saint Vincent's University Hospital, Walter Kolch of University College Dublin, Bryan Hennessy of Beaumont Hospital, Des Higgins of University College Dublin, Michael Kerin of the National University of Ireland–Galway, Jochen Prehn of the Royal College of Surgeons in Ireland, Rosemary O'Connor of University College Cork, Kathleen Bennett of Trinity College Dublin, and Leonie Young of the Royal College of Surgeons in Ireland. Experts around Ireland will conduct clinical research with direct patient contact; lab researchers will determine if particular...
treatments are or are not effective; and demographic experts will analyze population trends.

Although breast cancer research has been an important focus of the Irish Cancer Society, some of the other projects funded by it include Amanda Tivnan's research into drug-resistant brain tumors and Clare Butler's development of drugs for the treatment of colorectal cancer. Other researchers working with colorectal cancers under funding by the society include Sudipto Das, Mary Clare Cathcart, Aideen Ryan, Catriona Dowling, and Nicholas Clarke's male-oriented research into population screening for colorectal cancers. The society reported in 2013 that Irish men are more likely to die of all cancers that both men and women can get than are Irish women, sometimes at as much as three times the rate at which women will die. Some of the reasons include lifestyle factors, but diagnoses at later ages also figure into the problem. One cancer that only men can get is prostate cancer, and prostate cancer research also has been extensively funded by the Irish Cancer Society under Maria Prencipe, Ciaran Morrison, William Watson, Caitriona O'Driscoll, Laure Marna, James Evans, Therese Kinsella, Silvin Knight, and Mark Tangney. Research also has been funded for esophageal, ovarian, and lung cancers, as well as leukemia.

Public Outreach

As part of the Irish Cancer Society's public outreach programs, it maintains an informational Facebook page in which it has posted warnings against ultraviolet (UV) radiation exposure with daily charts of UV indexes per hour from 6 a.m. through 6 p.m. around the country in Dublin, Cork, Galway, and Limerick. It also posts anticancer advice on being sun smart, how to reduce the risk of bowel cancer, the benefits of physical activity to reduce the risk of cancers, and advertisements and notifications of lectures, informational meetings, workshops, and other events. Even Podge and Rodge, RTE's cantankerous puppets, have supported the Irish Cancer Society by making a video (www.cancer.ie/bottomline) in which Podge insists that Rodge get a colonoscopy to determine the cause of his abdominal discomfort symptoms. Joan Kelly, who is nursing services manager at the society, believed that, by treating the subject with humor, it might not be so embarrassing for people. On April 22, 2014, the RBS Six Nations Rugby trophy was on display for public viewing and photography at the society's Northumberland Road headquarters, which further raised awareness of the Irish Cancer Society and its mission among yet another segment of the population.

Islet Cell Carcinoma
(Endocrine Pancreas)

Pancreatic cancer ranks as the fourth-most common cause of cancer-related death in men and women, and the number of cases diagnosed each year continues to increase. At this time, approximately 90 percent of patients diagnosed with pancreatic cancer are considered incurable and undergo an average survival rate ranging from six
to 12 months. Based on the rapid deterioration of a pancreatic cancer patient and the lack of effective treatment strategies, an early detection method is imperative, which in turn may significantly improve patient outcomes.

Pancreatic endocrine tumors are rarely occurring neoplasms that involve the exocrine pancreas cells (also known as islet cells or islets of Langerhans), which are responsible for generating chemicals that regulate specific activities of cells and organs, including the production of insulin for the maintenance of blood sugar levels. Pancreatic endocrine tumors rarely cause any symptoms, thus making it very difficult to diagnose. Furthermore, the details of its molecular pathogenesis remain elusive. In an effort to shed light on this fascinating, yet dreadful disease, clinicians and researchers have embarked on molecular and genetic investigations to establish its mechanisms of development.

A few years ago, Giorgio Malpeli and colleagues conducted an investigation on gene silencing, mainly focusing on the Ras Association Domain Family 1 (RASSF1) gene, which is a putative tumor suppressor gene that has been localized to chromosomal region 3p21.3. The protein product of the RASSF1 gene has been reported to suppress tumor growth using in vitro as well as in vivo systems. RASSF1 has been regarded as a major component in the inhibitory effects of Ras on cell proliferation by regulating downstream agents, thus inactivating the entire Ras signaling pathway. The investigation was based on the fact that the RASSF1 gene harbors two CpG islands, one extending into the regulatory segment that occurs in gene types A, D, E, F, and G, whereas the other one is present in the regulatory segment of the RASSF1 type C gene. The research study thus evaluated the possible role of methylation of the RASSF1A gene in regulating transcription in pancreatic endocrine tumors.

Approximately 20 primary pancreatic endocrine tumors, as well as matched healthy pancreases, were used as controls in the genomics study. In addition, the methylation status of the RASSF1 gene of three pancreatic endocrine tumor cell lines was assessed using methylation-specific polymerase chain reaction, together with pyrosequencing. Reverse transcription-polymerase chain reaction was also performed on 13 tumors. The results of the study showed that the RASSF1A gene of 16 of the 20 primary pancreatic endocrine tumors were methylated, whereas 13 of the 20 normal pancreases showed the same particular epigenetic modifications. Despite similar findings in both tumor and normal tissues, pyrosequencing showed that the amount of methylation in the pancreatic tumor tissues were almost sevenfold higher than that observed in the normal tissues. In addition, an inverse correlation between the degree of methylation and the level of RASSF1A expression was observed. Although this study was unable to confirm that the RASSF1A gene could serve as a specific biomarker for this specific neoplasm, its elevated expression in relation to its methylation status may provide additional hints on the mechanism of pathogenesis of pancreatic endocrine tumors. The findings of this study have thus paved the way for future studies in the area of molecular pathology of cancer.

Another study involving methylation was conducted by Albertas Dauksa, who examined the significance of employing these specific epigenetic marks as predictive biomarkers in pancreatic tumors. In this particular study, methylation levels at specific sites within CpG-rich domains of the promoter sequences of various pancreatic endocrine tumor-related genes were assessed. The genes examined were ACIN1, APC, BCL2, CD44, DAPK1, p16, RARbeta,
Using blood collected from a total of 30 patients diagnosed with pancreatic endocrine tumors, methylation levels of selected CpG sites were assessed. The results of the investigation showed that several CpG areas were significantly highly methylated, whereas sites consisting of repeat sequences showed a slightly lower degree of methylation relative to that of the control. Furthermore, a positive correlation between the degree of methylation and risk for pancreatic endocrine cancer was observed. Interestingly, the study also detected potentially useful correlations such as that between elevated methylation levels in TNFRSF10C and ACIN1 and a lower survival rate for a patient. This promising and significant finding could be applied eventually in the clinics, although a larger-scale study should be conducted initially to further strengthen and validate this correlation. Should this be achieved in the near future, then a simple blood test could assist clinicians in detecting pancreatic endocrine tumors as well as predict the survival time of a patient.

A recent study conducted by MingZhou Guo further strengthened the usefulness of epigenetic modifications in detecting and assessing neoplasms involving exocrine as well as endocrine pancreas. By extracting the DNA from a total of 48 paraffin-embedded pancreatic tumors, the levels of methylation were examined using nested methylation-specific polymerase chain reaction (PCR). The tissue samples used in the study consisted of acinar cell carcinomas (12 cases), adenocarcinoma (18 cases), and islet cell tumors (18 cases). This study was able to describe a methylation signature involving various pancreatic tumor-related genes. Thus, the pattern of methylation of specific genes involved in pancreatic cancer in a decreasing order was as follows: APC gene (50 percent), BRCA1 gene (46 percent), p16INK4a gene (35 percent), p15INK4b (35 percent), RAR (35 percent), and p73 gene (33 percent).

In addition, the majority (94 percent) of the pancreatic tumors showed methylation in at least one of the studied genes, whereas 69 percent of the neoplasms showed methylation in two or more of the genes investigated in the study. Another significant finding of this particular study was that the patterns of methylation of these genes in pancreatic adenocarcinomas could be distinguished from those of pancreatic endocrine tumors. This difference could therefore be applied in the clinics, specifically in diagnosing the type or subtype of pancreatic cancer. For decades, pancreatic cancer has been considered as a very difficult neoplasm to detect, diagnose, and predict in terms of its progression. These molecular signatures involving methylation in specific genes may therefore help in resolving the major challenges experienced by clinicians, particularly oncologists.

Israel

The Middle Eastern nation, officially termed the State of Israel, is one of the newest states on the global stage, having been established in 1948, when the local populace declared its independence after British forces retreated from the territory. As of 2014, Israel is the only country in the world that bears a Jewish majority population. Though the nation of Israel is young, it has quickly established itself in recent decades as a major cultural and intellectual player on the world stage, especially with regard to the field of medicine. Presently, the nation has one of the top 50 economies in the world and is composed of a population of more than 8 million citizens.

Though cancer is currently the most common source of mortality in Israel, survival rates are rising fortunately in the country. In 2012, more than 10,000 Israelis passed away as a result of cancer.
Members of the Israel National Cancer Registry, the Israel Cancer Association, and the Health Ministry’s National Center for Disease Control all work closely together in order to track domestic trends in the disease and to garner more effective ways to combat it. Such institutions provide invaluable statistics with regard to cancer in the country; this information allows Israeli specialists to deduce information about the disease that they would not be able to otherwise, such as the fact that women and Jews in the country are at a higher risk for the disease than their male and Arab counterparts.

In the past several years, promising cancer research has been conducted in the country. For instance, the Israeli researcher Dr. Sarit Larisch has discovered that cancer cells lack the protein that regulates cellular destruction when a cell is no longer functioning properly. Dr. Larisch’s research has opened up possibilities for new diagnosing methods based on the particular protein he has been studying. Moreover, the Israeli scientist Dr. Aaron Avivi discovered as recently as January 2014 that certain mole rats discharge a substance that has been found to obliterate cancer cells.

As of late, the most prevalent forms of cancer in Israel are bowel, breast, lung, and prostate cancer. Bowel, lung, and prostate cancers are the most common forms of cancer incidences in males in Israel, while breast, bowel, and lung cancers make up the most common forms of cancer incidences in females there; altogether, the top three most common cancers observed in both genders of the Israeli population account for over half of all cancer cases in the country. Moreover, Israel has some of the highest rates of cancer incidences in the entire Middle Eastern region, especially with regard to bowel cancer. Incidences of non-Hodgkin’s lymphoma and bladder cancer have been consistently increasing in Israel over the last decade, while incidences of esophageal cancer have been decreasing, making the country have one of the lowest rates of esophageal cancer in the world.

Sadly, and in line with the fact that cancer is a global disease, many Israeli citizens have experienced cancer during the nation’s relatively short history. For example, Israel’s popular, strong-willed, and first female prime minister, Golda Meir, succumbed to her battle with lymphatic cancer in 1978 at the age of 80. Lily Sharon, the wife of another one of Israel’s prominent prime ministers, Ariel Sharon, died in the year 2000 after losing her own bout with lung cancer. More recently, the beloved Israeli comedian and television entertainer Sefi Rivlin passed away in 2013 after struggling for a few years with lung cancer.

There are numerous cancer centers in Israel where some of the nation’s most talented doctors work together to stem the tide of the disease. For example, Dr. Tamar Peretz, who oversees the Department of Oncology at the Sharett Institute of Oncology in Jerusalem, is an internationally acclaimed physician who contributes her oncological expertise to the treatment of thousands of domestic and international patients every year. The D.R.A. cancer center located in Haifa, Israel, is home to some of the nation’s most highly trained specialists, such as Dr. Abraham Kuten. Dr. Kuten oversees the Oncology Department at the D.R.A., where he and his staff utilize novel and innovative treatment plans to attack each of their patients’ cancers with a unique and personalized approach. Dr. Kuten and his staff have helped to establish the D.R.A. cancer center as one of the most preeminent cancer treatment facilities in the whole world.

---

**Italy**

The Republic of Italy is a parliamentary democracy located in southern Europe, bordered to the north by France, Switzerland, Austria, and Slovenia, and is part of the Italian peninsula. As a highly industrialized and densely populated nation, Italy is the fifth-largest economy in Europe and the ninth largest in the globe in terms of gross domestic product (GDP). The health care system in Italy is widely considered one of the best in the world and represents a national health service funded in large part by general tax revenues. Home to some of the world’s oldest universities, Italy has a tradition of supporting research, including that involving cancer. A variety of private organizations also support cancer research and are involved in conducting basic research and finding ways to reduce the risk of cancer to Italians.

**Background**

Significant politically for more than 3,000 years, Italy has a rich history that affects its current culture. After the collapse of the Roman Empire, which by the 2nd century C.E. controlled most of the known world, Italy developed a series of city-states, independent but interrelated. The Renaissance, which began in Italy, was a result of the great wealth accumulated by merchants in the region and a desire for knowledge. After several hundred years during which foreign powers such as Spain, Austria, and France exerted control over the Italian peninsula, the conclusion of the Napoleonic Wars resulted in returned independence to the Italian city-states. The growing sense of nationalism in Europe, however, increased pressure for a unified Italy, which came about after a series of revolutions, resulting in the establishment of the modern Italian state in 1870.

Siding with the Allies during World War I, Italy waged battle against the German and Austrian-Hungarian empires, incurring more than 650,000 casualties as a result. The conflict also resulted in the near bankruptcy of Italy, leaving the embattled monarchy susceptible to the fascist dictator Benito Mussolini. During his 21-year rule in Italy, Mussolini promoted a corporatist economic system where workers and business owners theoretically set economic policy with the state. After Italy’s defeat during World War II, Italy became a republic, and with help from the Marshall Plan, rebuilt its economy. The Italian economy grew rapidly during the 1950s and 1960s, a period known as the Italian miracle, during which the previously agrarian nation became rapidly industrialized. Postwar Italy established a social health insurance system that administered sickness funds for those afflicted by disease or other medical conditions. Financial instability plagued the system, and in 1978, the Italian government established the Servizio Sanitario Nazionale (SSN), a national health care system that provides all citizens and residents access to medical services through a mixed public–private system.

SSN pays all family physicians, who must offer office hours five days a week and are limited to a total of 1,500 patients. The SSN assigns patients doctors, although each patient is free to change doctors if dissatisfied, provided the doctor chosen has free slots. Prescription medications, which can be obtained only with a doctor’s authorization, are
subsidized by the SSN, and the co-payment is based upon the patient’s income. Hospital stays and visits to specialists require a co-payment if ordered by a family physician, while all surgeries are free, regardless of the patient’s income level.

Cancer Care and Research
Italians enjoy the world’s fourth-highest life expectancy and generally enjoy very good health. Concerns about certain diseases and medical conditions exist, of course, and are the focus of government policies regarding health care and research. At 278.6 per 100,000, Italy has the 21st-highest rate of diagnoses for cancer for men and women in the world, although this rate trails many other industrialized nations such as France, Canada, the Netherlands, and the United States. Italy’s death rate from cancer, at 124.2 per 100,000, ranks 57th highest on the globe. Certain policy decisions made by Italy’s leaders have been intended to reduce the risk of cancer. Nearly 70 percent of Italian men, for example, smoked cigarettes during the late 1960s, a rate that had been reduced to 25 percent by 2012, largely through increases in tobacco taxes, public health campaigns, and prohibitions on where one could smoke. Similar programs to increase air and water quality are also believed to have had a positive effect on cancer rates.

In certain areas of Italy, cancer rates are much higher than in other parts of the country. The government’s compilation and monitoring of cancer rates have assisted in identifying these areas. In an area within the province of Campania, for example, there is a region comprised of the area around the towns of Acerra, Marigliano, and Nola known as the Triangle of Death because of cancer rates that greatly exceed that of Italy as a whole. In this region, for example, the incidence of cancer of the bladder, central nervous system, and liver greatly exceeds that of Campania and Italy as a whole. This discrepancy is believed to have been caused by the illegal dumping of toxic wastes and has caused reform efforts to attempt to reduce the level of dioxins and other substances in the area as a result of this activity.

A variety of universities and other institutions conduct research on cancer, its causes, and potential treatment options in Italy. The European Institute of Oncology and the Istituto di Candiolo, for example, are two organizations that engage in cancer research. The European Institute of Oncology was founded in 1994 in Milan to conduct basic research, train physicians and other health care providers, and provide patient care to those facing cancer. In keeping with these goals, the European Institute of Oncology works to improve prevention and diagnosis services, provide health education and training, and investigate the best research and treatment options. The Istituto di Candiolo is located in Torino and is a collaborative effort of the Fondazione Piemontese per la Ricerca sul Cancro-Orlus (FPRC), which provides funding, and the Fondazione del Piemonte per l’Oncologia (FPO), which operates it. The Istituto di Candiolo works to make a significant contribution to the fight against cancer. It strives to do this through improving understanding of the basic causes of the disease and by providing world-class diagnostic and therapeutic services to patients. The institute, which collaborates with the University of Torino, is especially interested in the interaction between molecular biology and medicine. These and other institutions are working in collaboration with others around the globe to improve understanding of cancer and the best ways to prevent and treat it.

Further Readings
Japan

In 2011, Japan’s Ministry of Health, Labor, and Welfare announced cancer, heart disease, and pneumonia are the top three causes of death in Japan, accounting for 28.5, 15.5, and 9.9 percent of total deaths, respectively. Cancer has been the leading cause of death in Japan since 1981. Because cancer incidence and mortality rates generally increase with age, peaking at 80 to 94 years, Japan is particularly vulnerable to cancer-related deaths as it is experiencing population aging that is unprecedented in the world. Its proportion of people age 65 and more is the highest in the world: 23 percent in 2009. By 2030, one in three people in the population will be more than 65 years old, and one in five will be more than 75 years old. Between 1930 and 1950, the leading causes of death in Japan were tuberculosis, pneumonia, and cerebral vascular disease. Postwar economic recovery and significant reductions in stroke and other major diseases have contributed to these changes in cancer trends. Many of the common cancers in Japan often are associated with an infection. For example, stomach cancers often are associated with a *Helicobacter pylori* infection, which has the highest prevalence among those born during World War II and the 1950s. During this time, the overall cancer mortality rate rose but began to decline in the early 1960s. In the 1960s, gastric and liver cancers were the top two common cancers among Japanese men, and gastric and uterus cancers the top two among Japanese women. Currently, the overall cancer incidence is increasing.

The availability and affordability of alcohol and cigarettes and the Westernization of dietary practices and lifestyle have contributed to some of the top common cancers in Japan: liver, lung, and the digestive system (e.g., stomach and colorectal). While gastric cancers continue to have the highest incidence rate among men, there is a declining trend, especially in the younger population. For women, the most common cancer is now breast cancer.

Ovarian cancer occurs more often in industrialized countries, except Japan. While some researchers noted the possibilities of genetic factors, others found that second and third generations of Japanese women who moved to the United States share a similar occurrence rate as the U.S. general population, suggesting the importance of environmental factors. Several studies have identified that Japanese individuals’ increased cancer risk is associated with increased acculturation to the West. The unique cancer trends in Japan often are shaped by dietary practices, social trends, health behaviors, and beliefs and attitudes.

**Risk Factors and Common Cancers: Diet**

Traditional Japanese diet and changes in diet have diverging impacts on cancer. Traditional Japanese
diet is rich in isoflavone, which is found mainly in soybeans and soy products, such as tofu (bean curds) and natto (fermented soybeans). Frequent intake of isoflavone is associated with a reduced risk of breast cancer and of localized prostate cancer. Despite the prevalence of a Westernized diet, the amount of isoflavone intake in Japan is high compared to other Asian countries. Frequent consumption of cooked or raw fish is believed to reduce lung and prostate cancer risks. Green tea, a common beverage in Japan, has been demonstrated to reduce gastric cancer among Japanese women.

Traditional Japanese cuisine, however, includes foods that are high in salt. In addition to soy sauce and miso soup, there are many salt-preserved foods, such as umeboshi (pickled plums), taku-an (pickled daikon radish), and salt-cured vegetables and fish. Habitual salt intake is a strong risk factor to developing gastric ulcers and gastric cancer among individuals infected with *Helicobacter pylori*.

In Japan, only about 15 percent of the calories in the diet come from fat, whereas in the United States, 35 percent of calories are from fat intake. A high-fat diet can lead to high production of estradiol, a form of estrogen, resulting in increased risks for breast cancers. The Westernization of diet has brought increased consumption of red meat and fat, which are associated with increasing trends in colorectal and prostate cancers in Japan. This change was noticeable around the Meiji period (1868–1912), bringing sukiyaki (Japanese hot pot with beef) and tempura (battered and deep-fried seafood or vegetables) to the public diet. It is noteworthy that the highest quintile of red meat consumption by Japanese individuals would be considered a moderate level of consumption by Western standards. Based on a 1955 to 1993 National Nutritional Survey in Japan, Westernized dietary habits are associated with increased mortality by colorectal and prostate cancers in Japan. In contrast, traditional Japanese dietary habits are associated with increased mortality by stomach cancer.

**Social Trends**

The changes in social trends in reproduction and fertility provide insights into the increased mortality by breast cancer in Japan. In the 1900s, the mean age of menarche was 16 years old, and Japanese society encouraged early marriage and large families. With some short-term fluctuations, a Westernized diet contributed to lowering the age of menarche to 13 years old in the 1960s and 12 years old in 2009. The mean age of menopause has been around 50 years old during that time, due to the complex influences from both an increase in life expectancy and expanded stressors. Along with the tendency to put off marriage and the downward trend in the birthrate, the mean age of birth of the first child increased from 25 to 28 between 1975 and 2005. In short, the decreased age at menarche, late child-bearing, fewer pregnancies, and the increased use of postmenopausal hormone therapies are all factors that are prevalent in Western countries and that are associated with an increased risk for breast cancer; the same trends have been affecting the Japanese population.

**Health Behaviors**

A 2011 national survey found that 34.1 percent of Japanese men and 9.0 percent of Japanese women smoke, among which 10 percent consume more than 21 cigarettes a day. The number of these heavy smokers has decreased, but the overall number of smokers has not changed significantly. In Western countries, smokers have a 10 times higher risk of developing lung cancer compared to nonsmokers. Despite the lack of strict laws and restrictions on tobacco products and consumption, Japanese smokers have a four times higher risk of developing lung cancer compared to Japanese nonsmokers. The phenomenon is also known as the Japanese smoking lung cancer paradox.

Some studies indicate that this is because (1) Japanese smokers’ risk for developing cancer is not as high as those in Western countries and (2) nonsmokers are at a higher risk of having cancers in Japan. Cramped offices and rooms within a limited national space bring smokers and nonsmokers in close physical proximity, causing passive exposure to tobacco smoke. Smoking has been determined to be the cause of approximately 40 percent of Japanese individuals diagnosed with lung cancer. The other 60 percent have been determined by other factors, such as eating habits, secondhand smoke, and alcohol consumption.

Drinking has been an important communicative component in Japanese business culture. Comparisons between individuals in Western countries
and Japan have revealed that approximately one in two Japanese people has an atypical allele of a group of enzymes (aldehyde dehydrogenase 2 gene [ALDH2]). Because these enzymes catalyze the acetaldehyde metabolism less, resulting in a high blood level of acetaldehyde after drinking, Japanese individuals with ALDH2 heterozygotes are more susceptible to subsequent risk in developing breast and esophageal cancers compared to people in the West. Japanese drinking culture is always harmful because alcohol consumption appears to be a moderator for certain cancer risks. Alcohol consumption among smokers increases the risk of developing distal colon cancer, whereas alcohol intake among nonsmokers decreases the risk of both cancers’ incidence and mortality.

Beliefs and Attitudes
In 2012, approximately 27 percent of the Japanese population had been screened for cancer. Although the cancer-screening rate in Japan has increased over time, it is still low compared to other economically developed countries. Misconceptions about cancer seem to contribute to a low cancer-screening rate. Based on the National Cancer Center’s report of 2006, the understanding of cancer risk factors in the Japanese general population tends to be governed by cancer-causing bacterial and viral infections, occupational exposure to hazardous substances, air pollution, and food additives or pesticide chemicals rather than major lifestyle factors, such as diet and alcohol consumption. Although the belief in cancer-causing bacterial and viral infections stems from the long-term prevalence of gastric cancer, such understanding seems largely influenced by the mass media and other sources rather than health professionals. In dealing with life-threatening diseases like cancer, medical professionals and patients’ family members in Japan tend to avoid disclosing a diagnosis to the patients, believing such information may overwhelm the patients and diminish their willingness to participate in treatments.

Japan Lung Cancer Society

The Japan Lung Cancer Society (JLCS) has been in operation since 1960, when it was first referred to as the Society for the Study of Lung Cancer (SSLC). The purpose of this group was to initiate a 35-year lung study group Showa. The aim of the initial group was simply to study cancer, given the disease at the time had very little known about it. The SSLC was renamed officially the Japan Lung Cancer Society in 1966; therefore, some literature will quote the establishment of the JLCS as being 1966. The aim of the society was and still is to promote diverse research on lung cancer and its related fields as well as helping to diffuse knowledge and understanding of the disease among society. In 1984, JLCS became a full member of the Union for International Cancer Control (UICC). In 2007, the establishment was pronounced as being a nonprofit organization.

To achieve the set objectives of the society, JLCS has a number of activities; the society holds various meetings and congresses for members, produces official publications and books that include the society’s journal and proceedings, research work, study, education on matters and issues concerning lung cancer, and close contact, cooperation, and coordination with related academic organizations at home and internationally.

Individuals can register as members of the society. In 2014, the society had 7,404 regular members, 85 associate members, 12 honorary members, 149
special members, 12 groups for supporting members, 65 subscription members, and 15 honorary presidents.

While the guiding objective of the society is to promote diverse research on lung cancer and its related fields, as well as helping diffuse knowledge and understanding of the disease among society, the society has a business objective, whereby the object is to measure the dissemination of knowledge as well as the progress of research in this area and to contribute to the promotion of human health and welfare widely. The headquarters of JLCS is at Nihonbashi, Chuo-ku, Tokyo 3-chome, No. 8, No. 16, Buyo Building, Fourth Floor.

JLCS activities are mainly organized and run by committees. The society therefore has a number of committees that are headed by different individuals at the leadership position of committee chair. These include the general administration committee with T. Goya as the committee chair, the finance committee with I. Yoshino as the committee chair, the editorial committee with the chair as T. Tamura, the scientific committee with the chair as K. Nakagawa, the mass screening committee with T. Kondo as the committee chair, the subcommittee for mass screening by sputum cytology with M. Sato as the committee chair, the subcommittee for mass screening by chest X-ray with the chair as C. Konaka, the future planning committee with Y. Hasegawa as the committee chair, the collaborative activities committee with N. Ikeda as the committee chair, the subcommittee for promotion of smoking cessation with H. Nomori as the chair, the subcommittee for data management with Y. Takiguchi as the committee chair, the international affairs committee with the chair as H. Asamura, the bylaws and constitution committee with the chair being M. Noguchi, the election management committee with S. Miyoshi in the chair position, the committee for evaluation of guideline proposals with K. Hayakawa as the chair, the subcommittee for pharmacotherapy and multidisciplinary treatment with N. Yamamoto in the chair position, the subcommittee for diagnosis with K. Kasahara in the chair position, the subcommittee for surgical treatment with Y. Ichinose in the committee chair position, the subcommittee for radiotherapy with the committee chair being K. Hayakawa, the subcommittee for pleural mesothelioma with T. Nakano in the chair position, the subcommittee for thymic tumor with M. Okumura as the committee chair, the ethical behavior committee with A. Gemma as the committee chair, the COI committee with the committee chair being S. Negoro, the biomarker committee with T. Mitsudomi as the committee chair, the lung cancer registry committee with K. Yokoi as the committee chair, the committee on guidelines for management of lung cancer with T. Mitsudomi as the committee chair, the diagnostic imaging committee with K. Eguchi as the committee chair, the TNM classification committee with T. Mitsudomi as the committee chair, the committee for cytologic diagnosis with H. Akita as the committee chair, the working group for cytologic criteria of mesothelioma with T. Kamei as the committee chair, the committee on classification of bronchoscopic findings with H. Isobe as the committee chair, the committee on surgical records with the chair being H. Date, the committee on pathological diagnosis with M. Noguchi as the committee chair, and the committee on criteria for therapeutic effectiveness with the committee chair being H. Senba.

In 2005, the guideline committee of the JLCS revised the role of chemotherapy and of chemotherapeutic agents with a clinical practice guideline for lung cancer in Japan, which had been published in 2003 by an expert multidisciplinary panel. The guideline covers points on standard diagnostic functions and how to adapt different methods for treatment based on the stage that the patient is in at a given time. This often includes a full analysis of what can be done. The revisions will renew the decision trees for standard treatment procedures and molecular-targeted therapies based on the new TNM classification and add parts to the treatments for malignant mesothelioma and the management of bone metastases with bisphosphonates.

In addition, JLCS has a journal as the major form of publication that it uses to provide information related to lung cancer to the entire world. The journal can be accessed online as well as in print form through subscription and through purchase.

Japanese Cancer Association

The Japanese Cancer Association is the premier organization devoted to the diagnosis and cure of all cancers. The stated purpose for the association is to promote cancer research and cure.

The history of the association is as follows: Lecture meetings about cancer started in 1908. The loosely knit organization was called the Japanese Foundation for Cancer Research. Yearly meetings were conducted until 1935. In about 1935, the members of the foundation agreed that cancer research in other settings had advanced quickly and that a new association should be born to cover all of these activities. They saw they needed to call in more qualified medical personnel. The association was formed in March 1941.

Japan, the Country, and Its People

The Japanese people (Nihonjin, Nipponjin) occupy the islands of Japan. Japanese people comprise 98.5 percent of the total population there. Their culture and art are unique anywhere in the world. They live in a colorful world of multicolored clothes and accessories like the umbrella. Yet, this tiny place has an incidence of cancer that just about trumps any in the world. The atom bombs dropped on Hiroshima and Nagasaki still are having their effects felt. Nowhere in the world can cancer and its causes be studied so thoroughly.

Nevertheless, the people are polite to a fault and generous beyond belief. There is no better place to have an organization like the Japanese Cancer Association than on the front lines of a country where carcinoma is the leading cause of death.

Cancer Registration System in Japan

The association is involved with the registration system, an invaluable tool in studying incidents of cancer deaths in the country. Currently, cancer is the number one killer among the population. In 2012 there were 360,963 deaths from cancer, with lung cancer the most common type of fatal cancer for men, and colon/rectum cancer the most common type for women. Cancer registration and investigation began in the late 1950s and first focused on the cities of Hiroshima and Nagasaki, the places bombed by the Allies in 1945.

The registration system has been criticized for collecting invaluable data on cancer deaths but then doing nothing about it in a statistical way to track the deaths to locations, types of cancer generic to certain areas, and generally not putting the data to its full use. More surveillance services may be needed, and the registry system may need to become more standardized.

Diabetes and Cancer

The Japanese Cancer Association has joined with the Japanese Diabetes Society to explore the link between diabetes and cancer. They found a link between the two diseases as late as the 1980s. There is substantial evidence that demonstrates that diabetes increases cancer risk, notability colorectal, liver, and pancreatic cancers. Diabetes promotes oncogenesis, the mechanism that turns normal cells to cancer cells.

Diabetes includes insulin resistance associated with hyperinsulinemia (making one insulin resistant), hypoglycemia (low blood sugar), and inflammation. Risk indicators for diabetes causing cancer are aging, male sex, obesity, physical inactivity, inappropriate diet (red meat intake and little fresh vegetables), alcohol drinking, and smoking. There is no substantial evidence that anti-insulin medications can cause cancer.

It has been shown recently that diabetes can be a cause of breast cancer, in which the Japanese Cancer Association is involved. Hyperinsulinemia is common in type 2 diabetes. Again, the condition and its insulin-resistant properties have been shown to cause or worsen breast cancer. The high rate of death persists as the cancer metastasis sets in. Metastasis is the spreading of cancer into other parts of the body.
The Journal
The association publishes Cancer Science, a monthly medical journal focused on cancer research. First published in 1907, the journal continues today to publish current, relevant articles on oncology and translational and clinical cancer research. Journal Citation Reports evaluates the journal as having a 2012 impact factor of 3.479, making its ranking 69 out of 196 journals in the world category on oncology. The impact factor is a number representing how many times the journal quotes or refers to previous articles. Journals that have a higher ranking are considered more important than others.

The purpose of the Japanese Cancer Association is to spread the word about cancer and its most up-to-date treatments. The journal has a significant role in fighting the battle against cancer. Original research articles are put to press as fast as possible to keep the medical community (and the public) aware of the deadly disease and the treatment thereof. The latest breakthroughs in the field are available every month giving readers an overall picture of cancer appearing in its various manifestations in the human body. The publication is limited to cancer, its research, and treatment and is not cluttered by information that is not useful in real time.

All of the volumes published are available for order at http://onlinelibrary.wiley.com/. Each issue has 10 to 12 pertinent articles essential to medical practice wherever it may be. It is not just for oncologists as all specialties can benefit; cancer is capable of invading the body anywhere. Cancer often is missed as an initial diagnosis because it may be hiding behind ordinary symptoms such as come with a cold or flu. Each volume gives early detection clues to better care for patients.

Awards
The Japanese Cancer Association has proved its excellence by winning the most highly regarded awards in the field: the Tomizo Yoshida Award, Mataro Nagayo Award, Japanese Cancer Association Incitement Award, JCA-Mauvernay Award, and JCA-CHAAO Award.

The Japanese Cancer Association is applauded the world over for its innovative force in ridding the world of one of its biggest scourges.

Japanese Gastric Cancer Association

In 1962, the Japanese Research Society for Gastric Cancer was established. The society’s aim was to research and provide information about gastric cancer. The society did a thorough job in regard to its mandate and played an important role in the promotion of basic and clinical research on gastric cancer. However, it was a closed association organized by 352 leading institutions in Japan. In 1997, the society was changed to an open association composed of individual members. The change saw the organization rebranded as the Japanese Gastric Cancer Association (JGCA). This is a global organization that offers plenty of services for members in all parts of the world.

Even though the organization changed its name from Japanese Research Society for Gastric Cancer to JGCA and even its systems and operations to allow foreign and international members, the aim of the organization has not changed in principle. The only change to the aim is in terms of scope. Initially, the objective was supporting many studies on gastric cancers and other issues in the body with the intention of managing different foreign controls and to take a look at how people from different parts of the world are studying the functions of cancer. The goal now is to create an international
approach to supporting the research needed for managing cancer in all of its dangerous and potentially fatal forms.

The major activities of JGCA with regard to realization of the set objectives are as follows. These are all activities designed with the intention of ensuring that all cancer patients receive the help that they deserve in all stages in their lives based on the treatments that they might require.

The Japanese Gastric Cancer Congress is a meeting that is held annually. The 2014 event was the 86th congress of the society. The theme of the congress was *Total Control of Gastric Cancer: Wisdom and Practice*. Each congress is chaired by the congress president, and the 86th congress was chaired by Wasaburo Koizumi, professor and chair from the Kitasato University School of Medicine Department of Gastroenterology. The congress started March 20 and ended on the 22nd of the same month in 2014. The congress is held annually, and the recommended time is February; it is organized most often by the congress president. English abstracts, English presentations, and English discussions are accepted from international members.

*Journal of Gastric Cancer* is published by the society's editorial committee; *Gastric Cancer* is a key journal that provides people with information in the English language on cancer research and how it is being utilized in a number of critical ways for the enhancement of society as a whole. It has a global audience, and at its initial publication and circulation, the journal received approximately 3,000 in readership and later expanded to 5,000. Even though it is not possible to provide the exact readership of the journal because of the online access option, 7,000 members have subscribed. The journal provides people with critical pieces of information that are relevant to the needs that people have when it comes to studying at large and seeing how certain functions are to work.

A new manual was also produced as a means of analyzing cancer treatments and how they are operational for many requirements. This has helped to take a look at the ways the body is able to handle different problems that it might get into and how it may requires assistance in some way.

The JGCA is also functional with the intention of registering gastric cancer patients. This is to ensure that there are enough data around with regard to the treatments that different patients might require at given times. The solutions that are of use may be essential and critical as there are more than 10,000 bits of patient data being collected each year.

In addition to the above activities, JGCA is involved with or undertakes other activities to foster the promotion of basic and clinical research on gastric cancer. For instance, JGCA is working with the International Gastric Cancer Association (IGCA) and the World Health Organization (WHO) to help with studying gastric conditions and various aspects relating to cancers in these parts of the body as a means of checking on how the body can respond to such issues at large. All the members can get information from these international organizations. All members contribute to the activities of JGCA, particularly in election of the council members every two years and approval of various activities and decisions.

The various activities and operations of the association are under committees. JGCA has a number of committees, and each committee is under a committee head. Some of these are the manual committee and the registration committee.

For an individual to join the society, a registration fee is required together with an application. The membership fee is 12,000 yen. There is no difference between the amount paid by Japanese members and those from the international community. The application form for anyone interested in joining JGCA is available online. The majority of the members are professionals interested in JGCA and in the gastric cancer profession, namely clinicians, educators, researchers, and students. The membership fee indicated is required to be sent together with the filled-in membership application form, and it is an annual fee.

Japanese Society for Therapeutic Radiology and Oncology

The Japanese Society for Therapeutic Radiology and Oncology (JASTRO) has been in operation since 1988. At its establishment, it was a membership group that featured persons working in health care, the field of oncology, and other general functions. The society's office is located in Tokyo, Japan. The aim of JASTRO is to promote communication and cooperation in studies to determine how radiotherapy works.

JASTRO has an executive and a board of directors, which are responsible for running the society. The members of the board include people from many different schools from cities all around Japan. These include people from the University of Tokyo, Keio University, the Yamanashi Faculty of Medicine, and the Osaka Medical Center, among several other critical organizations. There are many board members and auditors who work together, with the key leaders being Yasumasa Nishimura of Kinki University as the president of the society and Kenji Nemoto of Yamagata University as the secretary general.

At the inception of JASTRO, little was known about cancer as a disease. This inadequacy of reliable information required research into the field so as to understand cancer better and improve treatment. Hence, the purpose of JASTRO became to communicate, cooperate, and promote general and professional research relating to the identification of cancer through many techniques like radiotherapy to analyze patients. To realize this purpose, the society has undertaken various projects, each appropriate for the promotion, advancement, and realization of a specific aspect in the society's aim. These include to hold academic conferences, symposia, and lectures: Individuals among them, clinicians, researchers, educators, or students in the field of therapeutic radiology and oncology, hold conferences and present research work and findings. So far, the society has successfully held 26 meetings. The 2014 meeting focused on analyzing the overall functions in the industry.

Members of the society are required to make publications of their research work. One of the major and popular publications made by the society is the Journal of JASTRO. The journal was published on a quarterly basis, at least up to 2008. However, from 2009, only a single publication was made per year. The journal has surpassed volume 21.

JASTRO has several associations with both local and international societies, organizations, and bodies for the aim of furthering their scope and knowledge in terms of cancer management and treatment.

To encourage study, research, education, and training concerning radiotherapy, the members of the society are required to actively engage in research work in the field of cancer and especially therapeutic radiology and oncology.

JASTRO has several commendations for excellent achievements in the research of cancer therapeutics. These are in the form of awards to those who excel in the field.

In addition to the projects already mentioned, the society undertakes various other projects to further their purpose. These are mainly projects that might be passed by the board.

JASTRO has a community in the form of members. An individual who meets the membership requirements can apply. The majority of members are researchers, clinicians, students in the field of cancer therapy, and honorary individuals. For admission into the society, a person who wishes to join must get a recommendation and submit a proper form for entry. The application should then be sent together with the membership fee for the applicable year, which must be approved by the board of directors.

JASTRO has various membership types. A member can enter, but an honorary member may also join. An associate member like a technician or nurse may also come in. Other supporting members may join provided that the organization endorses the applicant.
Jet and Rocket Fuels

In 2013, the society had 2,006 active members, 1,452 associate members, 24 honorary members, and 34 supporting members, totaling to 3,516 members. The society has 1,013 board certified radiation oncologists. Among the members are gold medalists and honorary members. JASTRO distinguished service gold medal members are Ritsuko Komaki and Hirohiko Tsujii.

The society has three awards: the Umegaki Award, awarded to Norio Katoh and Keiiti Zingu in 2013; the Abe Award, won by Takahumi Toita in 2012; and the Excellent Educational Lecturer Award, awarded to Yusuke Demizu, Norihiro Aibe, and Takayuki Ooguri in 2013.

Jet and Rocket Fuels

An often under-recognized risk factor for cancer and other health issues, jet or rocket fuels are comprised of a plethora of noxious and potentially carcinogenic compounds that can be linked to a plethora of health problems. Studies examining compounds found commonly in rocket fuel have suggested links to cancer, endocrine problems, and other health concerns for many years, beginning all the way back in the 1950s. This entry investigates the health risks associated with rocket and jet fuel exposure, common routes of exposure, issues surrounding its usage, and legal and illegal dumping across parts of the United States, its composition, and how that has exposed many individuals to contaminants, often unknowingly.

Rocket Fuel and Its Composition
Rocket fuel in its typical composition today consists of many different chemical compounds, some 2,000 approximately, not all of which have been formally identified. Many of these are either known carcinogens or at least noxious to human, aquatic, or animal life, including benzene, perchlorate, and halon. Moreover, upon combustion, many other dangerous chemicals are formed, such as the class of carcinogens called polycyclic aromatic hydrocarbons. Nitrogen dioxide is another commonly produced high-temperature combustion by-product, which is primarily associated in studies with potentially damaging the lungs. Other types of petroleum derivatives and by-products such as perchlorate, toluene, xylene, kerosene, and others are commonly used in rocket fuel or are produced through combustion. Accordingly, these chemicals are given off in exhaust trails from commercial and military planes as well as private jets and planes.

Common and Historical Routes of Exposure: The Example of Perchlorate
Elevated levels of these and many other chemical compounds are frequently found in air around airports in particular, causing local, knowledgeable residents much concern due to the mounting evidence suggesting certain types of cancer, respiratory problems, endocrine problems, and other health issues are strongly linked to exposure to such compounds. Additionally, these chemicals can settle onto crops, waterways, into livestock feed, and really anything in the proximity of highly traveled airspace. However, that has not been the only or necessarily the primary way some individuals have gotten exposed to, in some cases, high doses of rocket fuel.

Following World War II, there was much focus on developing new types of rocket fuel to compete with the burgeoning powers of the Soviet Union in the Cold War. Thus, highly combustible yet stable-enough compounds such as perchlorate began to be used and added in the manufacturing of such fuels in selected locales across the United States. At that time, concerns over communist invasion generally outweighed concerns about environmental
impact or public safety, and also at this time, perchlorate was not considered very dangerous, and thus, waste materials from rocket fuel manufacturing and usage were simply dumped at various sites across the United States, especially in the desert southwest region. To explicate, perchlorate, dubbed powdered oxygen, is combusted inside a rocket engine with aluminum powder and a rubberlike polymer to stoke an intense burn. To propel a rocket, the solid fuel must be ground and molded into a particular shape.

Over time, the fuel breaks down, requiring continual replacements. That’s why, for more than 40 years, tons of perchlorate were routinely flushed from rockets and missiles onto the ground and into water supplies. In fact, literally millions of tons of this contaminated wastewater were dumped into unlined pools, holes, and ponds and onto the ground, allowing it to seep into underground aquifers, rivers, and ultimately municipal water supplies, which have been historically ill equipped to filter it out. Unfortunately, due to a myriad of factors such as poor testing, pushback from manufacturers, and unclear advisory standards for exposure, more legal and illegal dumping continued from the late 1940s all the way into the late 1970s, before the Environmental Protection Agency (EPA) and other regulatory bodies (after the passage of the clean water bill) began asserting greater authority and regulatory control on manufacturers, pushing them to start cleanup efforts. However, unfortunately by that time, much of the damage had already been done from nearly 30 years of dumping into ground pits, unlined pools, and so on. To date, the EPA has cataloged at least 75 perchlorate releases across 22 states that exceed safety standards and require years of cleanup efforts. Of course, this does not include all of the additional chemical exposure the vast majority of the country gets from airplane traffic crisscrossing all states.

One of the most troubling routes of potential exposure is through the consumption of produce that has absorbed rocket fuel metabolites, such as perchlorate, from contaminated water. One preliminary study conducted by the Environmental Working Group in the San Bernardino Valley east of Los Angeles found that lettuce grown in a known area of perchlorate contamination in well and city water from years ago showed levels 65 times that of what was found in the water samples. Essentially, this means that plants are concentrating the perchlorate and thus subjecting those who consume the produce to drastically higher levels of the contaminant beyond what they may already be getting through the water.

**Health Risks Associated With Rocket Fuel Exposure**

In the human body, perchlorate affects production of thyroid hormones, which according to the EPA, can cause thyroid ailments such as Graves’ disease and thyroid cancer in adults. Fetuses and newborns are at even greater risk, susceptible to neurological and other developmental damage. The EPA worries that even the smallest traces of perchlorate are dangerous to newborns and fetuses because thyroid hormone production is crucial to normal brain development. Animal studies as far back as 1957 have illustrated how this can be readily passed from mother to newborn in utero, as such was the case in a 1957 Harvard University study on guinea pigs, where the transmission of perchlorate via the placenta to newborn guinea pigs was witnessed.

Of course there are many other chemicals noxious and carcinogenic to human health in rocket fuel. Polycyclic aromatic hydrocarbons (PAHs) are known to be extremely carcinogenic even in tiny quantities. Exposure to NO₂ (i.e., nitrogen dioxide) induces pulmonary injury in a multitude of ways.
NO$_2$ is converted to NO, HNO$_3$ (nitric acid), and HNO$_2$ (nitrous acid) in the distal airways, where it exerts toxic effects on type I pneumocytes and ciliated airway cells. NO$_2$ also initiates free radical generation in the terminal bronchioles, resulting in protein oxidation, lipid peroxidation, and subsequent cell membrane damage. NO$_2$ furthermore alters macrophage and immune function, causing impaired resistance to infection. Benzene has hematological, immunological, and lymphoreticular effects and is classified in EPA Group A as a human carcinogen. Children and fetuses may be at increased risk to benzene toxicity because their hematopoietic cell populations are expanding and their dividing cells are at a greater risk than quiescent cells. Furthermore, based on studies of benzo(a) pyrene in animals, women may be at increased risk of reproductive dysfunction following exposure to high levels of benzene types of compounds.

Individuals with impaired pulmonary function may be more susceptible to the respiratory irritant effects of the many volatile petroleum hydrocarbons found in or given off via jet fuels. Acute inhalation or aspirating such aromatic petroleum hydrocarbons can lead to pulmonary irritation and even hydrocarbon pneumonia, which is an acute hemorrhagic necrotizing disease. Furthermore, these aromatic and aliphatic hydrocarbons found in petroleum products, including jet fuel, are metabolized through the cytochrome P-450 pathways in the liver, which are then transformed into metabolic metabolites. Some of these (such as intermediary metabolites of benzene and other PAHs) are known to cause cancer from chronic exposure as well as peripheral neuropathy. At this time, there are no known, proven clinical treatments to interfere with these mechanisms of action.

The comprehensive listing below illustrates the sheer magnitude of many potential health issues linked to persistently elevated levels of jet fuel and jet exhaustion: asthma, brain cancer, conjunctive irritation, coughing, delayed hypersensitivity, distorted perceptions, drowsiness, dyspnea, headache, EEG changes, emphysema, flushing, hallucinations, heart disease, high blood pressure, Hodgkin’s disease, lacrimation, liver damage, lung disease, lung structured damage, lung tightness, lymphoma, mental depression, muscle weakness, myeloid leukemia, nausea and vomiting, pulse rate decrease or increase, pulmonary irritation, respiratory system damage, skin and eye irritation, systemic irritation, and wheezing.

Last, according to researcher Dr. Hitomi Suzuki, the compound 3-nitrobenzathrone, given off in the exhaust of jet fuels, may be the most hazardous compound ever to be tested for carcinogenicity. Researchers such as Dr. Suzuki and others have remarked that there are also very likely synergistic effects increasing the carcinogenicity of isolated compounds in jet fuel when interacting with the sun and the atmosphere when given off as exhaust, causing even further concern for those who live especially close to airports. Studies as far back as the early 1990s have drawn this conclusion, for instance, when the EPA conducted a study looking at cancer cases in the proximity of Midway airport in Chicago. This study concluded that nearly 99 percent of the cases of cancer reported in the vicinity of Midway airport were directly linked to aircraft emissions.

**Past Exposure, Cleanup, and Continued Insidious Exposure**

Limiting exposure to items such as perchlorate and other chemicals found in jet fuel is hampered by the fact that, for many years, such compounds were freely dumped into the Earth in unlined pits and such, allowing it to seep deeply into underground aquifers and rivers and, in some cases, out of the reach of remediation efforts by companies trying to make right their previous environmental faux pas. Limiting exposure from commercial and private jet planes is obviously very limited for the public by not being able to control what is released into the air across the country, thus leaving a potential considerable route of exposure largely unmitigated for many people. Last but not least, while the EPA has released public statements agreeing that perchlorate is dangerous and must be regulated in public water supplies at a deemed safe level (which is based on review of extant scientific literature as of 2012), this has not translated into mandatory meaningful action on a large scale as of yet. This is because the EPA has not posed any regulatory requirements on public water supplies and systems at this time, even though some 4 percent of public water supplies routinely test positive for perchlorate contamination.

Jimmy Fund

The Jimmy Fund was introduced in 1948 to collect donations for improving the survival rates for children and adult cancer patients through the support of cancer research and patient care. The Jimmy Fund is associated with the Dana-Farber Cancer Institute in Boston, Massachusetts. The organization emerged when a child patient of Dr. Sydney Farber, founder of the Dana-Farber Institute and the father of modern chemotherapy, took part in a broadcast at the hospital bedside of an inspirational 12-year-old cancer patient, Einar Gustafson. He was dubbed the original Jimmy to protect his privacy. Gustafson’s cancer went into remission, and he returned to his home in Maine, where he lived out of sight until 1998, the 50th anniversary of the Jimmy Fund, when people were shocked that he had survived pediatric cancer. He died at the age of 65 of a stroke and remains a beacon of hope for all cancer patients. His story established the mission of the fund to sustain research and care that improves cancer survival rates because most doctors believed that his long-term prognosis was not strong.

The Jimmy Fund, a nonprofit organization, began as a grassroots effort that included events like lemonade stands, bake sales, and various runs and walks. In 1953, the Major League Baseball team the Boston Red Sox became a proud partner of the Jimmy Fund along with the Massachusetts Chiefs of Police Association, Pan-Mass Challenge, and Variety Children’s Charity of New England. The Jimmy Fund serves as the official charity of these key Massachusetts institutions. Today, there are countless national fund-raising events held each year to raise money for the Jimmy Fund.

The Dana-Farber Cancer Institute boasts an equal commitment to both patient care and research in cancer advances. Dana-Farber is associated with several areas of Harvard University, including the Medical School and the Stem Cell Research Institute. Dana-Farber services more than 300,000 patients and sponsors in more than 700 clinical trials a year. It is continually ranked as the number-one cancer hospital in New England and number five in the United States by U.S. News and World Report. It is affiliated with Brigham and Women’s Hospital, Boston Children’s Hospital, and Massachusetts General Hospital.

In 2013, the Jimmy Fund and the Boston Red Sox celebrated their 60th year together, making it the oldest and most effective partnership between a sports team and cancer charity in the United States. The Jimmy Fund has raised millions of dollars for research and patient care for the Dana-Farber Cancer Institute. The fund reports that 89 cents of every dollar collected goes directly to patient care and cancer research. One of the fund’s largest fund-raising events is the WEEI and New England Sports Network (NESN) Jimmy Fund Radio Telethon, which has been held for the last 13 years. The radio and television telethon runs for two days in mid-August. Celebrities who have donated to the Jimmy Fund include Matt Damon, the late George Steinbrenner (the Yankees’ owner), Donald Trump, and countless others.

The Boston Marathon Jimmy Fund Walk continually raises the most money of any one-day walk in the United States, raising close to $95 million toward the fight against cancer since 1989.

The Jimmy Fund is an impactful and inspirational not-for-profit organization strategically paired with several long-time Massachusetts historical
institutions including the Boston Red Sox. It continues to be a thriving fund-raising organization with the sole purpose of supporting the Dana-Farber Cancer Institute. The patient stories of those helped by the amount of positive research and clinical trials to emerge from the Dana-Farber Cancer Institute highlights the real promise of the Jimmy Fund to one day eradicate cancer.

Johnson & Johnson (United States)

Three brothers (Robert Wood Johnson, James Wood Johnson, and Edward Mead Johnson) started the Johnson & Johnson Company in 1886 in New Brunswick, New Jersey. Their product line involved medical supplies. The company published “Modern Methods of Antiseptic Wound Treatment” and facilitated the growth of routine sterilization for surgical methods in the United States and globally. By 1901, Johnson & Johnson placed the first “Handbook of First Aid” in the company’s first aid kits. The company developed many over-the-counter medications to meet the health needs of individuals in the early 1900s. Johnson & Johnson truly represented a company ahead of their time with the publication of education material along with the items sold. When the company provided supplies and money to Galveston, Texas, after a hurricane in 1900, the practice of disaster relief by private enterprise began.

Fast-forward to 1957; Johnson & Johnson introduced Tylenol as the first prescription aspirin-free pain reliever. Then in 1968, RhoGam became the first product to treat babies with hemolytic anemia caused by the mother’s Rh-negative blood. With the company’s past history of breakthrough treatments, it brought a new method, GeneSearch Breast Lymph Node Assay, to market in 2007 as the first gene-based test to uncover the extension of breast cancer into the lymph nodes. Johnson & Johnson continuously stayed abreast of the needs of the consumer.

Under the leadership of Robert Wood Johnson, the concept of a global market changed. He realized after World War I that the company needed to stop working through sales agents in other countries. The company needed to get to know local economies worldwide and open locally managed Johnson & Johnson companies capable of understanding local needs in order to truly serve the populations in each setting worldwide. The company expanded to New Zealand, Australia, Canada, and the United Kingdom after World War I.

More recently in the millennium, Johnson & Johnson developed a program for cancer prevention, called the chief executive officer (CEO) Cancer Gold Standard. The company leadership felt that employers perform a major responsibility in the battle against cancer by supporting a workplace conducive to a healthy environment and safe health practices. Consequently, Johnson & Johnson outlined a program to reduce health risks by detailing activities to prevent cancer, to detect the disease early, and to guarantee access to the most suitable treatments for their employees.
The company took the leadership role by integrating the Cancer Gold Standard Program into their prevailing health promotion practices. The guidelines in the program highlight tools to monitor progress in their cancer prevention and treatment initiatives. Since execution of the program in 2013, Johnson & Johnson has collated and interpreted data analysis of health care eligibility, claims, and health risk assessment to uncover progress in their own institution.

Organizations can join the Cancer Gold Standard group. The Gold Standard outlines how business leaders and CEOs can alter the course of cancer. Companies in the CEO Cancer Gold Standard Program can collectively as a group impact formulators of policy, payers, and the establishment at large in altering behaviors and generating a belief in health and wellness to reduce cancer or adverse outcomes of the disease.

Why support a program about cancer? The cancer statistics tell a compelling tale of risk and death. In the United States, the risk of developing cancer over a lifetime remains at slightly less than one in two for males and a little more than one in three for females. Cancer comes in second as the most frequent cause of death in the United States. The collective cost entails direct medical costs, lost productivity, the price of disability claims, and the burden of cancer on the individual and family. The number one preventable activity contributing to cancer development remains tobacco use, with heavy alcohol use as a second influencing factor. A few other controllable aspects associated with cancer include inadequate diet, insufficient exercise, and infectious diseases.

What does the Cancer Gold Standard Program entail? The primary tenet of the Cancer Gold Standard Program remains the concept of health and safety of the workforce. By advocating wellness, lessening the health risks of the workforce, and alleviating the complications of chronic illness, R. Fabius and colleagues describe companies adhering to these concepts as realizing a reduction in health care costs, an increase in productivity, and elevated levels of performance.

The Gold Standard Program uses five pillars to describe the areas of emphasis in its agenda. The first pillar entails prevention, with the five subcategories of nutrition, physical activity, healthy weight, vaccines, and a tobacco-free workplace. The second pillar favors screening for breast, cervical, and colorectal cancer as early detection is known to provide better outcomes. The third pillar promotes participation of employees in cancer clinical trials as new, more effective cancer treatments can be discovered. The fourth pillar advocates access to quality treatment when cancer diagnosis occurs and linkage to educational resources on cancer survivorships. The fifth pillar focuses on health education and health promotion, so employees understand the rationale for the first four pillars.

Support for the CEO Cancer Gold Standard Program continues to rise. Just in 2014, many companies became accredited by the program to support the healthy lifestyles and battle against cancer. Companies come from all the different niches in society. Some of the companies include Bayer Healthcare, Amgen, Latham & Watkins (a global law firm), Boehringer Ingelheim Pharmaceuticals, North Dakota State College of Science, Texas A&M Health Science Center School of Rural Public Health, Putnam Hospital Center (Carmel, New York), Georgia Regents Medical Center, and Carroll Hospital Center (Westminster, Maryland).

Johnson & Johnson continuously shows its commitment to healthy issues within the company. Its actions motivate other organizations to change and pursue avenues of not only reducing the risk of cancer but also supporting innovations in the treatment of cancers. Because research indicates that fully half of all cancers are preventable, Johnson & Johnson uses the best evidence available to pursue health prevention and to engage in promotion of treatment like gene-based therapy.

Further Readings
The country of Jordan has a population of 6.2 million people. It spends 8 percent of its gross national product (GNP) on health care. There are high frequencies of leukemias and lymphomas in this region, especially in children: 33.2 percent leukemia and 18.1 percent lymphoma. The country lacks resources in cancer research. Prior to the 1980s, in order to obtain treatment, wealthy patients had to travel to another country. Those who lacked the financial means to go abroad were treated using Jordan’s limited resources, most with poor results.

In 1997, the Al-Amal Center, which means the “Center for Hope,” opened. While the center was established to provide care to those living in Jordan, many still traveled abroad for treatment because the technology was years behind that of the United States or Europe. For example, in 1998, King Hussein flew to the United States be treated for lymphatic cancer at the Mayo Clinic in Rochester, Minnesota. The type of non-Hodgkin’s lymphoma that King Hussein had generally responds to treatment, but treatment was not available in Jordan. King Hussein died on February 1999. In 2002, the Al-Amal Center was renamed the King Hussein Cancer Center (KHCC), after King Hussein. This is the only cancer center in Jordan.

When Mahmoud Sarhan was hired as the Director for the KHCC, he founded the bone marrow transplantation program (BMT). This program is now one of the largest in the Middle East, with a success rate that rivals those in the United States and Europe. The center performs matched allogeneic and autologous transplants, and uses umbilical cord blood collected from the placentas after birth in healthy pregnancies. Currently, stem cells, such as those harvested from umbilical cord blood, are used in the treatment of acute leukemia, chronic leukemia, high-risk solid tumors, Hodgkin’s and non-Hodgkin’s lymphoma, multiple myelomas, and myelodysplastic syndromes, in addition to numerous blood, immune, and metabolic disorders. Internationally, 34 percent of hematopoietic stem cell transplants are done using umbilical cord blood.

In 2007, the first national breast cancer program, the Jordan Breast Cancer Program (JBCP), was established. The objectives of this program were to reduce morbidity and mortality from breast cancer using awareness campaigns, early detection, and access to screening for Jordanian women when the survival rates are best. In 2010, the KHCC formed an alliance with the American University of Beirut Medical Center to create a joint cancer research program. On October 31, 2013, Leeds Teaching Hospitals NHS Trust signed a formal Memorandum of Understanding. This agreement created a partnership in which Leeds will share its expertise and innovations and allow development of cancer treatment in the Middle East. Leeds Cancer Centre, located at St. James’s University Hospital, is one of the largest providers of oncology services in the United Kingdom, and is a leader in cancer research and treatment. Healthcare UK was instrumental in bringing Leeds and the KHCC together. Additional partners include St. Jude’s Research Hospital and the University of Texas MD Anderson Cancer Center.

There are over 3,500 new cancer patients each year, with more than 110,000 outpatient visits. The KHCC has 200 oncologists and consultants, 617 trained oncology nurses, and 82 pharmacists, and it performs 120 bone marrow transplants each year. The facility has six operating rooms and 18 intensive care beds, with 6 for pediatric patients. The KHCC is actively involved in academics and research. The Academic Affairs Office promotes education and training at the center. There are five parts to this office: the Education Center, Training Center, Life Support Center, International Affairs Center, and Library & Education Recourse Center, and two committees, the Ranking and Promotion Committee and the KHCC Regional and International Scientific Activities Committee. Two research projects that came from Jordan are on cancer-related outcomes in colorectal cancer and type II diabetes, and the prevalence of biallelic mismatch repair gene alterations in pediatric high-grade glioma and supratentorial primitive neuroectodermal tumor. Additional research projects include treatment of tobacco dependence, BRCA1/2 breast cancer mutations, and breast cancer molecular subtypes.

The number of patients diagnosed with cancer is on the rise in Jordan, and the current infrastructure does not support the current demand, let alone the growing cancer population. Combine this with more patients coming to Jordan for treatment from other countries, such as Palestine, Iraq, Yemen, and Sudan, and cancer patients will
be turned away for lack of facilities. To meet this
demand, the KHCC is expanding to double the
current capacity. This expansion will include an
inpatient tower and an outpatient building, costing an estimated $186 million. The expansion is
scheduled to be completed the middle of 2015.

The Inpatient Tower will consist of 13 floors, containing 182 single-occupancy rooms, an expanded
diagnostic imaging and radiotherapy unit, an
expanded bone marrow transplant unit, and intensive care units, including a specialty pediatric unit, and medical floors specializing in both adults and pediatric patients. The 10-floor outpatient building will house the first public umbilical cord blood
bank in Jordan. The Khalid Shoman Educational
Center and Auditorium will also be located here. This will focus on the education of health care providers, and will include a skills lab, lecture room, medical library, and an interactive lounge. The
Women’s Health Center and the dedicated space for pediatrics is designed to cope with the rising num-
ber of women and children diagnosed with cancer. Finally, the Cell Therapy and Applied Genomics
Department will continue research in laboratories
studying stem cells while increasing the research
capacity of the center.

Kaposi’s Sarcoma

Kaposi’s sarcoma (KS) is a tumor of lymphatic endothelial cells caused by human herpes virus 8 (HHV8), also known as Kaposi’s sarcoma-associated herpes virus (KSHV). KS lesions typically present as palpable cutaneous violaceous papules that are nonpruritic but may also involve visceral organs such as the gastrointestinal and respiratory tracts. Rapid tumor progression is associated with substantial morbidity and mortality. Clinical familiarity with KS is crucial as KS is the most common acquired immune deficiency syndrome (AIDS)-associated cancer in the United States and accounts for up to 50 percent of all cancer diagnoses in certain African countries.

Since the discovery of HHV8 in 1994, overwhelming evidence has accumulated to demonstrate that KS is a direct consequence of HHV8 infection. KS lesions, regardless of source or clinical subtype, have been shown to contain HHV8 proteins. Recent evidence suggests that a widely expressed 12-transmembrane light chain of the human cystine–glutamate exchange transporter system and the C-type lectin DC-SIGN serve as receptors for HHV8 in vivo. Once the virus has infiltrated the host’s cells, multiple HHV8 gene products have exhibited the potential to transform cells in vivo. These gene products are homologous to human genes involved in the regulation of apoptosis, cell proliferation, and angiogenesis and may be directly responsible for the carcinogenic properties of KS. The latency period between HHV8 infection and the clinical manifestation of KS is variable but is clearly dependent on immune system functionality. Immunosuppressed organ-transplant recipients develop KS within one to two years, whereas human immunodeficiency virus (HIV)-infected patients present with KS after five to 10 years, traditionally with CD4 at less than 200 cells/mm³.

Histologically, early KS is a highly vascular neoplasm consisting of proliferating spindle cells of endothelial origin that surround dense, irregular, vascular-like spaces that leak red blood cells, hemosiderin-laden macrophages, and lymphocytes. In more-developed solid tumors, the spindle cells are arranged in more compact bundles and interlacing fascicles. Though KS was previously considered a monoclonal proliferation of endothelial cells, new studies comparing viral HHV8 DNA suggest a partially multifocal process, where each tumor arises independently from a distinct clone.

Four clinical variants of KS have been described, distinguished by epidemiology, sites of involvement, and rates of progression.

Classic KS predominantly affects men of Mediterranean and eastern European origin, commonly in the seventh decade of life. Lesions start as unilateral or bilateral firm, blue-red macules on the skin of the distal extremities. With time, lesions
grow and coalesce to form nodules or plaques and may assume a brown color. The overlying skin typically becomes hyperkeratotic, which clinically manifests as thickened skin in the affected region. Classic KS may follow a benign course for years to decades after the development of sentinel lesions. In approximately 10 percent of patients, the tumor may disseminate to involve lymph nodes, mucosa, or viscera such the gastrointestinal tract. Symptoms directly attributable to disseminated lesions are rare. In most cases, patients affected by classic KS die from other causes prior to the full spread of the disease.

Endemic African KS was recognized in sub-Saharan Africa in the 1950s, several decades prior to the outbreak of the AIDS pandemic. Though endemic KS may present worldwide, it is most prevalent in central Africa, where it accounts for up to 10 percent of all malignancies in men. Like classic KS, endemic KS is also more common among males but follows a more aggressive clinical course with extensive infiltration of subcutaneous tissues.

Immunosuppression therapy associated KS affects organ-transplant recipients and others receiving immunosuppressive therapy, particularly if they belong to ethnic groups at increased risk of KS. The prevalence of immunosuppression therapy-associated KS rose precipitously in the 1980s, corresponding with the rising use of calcineurin inhibitors as first-line immunosuppressants. Clinical course may be slow or rapidly progressive, based on the type and dose of immunosuppressive drug being employed. Cyclosporine has been known to induce earlier onset of the cancer and more aggressive clinical course relative other immunosuppressive agents, such as glucocorticoids. Immunosuppression therapy-associated KS affects the skin in 85 percent of cases, but isolated visceral involvement has been reported in a minority of cases.

AIDS-related KS, first described in 1981, is the most common AIDS-associated cancer in the United States. HHV8 is frequently sexually transmitted among people who are also at risk of sexually contracting the HIV infection, while immunosuppression caused by AIDS provides an opportunity for the development of KS lesions. AIDS-related KS follows a more rapid course than classic KS and exhibits prompt multifocal dissemination. Initially small, purple-red macules rapidly transform into plaques, papules, and nodules, which are often present at multiple locations at the time of presentation. AIDS-related KS has a predilection for the face, trunk, and mucous membranes, with the oral mucosa representing the most frequent initial site of involvement. Untreated, lesions may coalesce to involve large parts of the body, with the potential to cause significant functional impairment. Involvement of extracutaneous sites occurs more rapidly than with classic KS and most frequently involves the lymph nodes, the gastrointestinal tract, and the lungs.

Definitive diagnosis of KS requires biopsy and microscopic examination of lesions. Typically, specimens are taken by punch biopsy of cutaneous lesions, but bronchoscopy and esophagogastroduodenoscopy may be utilized to sample the respiratory tract and gastrointestinal lesions, respectively. Diagnosis is confirmed by the presence of spindle cells on microscopy and the detection of KSHV protein latency-associated nuclear antigen (LANA) in tumor cells.

KS treatment modalities are determined based on the clinical subtype, the extent of disease, and the organ systems involved. In classic KS that is confined to a limited number of cutaneous lesions, the elimination of lesions by surgical excision, liquid nitrogen, or laser, photodynamic, or radiation therapy is typically the first step in management. Intralesional injections of the chemotherapeutic agents vinblastine or interferon-alpha have also proven effective. In addition, isolated KS lesions may be targeted with topical retinoids, such as 9-cis-retinoic acid, though this approach is associated with local erythema and irritation at the site of application.

Rapidly progressive or widespread classic KS that involves visceral organs is targeted with chemotherapeutic agents such as doxorubicin and bleomycin. Immunosuppression therapy-associated KS has shown excellent response to a reduction of immunosuppressive therapy. Interestingly, complete remission of advanced KS lesions may also be induced by the replacement of calcineurin inhibitors by rapamycin. Experience with AIDS-related KS has demonstrated that KS confined to the skin is often controllable by the initiation or adjustment of HAART therapy. For advanced AIDS-related KS, the addition of chemotherapeutic agents, namely liposomal anthracyclines
and paclitaxel, have proven to be to be an effective and well-tolerated treatment regimen.

Kazakhstan

Kazakhstan, located in the middle of central Asia, lays on the ancient Great Silk roads. Its vast territory covers 2,724,900 square kilometers and is the world’s ninth-largest country. Kazakhstan is ethnically and culturally diverse in part due to the forced migration of numbers of settlers from the Russian empire, who began colonizing the territory of present-day Kazakhstan during the 19th century and the first third of the 20th century, and partly due to mass deportations of many ethnic groups to the country during Joseph Stalin’s rule. Kazakhstan has a population of 17 million, with 131 ethnicities, including Kazakh, Russian, Ukrainian, German, Uzbek, Tatar, and Uyghur, and approximately 63 percent of the population is Kazakh. According to the World Bank, Kazakhstan is an upper middle-income country with a gross domestic product (GDP) of $203.5 billion in 2012, and gross national product (GNP) per capita was $11,780.

Epidemiology of Cancer
The prevalence of noncommunicable chronic diseases is increasing globally owing to improvements in sanitation, housing, and education. Further, with reduction in mortality due to infectious diseases, life expectancy has increased and, consequently, so has the prevalence of age-related diseases, such as cancer and cardiovascular and metabolic diseases. In Kazakhstan, the life expectancy at birth for males was 63 and that for females was 72 years of age.

Cancer is the second-leading cause of mortality in Kazakhstan, and approximately 17,000 people die each year from cancer. While the number of patients with malignant neoplasm has increased by 6 percent between 2006 and 2011, cancer mortality during this time has declined from 113.7 per 100,000 in 2006 to 101.6 per 100,000 in 2011. The observed changes are likely to be due to a combination of better reporting systems, early detection, and improved treatments.

In Kazakhstan, the leading causes of death from cancer among adults in 2011 were breast cancer (11.6 percent), lung cancer (11.4 percent), and skin cancer (10.7 percent) followed by gastric cancer (8.8 percent), cervical cancer (4.8 percent), esophageal cancer (4.4 percent), hematological malignancies (4.4 percent), colorectal cancer (4.4 percent), and rectum (4.1 percent). Among men, highly prevalent cancers were tumor of the trachea, bronchus, and lung (20.4 percent), stomach (12.0 percent), and skin (9.6 percent) followed by prostate tumors (6 percent), esophagus (5.3 percent), hematological malignancies (4.9 percent), rectum (4.6 percent), colon (4.1 percent), and bladder (3.7 percent). Among women, breast cancer (21.4 percent) was the most prevalent cancer followed by skin (11.6 percent), cervix (8.8 percent), stomach (6.2 percent), ovary (5.7 percent), uterus (5.5 percent), colon (4.6 percent), hematological malignancies (3.9 percent), and lung cancer (3.9 percent). Among children, approximately 350 to 400 under 15 years are diagnosed with cancer annually. The most prevalent cancers are cancers in the lymphatic and hematopoietic systems, central nervous system, and bone and soft tissues.

The distribution of cancer mortality varies widely by region. Among 14 Kazakhstani provinces, the industrial regions in east Kazakhstan, north Kazakhstan, and Pavlodar regions have the highest mortality from cancer. Elevated levels of environmental pollutants, such as coal dusts, hard metals, silica exposures, and asbestos, have been implicated. Particularly, the Semipalatinsk nuclear testing site located in east Kazakhstan had been
used for numerous underground and atmospheric explosions between 1949 and 1989 during the former Soviet Union era. Multiple studies have been conducted to investigate the health impact on local residents as well as the ecosystems. Some studies have reported elevated risks of esophageal cancer and thyroid abnormalities. In addition, detailed reports on the effects of radiation on the ecosystems have been published.

**Cancer Screening Programs**

The Kazakhstani government has implemented several programs to reduce the burden of cancer, modernizing oncological clinics and introducing new diagnostic and treatment tools for cancer. The main goal was to screen and diagnose these cancers at early stages through screening programs in order to improve five-year survival rates and reduce treatment costs.

**Medical Care**

Over the past decade, the amount of funds spent on medication for cancer patients has increased by 17-fold to 13.7 billion Tenge in 2012 (approximately $76 million). At the same time, only about 70 percent of the medication needs are met so that it is difficult to provide sustained treatments. Although the Kazakh federal government pays for the specialized drugs that can target tumor cells only, only 51 percent receive the drug, and 46 percent are detected at early stages (stages I–II) of cancer.

At the health policy level, the Kazakhstani health care system fully supports cancer patients as patients are guaranteed free medical care, including the provision of medical services in foreign clinics. Currently, guidelines are being developed for cancer centers, diagnostic laboratories, clinical practices, and patient management. The main goals of the cancer care strategies in Kazakhstan are to (1) improve preventative primary health care, (2) develop the infrastructure to provide accurate diagnosis and treatment, and (3) improve the infrastructure for oncology service. To combat these cancers in children, for example, two institutions were established under the auspices of the Ministry of Healthcare, including the Treatment Center at the Kazakh Research Institute of Oncology and Radiology and the Bone Marrow Transplant Center at the Scientific Center of Pediatrics and Pediatric Surgery. These centers are to develop and introduce the state-of-the-art cancer treatments that will meet the international standards for Kazakhstans.

To provide better translational use of various biological markers (e.g., hormones, molecular profiling, etc.) to clinical practice for Kazakh populations, research is being carried out.

**Kenya**

Kenya is situated in eastern Africa. It is bordered on the north by Ethiopia, on the east by Somalia, on the east and south by the Atlantic Ocean, and on the west by Tanzania and Uganda. It is the sixth-most populous country in Africa and 31st most in the world, with a population of more than 43 million. The two official national languages are English and Kiswahili, and there are 67 living indigenous languages still spoken by respective ethnic groups in Kenya. The most widely spoken ethnic languages include Kamba, Kigiryama, Kikuyu, Kimiiru, Kipsigis, Lubukusu, Maasai, Nandi, Somali, and
Each ethnic group has its own rich traditions of ethnomedicine. For example, a traditional healer who uses medicinal plants for treating ailments is known as *mundu mugo* in Kikuyu and *mganga* in Kiswahili.

There are many traditional medicinal preparations used in Kenya for treating cancers that incorporate local plants. *Prunus africana* is used as an herbal remedy for benign prostatic hyperplasia. (Wikimedia)

Turkana. There are serious deficiencies of modern pharmaceutical supplies, as opposed to traditional preparations, and in modern medical services for cancer and similar conditions in Kenya. For example, there are only about 1,800 licensed pharmacists in Kenya; of these, about 600 work in the public sector. According to the World Health Organization's (WHO's) "Health System Response and Capacity," as of 2010, there was no general availability of radiotherapy in the public health system in Kenya, although chemotherapy was generally available.

Kenya is a signatory to the Single Convention on Narcotic Drugs, the Convention on Psychotropic Substances, and the UN Convention against the Illicit Traffic in Narcotic Drugs and Psychotropic Substances; consequently, laws exist to control narcotic and psychotropic substances and precursors. Therefore, the annual consumption of controlled substances is thus highly regulated to curtail abuse. Accordingly, the annual consumption of morphine is 0.575 milligram per capita (mg/capita), fentanyl is 0.000074 mg/capita, and pethidine is 1.215 mg/capita. These factors create a serious lack of access for many individuals to appropriate palliative care for cancers and other conditions, which makes the experience of living with and dying from cancer very different in Kenya from that in the developed world.

Due in part to the shortage of medical services and supplies, health problems are endemic in Kenya. The 10 leading causes of morbidity, in rank order, are malaria, respiratory diseases, skin diseases, diarrhea, intestinal worm infestation, accidents, pneumonia, eye infections, rheumatism, and urinary tract infections. The average number of cancer cases annually is 132.8 per 100,000 population.
Cancers account for a substantial amount of disability and suffering among impacted populations. According to the WHO’s “Disease and Injury Country Estimates,” the age-standardized disability adjusted life-year estimates for 2004, the 10 most prevalent cancers in Kenya were led by esophageal cancer at 182 per 100,000 population; stomach cancer at 95 per 100,000; breast cancer at 93 per 100,000; cervical and uterine cancers at 85 per 100,000; lymphomas at 79 per 100,000; prostate cancer at 64 per 100,000; liver cancer at 63 per 100,000; mouth and oropharynx cancers at 59 per 100,000; trachea, bronchial, and lung cancers at 48 per 100,000; and leukemia at 45 per 100,000.

Modern pharmacological supplies, as opposed to traditional preparations, are generally, if available at all, in short supply in Kenya. Both prescription and over-the-counter products are often unavailable. Consequently, health problems are endemic and limit development. For example, an estimated 1.2 million people live with human immunodeficiency virus (HIV) in Kenya, which ranks the country eighth highest in Africa and ninth highest in the world. Debate continues on the relative risks in Africa for respective cancer types for those infected with HIV.

The mortality rate for tuberculosis is 140 per 100,000 population, and that for malaria is 154 per 100,000. Furthermore, according to the WHO’s “Global Health Observatory Data Repository,” in 2008, the age-standardized estimates of deaths from all cancers were 119 per 100,000 population for males and 113 per 100,000 population for females. As a consequence, life expectancy is only 47.2 years, which ranks Kenya the 33rd highest country in Africa and 204th in the world. There is a clear and urgent need for improved cancer awareness, early detection programs, and health services infrastructure in Kenya.

Kidney (Renal Cell) Cancer

Renal cell carcinoma (RCC) accounts for the vast majority of all kidney tumors and is responsible for many cancer-related deaths each year. While some cases arise from hereditary genetic abnormalities, a large portion arises sporadically, with several well-known modifiable risk factors including tobacco use and obesity. Not unlike other cancers, early detection is paramount to increasing overall survival and a potential cure via tumor removal. Despite most often being diagnosed incidentally through the use of imaging, patients with RCC can present with a wide range of signs and symptoms.

In addition to their function as the body’s filter, the kidneys serve to metabolize certain drugs and
act as endocrine organs, producing hormones such as vitamin D and erythropoietin (EPO), a hormone that signals the bone marrow to produce more red blood cells. The kidneys receive their blood from the renal arteries, which branch directly off of the aorta (the largest artery branching off of the heart that delivers oxygenated blood to the rest of the body). Blood leaves the kidneys via the renal veins, which drain directly into the inferior vena cava (a large vein that delivers blood from the lower body back to the heart). The portion of the kidney responsible for filtration consists of microscopic tubules lined by specialized cells with various functions. It is within these cells that RCC arises.

RCC accounts for 85 to 90 percent of cancers that arise within the adult kidney and 2 to 3 percent of all adult cancers, making it the seventh- and ninth-most common cancers among men and women, respectively. It is responsible for approximately 14,000 deaths each year in the United States. RCC affects men more often than women, at a ratio of approximately two to one, and occurs most commonly in the sixth and seventh decades of life. Geographically, RCC occurs more often in North America and Europe, with markedly lower rates in Asia and South America.

Cigarette smoking is a well-established risk factor for development of RCC, increasing risk by 54 percent in men and 22 percent in women. Furthermore, studies have shown a direct relation between incidence and number of packs per day. There is also evidence to suggest that long-term smoking cessation (greater than 10 years) may reduce the elevated risk of developing RCC. Strong evidence indicates that hypertension (persistently elevated blood pressure) is a risk factor. Obesity is yet another risk factor for RCC, with an increase in incidence directly related to body mass index (BMI). It is estimated that, for every five-unit increase in BMI, there is a 24 and 34 percent increase in incidence in men and women, respectively. Other risk factors with convincing data include chronic hepatitis C infection, acquired polycystic kidney disease (which develops in 35 to 50 percent of patients with kidney failure in need of long-term dialysis), and several inherited genetic disorders. Potential risk factors with less convincing data include occupational exposures (asbestos, gasoline, and trichloroethylene) and diabetes mellitus. An inverse relationship has been found between alcohol use and incidence of RCC.

Greater than 90 percent of all RCCs arise sporadically from random genetic mutations. The remaining cases of RCC are due to inherited conditions, most notably von Hippel-Lindau (VHL) disease. VHL disease is an autosomal dominant disorder that results from a deletion of the VHL tumor suppressor gene on chromosome 3. Lack of both copies of this gene leads to formation of multiple tumors, including hemangioblastomas (tumors of blood vessels in the central nervous system), RCC, and pheochromocytomas. The majority of sporadic clear cell RCCs (the most common subtype of RCC) also result from random mutations or deletions of the VHL gene. Clinical factors associated with an inherited RCC include tumors occurring in both kidneys, age of onset less than 40, and first-degree relatives with RCC.

RCC is associated classically with the triad of flank pain, hematuria (blood in the urine), and palpable abdominal mass. However, these manifestations only occur together in fewer than 10 percent of cases. Indeed, with the increasing use of imaging, the majority of RCCs diagnosed nowadays are discovered incidentally, appearing as a mass on imaging obtained for another purpose. Of the patients not diagnosed incidentally, hematuria and flank pain are among the most common complaints. Other signs and symptoms include anemia (low red blood cell count), weight loss, fever, and night sweats.
Kidney Cancer, Childhood

Rarely, RCC may present as a paraneoplastic syndrome (signs or symptoms resulting from abnormal production of hormones by tumor cells). Hypercalcemia (elevated calcium levels in the blood) can be caused by tumor secretion of parathyroid hormone related protein (PTHrP), which acts like endogenous parathyroid hormone to increase blood calcium concentration. Erythrocytosis (elevated red blood cell count) may result from tumor production of excessive EPO. RCC has a tendency to metastasize to the brain, lungs, bones, and liver. Interestingly, this tumor also has a tendency to invade into the renal vein and inferior vena cava, with potential to restrict blood flow from the organs that are drained by these vessels (i.e., testes and legs).

Diagnostic imaging typically begins with a renal ultrasound and may be confirmed by computed tomography (CT) scan. CT scanning must include the chest and abdomen so as to assess for evidence of metastasis. Finally, a biopsy of the tumor is used to evaluate the specific subtype.

The treatment of RCC varies depending on several factors including tumor size, presence of metastases, and the presence of various comorbidities specific to each patient. For tumors that are confined to the kidney and are less than seven centimeters in size, the preferred treatment is a partial nephrectomy (removal of only the portion of the kidney containing the tumor). These cases have five-year survival rates greater than 90 percent. Tumors confined to the kidney measuring greater than seven centimeters require nephrectomy (removal of the entire kidney). For tumors that have grown large enough to extend beyond the tissues of the kidney but have not yet metastasized, radical nephrectomy (removal of the entire kidney). For tumors that have grown large enough to extend beyond the tissues of the kidney but have not yet metastasized, radical nephrectomy, with removal of invaded tissue, is the standard of care. With lymph node involvement, the five-year survival rate decreases to 32 percent. With distant metastases, patients require systemic chemotherapy, and possible nephrectomy, and survival beyond five years is exceedingly rare. Depending on symptoms, prognosis, and accessibility, metastatic tumors to the lungs also may be surgically removed. Radiation therapy is typically reserved for the control of large, symptomatic metastatic tumors, particularly to the brain and bones.

Kidney Cancer, Childhood

Kidney cancer refers to a number of different cancers that begin in the kidney. While in adults most kidney cancers are either renal cell carcinoma or transitional cell carcinoma, in children the overwhelming majority of kidney cancers are Wilms’ tumor. However, other kidney cancers can present in children, including the aforementioned carcinomas and clear-cell sarcoma of the kidney.

The kidneys are the two bean-shaped organs in the body that assist in metabolism, principally by filtering out waste products. Kidneys produce urine, for instance, by excreting urea and ammonium waste products, which empty into the bladder via a ureter. Proper kidney function is required to regulate electrolytes, blood pressure, and the acid–base balance of the body, all of which are critical to human health. Kidneys also produce some of the body’s hormones. All of these functions are jeopardized by kidney cancers.

Wilms’ tumor rarely manifests in adults but is the most common kidney cancer in children, occurring primarily in 3-year-olds. It is named for German surgeon Max Wilms, who first described it in the early 20th century. Sidney Farber of the Dana–Farber Cancer Institute was the first to develop a treatment for Wilms’ tumor that sent the cancer into remission, combining surgery, radiation therapy, and an antibiotic, and since then, five-year survival rates have climbed to 90 percent.
Wilms' tumor is a nephroblastoma that is almost always unilateral, consisting of the blastema, mesenchyme, and epithelium. Cartilage, fat, bone, and fiber may be found in the spindled cell stroma that surrounds a bundle of abortive tubules. The tumors are classified as either favorable or anaplastic, with anaplastic tumors being more poorly developed and differentiated than described here.

The first signs of Wilms' tumor are usually a painless abdominal lump discovered by the child's pediatrician during a physical examination. Other symptoms may include abdominal swelling or pain, fever, nausea, or high blood pressure, and in a minority of cases, there is blood in the urine. The tumor is diagnosed with imaging informed by the assumption that most childhood kidney cancers will be Wilms' tumors. Because a needle biopsy poses the danger of releasing malignant cells into other parts of the body, it is usually not performed until after surgical removal, which sometimes leads to other kidney cancers being misdiagnosed initially as Wilms' tumors.

Certain conditions predispose the patient toward Wilms' tumors, such as Beckwith–Wiedemann syndrome (BWS), an overgrowth disorder present from birth. While most BWS children do not develop cancer, they are hundreds of times more likely to develop Wilms' tumors as well as similar tumors in the pancreas and liver. This risk seems to apply only to childhood cancers, especially in the toddler years. Perlman syndrome, another overgrowth disorder, which begins with fetal overgrowth, also predisposes toward Wilms' tumor as well as dysmorphic facial features and macrocephaly. Denys-Drash syndrome is a rare disease almost always caused by an abnormality in the WT1 gene, leading to Wilms' tumors, gonadal dysgenesis, and nephropathy. WAGR syndrome is another genetic syndrome that predisposes children to develop Wilms' tumors, aniridia (a lack of colored iris in the eye), genitourinary anomalies, and retardation.

Rhabdoid tumor was originally considered a variant of Wilms' tumor, is highly aggressive, and has a poor prognosis. It nearly always occurs in children under two years old. A substantial minority of patients with rhabdoid tumors also have malignant brain tumors.

Other types of childhood kidney cancer include renal cell carcinoma, which originates in the lining of small tubes in the kidney called proximal convoluted tubules and is the most common adult kidney cancer as well as one of the deadliest genitourinary cancers; transitional cell carcinoma, which can occur in the kidney, bladder, or accessory organs, and is usually caused by environmental carcinogens; angiomylipoma, a benign kidney tumor that can impair kidney function or cause blood vessels to hemorrhage; renal oncocytoma, an epithelial kidney tumor made up of oncocyes, cells abundant in mitochondria, developing in the intercalated cells of the kidney’s collecting ducts, and usually asymptomatic unless they become both malignant and metastasized; squamous cell carcinoma of the kidney, which is especially uncommon in children; clear-cell sarcoma of the kidney, which develops from mesenchymal tissue and often includes a cyst; Bellini duct carcinoma, which originates in the kidney’s duct of Bellini, another name for the collecting duct and which appears physically similar to bubble wrap; and mesoblastic nephroma, which is largely similar to Wilms' tumor but develops in the fetus.

Kidney Cancer Association

The Kidney Cancer Association (KCA) was founded in 1990 by medical doctors and a small group of patients in Chicago, Illinois. It is a non-profit and is tax exempt under the U.S. Internal Revenue Service code. Members currently include patients, family members, researchers, physicians, and other allied health professionals. It is the first international charity dedicated to eliminating suffering and death from renal cancers. Members are found in more than 100 countries. The KCA funds, promotes, and collaborates with multiple institutions, including the American Society for Clinical Oncology, the National Cancer Institute, and the American Urological Association, on research projects. Advocacy for patients and families, including education and continuing medical education, are also key to the KCA at the state, federal, national, and international levels. The KCA’s vision is a world without kidney cancer. Their mission is the elimination of suffering and death from renal cancers. KCA’s three primary goals are advocacy, research, and education.

Kidney cancer occurs two times more often in males and represents about 3 percent of the total diagnoses of cancer. In 2005, 12,660 people died from kidney cancer. Currently, there are more than 100,000 kidney cancer survivors in the United States. The most common kidney cancer is renal cell carcinoma (RCC). If caught early and treated (typically with surgery), chances of its return are low. However, early stage RCC has few symptoms. Usually, it is found incidentally. Thirty percent of RCC cases are advanced when first diagnosed. Approximately 15 to 25 percent have metastatic disease by the time it is diagnosed. Painless, bloody urine is the most common symptom of kidney cancer. Some 40 to 50 percent will have this symptom. Often, blood in the urine will be present one day and then not the next. Other symptoms that are common to kidney cancer include an abdominal mass, back pain or pressure, flank pain or pressure, weight loss, fever, anemia, and high blood pressure.

The subtypes of RCC include clear cell RCC (the most common and associated with a gene mutation), chromophobe RCC (rare and usually successfully treated as it metastasizes very late), renal oncocyotoma (a benign tumor that can grow quite large and invade local tissue), collecting duct carcinoma (which is aggressive and associated with sickle cell trait), sarcomatoid RCC (which is typically metastasized throughout the body and therefore has a poor prognosis), and unclassified RCC.

Most kidney cancers are treated through surgical procedures. A nephrectomy entails removing the affected kidney. A radical nephrectomy entails removing the affected kidney, some healthy tissue around the border, and adjacent lymph nodes. In this case, the adrenal gland also may be removed. Nephron-sparing surgery is a procedure that removes the tumor and a small border of healthy tissue but does not remove the entire kidney. When surgery is not an option, treatments can include freezing the cancer cells (cryoablation), heating the cancer cells (radiofrequency ablation), biological therapy (immunotherapy), targeted therapy (drugs), and radiation therapy.

KCA promotes research in private and public institutions. Financial grants are competitive and provided from funds named in honor for their founder, Eugene P. Schonfeld, Ph.D. Funds are raised by KCA members, donations, and the Penn State Football Team’s Lift for Life fund-raisers. The Young Investigator Award provides funds to promising researchers who are transitioning from fellowship programs to faculty appointments. Awards are based on fund availability and individual merit. Other awards include the Eugene P. Schonfeld Medical Research Awards, ASCO Conquer Cancer Foundation Award, Andrew C. Novick and P.H.M. de Mulder/AUA Urology Care Foundation Research Scholar Award, ASCO Cancer Foundation Young Investigator Award, AUA Foundation Research Scholar Award, David A. Stulberg Career Investigator Award, and Senior Career Investigator Award.

From October 2012 to October 2013, KCA provided greater than 60 education and support opportunities for caregivers, survivors, and patients. Two national meetings were held in Houston, Texas, and San Francisco, California. KCA also has hosted an online Facebook group for survivors and caregivers. There are more than 85,000 people around the world who have joined the group. KCA launched a peer-to-peer Web site two years ago for caregivers, survivors, and patients, called Kidney-Cancer.me. They have developed three educational
applications for smartphones, iPads, iPhones, and android platforms. KCA also sponsored the European Kidney Cancer Symposium. Hundreds of allied health professionals attended in Budapest, Hungary. Furthermore, more than 200 attended the International Kidney Cancer Symposium in Chicago. KCA also mails information packets to families and patients. More than 100 countries are represented in KCA membership. Approximately 20,000 monthly newsletters are e-mailed, and hundreds watch Kidney Cancer News, a monthly video magazine featured on KCA’s homepage.

KCA has increased its outreach to global patients by translating their publications into 13 languages. Their goal is to add at least one new language each year. KCA has also increased its outreach to global medical professionals by sponsoring two international symposiums per year. One meeting is held in Chicago and the other in a different European country every year. KCA’s Nurse Advisory Board has completed a review of the more than 100-page publication We Have Kidney Cancer, and distribution is now global. KCA has also partnered with EmergingMed, which has resulted in patient referrals to clinical trials. Patient advocacy remains an important goal and is accomplished by identifying new opportunities for collaboration with other voluntary health organizations. Collaborative relationships continue with the following organizations: Friends of Cancer Research, Cancer Leadership Council, the National Coalition for Cancer Research, Foundation for NIH, Patient Advocate Foundation, and the National Cancer Comprehensive Network.

Research at Kimmel Cancer Center
The mission and values of KCC focus on providing a respectful and multidisciplinary approach to research, teaching, prevention, and the treatment of cancer. The core values, as outlined on the KCC Web site, are that KCC members are focused on working toward perfection and building excellent teams. Outstanding teams at KCC are to be built through treating other team members with respect, dignity, integrity, always giving hope, and supporting and recognizing others’ achievements.

Research at KCC is supported through KCC’s shared resources. Some of the shared resources include bioimaging; biostatistics; cancer genomics; informatics; proteomics; laboratory animal research; translational research; and X-ray crystallography and molecular characterization. KCC also

Kimmel Cancer Center

The Kimmel Cancer Center (KCC) at Thomas Jefferson University is located in Philadelphia, Pennsylvania. It was founded in 1991. At that time, it included 30 cancer researchers and presently has grown to approximately 150 physicians and scientists. Through KCC’s affiliation with the Thomas Jefferson University Hospital system, the center collaborates with 22 hospitals and partners as well as 400 members to provide research in oncology, treatment of cancer, education, and information.

In 1996, the National Cancer Institute (NCI) designated the KCC as an NCI-designated cancer center, which is the highest ranking bestowed on organizations dedicated to research, treatment, and prevention of cancer. KCC also has received recognition as a top treatment center. The Jefferson University Hospital system, which is affiliated with KCC, was rated by U.S. News and World Report as the 17th-best hospital for 2013 and 2014. KCC, in particular, was listed on Becker’s Hospital Review as one of 70 health institutes with a great oncology program.

has four basic science research programs: cancer cell biology and signaling, molecular biology and genetics, the biology of prostate cancer, and the biology of breast cancer.

The Biology of Prostate Cancer (BPC) is one of the newer programs at KCC. The BPC is a collaborative interdisciplinary research program that involves 10 departments and three institutions. Research in the program has generated more than 343 publications in five years. The program strives to advance new strategies for detection, diagnosis, and treatment of early to advanced forms of prostate cancer through research on hormone action in malignant tumors as well as predictive markers for rational therapy delivery. Of primary interest is translational research or research that can be moved to clinical trials so that patients can receive cutting-edge treatment. Through the KCC Web site, patients can access information on current clinical trials to which they can apply.

**Patient Care**

KCC strives to provide high-quality oncology treatment to patients including minority populations. To that end, KCC includes 10 multidisciplinary centers including a Brain Tumor Center, Breast Cancer Center, Liver Cancer Center, Lung Cancer Center, and Senior Adult Oncology Center. In addition, the Bodine Center for Cancer Treatment provides advanced radiation oncology services, which include the ability to use 3-D images to guide in radiotherapy treatment of cancer. Other service centers include a Breast Imaging Center, Prostate Diagnostic Center, and Integrative Medicine Center at Jefferson, Myrna Brind.

In terms of support for cancer patients and their families, oncology social workers assist families in the maintenance of their disease. Oncology social workers can support families through providing couple and family counseling associated with the cancer diagnosis and treatment; referrals to specialists to help with psychological stress and anxiety; assistance with telling children about the cancer diagnosis; and information to help with financial concerns and opportunities. Financial counselors at KCC can also provide assistance to families.

Nutrition, dietetics, and survivorship are also part of the support given families through KCC. KCC’s outpatient oncology dietitian can work with families to develop nutrition plans that can help alleviate symptoms from cancer treatments. The survivorship program includes a Celebration of Life yearly event and a new Cancer Survivorship Program. The Celebration of Life event is comprised of a health fair, stories of survivors, guest speakers, and an art exhibit. The Cancer Survivorship program includes biannual conferences with guest speakers and breakout sessions where patients and families can work through what happens after they are diagnosed with cancer. The conferences are free.

**Education and Training**

KCC, as part of the Jefferson University and Jefferson Hospital system, includes pre- and postdoctoral training to health care practitioners. Specific training programs include a Hematology and Medical Oncology Fellowship Program and Radiation Oncology Residency Program. Continuing education is offered as well as pharmacy, biomedical sciences, nursing, population health, and health professions training through programs at Thomas Jefferson University.

**Conclusion**

The Kimmel Cancer Center is an NCI-designated cancer center that provides multidisciplinary treatment of, education about, and research on cancer. The mission of KCC is to provide cutting-edge treatment with a focus on the comfort and support of patients and their families. To achieve this, KCC strives to promote the building and maintenance of excellent teams focused on members who support and treat each other with respect.

Kyrgyzstan

Kyrgyzstan, officially known as the Kyrgyz Republic and formerly known as Kirghizia, is a country located in central Asia. It is a parliamentary republic in spite of many of its ongoing internal troubles. The official language is Kyrgyz, and it is closely related to the other Turkic languages; however, the country is under a strong cultural influence from Russia and is rather Russified. The majority of the population (64 percent) is nondenominational Muslims.

The country's population is estimated at 5.6 million as per the 2013 estimates. Of the total population, 34.4 percent are under the age of 15, and 6.2 percent are over the age of 65 years. The country is rural, and approximately one-third of the population lives in urban areas. The country is among the poorest of the post-Soviet countries. In 2004, the poverty rate was officially estimated at 40.8 percent, although Western estimates place it at around 84 percent. Kyrgyzstan is considered to have considerable coal, gold, mercury, and uranium deposits and some oil and gas reserves. However, the country’s economy is primarily agricultural, with cotton, tobacco, wool, and meat being the primary agricultural products, although only cotton and tobacco are exported in any significant quantities. In 2005, the agricultural sector contributed 37.1 percent of the gross domestic product (GDP), and more than 50 percent of the labor force is in the agriculture sector.

The country’s health care system has suffered increasing shortages of health and medicine, especially in the post-Soviet era. The country has to import nearly all its pharmaceuticals. Health care in Kyrgyzstan has been state run and in deteriorating status, but the entry of private health services has helped to supplement it. A national primary-care health system, the Manas Program, was adopted in 1996 to restructure the Soviet system that Kyrgyzstan inherited. The number of people participating in this program has expanded gradually, and province-level family medicine training centers now retrain medical personnel. A mandatory medical insurance fund was established in 1997.

Due to the poverty status of the country, cancer diseases in the country are poorly addressed. In 2005, it was reported that the use of outdated radiotherapy equipment to treat Kyrgyz cancer patients significantly reduces their chances of survival. In addition to use of outdated equipment, the country has a single specialist oncology unit. The National Oncology Center’s equipment was left from the Soviet period, and it has already exceeded its expiration date. However, the high cost involved, lack of parts, and a dearth of qualified technicians all mean it cannot be replaced or at least repaired.

Recently, the number of patients with malignant tumors has increased drastically in the country. The majority of cancer cases require radiotherapy, and the 60 percent of cancer-related mortality is due to inadequate medical care. In addition, Kyrgyzstan has very few specialists capable of servicing the machinery.

The prevalence of cancer in Kyrgyzstan is at its all-time high, with the major type being stomach cancer. According to statistics, stomach cancer has a rate of 21.32. Other high-ranking cancer types in the country are breast cancer, with a rate of 15.55, lung cancer with a rate of 15.18, liver cancer with a rate of 8.56, colon–rectum cancer at 8.18, cervical cancer at 6.47, esophagus cancer at 5.31, pancreas cancer at 4.75, oral cancer at 3.9, and ovary cancer closes the top 10 at 3.39. Other types of cancer that are high rating include leukemia, lymphomas, uterine cancer, bladder cancer, skin cancers, and other neoplasms. Stomach cancer rating in the country is at position 11 in the global standings, which makes it one of the major types of cancer in Kyrgyzstan.
As per data provided by the World Health Organization (WHO) in 2011, breast cancer deaths in Kyrgyzstan reached 356, or 0.84 percent of total deaths. For lung cancer, deaths in Kyrgyzstan reached 579, or 1.36 percent of total deaths in 2011.

In Kyrgyzstan, the breast cancer incidence rate is nine per 100,000 women per year in the entire country. Death due to breast cancer is at the rate of 8.5 per 10,000 women. Cancer services are not covered by the health insurance fund, and treatment often is not affordable or available. The country does not have breast cancer as a priority disease and does not have mammography screening. In 2007, the Breast Cancer Early Detection and Advocacy Program was begun. The program seeks to advocate for training coupled with public events that serve to raise awareness for women's health in Kyrgyzstan.

According to health specialists in the country, both local and those working for nongovernmental organizations, the number of cancer cases is on the rise. On the other hand, access to proper treatment is not widely available, particularly in rural areas. As per the health ministry of Kyrgyzstan, each year, there are more than 4,000 newly registered cases of cancer, with more than 3,000 people dying annually from the disease. However, given the shortcomings in the registration process, the number of people suffering from cancer in the country is definitely much higher. The sharp rise and high prevalence of cancer in Kyrgyzstan is due to poverty, lack of awareness about how to reduce risks, and unhealthy lifestyles, including heavy smoking and drinking.

In addition to the above challenges, there is a lack of places where proper testing for cancer can be carried out; the only places where people can get treated or be diagnosed for cancer are in Bishkek, Tokomak, or Osh. Due to late or poor diagnosis, the number of deaths from cancer is high and keeps on increasing annually. Part of the problem is also the high cost of treatment, which also drives up mortality cancer rates.

In an effort to increase diagnosis, there were mobile cancer diagnosis units that used to operate in rural parts of Kyrgyzstan. These units ran tests every month or so in remote areas, therefore increasing early detection. However, due to limited resources, the program can be run only once in every six months. The result is that many Kyrgyz citizens go undiagnosed.

There are several organizations, initiatives, and societies that deal with cancer matters with the majority being specific to cancer types. Some of these are for prostate cancer: Kyrgyzstan American Urological Association, Kyrgyzstan National Prostate Cancer Coalition, Kyrgyzstan Prostate Cancer Charity, and Kyrgyzstan Prostate Cancer Foundation. Lung cancer, on the other hand, has Kyrgyzstan British Lung Foundation, Kyrgyzstan International Association for the Study of Lung Cancer, and Kyrgyzstan Roy Castle Lung Cancer Foundation, among others.

Further Readings
Laos

Laos People’s Democratic Republic is located centrally within southeast Asia. It lies between China, Vietnam, Cambodia, and Thailand. Laos has gained some popularity in recent years as a tourist destination, and its economy is growing; however, it is still a developing country, and life expectancy in the area is still relatively low at around 60 for men and 65 for women. Traditional herbal medicinal practices are the most common in Laos as Western medicine is not readily available, especially to those people living in rural areas.

One of the largest reasons for the higher mortality rate and lower life expectancy among the people of Laos is because of lacking information about preventative care and self-screening. This is particularly indicative of the attitudes to self-screening in women in developing countries in southeast Asia.

Because of the statistics surrounding the disease, cervical cancer has become a topic of interest in recent medical studies regarding southeast Asian women and their knowledge and awareness about the disease. In 2010, a study about cervical cancer in rural Laos concluded that the majority of women have a limited understanding of the disease and prevention practices in general.

A proactive program to prevent cervical cancer is on the rise in Laos. Thousands of women die each year from cervical cancer, which has called to action the necessity of vaccination among young girls. In the fall of 2013, thousands of Laos’s schoolgirls were given the human papillomavirus (HPV) vaccine.

Because the HPV vaccine is so expensive, it has been difficult for lower-income countries to provide; however, the GAVI alliance is working to make this a possibility for women in Laos and other southeast Asian countries.

In addition to concerns regarding women’s health and cervical cancer, liver cancer is also rampant in Laos. Though incidents of liver cancer are low in Europe and North and South America, the staggering majority of liver cancer incidents are localized to low-income countries in southeast Asia. Currently, Mongolia leads the world in liver cancer incidents, but Laos follows closely behind.

Research by the National Cancer Institute attributes many of the liver cancer incidents to the prevalence of Hepatitis B throughout the region as well as the consumption of raw fish containing parasites. The prognosis is generally poor for those afflicted with liver cancer, partly because symptoms of the disease are not apparent until later stages, when the cancer is more difficult to treat. Liver cancer in these areas is a large issue that is attracting international attention. While the greatest incidence of liver cancer and seafood infestation occurs in regions of northeast Thailand, it is also a major area of concern in Laos as well.
Fish in these regions are infected by the parasitic worm known as *Opisthorchis viverrini*. This worm latches onto a human host after the consumption of infected fish. The worm infestation leads to a recurring infection of tissues that eventually leads to cancer. Studies on the subject have concluded that almost a quarter of those who come into contact with the parasite develop cancer.

Cancer, though, in general in Laos, has a higher mortality rate than in other countries due to lack of screening. While there are options for modern medical treatment in Laos, many people still turn to traditional medical practices.

In 1976, the Traditional Medical Research Center opened in Laos and is dedicated to the study and practice of traditional herbal medicine to treat diseases and ailments. Traditional medicine is especially popular in rural areas of Laos and is deeply rooted in cultural beliefs and traditions.

More than 75 percent of households in Laos turn to traditional medical practices largely because they have found them effective for treating many types of illnesses. In addition to perceived efficiency of these treatments, many people find that it is difficult and more cumbersome to gain access to modern medical care. For instance, the cost of treatment and pharmaceuticals is definitely significant, but people of rural villages must also consider the cost of travel to these medical centers where they can obtain care.

Even for those who are willing to pay for the cost of modern medical care, they generally have low expectations, given that the prognosis is typically grim especially for cancer patients who are typically not diagnosed until later stages in cancer development.

While cancer treatment in Laos is available, it is still limited, and people must often travel to outside countries in order to receive treatment. Recent studies show that cancer treatment is on the rise since the 1990s and that, each year, more people seek treatment. Overall, cancer in Laos and other developing countries is an area of major concern. The introduction of the HPV vaccine and the opening of discourses regarding preventative care are the first steps toward an intervention plan to tackle this issue.

**Laryngeal Cancer**

Laryngeal cancer involves malignant cells occurring in the larynx. The larynx opens and closes to let a person breathe, talk, and swallow. The larynx is composed of three parts: the supraglottis (an area above the vocal chords); the glottis (located in the middle of the larynx and containing the vocal chords); and the subglottis (which connects the vocal chords and the windpipe).

Symptoms of laryngeal cancer may include hoarseness, persistent sore throat, difficult or painful swallowing, and possibly pain in the ear or a lump in the neck. Approximately 95 percent of laryngeal cancer involves squamous cell carcinomas that occur in the lining of the throat rather
than in the muscle or cartilage cells. Approximately 5 percent of laryngeal cancer involves the less-aggressive, slower-moving, verrucous carcinoma.

Some of the tests and procedures that can be used in determining whether laryngeal cancer is present include biopsy, a head and neck exam possibly involving fiber-optic laryngoscopes (narrow, flexible tubes inserted in the mouth or nose), examination of the larynx under general anesthesia, chest X-rays, barium swallow, bone scan, or a magnetic resonance imaging (MRI), positron emission tomography (PET), or computed tomography (CT) scan. Such tests may show precancerous conditions called dysplasia, but although dysplasia may lead to cancer, in the vast majority of cases, it does not.

Although it is the most common source of cancers in the larynx, accounting for approximately 60 percent of all cases, cancer in the glottis is slower to spread than cancer in the subglottis and the supraglottis. The supraglottis is the originating site of approximately 35 percent of laryngeal cancer, and the remaining 5 percent originates in the subglottis.

Laryngeal cancer accounts for approximately 30 percent of all cancers of the throat and between 2 and 5 percent of all cancers overall. Approximately 13,000 people in the United States were diagnosed with cancer of the larynx in 2013, and approximately 3,630 deaths from laryngeal cancer were reported.

Men are affected by laryngeal cancer far more than women, and people over the age of 65 are much more likely to develop it than younger people. African Americans have a much higher rate of laryngeal cancer than Caucasians.

The primary behavioral risk factors for laryngeal cancer are smoking and alcohol. However, not all people who drink or smoke heavily will develop laryngeal cancer.

The single most effective way to prevent laryngeal cancer is to never smoke or to stop smoking. For people who already have laryngeal cancer, quitting may reduce the chance of recurrence of the cancer and may also reduce the chance of another different type of cancer developing (such as lung, esophagus, or oral cancer). Stopping smoking can also improve the effectiveness of cancer treatments. Some people find it effective to join a group or to seek professional help in quitting smoking. Others use nicotine replacement therapy.

Secondary risk factors that may contribute to the development of laryngeal cancer include poor nutrition, human papillomavirus, chronic gastric reflux, a weakened immune system, and certain forms of chemical exposure.

Treatment for laryngeal cancer depends on the specific location of the cancerous cells and the stage of the cancer. Like many other forms of cancer, the earlier that laryngeal cancer is diagnosed, the more effective treatment becomes. Likewise, the survival rates for laryngeal cancer vary according to the stage at which the cancer was first detected. It is always wise to get a second opinion before commencing treatment.

If laryngeal cancers are detected in stage 0 (the earliest stage), they can almost always be cured by either surgically removing them or vaporizing them. In stages 1 and 2, most laryngeal cancers can be treated successfully with radiation therapy, though surgery is sometimes another option. In stages 3 and 4, treatment can include the total or partial removal of the larynx through surgery, chemotherapy, and radiation therapy, or any combination of those treatments. Surgery often includes a neck dissection and the removal of lymph nodes. With any surgery, there are risks and possible side effects, so it is always important to discuss these with the treating physician.

Sometimes, a surgeon may need to create a stoma—a new airway through an opening in the front of the neck. This opening then becomes the place where air enters and leaves the trachea and lungs. The new airway is kept open by a metal or plastic tube, known as a trach tube. For some patients, the stoma is permanent. However, for others, the stoma is only necessary until the patient recovers from surgery. In those cases, the tube is removed several days after surgery, and the stoma closes up.

If a person has a permanent stoma, it is important to learn how to care for it, including removing and cleaning the trach tube, cleaning the patient’s airway, and caring for the nearby skin. Some people with permanent stomas experience self-image issues and are encouraged to seek counseling or professional help if necessary.

Another problem that might arise after surgery is trouble swallowing. Because diet is an essential ingredient of treating laryngeal cancer, it may be necessary to insert a temporary feeding tube.

Learning to speak again is an important part of the rehabilitation process for some people with
Laryngeal cancer. A speech–language pathologist becomes an essential member of the treatment team in this situation. Whether people need speech exercises or more invasive treatment (such as an electric larynx or a tracheoesophageal puncture), the speech therapist will work with the patient to maximize recovery. Another approach might involve the speech therapist teaching the patient esophageal speech.

After surgery, patients need regular checkups. These may occur every month for the first year, and they are important because cancer is most likely to recur in the first two years after medical treatment. Some patients find complementary therapies (such as stress-reduction classes or acupuncture to help relieve pain) useful in dealing with cancer. They are often used alongside regular treatment, but they will not cure cancer. Sometimes, ruthless people promote more radical, “alternative” treatments that have not been tested, have been proven not to be helpful, and some of which are even harmful. Therefore, it is always important to be careful and to discuss all treatment options with qualified specialists.

Clinical trials involving chemoprevention and radiosensitizers for laryngeal cancer are now being explored. People with laryngeal cancer may wish to consult their physicians and specialists about the value of such trials.

Laryngeal Cancer, Childhood

The renewed global health focus of noncommunicable disease such as cancer has great impact on the diagnosis, treatment, and outcomes of the world’s bottom billion poor. In childhood, the pediatric population poses extreme challenges to the primary prevention of disease, halting it before it even starts. Pediatric laryngeal cancer is rare, and therefore, studies about the etiology, pathology, diagnostic workout, and treatment protocols are lacking and not standardized. Among many other risk factors, secondhand smoking, indoor burning and cook stoves, poor air hygiene, and various environmental exposures may increase the number of new cases of laryngeal cancer in childhood. Opportunities to reduce global morbidity and mortality of laryngeal cancer in the pediatric population are discussed in this very brief entry.

Definitions and Basic Anatomy
Laryngeal cancer is the development of uncontrolled growth of cells in the larynx or voice box. As with all morphologic disease, anatomical reference aids understanding. The larynx is a tube-shaped organ in the neck that is important for breathing, talking, and swallowing. It is located at the top of the trachea. The front walls come out from the neck to form the Adam’s apple. The larynx contains the vocal folds responsible for speech and song that vibrate to make sound. During breathing, the larynx opens like a valve to allow air to pass into the lungs. During swallowing, the vocal folds come together with the epiglottis protecting the airway and preventing food from entering the lungs.

The larynx is divided into the supraglottis (composed of the epiglottis, aryepiglottic folds, false vocal cords [vestibular folds], and ventricles or saccules); the glottis or true vocal cords, plus their undersurfaces, and the anterior and posterior commissures; and finally the subglottis, which extends from approximately 10 millimeters below the true vocal cords to the inferior margin of the cricoid cartilage.

Cancers in the throat refer to tumours that develop in the pharynx or larynx. Cancers of the throat include the nasopharynx (the upper part of the throat behind the nose), the oropharynx (the
middle part of the pharynx), and the hypopharynx (the bottom part of the pharynx). Cancer of the larynx is also called pharyngeal cancer. When cancer or tumors develop in these areas, voice changes can be heard, and the airway can slowly become compromised. Laryngeal and hypopharyngeal cancers are two of the main types of cancer in the head and neck.

**Epidemiology**
In general, cancers in the head and neck in childhood are rare, comprising an estimated less than 0.1 percent of the population, making global prevalence and incidence difficult to describe and calculate. The Web site Cancer.net does offer some surveillance information, and the editorial board has approved data purporting that, in the United States, laryngeal cancer is one of the most common head and neck cancers across pediatric and adult populations. Globally, it is predicted that laryngeal cancer is rare, with less than 0.1 percent of head and neck cancers in childhood with distribution between the sexes at 40 percent female and 60 percent male, report several researchers.

**Risk Factors**
Radiotherapy, laryngeal papilloma, gastroesophageal reflux, human immunodeficiency virus (HIV), immunosuppression, exposure to drug use during pregnancy, active and passive smoking, alcohol use, poor oral hygiene, and a family history of cancer are leading risk factors for children to get cancer in the larynx, describe A. Ferlito, A. Rinaldo, and G. Marioni. The authors of this cited research observed that risk factors as previous radiotherapy, intrauterine exposure to ionizing radiation, smoking, and tobacco were lacking in the clinical histories of some affected patients. Therefore, pediatric laryngeal cancer is more likely a genetic disease with specific chromosomal damage.

**Pathology**
The most common type found in childhood is rhabdomyosarcoma, closely followed by squamous cell carcinoma, and very rare are adenoid cystic carcinomas. Clear-cell carcinoma, adenoid carcinoma, synovial sarcoma, malignant fibrous histiocytoma, non-Hodgkin's lymphoma, chondrosarcoma, Ewing's sarcoma, fibrosarcoma, malignant schwannoma, mixed sarcoma, mucoepidermoid carcinoma, and primitive neuroectodermal tumor are also cancers found in the neck with varying prevalence and incidence across age-groups in the pediatric spectrum, according to R. H. Ossoff, G. F. Tucker, and C. M. Norris.

**Clinical Features and Diagnostics**
Some leading presenting clinical signs and symptoms that pose an index of suspicion for laryngeal cancer in children are shortness of breath, or dyspnoea, hoarseness of the voice, and dysphagia. Delayed diagnoses because hoarseness is presumed to be secondary to puberty voice change, voice abuse, and recurrent respiratory infection can delay appropriate diagnosis and potential initial treatment.

Advanced diagnostic techniques include the combination of computed tomography (CT) and magnetic resonance imaging (MRI) and have more accuracy to visualize in a three-dimensional format the extent of the disease and exact location. Ultrasound is less sensitive but very easy to use with little risk to the patient. Finally, visualization of the larynx via bronchoscopy and direct biopsy offers direct diagnosis for confirming uncontrolled cell growth in tissues, reports D. A. Schwartz and colleagues.

**Treatment: Trends and Opportunities**
Rhabdomyosarcoma is treated with radiotherapy and chemotherapy (vincristine sulfate, actinomycin, cyclophosphamide, and Adriamycin); researchers have found that, if positive metastasis to the neck lymph nodes are observed, then neck dissection may be required with or without radiotherapy, depending on the extent of the disease. However, for squamous cell carcinoma, organ preservation therapy does include chemotherapy with radiotherapy, partial laryngectomy, and rarely total laryngectomy, with laser surgery in combination with radiotherapy showing some results as well. Conversely, with non-Hodgkin's lymphoma in the head and neck, radiotherapy of synovial sarcoma may be chemosensitive to ifosfamide (a synthetic analog of cyclophosphamide, which inhibits DNA synthesis and protein synthesis) in combination with radiotherapy, and neck dissection is not indicated, observes J. Kaur and colleagues.

**Risk and Prevention**
Causal links between laryngeal cancer in children and exposure to a specific carcinogen or genetic determinants are not yet described in the literature definitively. Avoidance of exposure to asbestos,
dusts, paint fumes, and a myriad of household chemicals may reduce the risk of laryngeal cancer in children. A diet high in vitamins A and E may reduce risk of laryngeal and hypopharyngeal cancer as some data support its anticarcinogenic properties. Prevention of cancer and early diagnosis remain the best tools in the fight against uncontrolled cell growth.

Latitude

As the controlled environments and modern medicines of industrialized countries have curtailed early deaths from classic infectious disease, cancer and other degenerative diseases have increasingly become significant sources of mortality. Cancer risk advances steadily in the post-reproductive years after which there is less pressure to strictly limit, and correct, mitotic copy errors. Latitude and cancer show a number of correlates, ranging from obvious to arresting. Some of these correlations are culturally explained, such as the relationship between access to essential medicines and healthcare services, which differ from country to country along a rough latitudinal gradient; others are biologically explained, such as ecologically derived racial differences in cancer’s age of onset.

The Special Case of Cancer
Cancer incapacitates and kills in great numbers: As reported by the World Cancer Research Fund, cancer afflicted 14.1 million in 2012, with the World Health Organization estimating 8.2 million deaths in that same year. Despite medical advances, humans continue to be pathetically at the mercy of cancer, such that we cannot foresee what it would be like if we powerfully checked its progress. Though, as with other afflictions, cancer is fought by physicians and pharmaceuticals, it is more correctly apprehended as a predictable by-product of age than as a chance product of illness. Precancerous and even cancerous uprisings are commonplace, though they are
arrested and neutralized by genetic elements that copyedit and correct errors and immune cells, such as macrophages, that phagocytose, or ingest, cancer cells. Unlike acquired immune deficiency syndrome (AIDS) and Ebola, which are of recent origin, or smallpox and rheumatic fever, which periodically stalk populations, cancer has been with the human race in perpetuity. Cancer has its own hieroglyph, was treated by Galen, described in millennia-old papyrus scrolls, and found in Paleolithic hominid bones. Cancer is a perpetual and pervasive part of the human condition because it is part and parcel of multicellularity; it is simply cell division gone awry. Animals from dinosaurs to dogs suffered from cancer; in fact, among large and long-lived multicellular organisms, cancer is only vanishingly rare in plants. This is because plants lack the Weismann Barrier, a division between the soma or body of the organism and its germ line. Though many plants reproduce sexually, any cancer that they acquire can be passed onto their offspring. Thus, any cancerous uprisings among plants have been ruthlessly and relentlessly selected against. On the other hand, even as individuals suffer, animal populations, having a Weismann Barrier with its insulation of sperm and egg cells from bodily cancer, can tolerate and even thrive in the midst of cancer.

Still, cancer deaths, judging by rates of paleo-oncological studies reported by Shi-Ming Tu, were relatively rare as a result of the low mean age of death among pre-industrialized societies. Industrialization, bringing with it modern medicine and bounteous provisions, limited early deaths, making old age common. It is only in the modern era, with so many other mortal threats checked, that cancer has become a prime killer. Cancer disproportionately afflicts the aged because with age comes neglect. Old age brings with it a relaxation of the aforementioned policing mechanisms, such that undetectable cancerous cells, surviving, proliferating, and vascularizing, are increasingly likely to become life-threatening cancerous growths. This explains why rates of childhood cancer are so low. Fitness is greatly undermined when cancer strikes
prior to, or during, the reproductive years, as it then limits the number of offspring produced. Yet, post-reproductive cancer does not greatly reduce fitness and so is not readily selected against by evolution. Most women, for example, reach menopause between 45 and 50, and this is precisely when cancer rates among women rise precipitously. Graphic illustrations of cancer incidence provided by the United Kingdom Cancer Research Foundation show menopausal-age women in a transitional state between extremely low cancer rates of the young and uniformly high cancer rates of the sexagenarians, septuagenarians, and octogenarians.

Latitude and Life History Evolution
Cancer comes when it does because of the balance struck between investment in survival and investment in reproduction. While survival is, of course, important, so is reproduction, and consequently, the former is to some extent sacrificed to the latter. Among men, this is most conspicuously illustrated by the prostate, a reproductive gland whose cancer proneness and metabolic activity are strongly and positively correlated. Among women, this is most conspicuously illustrated by the breast, a mammary gland whose cancer proneness comes of cyclical restructuring of its tissue.

More metabolically active prostates make males more fecund, while more metabolically active breast tissue makes the offspring of females more fit. Thus, it is adaptive to be metabolically active. Alternatively, more metabolic activity and cell turnover equate to more chances for cancerous divisions. Though the exigencies of reproductive fitness have certainly curtailed our longevity, as a species, *Homo sapiens* are very long-lived and invest much in gestation, growth, and survival. In the parlance of life history evolution, a branch of evolutionary biology that studies why organisms age, mature, and die when they do, humans are highly K selected. This means that humans, growing slowly, lavishing much parental care on offspring, and maintaining flexibility throughout adulthood, will invest much in maintenance, hence our extremely long lives. Nevertheless, there may be subtle differences among human populations on life history traits, with ecological variables, including latitude, playing a mediating role. Those persons historically occupying southern climates may have faster life histories, acquiring, and dying from, cancer earlier in life.

Paradoxically, if one looks at global distributions of cancer, they are lowest precisely in these southern climates. However, this is because these cancer rates are confounded by life expectancy. Africa, for example, reports an extremely low rate of cancer because its inhabitants have an extremely short life expectancy, which makes sense when recalling the aforementioned relationship between age and cancer. Infectious diseases like Ebola, trypanosomiasis or sleeping sickness, and malaria claim most lives prior to the onset of degenerative diseases, such as cancer. Scrutinizing diverse industrial countries such as the United States removes this confound, showing the true relationship: Cancer rates among Americans of African descent are highest, as reported by the Centers for Disease Control and Prevention, for the years between 1999 and 2010. Why might this be so? The answer comes from juvenile mortality rates. Across species, as biologist David Reznick explains, high juvenile mortality predicts rapid maturation, aging, and death. Humans inhabiting equatorial habitats are exposed to many more parasites and infectious agents, making life precarious. This, in turn, favors a shift away from long-term investment in bodily maintenance, leaving persons of post-reproductive ages more immediately susceptible to developing cancer.

Latitude, Infectious Disease, and Cancer
The relationship between infectious agents and cancer, however, not only is mediated historically through the action of evolution but also is directly demonstrable in the present. Though only the human papilloma virus has received popular attention for its ability to cause cancer, the discoverer of this link, Harold zur Hausen, reports that upward of 20 percent of cancers are associated with infectious agents. As a consequence, studying the epidemiology of infectious disease becomes relevant to understanding the distribution of cancer. Sometimes this linkage is direct, as in the case of cervical cancer; other times, it is indirect, as in the case of the bacteria *Helicobacter pylori*, which causes stomach ulcers and can ultimately promote stomach cancer. Further still, as described by Claudia Cornwall, sometimes geography, susceptibility, genetics, bacteria, and viruses combine to promote complex pathways to cancer. Dr. Denis Burkitt, recognizing regional variation in lymphoma distributions, conducted a geographical biopsy. This geographical
biopsy found that what came to be called Burkitt’s lymphoma was almost exclusively restricted to malarial regions. There is, in fact, a complex interaction between the Epstein-Barr virus and malaria in causing this kind of lymphoma. Similarly, the research of Lawrence Kingsley, an epidemiologist, and Patrick Moore, director of the University of Pittsburg’s Cancer Virology Program, found that skin cancer can arise through concomitant infections of Kaposi’s sarcoma-associated herpesvirus and AIDS. In this case, the virus inhibits normal cell death and induces abnormal cell proliferation.

While relationships can be complex, infectious agents sometimes simply undermine immunity. Psychoneuroimmunology, a hybridized discipline studying the interaction between psychological states and immune function, has repeatedly shown that stress can undermine the immune system’s ability to battle disease, including cancer. A classic study of rats showed that subjects stressed by shock but given a coping mechanism subsequently fought off injected cancer better than those rats shocked without a coping mechanism and controls. With this in mind, it is important to recall that cold is a stressor. And in fact, cold shows a relationship with cancer, which seems to be nonspecific, in that prolonged exposure to cold decreases immune function, which limits the body’s ability to fight cancer. Alternatively, heat is also a stressor. As detailed in the work of Quan Liao and colleagues, heat seems to have a more direct relationship to specific forms of cancer, such as pancreatic cancer, by inhibiting apoptosis or programmed cell death. Similarly, Philip Cornford and associates discuss the increased rate of prostate cancer that comes of prolonged exposure to heat with the resultant expression of heat shock proteins.

Conclusions
Latitude and cancer have other ties worthy of mention. First, as one progresses north, melanin formation and pigmentation decrease, thus allowing more ultraviolet light to penetrate the skin surface, which in turn continues to allow vitamin D synthesis. This has consequences for skin cancer, especially for those fair-skinned persons who migrate to equatorial climates, far from where their ancestors originated. Further still, latitude predicts differences in culture, economics, health care, and technology, all of which can relate in some way to cancer. Industrialized countries, principally found in northern latitudes, have not only fewer infectious diseases but technologies and treatments able to quickly detect, manage, and even eradicate certain cancers. On the other hand, these same high-latitude societies may have higher rates of teratogens and toxins produced by modern manufactures and industrial waste. According to the National Cancer Institute, for instance, American farmers have elevated rates of leukemia, non-Hodgkin’s lymphoma, multiple myeloma, and soft tissue sarcoma, as well as cancers of the skin, lip, stomach, brain, and prostate, possibly as a consequence of exposure to fertilizers, pesticides, fuels, and engine exhaust. On balance, however, industrialization may cure more cancer than it causes. In conclusion, the relationship between skin color and skin cancer aside, latitude and cancer, upon a superficial glance, seem as two unrelated variables. Upon closer inspection, it becomes clear that latitude mediates the relationship between cancer and a host of other variables.

Lead
Lead is a chemical element that has widespread occurrence and extensive usage within society.
Historically, lead has been utilized in a range of industrial processes, recreational endeavors, and household practices that have been accepted and engrained within the lifestyles of many people. However, lead has also been associated with increasing morbidity and mortality of a number of health conditions. Of primary concern, however, is its association with different types of cancer, including lung, stomach, bladder, lymphatic brain, and the nervous and hematopoetic system. This entry seeks to highlight some of the research that has been conducted, along with the challenges and weaknesses associated with the research, and also highlight agencies that have been instituted to monitor and evaluate lead usage and its applications. The link between lead exposure and cancer is clearly a concern, and more research is needed to better define the possible relationship. This entry also highlights the need for more extensive and focused research on lead and cancer that will utilize longitudinal research with adequate controls.

Lead is a naturally occurring metallic element that has had great utility in society. It can be readily combined with other substances in order to produce a variety of compounds that have been very useful. Some of these compounds are leaded gasoline, tetraethyl lead, lead oxide, and lead chloride. Lead compounds have made considerable contribution to the development of society over the years. The products have been used in industrial processes for the production of machinery, ammunition, motor vehicle batteries, gasoline, matches, brass and bronze, dyes and paints, cable coverings, and building materials such as water pipes, plumbing fixtures, and lead sheeting. It has also been extensively used in the visual and creative arts in photography, crafts, and ceramics as well as in the production of medicines and cosmetics. M. C. Rousseau and colleagues reported that lead metal consumption worldwide was approximately 8 million tons, mainly from the production of lead batteries, pigments, building materials, ammunition, and cable sheathing. Even with the application to different areas of national development and the tremendous economic contribution, there have been expressions of concern regarding the possible contribution of lead to cancer.

Cancer is an abnormal malignant condition that can occur within any tissue of the body. It is characterized by uncontrollable replication of cells, which may result in invasion and the damage of surrounding tissues by the neoplasm with possible metastases to other body structures. Cancer usually occurs because of an alteration or damage to the deoxyribonucleic acid (DNA). DNA is the nucleic acid that encodes the genetic instructions for the development and functioning of cells. Two of the substances that have been incriminated in causing damage to the DNA and subsequent malignancy are lead and lead products.

Based on the extensive usage of lead products and the natural occurrence of lead, it is believed that individuals may be at increased risk of exposure in a number of different ways. People may be exposed by breathing or swallowing air or water within the environment. Lead may also be available directly from automobile exhaust or from soil or other materials that have been contaminated with exhaust. Much lead still exists in society from being deposited in the soil decades ago. Another source of exposure is lead-based paints, which may be found in older structures such as houses and bridges. Drinking water is another potential source of lead exposure based on the historic use of lead pipes, fixtures, and solder. Exposure to lead also may be recreational as in the smoking of cigarettes or exposure...
to ceramics and the creative arts. Exposure to lead also may occur through agricultural practices based on the inclusion of certain pesticides. Even with the development of preventative guidelines in restricting lead exposure, there are still increasing health risks, particularly in older residential housing facilities based on poor disposal practices and changes in land use of previously industrial sites.

Exposure to lead has been identified as a primary occupational hazard that is associated with cancer. The occupations that have been identified are battery manufacturers, cable splicers, and lead refinery and foundry workers. Persons in the automotive industry such as radiator repair workers and battery and gasoline workers are also at increased risk. Miners, painters, and construction and demolition workers are also at increased risk. There is also excessive exposure for gun and ammunition makers as well as brass and bronze workers. Extensive research conducted among many of these professional groups has failed to provide conclusive evidence on the contribution of lead to cancer.

**Research on Lead and Cancer**

Although extensive research has been conducted on lead and cancer in laboratory animals and among humans, the reports have been inconclusive. Some of the possible reasons are based on the fact that lead is naturally occurring within the environment through water, soil, or air pollution and that there are diverse sources for exposure, including industrial, recreational, agricultural, and household. Now these research findings may appear inconclusive based on the fact that there is an increasing likelihood of exposure to lead products by respondents in the research. The inconclusive findings also may have resulted from the lack of adequate standards and control measures being incorporated within the research methodologies. Another reason for an inconclusive report on the relationship between lead and cancer is that, to date, there has been no confirmed report of lead as a carcinogen. There is therefore a great need for further and more extensive research that will utilize a longitudinal approach and the incorporation of adequate standards and controls in the methods.

**Implications of Lead Exposure and Cancer**

Lead exposure is believed to have an impact on cancer of certain organs of the respiratory, gastrointestinal, and urinary systems in addition to the brain. Research on the relationship of occupational exposure and lung cancer mainly among battery workers and smelter workers revealed a small increase in cancer risk. One of the weaknesses of the research was that it was conducted among workers who had high levels of occupational exposure to lead. Additionally, the research failed to address other contributing factors such as exposure to other heavy metals and the impact of smoking. Research done on stomach cancer revealed that there was an increased risk of stomach cancer with high lead exposure. However, as in previous research, adequate controls were not in place, and specific control variables that are associated with increased risk of stomach cancer were not considered. Further research investigating lead and other cancers such as of the brain, kidney, bladder, colon, and rectum also revealed inconclusive results.

To date, research has not conclusively confirmed lead and lead products as being carcinogenic. The National Toxicology Program (NTP), based on extensive research on both laboratory animals and humans, reported that lead and lead products are reasonably anticipated to be carcinogenic. The International Agency for Research on Cancer (IARC) reported based on evidence obtained from research that inorganic lead compounds are probably carcinogenic. The Environmental Protection Agency (EPA) also reported that, based on its research, lead and inorganic lead compounds are probable human carcinogens. It further reported that there was inadequate evidence to classify organic lead compounds as carcinogenic. Currently, after extensive research, it is still inconclusive to what extent lead and its products are carcinogens, thus causing cancer. Recognizing that the pervasive nature of lead and lead products in society may present some challenge to obtaining a conclusive result, development of continued research incorporating proper standards and adequate controls can result in more-conclusive results. Based on the fact that lead is classified as an occupational hazard, government policies and legislation to control exposure and safeguard health would be supported.

**Corporate Strategies to Regulate and Control Lead Exposure**

Although there has been inconclusive proof of the specific contribution of lead and lead products to
cancer, several strategies have been instituted in order to protect society from undue exposure. One such measure was the ban on lead additives in motor vehicle gasoline and lead soldering on food cans. There is also the continued monitoring of public and household water supplies by the EPA and bottled water by the Food and Drug Administration (FDA). The Consumer Product Safety Commission (CPSC) also monitors lead levels in consumer products, particularly paints and children's toys. The Occupational Safety & Health Administration (OSHA) also has established guidelines to regulate and monitor lead exposure within industries and the workplace. Employers are also made responsible to provide protective equipment such as respirators, gloves, and medical monitoring of employees who are working in at-risk environments.

**Conclusion**

Lead and its compounds are very pervasive in society. They exist within a wide range of social, agricultural, and industrial environments. Historically, lead and lead products have contributed significantly to development and industry in many spheres of society. However, it is believed that lead and lead products also contribute to increasing morbidity and mortality of different types of cancer. To date, the reports from extensive animal and human research by leading environmental and cancer experts are still inconclusive regarding the carcinogenic effect of lead and its impact on cancer. Weak relationships were identified between lead and lung and stomach cancers, respectively. However, in this research, the workers were exposed to very high levels of lead without adequate controls being considered. The quest to determine the link between lead exposure and cancer continues to be a great concern. It is therefore necessary to have more extensive research on lead and cancer that utilizes robust research design with adequate standards and controls being incorporated. In the meantime, the government and other related agencies such as the NTP, IARC, EPA, FDA, CPSC, and OSHA continue to monitor lead within society.

**Leukemia, Acute Lymphoblastic, Adult**

Acute leukemia is a hematological condition that is strongly associated with significant morbidity and mortality, mainly due to the disease itself and the aggressive treatment utilized. Although extensive studies have been conducted in its diagnosis, progression, and treatment, information on the social and psychological aspects of acute leukemia have not been well established. Information generated from research investigations on these behavioral components may thus improve the standard of care for patients diagnosed with acute leukemia.

One of the most recent and significant studies conducted on acute leukemia, which includes acute lymphoblastic, acute myeloid, and promyelocytic leukemia, involves posttraumatic stress. This condition directly reflects the emotional state of an individual in response to an intense or traumatic incident. The symptoms of posttraumatic stress include emotional detachment or numbness; a
general avoidance of things, events, and people that remind an individual of the incident; and hyperarousal. Previous studies have observed a direct correlation between the degree of trauma and the subsequent level of posttraumatic stress. Interestingly, the incidence of posttraumatic stress symptoms is higher in cancers that are of acute onset or follow a fluctuating disease progression compared to cancers that more slowly progress. For example, patients diagnosed with solid tumors are more likely to develop posttraumatic stress when the treatment that they receive is more aggressive than other cases due to the advanced stage of their cancer or the rate of progression.

In Canada, Gary Rodin conducted a research study on the psychological impact of acute leukemia and its corresponding treatment in terms of posttraumatic stress symptoms. A total of 205 patients (58 percent male) with various types of leukemia, including acute lymphoblastic, promyelocytic, and acute myeloid, were included in the investigation. These adult patients were also classified according to their treatment stages, namely, newly diagnosed and thus just about to start or have recently received treatment, patients who recently relapsed, and patients who failed in a specific treatment regimen. To collect information from patients regarding stress in relation to acute leukemia, the study participants were asked to complete the Stanford Acute Stress Reaction Questionnaire as well as undergo assessment using various psychosocial measurement tools such as the Memorial Symptom Assessment Scale and the CARES Medical Interaction Subscale.

The results of the study showed that 86 percent of the study population was recently diagnosed with acute leukemia, and 94 percent were currently undergoing active treatment for said disease. In addition, 14 percent of the patients were determined to have acute stress disorder based on the criteria of the Stanford stress questionnaire. On the other hand, 18 percent of the study participants were described as having subsyndromal acute stress. The most common posttraumatic stress symptoms in the acute leukemia patients were physical signs of distress, difficulty in interacting with their physicians, poor spirits, and attachment anxiety. The research study thus highlighted the association between acute leukemia in adults and traumatic stress, wherein a more-advanced stage of acute leukemia results in more mental suffering, notwithstanding the aggressive treatment given to the patient. These findings also indicate the importance of mental health interventions for adult patients with acute leukemia.

Another topic of social and psychological concern in adult acute lymphoblastic leukemia is the fear that the disorder could be linked to advanced parental age. The first observations of this association were reported at least 50 years ago, and subsequent research studies have supported this association. However, not all epidemiologic studies on acute lymphoblastic leukemia showed this specific correlation. Furthermore, the association between the development of acute lymphoblastic leukemia and advanced parental age were based on pediatric cases, not adult cases. To revisit this long-standing association, Gunnar Larfors recently conducted a case-control study on the incidence of pediatric and adult acute lymphoblastic leukemia in relation to parental age. The investigation involved reviewing five Swedish health registries for cases involving acute lymphoblastic leukemia. To avoid multiple entries of the same cases, because several health registries were included in the study, the unique identification number of each Swedish citizen was employed in the review.

The comprehensive epidemiological studies included 2,660 pediatric and 4,412 adult cases of acute lymphoblastic leukemia, which were then compared to 28,288 age-matched healthy controls from a Swedish population-based register. Conditional logistic regression was employed to estimate the relative risk for acute lymphoblastic leukemia in each cohort. The results of the study showed that there was a small increase in the risk for acute lymphoblastic leukemia in children based on advanced parental age, whereas the adult cases showed no association to advanced parental age. Interestingly, a lower risk for adult lymphoblastic leukemia was observed with higher numbers of siblings. The information generated from this study could decrease the incidence of social and mental health issues (i.e., anxiety and depression) that emerge upon receiving a diagnosis of acute lymphoblastic leukemia.

In another vein, Suzanne Danhauer and colleagues recently completed a research study on the positive changes involving the psychological conditions of patients diagnosed with adult acute
Leukemia, Acute Lymphoblastic, Childhood

Childhood acute lymphoblastic leukemia (ALL) is the most common cancer of childhood, comprising about 30 percent of all childhood cancers. The majority of children diagnosed with ALL are between 1 and 5 years old. Standard risk ALL is also the most curable of childhood cancers, with a more than 90 percent cure rate. However, even today, 25 percent of children who are in remission for ALL will suffer a relapse. The development of a cure of ALL, or childhood leukemia, is one of the great medical stories of the 20th century. Childhood acute lymphoblastic leukemia was the first cancer in which chemotherapy was successfully used and in which a multimodal approach using chemotherapy combinations and radiation was taken. In the history of cancer treatment, the development of a cure in childhood ALL has served as the prototype or paradigm for approaching cancer treatment in adults as well.

Acute lymphoblastic leukemia is cancer in which the bone marrow makes too many immature lymphocytes (a type of white blood cell). It is a cancer of the blood and bone marrow. ALL usually progresses very quickly if not treated. In a child with ALL, the stem cells that produce infection-fighting cells are out of control—they do not work like normal lymphocytes and aren’t able to fight infection. As the number of leukemia cells increases in the blood and bone marrow, there is less room for healthy white blood cells, red blood cells, and platelets. This can lead to infection, anemia, and easy bleeding.

Although the causes of childhood ALL are not known, there do seem to be certain risk factors. Possible risk factors include being exposed to X-rays before birth, being exposed to radiation, past treatment with chemotherapy, certain changes in genes, and having certain genetic conditions (Down syndrome, Bloom syndrome, Shwachman syndrome, and neurofibromatosis type 1, ataxia-telangiectasia).

The following are often symptoms of childhood ALL: fever; easy bruising or bleeding: petechiae (pinpoint dark red spots under the skin caused by bleeding); bone or joint pain; painless lumps in the neck, underarm, stomach, or groin; pain or feeling
of fullness below the ribs; loss of appetite; weakness; and feeling tired or looking pale.

The diagnosis of childhood ALL is made after a physical exam and history, complete blood count with differential, blood chemistry studies, and a bone marrow aspiration and biopsy. Cytogenetic analysis is also critical to look for certain changes in the chromosomes in the lymphocytes. The Philadelphia chromosome is one such change.

There are certain factors that affect prognosis and treatment options in cases of childhood ALL. Staging is not a factor as ALL is systemic or stage IV. The age at diagnosis, gender, and race are important. The number of white blood cells in the blood at diagnosis is critical as well as whether the leukemia cells began from B lymphocytes or T lymphocytes. Additional factors include whether there are chromosomal changes, whether there are leukemic cells in the cerebrospinal fluid, or whether the child has Down syndrome. How quickly and how low the leukemia cell count drops after initial treatment are also key factors. Treatment options relate to prognosis. These options take into account whether the child has standard-risk or high-risk ALL, the child's age, whether the leukemia cells are pre-B or T cell, whether there are chromosomal changes, and how fast and well the leukemia cells drop after beginning treatment. For leukemia that relapses after initial treatment, prognosis and therapy depend upon how long between the diagnosis and relapse and whether the leukemia comes back in the bone marrow only or in other parts of the body.

The first reported case of childhood leukemia was of a little German girl named Maria in 1846. According to the family physician, the child had a short history of fever, fatigue, and bruising. The 5-year-old girl died, and an autopsy was performed that showed a grossly enlarged spleen and liver. The blood of the child was thick and white, the Weiss blood that would later be termed leukemia.

Until the 20th century, leukemia was often thought to be an infection rather than the cancer that it really was. In the 1940s, Dr. Sidney Farber at Harvard Medical School sought to find a way to combat leukemia. Knowing that leukemia was a disease of the bone marrow, Farber sought to develop a drug that would stop the development of leukemic cells. This idea was not an entirely new one because researchers knew that accidental exposure to poison gas had suppressed bone marrow in exposed soldiers. In the mid-1940s, a folate was used as an antagonist in 16 children, of whom 10 went into remission. Although the children later died from their disease, the study proved that remission was possible. Farber’s report was published on June 3, 1948, in the New England Journal of Medicine and met with great controversy. Many physicians felt that using these drugs on children was torture because death would ultimately result.

During the 1950s, further progress against childhood leukemia was made with the development by Gertrude Elion of Purinethol or 6-mercaptopurine. This drug is still used today in continuation and maintenance therapy in children with acute lymphoblastic leukemia. Prednisone also was used as a treatment, although the side effects were difficult, and the remissions it produced were short lasting. The development of a series of clinical trials at the National Cancer Institute under Emil Frei and Emil J. Freireich were a turning point in the approach toward achieving long remissions. The trials began the process of cooperative groups trials of drugs and drug combinations to rely on statistical evidence to determine better therapy.

The development of total therapy led by Dr. Donald Pinkel at St. Jude Children's Research Hospital for the first time in the late 1960s brought about long-term remissions or cures for about 50 percent of children with acute lymphoblastic leukemia. The addition of cranial radiation became the gold standard that was later replaced in the early 2000s with only chemotherapy injected into the spinal fluid. Pinkel's Total Therapy consisted of a four-drug induction therapy and subsequent intensification and maintenance therapy. This therapy is still the backbone of ALL therapy today in children, with the major addition being stem cell transplant and the importance of tailoring therapy for chromosomal differences.

Acute myeloid leukemia (AML) pertains to a hematopoietic stem cell disorder that is characterized by the continuous clonal proliferation of myeloid progenitor cells without entering the subsequent differentiation stage. This endless cycle of proliferation results in the accretion of immature cells of different stages as well as in the decrease in the generation of normal components of the hematopoietic system, including fully differentiated cells such as erythrocytes, granulocytes, and platelets.

The incidence of AML currently stands at four in every 100,000 persons annually; therefore, AML is considered as a rare disorder, although it is responsible for a significant fraction of cancer-related deaths. In the United States, it has been estimated that approximately 14,590 individuals will be diagnosed with AML, and around 10,370 of these individuals will die from this disorder. A positive correlation between AML risk and age has been earlier established, and the average age of an AML patient at diagnosis is 67 years. Based on this information, AML is therefore considered as an elderly disease.

The diagnosis and treatment of AML has significantly improved in the last 40 years. The series of clinical trials conducted in the past several decades has resulted in the establishment of a standard of care for AML, with a 75 percent success rate in entering remission and a 50 percent survival rate. However, most of the clinical trials involved patients who were less than 60 years old, and therefore, this standard of care for AML is optimal for this specific age-group and remains ineffective and harmful to the majority of elderly patients. Reports have shown that elderly AML patients have poor tolerance to most chemotherapeutic drugs administered as well as show higher treatment-related mortality rates and major cytogenetic aberrations. Furthermore, the average survival of elderly AML patients who have undergone chemotherapy is only four to six months.

Recent research studies have thus focused on developing new drugs that could be better tolerated by elderly AML patients. To achieve this goal, the novel drug should utilize a mechanism of action that is different from that of the common chemotherapeutic drugs that have been administered in the last few decades. In addition, this novel drug should also be capable of enhancing antileukemic activity as well as be safe enough for administration.

In 2012, a research group led by Hagop Kantarjian presented the results of their phase II clinical trial using oral sapacitabine, a cytosine nucleoside analog, in elderly patients diagnosed with AML who were never treated (86 patients) or recently underwent a first relapse (19 patients). Approximately 105 elderly AML patients with ages ranging from 70 to 91 years old (average age: 77 years) were randomly assigned to any one of three treatment schemes: 200 milligrams (mg) of sapacitabine twice a day for seven days (Arm A), 300 mg sapacitabine twice a day for seven days (Arm B), and 400 mg of sapacitabine twice a day for three days and then once a week for the next two weeks (Arm C).

The results of the study showed that the survival rate of patients belonging to Arm A was 35 percent, for Arm B 10 percent, and Arm C 30 percent. In addition, the overall response rate of Arm A was
45 percent, Arm B 30 percent, and Arm C 45 percent. Arm C showed a higher number of complete remissions than Arm A and Arm B. The 30-day mortality was estimated as 13 percent, whereas the 60-day mortality measured 26 percent. The most frequent adverse events included pneumonia, anemia, and neutropenia. Observed severe adverse events included complications of myelosuppression. The findings of the phase II clinical trial indicated that sapacitabine was well tolerated by elderly AML patients and that the 400 mg dose showed a more effective response. The toxicity profile of sapacitabine on elderly AML patients was also classified as favorable, and the drug was also easier to administer to elderly patients. These promising findings have thus paves the way for a phase III clinical study on sapacitabine, which is currently in progress.

Another promising drug for the treatment of elderly patients with AML is decitabine, which, similarly to sapacitabine, is a cytosine analogue. Decitabine was initially synthesized 50 years ago and is currently distributed by Eisai Pharmaceuticals in Tokyo, Japan, using the brand name Dacogen. Earlier research studies using decitabine showed that the drug possessed antileukemic properties, as observed in experiments using cell lines. In addition, in vitro investigations have shown that decitabine was more potent than cytarabine. Its cytotoxic effects were attributed to its capacity to disrupt DNA synthesis by destroying the DNA structure. Based on its capacity to halt a specific biochemical activity, decitabine was first administered at high doses of 1,000 mg/m²/cycle, either as a single agent or in combination with other pharmaceuticals such as anthracyclines. However, this initial attempt at using decitabine resulted in significant hematological toxicities.

In the 1980s, preclinical studies on decitabine showed that the drug could induce differentiation when administered at low doses. Its mechanism of action involved the reversal of DNA methylation-induced gene silencing. Upon entry into a cell, the cytosine analogue is phosphorylated and then activated by an enzyme called deoxycytidine kinase, resulting in the triphosphate molecule, aza-deoxycytidine triphosphate. This product then competes with and exchanges cytosine in the CpG islands of the DNA strand. CpG islands frequently occur as clusters within the promoter regions of genes. This cytosine replacement thus inhibits subsequent methylation events involving the promoter regions. The molecular pathogenesis of AML involves the suppression of tumor suppressor genes by methylation, and thus, the inhibitory action of decitabine reverses this condition by promoting the expression of specific genes that prevent the abnormal proliferation of progenitor hematopoietic cells.

Various clinical trials using decitabine have been conducted, and some are currently in progress. At least seven clinical trials ranging from phase I to III have been completed using various doses and durations, which in turn have resulted in complete remissions ranging from 13 to 64 percent, whereas the observed survival rates were not significant. Researchers are also currently focusing on identifying specific subgroups within the elderly AML population that would largely benefit from this novel drug.

Leukemia, Acute Myeloid, Childhood

Childhood acute myeloid leukemia (AML) is a cancer of the blood and bone marrow that is diagnosed in children as young as infancy. It is a disease more
commonly found in adults and is particularly difficult to treat. Whereas great progress has been made in the treatment of childhood acute lymphoblastic leukemia, only about 25 to 50 percent of children with AML will have a long-term remission. AML is also called acute myelogenous leukemia, acute myeloblastic leukemia, acute granulocytic leukemia, and acute nonlymphocytic leukemia. In normal bone marrow, blood cells are produced that later make blood stem cells or immature cells. These cells eventually become mature blood cells. A blood stem cell may become a myeloid stem cell or a lymphoid stem cell. A lymphoid stem cell becomes a white blood cell.

In AML, the myeloid stem cells usually become a type of immature white blood cells called myeloblasts (or myeloid blasts). The leukemia cells can build up in the blood and bone marrow, so there is less room for healthy white blood cells, red blood cells, and platelets. When this happens, infection, anemia, or easy bleeding may occur. The leukemia cells can spread outside the blood to other parts of the body, including the central nervous system, skin, and gums.

There are subtypes of AML based on the type of blood cell that is affected. The treatment of AML is different when it is a subtype called acute promyelocytic leukemia (APL) or when the child has Down syndrome. AML may occur after treatment with certain anticancer drugs or radiation therapy.

Possible risk factors for AML include having a brother or sister, especially a twin, with leukemia, being Hispanic, being exposed to cigarette smoke or alcohol before birth, having a history of aplastic anemia or myelodysplastic syndrome, and past treatment with ionizing radiation or chemicals such as benzene. Having certain genetic disorders increases risk, including Down syndrome, Fanconi anemia, neurofibromatosis type 1, Noonan syndrome, and Shwachman–Diamond syndrome.

Childhood AML may produce the following signs: fever with or without an infection, night sweats, shortness of breath, weakness or feeling tired, easy bruising or bleeding, petechiae, pain in the bones or joints, pain or feeling of fullness below the ribs, painless lumps, or an eczema-like skin rash.

The diagnosis of AML in children is determined by a physical exam and history, complete blood count and differential, peripheral blood smear analysis, blood chemistry studies, chest X-ray, and bone marrow aspiration and biopsy. Cytogenetic analysis is also performed for chromosomal abnormalities.

Certain factors affect the prognosis of the child with AML, and treatment options depend on these characteristics. Key among these factors are the age of the child at diagnosis, the race or ethnic group of the child, whether the child is greatly overweight, the number of white blood cells in the blood at diagnosis, whether the AML was caused by previous anticancer treatment, and the subtype of AML. Other factors are whether the child has Down syndrome, whether the child has leukemia in the central nervous system, and how quickly the leukemia responds to initial treatment.

There is no standard staging system for childhood AML. There are different types of treatment for children with AML. The majority of children are treated in clinical trials. Induction therapy is the first phase of treatment. The goal is to kill leukemia cells in blood and bone marrow. This hopefully puts the leukemia into remission. Consolidation and intensification therapy is the second phase of treatment. The goal of post-remission therapy is to kill any remaining leukemia cells that may be active but could begin to regrow and cause a relapse.

Until the 20th century, leukemia was often thought to be an infection rather than the cancer that it really was. In the 1940s, Dr. Sidney Farber at Harvard Medical School sought to find a way to combat leukemia. Knowing that leukemia was a disease of the bone marrow, Farber sought to develop a drug that would stop the development of leukemic cells. This idea was not an entirely new one because researchers knew that accidental exposure to poison gas had suppressed bone marrow in exposed soldiers. In the mid-1940s, a folate antagonist was used in 16 children, of whom 10 went into remission. Although the children later died from their disease, the study proved that remission was possible. Farber's report was published on June 3, 1948, in the New England Journal of Medicine and met with great controversy. Many physicians felt that using these drugs on children was torture because death would ultimately result.

During the 1950s, further progress against childhood leukemia was made with the development by Gertrude Elion of Purinethol or 6-mercaptopurine. Prednisone also was used as a treatment, although the side effects were difficult, and the remissions it produced were short lasting. The development of a
series of clinical trials at the National Cancer Institute under Emil Frei and Emil J. Freireich were a turning point in the approach toward achieving long remissions. The trials began the process of cooperative group trials of drugs and drug combinations to rely on statistical evidence to determine better therapy.

Although the differences between AML and ALL were not clearly known until the late 1950s, similar therapies were used. However, by the 1960s, it became clear to physicians and researchers that AML was not as sensitive to chemotherapy, and therefore, more and more toxic therapies were developed. The majority of children today with AML will receive very intensive in-hospital therapy in preparation for a bone or stem cell transplant if possible. Maintenance therapy has proven ineffective in AML, and drug toxicity is considerably higher than in ALL treatment.

Leukemia, Chronic Lymphocytic

Chronic lymphocytic leukemia (CLL) is the most common malignancy involving B-lymphocytes that is associated with clinical heterogeneity. It is the most common type of adult leukemia occurring in Western countries. The standard treatment for CLL is chemotherapy, which could employ either a single agent or a combination of agents. Single-agent chemotherapy usually involves chlorambucil, fludarabine, and bendamustine; examples of combination chemotherapy are fludarabine with cyclophosphamide, cladribine with prednisone, and chlorambucil plus prednisone. CLL may also be treated with monoclonal antibodies such as rituximab and alemtuzumab or with a combination of chemoimmunotherapeutic agents such as fludarabine and rituximab; fludarabine, cyclophosphamide, and rituximab; or pentostatin, cyclophosphamide, and rituximab, and so forth. Based on the wide range of treatment options for CLL, it is therefore helpful to understand the cost of treatment of CLL from the point of view of the general public and evaluate the burden of the disease.

According to Carl Rudolf Blankart and coauthors, the burden of disease is relatively lower for CLL compared to other chronic illnesses such as diabetes or chronic obstruction pulmonary disease (COPD). This claim was based on a research study involving a total of 4,198 CLL patients for whom direct medical costs such as inpatient and outpatient care, medications, home nursing care, medical equipment or aids, service fees collected by nonphysicians, and finally, rehabilitation were calculated. Other nonmedical costs associated with CLL include expenses related to sick leave, traveling expenditures to visit the doctor, and fees for patient transport (i.e., use of an ambulance). The data was then compared to a control group consisting of 150 randomly selected individuals who matched each combination of age and sex of the CLL population.

Their study also showed that, aside from the direct medical costs of CLL, there are also indirect costs such as losses in productivity, which could be calculated by multiplying the patient's gross income by the number of days that have been used for sick leave. In addition, there are also drugs that are often prescribed to CLL patients other than those of chemotherapeutic value. These include antibiotics, which are immediately administered to chemotherapy-treated patients because they are at higher risk of contracting microbial infections due to the deterioration of the humoral and cellular immune systems of CLL patients.

For the point of view of the society, the burden of disease varies in CLL because this malignancy
afflicts various age-groups. Younger CLL patients generally spend less money for treatment compared to older patients because most physicians utilize the watch-and-wait approach on these individuals. The watch-and-wait approach also does not entail expensive therapeutic regimens (e.g., chemotherapy) or even hospitalization. The economic burden of this malignancy therefore varies across the age continuum.

The results of the study showed that the direct, nonmedical cost of CLL is twofold higher than the direct medical expenses of the disease. Furthermore, the cost of treating each CLL case is also twofold higher than the cost of treating any other common disease, despite the well-known fact that treatment is conducted only during the later phases of the disease. With the continuous improvements in medical technologies, the increase in size of the aging population, and the elevated incidence of CLL, it is thus highly likely that the cost of treatment of this particular disease will further increase over time.

In a more recent study led by Thitima Kongnakorn, the cost-effectiveness of various first-line drugs for the treatment of CLL was assessed. Because of the availability of various treatment options for CLL, a physician may choose from a group of chemotherapeutic drugs, antibodies, or combinations of two chemotherapeutic drugs or an antibody with a chemotherapeutic drug. A discrete event simulation representing the progression of CLL was developed to assess the cost as well as health outcomes that were associated with the administration of bendamustine, chlorambucil, or alemtuzumab for a CLL population that has never been treated (treatment naive).

Specific characteristics using information generated from a previous bendamustine trial were assigned to every simulated CLL patient in the cohort. Every simulated patient was then cloned to generate three identical cohorts. Every cohort was then assigned one of three treatments, namely, intravenous bendamustine at a dose of 100 mg/m²/day for the first two days of a 28-day cycle for a total of six cycles; intravenous alemtuzumab at a dose of 30 mg three times a week for a total of 12 weeks; or oral chlorambucil at a dose of 0.8 mg/kg/day for the first and 15th day of every 28-day cycle, for a total of 12 cycles.

To generate a simulated CLL patient population, data collected from previous clinical trials were used; these included risk equations in calculating for the progression-free survival rate as well as survival during post-disease progression. The response rates and the incidence of adverse events were also estimated. The cost of the disease and survival in terms of life years, as well as quality-adjusted life years, were calculated for the lifetime of each patient.

The results of the study showed that bendamustine was the dominant therapeutic scheme relative to alemtuzumab because it provided more benefits to the CLL patient, which included longer life years and higher quality-adjusted life years. In addition, the total cost of using bendamustine as the sole therapeutic drug for CLL was lower than that of alemtuzumab. However, bendamustine was more expensive than chlorambucil, although better health outcomes such as longer life years and quality-adjusted life years were observed. These observations thus indicate that bendamustine was the most cost-effective therapeutic regimen when compared to alemtuzumab and chlorambucil. Although the price of chlorambucil was the lowest of the three drugs assessed in the study, the shorter life years of each CLL patient were indicative of additional health issues, which in turn would result in more direct medical and nonmedical costs.

It is interesting to note that, when the study led by Thitima Kongnakorn was completed, the marketing and distribution of alemtuzumab was stopped and immediately became available to health care providers at no cost when specific requirements had been fulfilled. Although the study might have been conservative in its operation, and several limitations have been cited, the investigators successfully presented CLL from a socioeconomic perspective. This approach also could facilitate the review of the effectiveness of other CLL drugs based on medical and nonmedical costs.

Leukemia, Chronic Myelogenous

Chronic myelogenous leukemia (CML), also known as chronic granulocytic leukemia (CGL) and chronic myeloid leukemia, is a cancer that starts inside bone marrow due to uncontrolled growth of immature blood stem cells called myeloid cells. As a result, there is clonal proliferation of immature and mature granulocytes (neutrophils, eosinophils, and basophils). The diseased cells accumulate in the bone marrow and blood and affect normal blood cell growth. It is called chronic as it has slower rate of progression than acute leukemia.

Epidemiology, Causes, and Risk Factors

CML typically affects older adults and rarely occurs in children, though it can occur at any age. In Western countries it accounts for 15 to 20 percent of all leukemia affecting adults. It is mostly seen in middle-aged people but can occur in young as well as in elderly populations.

In most cases, no obvious cause for CML can be isolated. It is not a hereditary disorder as chromosomal mutation is not transmitted from parents to offspring. It is mostly diagnosed in people around 65 years of age, and it is seen more commonly in men than women with a ratio of 1.4:1.

Radiation exposure, such as radiation therapy for certain types of cancer, is a risk factor. Ionizing radiation exposure, like in Hiroshima and Nagasaki nuclear bombing survivors, has showed a 50 times increase in incidence of CML.

Pathophysiology

CML is known to be caused by a specific genetic mutation in hematopoietic cells in more than 90 percent of patients. It involves reciprocal translocation between the long arms of chromosomes 22 and 9 (t [9;22]) resulting in a shortened chromosome 22, called a Philadelphia (Ph) chromosome, which has part of the bcr gene from chromosome 22 fused with the abl gene on chromosome 9. The abl oncogene encodes a tyrosine protein kinase, and the resulting bcr–abl fusion gene produces protein with strong tyrosine kinase activity, which supports cancer by allowing affected blood cells to grow out of control and damage the bone marrow. The bcr–abl protein also inhibits DNA repair, resulting in further accumulation of genetic abnormalities. The presence of the bcr–abl rearrangement is the hallmark of CML and is considered diagnostic in a patient with clinical manifestations of CML.

Phases of Chronic Myelogenous Leukemia

Chronic myelogenous leukemia is grouped into three phases mainly on the basis of aggressiveness of the disease, clinical signs and symptoms, and laboratory findings. It is found by the proportion of the diseased cells to the healthy cells in blood or bone marrow. The more the number of leukemic cells, the worse the stage of disease. CML usually starts with the chronic phase and slowly progresses to the accelerated phase, and without treatment it turns into the phase of blast crisis.

The chronic phase is the earliest phase involving proliferation of mature cells as a result of genetic mutation, and patients may have few or no symptoms but are diagnosed when blood tests are done for other reasons. About 85 to 90 percent of the patients are diagnosed in this phase. This phase can last for months or years. Treatment at this stage of the disease usually gives the best response.

The accelerated phase is a more dangerous phase as it represents accumulation of more genetic abnormalities in addition to the presence of the Philadelphia chromosome, resulting in more rapid growth of leukemic cells.

Untreated CML leads to the blast crisis phase. It is a severe and aggressive phase of CML with proliferation of immature cells. The symptoms of blast crisis are similar to those of acute leukemia. Bleeding and infection may occur due to bone marrow failure.
Signs and Symptoms
Around 90 percent of the patients with CML are diagnosed during the chronic phase, which is most often asymptomatic. In these cases, it may be diagnosed as an incidental finding of raised white blood cell count on a routine laboratory test. It can also present with symptoms like the following:

- Fatigue
- Decreased exercise intolerance
- Joint pain (especially hip pain)
- Low-grade fever
- Unexplained weight loss
- Decreased appetite
- Pain or fullness below the ribs on the left side (due to enlarged spleen)
- Right upper quadrant pain due to liver enlargement
- Abdominal fullness and night sweats

Some patients are diagnosed in the blast phase in which the symptoms are mostly due to increased growth of immature cells in bone marrow and include the following: fever; petechiae (small red or purple spots due to bleeding into the skin); bruising; bone pains; and fullness under the lower left ribs from a swollen, enlarged spleen.

Diagnosis
The workup for CML consists of several things. A completed blood count (CBC) with differential shows a raised white blood cell count, usually more than 20,000/μL, with very low levels of leukocyte alkaline phosphatase in most cells. Eosinophil and basophil counts are almost always increased. There is also a decrease in the number of mature red blood cells. A bone marrow analysis is the diagnostic test for CML, and the characteristic finding is the presence of the Philadelphia chromosome, detected by cytogenetics. In a few patients with CML, 9:22 translocation, that is, the Philadelphia chromosome, is not detected by routine cytogenetics due to other added complex chromosomal abnormalities. In these patients, fluorescent in situ hybridization (FISH) or polymerase chain reaction (PCR) for the bcr–abl fusion are utilized for diagnosis. Bone marrow also shows hypercellularity with an increased number of granulocytes, their immature forms, and prominent megakaryocytes. It may also show fibrosis depending on the aggressiveness of the disease.

After making the diagnosis of CML, it is very important to find out its phase so that management can be done accordingly as presence of the accelerated phase means the disease is progressing, and conversion into blast crises is about to happen. Mostly World Health Organization (WHO) criteria are utilized, and if any of the following is present, then the patient is considered in the accelerated phase:

- 10 to 19 percent myeloblasts in the blood or bone marrow
- Greater than 20 percent basophils in the blood or bone marrow
- Platelet count less than 100,000 and unrelated to therapy
- Platelet count greater than 1 million and unresponsive to therapy
- Cytogenetic evolution with new abnormalities in addition to the Philadelphia chromosome
- Increasing splenomegaly or white blood cell count that is unresponsive to therapy

In a patient with CML, the presence of any one of the following defines blast crisis:

- Large clusters of blast cells in the bone marrow on biopsy
- Development of a chloroma (solid focus of leukemia outside the bone marrow)
- Bone marrow fibrosis
- Greater than 20 percent myeloblasts or lymphoblasts in the blood or bone marrow

Complications
CML can cause a variety of complications due to excess proliferation of diseased white blood cells as well as due to a decreased number of normal blood cells. Also, treatment with chemotherapeutic agents leads to various complications.

As the number of red blood cells decrease with disease progression, anemia results, which manifests as fatigue. Medicines used for treatment of CML also cause anemia and its symptoms.

A low number of platelets known as thrombocytopenia can result in easy bleeding and bruising, including frequent or severe nosebleeds and bleeding from the gums. CML can cause bone pain or
joint pain as the bone marrow expands when excess white blood cells build up. When more than the normal number of blood cells are in circulation, they get stored in the spleen and can cause it to become swollen or enlarged.

Patients may feel fullness in the belly or pain in the upper left side of the abdomen. In CML, white blood cells are increased, but they are not functional, and as a result, patients are more prone to infections and fever. If a patient shows no response to any treatment, then CML can result in the patient’s death due to progression of the disease’s blastic phase.

T reatment
Treatment of CML focuses on remission of blood cell counts as well as on remission at the molecular level. Loss of the Philadelphia chromosome is called a cytogenic response, and it is also desirable that normal chromosome returns to 0 percent Ph-positive cells. The blast crisis phase is very difficult to treat. This is because there is a very high count of immature white blood cells (leukemia cells).

The only proven curative treatment for CML is a bone marrow transplant or an allogenic stem cell transplant. Besides this, there are three major mainstays of treatment in CML:

- Tyrosine kinase inhibitors
- Myelosuppressive therapy
- Interferon alfa-2b therapy

Tyrosine Kinase Inhibitors. Imatinib mesylate is used for the treatment of chronic and accelerated leukemia and blast crises. Basically, it is the standard treatment of choice and first line of treatment in every patient with CML as it inhibits the progression of CML in a large number of patients (65–75 percent), which allows regrowth of the normal bone marrow stem cells and formation of mature blood cells. As few leukemic cells persist in almost all patients, the treatment with imatinib should be continued lifelong.

Dasatinib and nilotinib can be used for the treatment of the chronic phase in patients with imatinib-resistant CML. Studies have shown that it reduces the progression to the accelerated or blast phase. Bosutinib can be used for the treatment of chronic and accelerated as well as blast phases of CML.

Ponatinib is a tyrosine kinase inhibitor (TKI) used for chronic or blast phase T315I-positive cases for patients on whom imatinib, dasatinib, and nilotinib have no effect. In these patients, ponatinib has shown good treatment results. It is also effective in appropriate patients in whom no other TKI therapy is tolerated or indicated.

Myelosuppression. Hydroxyurea (Hydrea) is used along with TKIs to control high white blood cell count. Busulfan is a myelosuppressive agent that is also used to induce hematologic remission to achieve normal blood cell counts.

Omacetaxine is a protein translation inhibitor used for treatment of chronic- or accelerated-phase CML with resistance or intolerance to two or more TKIs and other chemotherapeutic agents.

Interferon-Alfa. Interferon-alfa was used as a first-line agent for treatment of CML, but nowadays, its main use is for the treatment of refractory cases in combination with newer drugs. It is also used for the treatment of CML in pregnant women.

Bone Marrow and Stem Cell Transplant. This is the only known cure for CML, but it is mostly considered in patients who show resistance to imatinib and other TKIs or those who do not achieve normalization of blood cell counts. Transplantation is mostly done in the chronic phase and after staging of patients as it has significant morbidity and mortality.

Prognosis
It depends on the phase of CML at diagnosis and extent of hematologic and cytogenetic remission as a response to treatment. Use of TKIs has affected survival rates drastically, especially in patients who achieve cytogenic response. Survival rates used to be three to five years from the time of diagnosis, but now the five-year survival rate is more than 90 percent.

This improvement is also due to earlier diagnosis and better supportive care. Patients who are diagnosed in the blast phase usually do not respond well to treatment, and their longevity is three to six months.

**Leukemia, Hairy Cell**

Hairy cell leukemia is a unique lymphoid cancer that is characterized by an enlargement of the spleen (splenomegaly) and a reduction in the number of cells in peripheral blood (peripheral cytopenia). This form of leukemia is caused by five somatic mutations, one of which is the heterozygous mutation defined as V600E occurring in the BRAF gene. The biological significance of the other four somatic mutations remains unknown at this time. Previous studies have shown that the V600E BRAF mutation is present in patients with hairy cell leukemia but not in patients diagnosed with peripheral B-cell lymphoma or acute leukemia. The identification of the V600E mutation in the BRAF gene has helped in making an accurate diagnosis of hairy cell leukemia as well as in distinguishing this cancer from hairy cell leukemia-mimicking conditions, which include B-cell chronic lymphoproliferative disorder, splenic lymphoma, and splenic marginal-zone lymphoma.

The V600E mutation identified in hairy cell leukemia patients also occurs as a mutational hot spot in other cancers, such as papillary thyroid cancer and melanoma. However, the involvement of BRAF in hairy cell leukemia is mainly due to the inhibition of the mitogen-activated protein kinase (MAPK) pathways, in which the BRAF protein serves as a component. Polymerase chain reaction and Sanger sequencing of the BRAF gene have shown that the V600E mutation involves a T>A substitution at position 1860 of the DNA strand, which in turn results in an amino acid change from Val to Glu at position 600 of the polypeptide chain (V600E).

Previous studies have shown that, although the V600E BRAF mutation also occurs in other cancers, its frequency in hairy cell leukemia is significantly higher than those reported for other malignancies. For example, the research study led by Enrico Tiacci reported that the V600E mutation was detected in 100 percent of the mononuclear cells that were isolated from the peripheral blood of patients diagnosed with hairy cell leukemia. On the other hand, other studies have reported that the frequency of the V600E BRAF mutation in melanomas was approximately 50 percent, whereas that of papillary thyroid carcinomas was around 40 percent. There are also reports that describe the frequency of the V600E BRAF mutation in Langerhans cell histiocytosis as approximately 57 percent, whereas several articles have indicated that various solid tumors have a markedly lower frequency for the same mutation.

Despite the extensive assessment of mutations in hairy cell leukemia and the claims that the frequency of the V600E BRAF mutation is 100 percent, there are also reports that contradict these findings. Michelle Lavin and Paul Browne recently published a case report involving a patient with hairy cell leukemia that showed all the symptoms of the disorder, including the clinical, cytochemical, and immunophenotypic features yet did not harbor the V600E BRAF mutation. The patient described in the case report initially presented in 1981 with severe pancytopenia, splenomegaly, macular hemorrhage, and bone marrow infiltration, which were suggestive of a lymphoproliferative disorder. The patient then underwent splenectomy, which resolved the symptom of pancytopenia. Analysis of the splenic specimen indicated a diagnosis of hairy cell leukemia.

The patient remained in remission until October 2009, when the patient suffered a relapse, which
was detected using a bone marrow aspirate. Analysis of the bone marrow specimen showed the classical immunophenotypic features of hairy cell leukemia, which included the presence of CD11c, CD19, CD20, CD22, CD25, CD103, CD200, and FMC7 markers and the absence of CD5, CD10, CD23, and CD79b markers. However, allele-specific polymerase chain reaction indicated the absence of the V600E \textit{BRAF} mutation. A five-day treatment using subcutaneous cladribine resulted in the remission of clinical and immunophenotypic symptoms.

Three years later, the patient again developed another relapse, as indicated by the presence of neutropenia. In addition, the patient presented the same clinical and immunophenotypic features as the previous relapse. Allele-specific PCR was again performed, which continued to indicate the absence of the V600E \textit{BRAF} mutation. A five-day treatment using subcutaneous cladribine resulted in the remission of clinical and immunophenotypic symptoms.

The case report also emphasizes the need to exercise caution in the diagnosis of a lymphoproliferative disorder. The absence of the V600E \textit{BRAF} mutation coupled with the occurrence of splenomegaly and severe pancytopenia may also indicate splenic lymphoma as well as splenic marginal-zone lymphoma. Thus, it would be most beneficial if the rest of the clinical, immunophenotypic, and cytochemical features of hairy cell leukemia were assessed in order to make a differential diagnosis of the condition despite the absence of the V600E \textit{BRAF} mutation.

Furthermore, the mere presence of a V600E mutation does not immediately indicate that a patient has hairy cell leukemia because this DNA variant also occurs in other types of neoplasms, such as solid tumors, acute lymphoblastic leukemia, Langerhans cell histiocytosis, and B-cell lymphoma. The burden of disease may also change in the absence of the V600E as additional tests and regular follow-up visits may be required in order to monitor the condition of the patient over time.

Further Readings
Leukemia & Lymphoma Society

The Leukemia & Lymphoma Society (LLS) of America is the largest voluntary organization dedicated to blood cancer. Their mission is twofold and includes curing leukemia, Hodgkin's disease, myeloma, and lymphoma while improving the quality of life of patients and their families. Rudolph and Antoinette de Villiers started an education and fund-raising organization in 1949 in the name of their son, Robert Roesler de Villiers, who died from leukemia when he was 16 years old, in the year 1944. The organization first changed its name to the Leukemia Society but was renamed in the 1960s as the Leukemia Society of America. The organization finally became the Leukemia & Lymphoma Society of America in the year 2000.

The LLS's key priorities aim to help blood cancer patients live longer and better lives. The key priorities include research; patient services; public policy; revenue, marketing, and field management; information technology; human resources; and finance. LLS's research aims to fund academic research and other special projects that advance the diagnosis and treatment of blood cancers. They specifically seek to support unmet research areas, including venture capitalists and pharmaceutical companies.

LLS aims to be the key source of information for patients and families through education and improved access to the latest treatment options and clinical trials. Public policy that efficiently reviews new treatments and accelerates the discovery of new treatments is a key priority of LLS.

Patients should also have quality care supported by their insurance coverage.

LLS's public policy initiative also includes supporting funding access for research of blood cancers. This leads to their next priorities—increasing public awareness of nonprofit research organizations and developing revenue growth for future research. Information technology is key to superior platforms that support research. LLS strives to hire, inspire, and train the best candidates for all positions. It seeks to expand diversity among all personnel. The final key priority is to reduce the time spent on preparation for researching and spend more on actual research by consolidating the forecasting and budgeting needs spent prior to research. LLS has four primary programs for research.

The Specialized Center of Research supports collaboration across boundaries among universities, national organizations, and labs. The Translational Research Program aims to speed up the process from promising findings in the laboratory to actual treatments and prevention measures. The Career Development Program offers stipends to new investigators so that they may devote themselves to blood cancer research. The Therapy Acceleration Program assists with bringing treatment to more patients in a faster manner by funding and supporting researchers so that they may get closer to the final product stage. LLS also offers research grants. While a number of them are not currently accepting applications (i.e., Translational Research Program, Specialized Center of Research Program, the Screen to Lead Program, the New Idea Award, the Quest for Cures, and the MPN Challenge Grant), two opportunities are being made available: the Career Development Program and the Therapy Acceleration Program.

The Career Development Program offers the opportunity to participate in basic clinical or translational research. This award changes with the various stages of the researcher's career. At the scholar level, the award is $110,000 per year for five years. The researcher must be highly qualified and demonstrate original research. Substantial support for the research also should be provided by a national organization, and the researcher should be at the independent faculty level or equivalent.

The Scholar in Clinical Research award is $110,000 per year for five years and is awarded to the...
researcher who is conducting original research that typically includes early-stage clinical trials that address prevention, diagnosis, or treatment of blood cancers. Equivalent support for the research also should be available from another organization. The Special Fellow award is $65,000 per year for two to three years.

The researcher must have completed at least two years of postdoctoral research but not more than four and one-half years. This research award aims to support the transition of the researcher from faculty to an independent research program. The Special Fellow in Clinical Research also awards $65,000 per year for two to three years. The researcher must hold a Ph.D. or M.D. (or equivalent) and must have completed at least two years of specialized clinical training in hematology or oncology. Evidence that the researcher's career will focus on preventing, diagnosing, or treating hematologic malignancies is required. The Fellow awards $55,000 per year for three years and is used to encourage researchers who have less than two years of postdoctoral research training.

The Therapy Acceleration Program is an initiative to speed up the development of blood cancer diagnostics and treatments. The primary focus is on projects that can change the standard of care for blood cancer patients. This program assists companies and clinical researchers alike. There are three divisions within the program: Academic Concierge, Biotechnology Accelerator, and Clinical Trials. The Academic Concierge Division supports development of projects that have clinical promise through partnering with companies that can manufacture treatment materials and with service providers that can participate in clinical studies. This department also assists in assembling the documentation required by the Food and Drug Administration (FDA) before any clinical trial can start.

The Biotechnology Accelerator Division invests in projects that demonstrate safety and efficacy for blood cancer patients that are new and novel approaches. The company seeking funding must demonstrate the therapeutic potential of the drug, capability of management and scientific staff, financial strength, freedom to operate, and well-designed strategies. The Clinical Trials Division helps patients gain access to clinical trials within the community. LLS plans to introduce a network of phase I II sites that will use new strategies to increase enrollment, most especially for underrepresented populations.

Libya

Lying on the southern shores of the Mediterranean, Libya is a vast north African country, roughly the size of Alaska, yet with a population of only 6 million citizens. In terms of natural resources, Libya is a wealthy country, having the 10th-largest proven oil reserves in the world as well as substantial reserves of natural gas.

However, despite its oil wealth, Libya has serious economic problems. The economy is overly reliant on oil, which makes up about 97 percent of exports. Furthermore, the economy is heavily distorted, with about 70 percent of Libyans being employed by the state. Youth unemployment is high, at around 21 percent. Other chronic problems include mismanagement, corruption, and insufficient investment in infrastructure, education, and health care. Thus the country’s wealth does not reflect the rundown condition of many of its health care facilities.

Politically, the country is in turmoil with some describing it as being on the verge of becoming a failed state. Having barely recovered from the revolution in 2011, which toppled Col. Muammar Qaddafi, the country’s long-standing dictator, the
country’s frail democratic institutions have struggled to maintain control.

Nowadays, many Libyans pursue an urban sedentary lifestyle, with an attendant rise in diseases such as diabetes, hypertension, and other negative health factors, such as obesity and smoking. Yet, the country enjoys free public health care, a relatively high life expectancy, a low infant mortality rate, and an effective national immunization program. Since the early years following independence in 1951, many infectious diseases such typhoid, cholera, and malaria have been brought under control. Cancer, however, appears to be on the rise, possibly due to increased longevity among Libyans, or perhaps due to better diagnosis, or possibly other factors such as environmental pollution or lifestyle changes.

There is a lack of definitive nationwide statistics; however, in 2003 the population-based Benghazi Cancer Registry published its first data, revealing that the most common cancers among male patients were lung cancer at 19 percent, followed by colorectal at 10 percent, head and neck at 9 percent, and bladder cancer at 9 percent. Among women, the most common cancers were of the breast at 26 percent, followed by colon at 9 percent, uterus at 7 percent, and non-Hodgkin’s lymphoma at 5 percent. The overall cancer incidence for that year was reported as 118 and 95 per 100,000 for men and women, respectively.

In Sabratha, the National Cancer Institute published hospital-based data in 2007 that revealed the most common cancers among Libyan men were lung cancer at 17 percent, closely followed by colorectal cancer at 15 percent and prostate cancer at 14 percent. Over a quarter of cancers among Libyan men were tobacco related, a fact that underlines the need for an effective cancer prevention strategy.

Among Libyan women, the most common cancers were breast cancer at 35 percent, followed by colorectal cancer at 11 percent and lymphoma at 10 percent. Breast cancer patients in Libya tend to be relatively young (70 percent are younger than 50 years old), with more advanced tumors at diagnosis that exhibit a relatively aggressive course.

There are five cancer treatment facilities throughout the country, two of which are dedicated oncology centers, the National Cancer Institutes at Sabratha and Misrata. The other three facilities are the Oncology and Hematology Departments of Tripoli Medical Center, Benghazi Medical Center, and Tripoli Central Hospital. These three hospitals also have radiotherapy facilities. The country’s only working positron emission tomography (PET) scanner is at Tripoli Medical Center.

In general, the quality of care provided to cancer patients is still inadequate. While the latest chemotherapy drugs and biological therapies are generally available, the supply can be unreliable, with not infrequent shortages.

Furthermore, there are long-standing systemic problems in the health sector as in other sectors of the Libyan economy, which include a lack of investment, mismanagement, corruption, poor training, and emigration of many of the country’s brightest doctors. In particular, the country has a weak primary health care infrastructure.

As a result of these shortcomings, many Libyan citizens have shunned the public (and indeed also the private) health care sector, preferring instead to travel to neighboring countries such as Tunisia and Egypt for medical treatment. Other favored destinations include Jordan and Turkey, whereas the more well-off travel to western Europe for treatment.

An effective national cancer prevention strategy potentially would have a great impact on cancer incidences, particularly as the population of Libya is so young (half the population is under 24 years old), and therefore, modifiable risk factors (such as smoking and diet) can be altered. A World Health Organization (WHO) report issued in 2013 estimated the prevalence of smoking to be 49 percent among Libyan men and 1 percent among Libyan women.

However, a formal national cancer screening program does not yet exist, and patients are all too often diagnosed at a late stage, when the tumor has already spread to nearby tissues or distant organs, making curative treatment generally unfeasible.

This delay in diagnosis is compounded by several social and cultural factors, principally a reticence to seek medical advice. In what still is a conservative society, elderly individuals in particular may feel embarrassed to discuss certain medical complaints. Another reason is the lack of confidence that some have in the health care system, preferring to use herbal or alternative medicines.

In recent years, attempts have been made to raise public awareness through media campaigns especially about breast cancer and lung cancer.
Liver Cancer, Adult (Primary)

Liver cancer, also known as hepatic cancer, is a malignant tumor that grows on the surface or inside the liver. They arise either from the liver itself or from structures within the liver, including blood vessels or the bile duct, and are called primary liver cancer. These cancers are one of the most frequently diagnosed cancers globally and the second-leading cause of cancer death worldwide. Cancers of other organs of the body, like the lungs, kidneys, and intestines, that spread to the liver are known as metastatic or secondary liver cancer. They are more common than primary liver cancer.

Types of Primary Liver Cancer

Primary liver cancers in adults are mainly of two types. Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer, accounting for approximately 75 percent of all primary liver cancers, and is also known as malignant hepatoma. It is formed by liver cells that become malignant. Cholangiocarcinoma is the cancerous growth that arises from the cells of the biliary duct system. There is also a variant type of HCC that consists of both HCC and cholangiocarcinoma.

Causes of Hepatocellular Carcinoma

HCC usually results secondary to cirrhosis, which is commonly caused by alcoholism or viral infections. Causes of liver cancer are viral infections like hepatitis B virus and hepatitis C virus (these infections are the main cause of liver cancer, accounting for more than 70 percent of HCC in the developing world), cirrhosis by any cause, alcoholism (the most common cause of cirrhosis in the developed world is alcohol abuse), aflatoxin B1 (it is a poison present in fungus grown on improperly stored nuts and grains), Wilson’s disease, chronic inflammation of the liver, hemochromatosis, alpha 1 antitrypsin deficiency, diabetes type 2, and obesity.

Epidemiology

Liver cancer is one of the leading causes of death worldwide. According to 2010 data, liver cancer resulted in 754,000 deaths, of which around 50 percent are as a result of Hepatitis C. HCC, the most common form of liver cancer, shows a specific
pattern, with 50 percent of HCC cases diagnosed mainly in China. HCC is more common where hepatic viral infections are more prevalent, which includes east Asia and sub-Saharan Africa. HCC is more common in men than women and seen in people age 50 or older.

**Signs and Symptoms of Hepatocellular Carcinoma**

Hepatocellular carcinoma is associated with weight loss, fever, anemia, back pain, abdominal mass, jaundice, itching, abdominal pain, and vomiting.

**Pathophysiology**

Viral infections cause HCC due to long-term inflammation, fibrosis, and especially, the resulting cirrhosis is the main cause of malignancy. Hepatitis B virus can cause HCC even without causing cirrhosis as viral genetic material when combined with hepatic cells can induce HCC. Chronic alcoholism also increases risk of HCC directly by affecting hepatocytes' genetic material and indirectly by causing cirrhosis. Basically, cirrhosis of any cause can lead to HCC, whether it is due to hemochromatosis (which is an iron overload disease with iron deposition in the liver, pancreas, and other body organs), primary biliary cirrhosis, or Wilson's disease (copper deposition disease). Aflatoxins are poisons produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*. These fungi usually are present in improperly stored grains, nuts, and certain vegetables. In patients with hepatitis B infection, aflatoxin exposure increases more than three times the risk of HCC than without aflatoxin exposure.

**Diagnosis**

Different sorts of imaging techniques are used along with some blood tests to aid in the diagnosis of HCC, and these include a liver function test, an ultrasound of the abdomen, a computed tomography (CT) of the abdomen, magnetic resonance imaging (MRI), and alpha-fetoprotein (AFP); high levels of this tumor marker in the blood along with a more than two-centimeter mass in the liver on ultrasound is about 95 percent suggestive of HCC.

**Treatment**

There are various treatment options for HCC with pros and cons for every modality. Surgical resection of the mass is often the treatment of choice for patients with noncirrhotic livers as there are more chances of complications, especially liver failure, if the liver is cirrhotic. After resection of the tumor, the recurrence rate is more than 70 percent, and its reason could be new tumor formation or by metastatic spots spread from previous tumor mass. Liver transplantation is considered only in patients who are eligible for surgery and transplant. Around 30 percent of patients can undergo liver transplantation due to its strict criteria and late diagnosis of HCC. Percutaneous ablation is a nonsurgical treatment modality for HCC and can be done in various ways: chemical ablation through ethanol or acetic acid injection directly into the liver or radiofrequency ablation, which uses extremes of temperature to destroy the tumor. Microwaves, lasers, and cryotherapy can also be used to treat HCC, but radiofrequency ablation gives the best results with cures, but it has its own limitations. Usually, local chemotherapeutic agents are used in the treatment of HCC in which cytotoxic drugs, like doxorubicin or cisplatin, are administered into the arteries supplying the liver, which are then blocked by gelatin sponges. This procedure is known as trans-arterial chemoembolization. For the last few years, a new drug, named sorafenib, has been in use in various parts of the world for the treatment of unresectable HCC. It acts by inhibiting several kinase inhibitors, including tyrosine kinases, raf kinases, and intracellular serine or threonine kinases. It has many serious side effects, which is the reason it is used very cautiously in specific HCC cases. It gives better results when used along with doxorubicin. Radiotherapy is used mainly as targeted radiation to the tumor. Combined therapy with chemoembolization rather than only radiotherapy gives better results.

**Prognosis of Hepatocellular Carcinoma**

Prognosis of HCC depends on many factors, which include resectability of mass, spread of tumor, as well as success of treatment. Duration of survival after diagnosis is usually three to six months in the case of a tumor that cannot be completely removed. But nowadays, in these patients, there is improvement in survival due to new medications, especially sorafenib.

**Prevention of Hepatocellular Carcinoma**

The most successful prevention against HCC is hepatitis B vaccination. Other forms of prevention
include screening of high-risk individuals, screening of blood products before use for donation, and safe injection practices. All these measures decrease the risk of HCC as they decrease spread of hepatitis B and C, which are the most common causes of HCC. Controlling other risk factors, like reducing alcohol intake, weight reduction, and better control of diabetes, are also important ways to decrease incidence of HCC.

**Cholangiocarcinoma Overview**

It is also considered as primary liver cancer as it arises from the epithelial lining of the bile ducts, which drain bile from the liver into the intestine. It is a rare cancer as well as slow growing as compared to HCC.

**Epidemiology**

Cholangiocarcinoma is a relatively rare cancer, but its incidence is increasing since the last few decades. It is more common in Asian countries, especially Thailand, than in the Western world due to the presence of chronic parasitic infections. It is more common in men than women, and its risk also increases with age.

**Pathophysiology**

According to most schools of thought, it is considered as a carcinoma of epithelial cells of the biliary tract lining and develops through stages of hyperplasia, metaplasia, dysplasia, and then carcinoma. More than 90 percent of cholangiocarcinomas are adenocarcinomas.

**Risk Factors**

In most patients diagnosed with cholangiocarcinoma, there may be no risk factor, but in some patients, any one of these factors can be found: primary sclerosing cholangitis (PSC), an inflammatory disease of the bile ducts (according to studies, in patients with PSC, there is a lifetime risk of cholangiocarcinoma of up to 15 percent); congenital liver malformations including choledochal cyst, Caroli’s syndrome, biliary papillomatosis, and Lynch syndrome II; parasitic infections, such as liver flukes like *Opisthorchis viverrini* (usually seen in Thailand, Laos, and Malaysia) or *Clonorchis sinensis* (found in Japan, Korea, and Vietnam); patients with chronic liver disease, whether in the form of viral hepatitis (e.g., hepatitis B or hepatitis C), alcoholic liver disease, or cirrhosis of the liver due to other causes; human immunodeficiency virus (HIV) infection; hepatolithiasis, the presence of intrahepatic stones; and thorotrast exposure, which is a form of thorium dioxide that was used as a contrast medium in radiography.

**Types of Cholangiocarcinoma**

These types are according to the site of the tumor: intrahepatic, referring to tumors occurring in the bile ducts within the liver; extrahepatic, a tumor occurring in the ducts outside the liver; perihilar, when tumors occur at the site where the bile ducts exit the liver; and a Klatskin tumor, which occurs at the junction where the left and right hepatic ducts meet to form the common bile duct.

**Signs and Symptoms**

Prominent signs and symptoms of cholangiocarcinoma include fever, weight loss, abdominal pain, jaundice (yellowish discoloration of the skin and sclera in the eyes), generalized itching, sweating, hepatomegaly, tenderness in the right upper quadrant, ascites, and changes in the color of stool or urine.

**Diagnosis**

Cholangiocarcinoma is diagnosed through a combination of blood tests, imaging, endoscopy, and pathological examination of a specimen. A liver function test usually shows increased levels of conjugated bilirubin, alkaline phosphatase, and gamma glutamyl transferase in the blood. This whole pattern is called obstructive as it shows obstruction in the flow of bile. Serum CA 19-9 (carbohydrate antigen) and CEA (carcinoembryonic antigen) levels are also found to be elevated in most patients. Endoscopic retrograde cholangiopancreatography (ERCP) usually shows common bile duct stricture and dilation of the proximal common bile duct. Biopsy is the definitive diagnosis for cholangiocarcinoma. It can be done either by ERCP or laparoscopy. Other methods include ultrasound of the liver and biliary tree, a computed tomography (CT) scan, and magnetic resonance cholangiopancreatography (MRCP).

**Treatment**

Treatment of cholangiocarcinoma varies as to the stage at which the disease is diagnosed. It is
Liver Cancer, Adult (Primary)

a very deadly disease if the tumor is not removed completely from the body. Only in patients with early disease does the curative option of surgery work. These patients usually have no local or distal metastasis or lymph node involvement as well as no involvement of the portal vein. Distal cholangiocarcinomas are generally treated surgically with a Whipple procedure. Intrahepatic cholangiocarcinomas are treated with partial hepatectomy, whereas perihilar cholangiocarcinomas are usually not operable. If surgery is possible, patients are usually treated with an aggressive approach, often including removal of the gallbladder and potentially part of the liver.

Most patients with cholangiocarcinoma are diagnosed when it has already spread locally to other nearby organs or metastasized to distant parts of the body. At this stage, the disease is usually inoperable; therefore, adjuvant therapy with radiation, brachytherapy (internal radiotherapy), and chemotherapy are utilized to control the disease. These therapies are used in cases when whole tumor masses cannot be removed and tissue margins are positive after surgery. Chemotherapeutic agents usually in use are 5-fluorouracil with leucovorin or a combination of gemcitabine with cisplatin, irinotecan, or capecitabine.

A new medicine, erlotinib, a tyrosine kinase inhibitor with possible good results, is still under study. Another important modality under study is photodynamic therapy, which has shown improved survival as well as quality of life. In this technique, light is applied endoscopically directly to the tumor, resulting in the release of toxic reactive oxygen species, causing killing of tumor cells.

**Prognosis**

Prognosis is related to the extent the tumor can be removed from the body. Most of the patients with cholangiocarcinoma present at a nonresectable stage and therefore have bad prognoses. Their five-year survival rate is 0 percent with average duration of survival of less than six months. In patients with no lymph node involvement, the five-year survival rate is better and more than 50 percent. Patients who have distal cholangiocarcinomas with no lymph node involvement usually have long-term survival rates ranging from 15 to 25 percent. Patients with intrahepatic cholangiocarcinomas after treatment by partial hepatectomy show a 22 to 60 percent survival rate, and it varies according to the involvement of the lymph nodes. Patients with perihilar cholangiocarcinoma, if diagnosed at an operable stage, usually show a five-year survival rate of 20 to 50 percent. The prognosis can be worse for patients with cholangiocarcinoma along with primary sclerosing cholangitis, as in these patients, cancer is diagnosed usually at a late stage.

**Further Readings**

Primary liver cancer is rare in children, representing only about 1 percent of all childhood cancers. In contrast, adult primary liver cancer is the fifth-most common adult cancer worldwide. Fortunately, primary liver cancer is much more curable in children than it is in adults.

Hepatoblastoma and hepatocellular carcinoma are the two most common types of pediatric primary liver cancer, representing 43 and 23 percent, respectively, of primary childhood liver cancer. The liver is a common site of metastasis, and in children (as in adults) metastatic liver cancer is more common than primary liver cancer.

Other rare pediatric liver cancers include undifferentiated embryonal sarcoma of the liver (UESL), infantile choriocarcinoma of the liver, and epithelioid hemangiendothelioma.

Hepatoblastoma

Hepatoblastoma typically is seen in very young children of 3 years or less. In fact, it represents 90 percent of liver cancers in children under the age of four. The incidence of hepatoblastoma has been slowly increasing over the past four decades. From 1975 to 1983, it was 0.8 per year per million children, whereas from 2002 to 2009, the incidence doubled to 1.6 per year per million children.

One possible reason may lie in the growing number of babies who are born with very low birth weights. Low birth weight is a known risk factor for hepatoblastoma.

Other risk factors for hepatoblastoma include a number of genetic syndromes that are characterized mostly by excessive or uneven growth. These are seen in about 15 percent of hepatoblastoma patients and include Beckwith-Wiedemann syndrome and hemihyperplasia.

Familial adenomatous polyposis (FAP) is another known risk factor. This condition is thought to be due to a genetic mutation. In adults, familial adenomatous polyposis patients are at very high risk of developing colon cancer. Thus, hepatoblastoma survivors who have FAP need to be screened for colon cancer in adulthood.

Other rare genetic disorders associated with hepatoblastoma include Trisomy 18, Aicardi syndrome, and the glycogen storage diseases (which also predispose to hepatocellular carcinoma). Parental smoking is now known to increase the risk of hepatoblastoma in children.

The cell of origin of hepatoblastoma is thought to be the embryonal hepatoblast, a precursor to the normal liver cell, the hepatocyte. Histologically, there are a number of subtypes that are important because they have different outcomes. Pure fetal histology (PFH) hepatoblastoma is one such variant, which has an excellent outcome if completely resected. Conversely, the presence of undifferentiated (i.e., not resembling any normal tissue) small cells in the tumor indicates an unfavorable outcome.

Hepatoblastoma patients tend to be very young, usually in the first or second year of life. Typically, they present with an abdominal mass. Other symptoms include fever, vomiting, jaundice, and lethargy. They may also be anemic and failing to thrive (i.e., they are not gaining weight as expected). Symptoms and signs of associated syndromes may also be present.

Generally, the workup is similar for both hepatoblastoma and hepatocellular carcinoma. An abdominal ultrasound scan usually will be done to determine the location and size of the tumor. Other imaging modalities include computerized tomography (CT) scan or magnetic resonance imaging (MRI) to assess the local extent of the tumor and involvement of nearby lymph nodes. CT scans are also used to detect metastases, for example, in the lung. Magnetic resonance angiography (MRA) outlines important blood vessels and helps to assess resectability. Additional scans may be done in certain situations, for example, a nuclear bone scan to detect bone metastases.

The most important diagnostic test is a liver biopsy. This is taken surgically, and a pathologist will determine the type of liver cancer and the biological aggressiveness of the tumor.
Other valuable tests include the tumor marker alpha-fetoprotein (AFP). This is usually raised; however, a low alpha-fetoprotein may be associated with the undifferentiated small cell type of hepatoblastoma, which has a poor outcome.

AFP, though not very specific, is especially useful to detect recurrence of a cancer after initial therapy.

Blood tests may also be done to check the general condition of the patient and include liver enzyme tests to determine the amount of liver damage and a complete blood count (CBC) to look for anemia as well as other routine tests.

Once diagnosed, a cancer must be staged; that is, an assessment needs to be made as to how advanced the tumor is.

Liver cancers (both hepatoblastoma and hepatocellular carcinoma) are staged according to two systems. The first is the Pre-Treatment Tumor Extension (PRETEXT) system by the International Society for Pediatric Oncology Epithelial Liver Tumor Study Group (SIOPEL). This system uses presurgical criteria based on imaging by CT or MRI. There are four stages, PRETEXT 1 through 4, depending on the size and distribution of the tumor within the liver.

The second major staging system was designed by the Children’s Oncology Group (COG). The COG system uses mostly postsurgical data to stage the tumor. Stage I tumors are those that were completely resected; stage II tumors have microscopic residual deposits that were not removed; stage III tumors are those that are either unresectable or only partially resected or where there are positive (i.e., involved) lymph nodes. Stage IV tumors are those that have distant metastasis. Both staging systems predict prognosis well.

The treatment of liver cancer in childhood is best undertaken by specialist pediatric oncology centers under the care of a multidisciplinary team.

The cornerstone of management in pediatric liver cancer is surgery. The aim, wherever possible, is to excise the tumor completely, thereby maximizing the chance of a cure. Unfortunately, only about a third of hepatoblastomas are resectable at presentation. In this group, a favorable outcome can be expected. Surgery is by either resection or orthotopic liver transplantation, a technique whereby the

---

*Very high magnification micrograph of fibrolamellar hepatocellular carcinoma, one of two main subtypes of hepatocellular carcinoma. Fibrolamellar hepatocellular carcinoma was previously thought to have a better prognosis than classic or conventional hepatocellular carcinoma, but this has not been confirmed. (Wikimedia Commons)*
The patient’s liver is completely removed and the donor liver is positioned in its place.

In Europe, preoperative chemotherapy is used routinely, whereas in the United States, there is a tendency to delay chemotherapy until after surgery, whenever possible. Commonly used chemotherapy agents are doxorubicin, cisplatin, 5-fluorouracil, and vincristine. The current standard of care is a regimen that combines cisplatin, 5-fluorouracil, and vincristine. Chemotherapy has an important role in shrinking the tumor, thus making it easier to remove. Moreover, lung metastases may be eradicated by chemotherapy alone. Chemotherapy may also be used to ease symptoms in advanced cancer.

The role of radiotherapy is limited, but it may be useful to treat microscopic disease at the resection margin or to treat lung metastases that do not respond to chemotherapy or in the palliation of bone pain.

In general, the prognosis of hepatoblastoma is better than that of hepatocellular carcinoma. Patients have an overall five-year survival rate of about 70 percent. The most important prognostic factor is the stage of the tumor at presentation as this affects the resectability of the tumor. Another important factor is the histological subtype. As mentioned previously, patients with a pure fetal histology subtype have a much better prognosis than those with undifferentiated small cell histology. Other adverse prognostic factors include older age and a low alpha-fetoprotein level at presentation.

**Hepatocellular Carcinoma**

The predominant risk factor in the development of hepatocellular carcinoma is hepatitis B and C infection, especially in Asia, sub-Saharan Africa, and Melanesia, where hepatitis B and C are endemic. In these areas, hepatocellular carcinoma is more prevalent than hepatoblastoma. Papua New Guinea is reported to have the highest prevalence of hepatocellular carcinoma in the world, where it represents 8.5 percent of all childhood cancers. Some countries that have introduced universal hepatitis B vaccination have seen a significant decline in the incidence of hepatocellular carcinoma.

Hepatitis B infection is particularly important as it can be transmitted vertically from mother to baby. Hepatitis C infection is not as important in children because it takes many years to cause cancer, so it is more relevant for adult hepatocellular carcinoma patients. Hepatocellular carcinoma often occurs on a background of liver cirrhosis, that is, liver damage due to underlying liver disease from a multitude of causes.

Boys have a higher chance of developing hepatocellular carcinoma. Other significant risk factors include genetic anomalies such as biliary atresia, Alagille syndrome, and progressive familial intrahepatic cholestasis and tyrosinemia.

Histologically, hepatocellular carcinoma displays two main subtypes: classic or conventional hepatocellular carcinoma and fibrolamellar hepatocellular carcinoma. Fibrolamellar hepatocellular carcinoma was previously thought to have a better prognosis, but this has not been confirmed.

The clinical picture of hepatocellular carcinoma is very similar to hepatoblastoma, although children with hepatocellular carcinoma are often older, usually 10 to 14 years old. The abdominal lump (due to enlargement of the liver) is often large and may be painful. As in hepatoblastoma, patients may complain of jaundice, itching, nausea, and vomiting. There may also be other nonspecific symptoms, such as a loss of appetite or a reduction in weight. In young children, a failure to thrive may be noted. Symptoms due to metastatic disease may also be present, for example, bone pain or chest symptoms. Patients with underlying chronic liver disease may notice a change in their usual symptoms.

The workup for hepatocellular carcinoma is essentially the same as in hepatoblastoma. AFP is raised in 50 percent of cases. Vitamin B12 binding protein is a useful tumor marker in the fibrolamellar variant. A viral screen to look for associated hepatitis B and C is necessary.

Staging for hepatocellular carcinoma is also the same as for hepatoblastoma. As in hepatoblastoma, surgery is the only treatment that is potentially curative. In hepatocellular carcinoma, it is particularly important to have complete resection of the primary tumor as adjuvant (i.e., postoperative) chemotherapy is not as effective. A chemotherapy regimen that is often tried is cisplatin with doxorubicin (PLADO).

Hepatocellular carcinoma patients with PRETEXT stage 1 tumors have a 44 percent five-year overall survival, whereas PRETEXT stage 4 patients have only an 8 percent five-year overall survival rate. Overall, hepatocellular carcinoma patients have a 42 percent five-year survival rate.
This compares less favorably to hepatoblastoma patients. Another important prognostic factor is the resection status of the tumor, that is, whether or not it was completely removed surgically. Complete resection is less likely in hepatocellular carcinoma compared to hepatoblastoma, possibly explaining the worse outcome in hepatocellular carcinoma patients generally. Unlike hepatoblastoma, hepatocellular carcinoma subtypes have not been shown to have different outcomes based on histology.

**Other Rare Childhood Primary Liver Cancers**

Other rarer pediatric liver cancers include uterine embryonal sarcoma of the liver (UESL) and infantile choriocarcinoma of the liver.

UESL is the third-most common liver tumor in children, comprising around 10 percent of cases. Typically, it affects children between the ages of 5 and 10. Patients tend to present with an abdominal mass, which may be painful, and vague symptoms such as fatigue.

It is usually an aggressive tumor that presents frequently with extensive local invasion and metastasis, often to the lung. Treatment is by surgery (where possible) and chemotherapy. Histopathologically, it needs to be differentiated from other tumors such as rhabdoid tumor of the liver and biliary tract rhabdomyosarcoma.

Infantile choriocarcinoma of the liver is very rare and is thought to arise from the placenta. Patients present in the first few months of life with an abdominal mass and are usually in serious condition due to a high risk of bleeding. The diagnosis can be made by a typical appearance on imaging and extremely high beta human chorionic gonadotropin levels with normal AFP. There is no need for a biopsy. Treatment is usually by chemotherapy followed by surgery. The mother may also be affected by metastases from the placenta.

Epithelioid hemangiendothelioma is a rare, low-grade malignancy of the blood vessels in the liver. Usually, symptoms include abdominal pain and weight loss. The treatment is surgical resection or transplantation, and the prognosis is generally good.

**Lombardi Comprehensive Cancer Center**

The Georgetown University Medical Center in 1970 authorized the establishment of a cancer center. The center was established with funds from the university, the federal government, and private sources. The founding director was John F. Potter, M.D. In 1974, in conjunction with Howard University, Lombardi became the 16th National Cancer Institute–designated comprehensive cancer center.
center. The facility has and continues to demonstrate significant growth in clinical and research faculty membership. Additionally, peer-reviewed funding for cancer research, treatment, education, and community outreach activities continues to increase.

The objective of Georgetown Lombardi was, and still is, to provide the most advanced treatments available to Lombardi patients and, ultimately, to find a cure for this devastating disease. The center maintains a commitment to the highest-quality patient care. In 2000, Georgetown University Hospital, in partnership with Lombardi, became part of MedStar Health, a nonprofit network of seven hospitals in the Washington, D.C., and Baltimore, Maryland, areas. This partnership ensures that patients have cutting-edge cancer care that is provided by dedicated cancer professionals in a supportive and caring setting. In addition, Georgetown Lombardi is a member of the Capital Breast Care Center (CBCC) to control the development of breast cancer. In addition, the center established a joint partnership with the University of the District of Columbia with the objective of establishing ways to increase cancer awareness and reduce cancer incidence among African Americans.

Georgetown Lombardi comprises more than 150 professionals in programs relating to breast cancer, cancer control, and molecular studies relating to the treatment of cancer at large. Recently, the center expanded its tissue-banking and clinical annotation capabilities to support systems biomedicine in collaboration with Indivumed GmbH. Also, the center launched the Georgetown Database of Cancer (G-DOC), a data integration platform and knowledge discovery system for the oncology and translational research communities.

To educate and train the leaders of tomorrow in cancer treatment and research are some of the core missions of the center. Toward this, the center has programs spanning from high school students to those with doctorates; the Tumor Biology Training Program is one of these programs.

Georgetown Lombardi treats almost every type of cancer but has emphasis on solid tumors and adult and pediatric hematologic cancers. According to the *U.S. News & World Report*, the center ranks among America’s 50 best hospitals in the area of cancer. Georgetown Lombardi offers the best advanced clinical technology and equipment, including Cyberknife, a system using radiation beams to manage tumors in the body that might have been deemed to be inoperable at one point in time.

A significant phase 1 clinical trials program brings potential new cancer therapies into the clinic; therefore, Lombardi physicians offer cancer patients access to the newest advances in cancer therapy.

The Jess and Mildred Fisher Center for Familial Cancer Research offers patients diagnosed or with a family history of hereditary cancers the opportunity to receive genetic counseling and testing.

Currently, Georgetown gets about $100 million every year in research grants. In addition, there are nearly 200 full-time faculty members, 220 ongoing clinical trials, and six established research programs. These programs include the Breast Cancer Research Program, which consists of faculty members working exclusively on finding a cure for breast cancer. This program is aligned with the Nina Hyde Center for Breast Cancer Research established in 1989 to concentrate on Lombardi’s breast cancer activities.

The Cancer Prevention and Control Program conducts research across the range of the cancer control process from risk factors and prevention through early detection to treatment and survivorship.

The Experimental Therapeutics Program is a comprehensive translational research program with the major mission of new drugs and target discoveries for cancer.

The center is credited with numerous achievements in the field of cancer in general. The Institute of Medicine (IOM) is one key group that should be explored in this particular case. Being a member of IOM is considered a high honor in the fields of health and medicine and includes participation of Lombardi researchers in the development of the human papillomavirus (HPV) vaccine and initiations of some of the first clinical trials to test anti-cancer vaccines, for example, the TRICOM vaccine.

To promote education and training in Georgetown, the center administers four master’s programs in tumor biology, health physics, and biostatistics. In addition, the center has a joint program with cancer genetics, epidemiology, and control in which a doctorate or a combined M.D. and Ph.D. in tumor biology is offered. Other scholarship opportunities
offered by the center are medical genetics fellowships, programs in the world of hematology, and end-of-life care plus tumor biology studies.

To enhance information dissemination, the center organizes a robust program of speakers and seminars that are presented by the best minds in the international cancer research field. In the same programs, the faculty, staff, and students of Lombardi are challenged and motivated. In addition, Georgetown Lombardi has several information dissemination methods in which research work on cancer is available to the public. These methods include publications, news, and media forums. Grants are made with different controls relating to social network approaches, disease risk reviews, and genetic testing needs. All solutions are designed to help review the general components that come with working in the field of solutions.

In addition to the center’s publications are the Lombardi Magazine and the annual report. Lombardi Magazine is produced twice a year for patients and their families, community members, and friends of Georgetown Lombardi Comprehensive Cancer Center. The annual report is an annual summary of the activities of the cancer center.

Lung Cancer, Non–Small Cell

There are three main types of non–small cell lung cancer (NSCLC): squamous cell carcinoma, adenocarcinoma, and large cell carcinoma. Approximately 85 to 90 percent of all lung cancers are NSCLC. The three main types are different in shape, chemical components, and size. However, prognosis and treatment for each of these is often similar. Squamous cell carcinomas account for 25 to 30 percent of all lung cancers. This cancer starts in the flat cells that line the inside airways of the lungs. Often linked to smoking, this cancer commonly is found near a bronchus in the middle of the lungs. Approximately 40 percent of all lung cancers are adenocarcinoma. This cancer starts in areas of the cells that secrete fluids like mucus. This type of cancer is found in nonsmokers, current smokers, and former smokers. More common in women, it is more likely to occur within the younger population than other forms of lung cancer. It is usually found in the outside parts of the lungs and grows slowly. This type of cancer is usually found before it has spread outside of the lungs. Because of this, people are more likely to have a better prognosis than with other forms of lung cancer. About 10 to 15 percent of lung cancers are large-cell carcinomas. This occurs anywhere in the lungs. It does tend to be difficult to treat as it spreads quickly.

Known risk factors associated with NSCLC include tobacco smoking, exposure to secondhand smoke, radon, asbestos, air pollution, personal or family history of lung cancer, exposure to arsenic in drinking water, and radiation therapy to the chest area. Smoking may account for 80 percent or more of lung cancer cases. Prior to the early 20th century, lung cancer was less common, before manufactured cigarettes. Cigars and pipes are nearly as likely to cause lung cancer. The more one smokes and the longer one smokes, the greater the chance of developing lung cancer. Living with a smoker (who smokes indoors) increases one’s risk for developing lung cancer by 20 to 30 percent. Radon naturally occurs in the environment. It is the second-leading cause of lung cancer in the United States. It is the leading cause of lung cancer in the nonsmoking population. Both smokers and nonsmokers have an increased risk of lung cancer when exposed to
Lung Cancer, Non–Small Cell

asbestos. Asbestos is found in multiple workplaces (i.e., mines, mills, textiles, shipyards, etc.). Air pollution, especially near heavy traffic areas, increases the risk of lung cancer. About 5 percent of lung cancer deaths may be from air pollution. People who have had radiation therapy to the chest area (i.e., breast cancer treatment, Hodgkin's disease treatment, etc.) have an increased risk for lung cancer as well. Lung cancer is more common in several parts of southeast Asia and South America, where arsenic in the drinking water is high. Genetic factors associated with lung cancer are being researched still. Preliminarly, changes in a chromosome have been linked to higher incidence of lung cancer, even in families who do not smoke or smoke very little.

Most of the time, lung cancers are not found until symptoms occur. Early diagnosis is linked to prognosis. The following are the most common symptoms: chronic cough (does not go away or worsens); chest pain (often worse when laughing, coughing, or deep breathing); hoarseness; loss of appetite; weight loss; blood in phlegm; shortness of breath; feeling tired; feeling weak; chronic infections (bronchitis and pneumonia); and wheezing. Once lung cancer has spread outside of the lungs, symptoms may include bone pain (hip and back); neurologic changes (headaches, weakness, numbness, dizziness, and seizures); jaundice; and lumps near the surface of the body.

If lung cancer is suspected, physicians typically start with a physical exam and a medical history. If risk factors are present, a number of tests may be conducted. Imaging tests consist of X-rays, magnetic fields, sound waves, or radioactive substances to create images of the body. A chest X-ray often is the first test ordered to look for masses or spots in the lungs. The computed tomography (CT) scan is more precise and can reveal size, shape, and position of any tumors present. It produces cross-sectional images instead of one dimensional, like a regular X-ray. A CT scan also can assist the physician during a biopsy procedure. Magnetic resonance imaging (MRI) scans are detailed like CT scans and produce images of soft tissue. An MRI is more likely to be used to look for cancer that has spread from the lungs to the spinal cord or brain. A positron emission tomography (PET) scan is useful if the physician suspects the cancer has spread from the lungs but the physician doesn't know where. PET scans are useful for the liver, bones, adrenal glands, and other organs. PET scans can reveal useful information about the whole body. A bone scan can be used to see if the cancer has moved into the bones. PET scans also can reveal this information, so a bone scan often is used to clarify or confirm information obtained.

If symptoms and any testing indicate NSCLC, the physician will utilize further tests for a definitive diagnosis. A sample of sputum (mucus coughed up from the lungs) is examined under a microscope to see if cancer cells are present. This test is referred to as sputum cytology, and typically, the sputum is collected in the morning three days in a row. A needle biopsy may be used to obtain tissue from a suspicious mass or area. Fine-needle aspiration biopsy uses a small, hollow needle, whereas core biopsies use a larger needle to remove one or more cores of tissue. Bronchoscopy uses a lighted, fiberoptic tube passed through the nose (or mouth) into the lungs. Small instruments are then moved through the tube to take samples of tissue that are then examined under a microscope. A bronchoscope also can be fitted with ultrasound to obtain internal pictures while inside the lung. This procedure is referred to as endobronchial ultrasound. An endoscopic esophageal ultrasound is the same procedure except that the images are obtained from the esophagus as the esophagus is close to lymph nodes. Therefore, this procedure can image and obtain biopsy samples if the physician suspects the cancer has spread to the lymph nodes.

There are four main treatments available after NSCLC has been found: surgery, radiation therapy, chemotherapy, and targeted therapy. Often, these treatments may be combined. The decisions regarding treatment involve the patient and the team of doctors, who may include a thoracic surgeon (a physician who uses surgery to treat diseases of the chest and lungs); a radiation oncologist (a physician who uses radiation therapy to treat cancer); a medical oncologist (a physician who uses medicine like chemotherapy to treat cancer); and a pulmonologist (a physician whose specialty is the medical treatment of lung diseases).

**Lung Cancer, Small Cell**

Small cell lung cancer (SCLC) is also known as oat cell cancer, oat cell carcinoma, and small cell undifferentiated carcinoma. It begins in the cells lining the bronchi, bronchioles, or alveoli and spreads quickly to nearby lymph nodes and the areas between the lungs and other organs, including the brain, liver, and bones. It grows and spreads fast and can form large tumors. SCLC comprises approximately 15 percent of all cases of lung cancer and is usually found in older people, with an average age of 70 at diagnosis. This cancer is usually caused by smoking and is rarely found in nonsmokers. Most cases of this aggressive, deadly cancer could be prevented if people never smoke or stop smoking. This entry describes the two types of SCLC, symptoms, exams used to diagnose it, treatment, prognosis, risk factors, and prevention.

**Types and Symptoms**

Most cases of SCLC are classified as small cell carcinomas, but some are classified as combined small cell carcinomas, which contain at least 10 percent of other cell types, often neoplastic squamous or gland cells. SCLC is described as limited-stage disease if it is found only in the chest and extensive-stage disease if it has spread beyond the chest area.

Symptoms include bloody or rust-colored sputum (phlegm and spit); chest pain that is worse with coughing, laughing, or deep breaths; a chronic cough; loss of appetite; weight loss; shortness of breath; wheezing; hoarseness; fatigue; and chronic or recurring bronchitis or pneumonia. Patients might also experience facial swelling, fever, difficulty swallowing, weakness, pain in the back or hips, headache, weakness or numbness of an arm or a leg, dizziness, balance problems, seizures, jaundice, and lumps near the skin in the neck.

SCLC tumors also can cause several associated syndromes, although these syndromes can also be caused by other things. Nerve damage caused by tumors in the upper part of the lung can cause Horner syndrome, which is characterized by severe shoulder pain, drooping or weakness in one eyelid, a small pupil in that eye, and reduced sweating on that side of the face. Tumors in the upper part of the right lung may press on the vein that brings blood back from the head and arms to the heart and result in superior vena cava syndrome. Symptoms include swelling in the face, arms, neck, and upper chest, headaches, and dizziness. Tumors can also cause hormonal imbalances including the syndrome of inappropriate antidiuresis and Cushing’s syndrome.

**Exams and Tests for Diagnosis**

SCLC might be found during a general physical exam or from a chest X-ray. Listening with a stethoscope may help detect fluid around the lungs or a partially collapsed lung. A history of smoking may also suggest lung cancer. Additional tests for identifying lung cancer or looking for its spread to other tissues include computed tomography (CT) scans of the chest and upper abdomen, endobronchial ultrasound, endoscopic esophageal ultrasound, tests of cells in the sputum or fluid from around the lungs, radionuclide bone scans, brain magnetic resonance imagings (MRIs), bone marrow aspirate or biopsy, liver function tests, or positron emission tomography (PET) with radioactive sugar. Diagnosis of the type of lung cancer is based on the appearance of cells from the sputum, fluid from around the lungs, or from a biopsy. In SCLC, the cancer cells are derived from epithelial cells and are seen as many small cells with little cytoplasm, ill-defined borders, finely granular chromatin, few or absent nucleoli, and nuclear molding (nearby nuclei appear attached).

**Treatment**

Treatment of SCLC may include surgery, radiation therapy, chemotherapy, or palliative therapy.
Chemotherapy often is used because the cancer spreads quickly throughout the body. It rarely cures the cancer, but it can often extend lifetimes for at least a few months. Radiation therapy is used to help treat the cancer, but it also can be used to treat some of the symptoms because it can cause shrinking of the tumors, help relieve breathing problems and swelling, and help relieve pain from cancer that has spread to the bones. Patients with SCLC often receive prophylactic cranial irradiation (PCI, radiation treatment to the brain) because there is a high risk that this type of cancer will spread to the brain. Surgery might involve removing part or all of a lung and nearby lymph nodes, but it is most helpful only for early-stage cancers. In most cases, surgery is less helpful because the cancer usually has spread to other tissues before diagnosis. Palliative therapy to aid in breathing for SCLC patients includes endobronchial laser therapy or brachytherapy to relieve pressure caused by tumors that are blocking or compressing the bronchi. Stents (tubes) can be inserted to help keep the airway open. Catheters can be used to remove fluid that builds up in the chest cavity around the lungs.

Prognosis
SCLC is the most aggressive form of lung cancer and often spreads to the brain, liver, adrenal glands, or bones before it is diagnosed. Median survival without treatment is only two to four months after diagnosis. Treatment might prolong life by six to 12 months, but only a small percentage of patients survive beyond five years. Some cases are found before metastasis during examination for another disease in the chest (heart disease, pneumonia, etc.), and some of those cases can be treated early enough for a cure, but even then, the cancer often relapses.

Risk Factors
At least 80 percent of all lung cancer deaths are likely to be caused by smoking. SCLC is characteristically found in heavy smokers and is rarely found in people who never smoked. The risk increases with the amount of smoking, both the number of years and the number of cigarettes per day. Secondhand smoke is also a risk factor. Exposure to radon or asbestos can also increase the risk. Genetics may also play a role, but the key factor is smoking.

Prevention
Don’t smoke. Stop smoking. Avoid secondhand smoke. SCLC is an aggressive, deadly form of cancer that can be prevented in most cases by not smoking. Avoiding radon, diesel exhaust, and air pollution also can help prevent some cases. Although decreasing smoking in developing countries could prevent many cases of SCLC there in the next few decades, the increasing number of people taking up this terrible habit in developing countries will result in a large increase of people suffering and dying from preventable lung cancers in those countries.

Further Readings
immune suppression. Studies have also proved a relationship between the degree of immunosuppression and risk of developing non-Hodgkin’s lymphoma. Most acquired immunodeficiency syndrome (AIDS)-related lymphomas (ARLs) are high-grade, aggressive, B-cell tumors. In AIDS, the incidence of non-Hodgkin’s lymphoma (NHL), primary central nervous system lymphoma, and Hodgkin’s disease are all increased. Histologically, there are three common variants of lymphoma: diffuse, large B-cell non-Hodgkin’s lymphoma; B-cell immunoblastic lymphoma; and small, non-cleaved cell lymphoma, which can be either Burkitt’s or Burkitt’s-like.

ARLs can be divided into three types according to their distribution: systemic NHL; primary central nervous system lymphoma (PCNSL); and primary effusion lymphomas (body cavity lymphoma).

**Systemic Non-Hodgkin’s Lymphoma**

Systemic Non-Hodgkin’s lymphoma is the most common type of lymphoma seen in AIDS patients, and according to some studies, its incidence is in up to 80 percent of patients. NHL is present in 1 to 3 percent of HIV seropositive people as they also have immunosuppression to an extent that results in the development of lymphoma.

There has been a decline in the incidence with today’s treatment of HIV seropositive people with Highly Active Antiretroviral Therapy (HAART). Distribution of NHL around the globe follows the geographical spread of AIDS.

**Histopathology and Pathophysiology.** Looking at the histopathology, NHL is of the following two variants: small, noncleaved cell lymphoma, which can be Burkitt’s lymphoma or Burkitt’s-like lymphoma; and diffuse, large-cell lymphoma, which includes centroblastic lymphoma, immunoblastic lymphoma, and plasmablastic lymphoma of the oral cavity.

Development of NHLs involves various pathways in molecular pathogenesis, including activation of c-myc, seen in all AIDS patients with Burkitt’s lymphoma. P53 inactivation is found in 50 to 60 percent of patients and Epstein-Barr virus (EBV) infection in 30 to 50 percent. BCL-6 proto-oncogene is present in 20 percent of patients. Mutation of other protooncogenes like PAX5, RHO/TTF, and PIM1 can also be seen commonly in NHL.

**Risk Factors.** These include race (in the United States, its incidence is lower in blacks relative to whites), sex (in people with AIDS, systemic NHL seems to occur equally in both sexes), age (in children and adolescents who are infected with HIV, NHL is the most common malignant disorder), EBV infection, homosexual behavior, and intravenous (IV) drug abuse.

**Etiology.** The exact cause of NHL is not known in most patients, but presence of several factors is considered to be its cause. These are EBV infection, human herpesvirus 8 (HHV-8) infection, continuous B-cell stimulation, and immunodeficiency.

**Signs and Symptoms.** With systemic NHL, patients may have no symptoms or may present with symptoms according to the organ involved in addition to the presence of B symptoms, which include fever, weight loss of more than 10 percent, and night sweats. Other symptoms include feeling a lump in the body, pain in the right upper quadrant, jaundice, fullness in the left upper quadrant (due to an enlarged spleen), bloating, and early satiety.

**Diagnosis.** Diagnosis includes following blood tests, imaging studies, and histopathology techniques: complete blood count; complete metabolic panel; chest X-ray; computed tomography (CT) scan; positron emission tomography (PET) scan; biopsy of a lymph node; bone marrow biopsy; and immunophenotyping and flow cytometry for cell surface markers.

**Treatment.** Chemotherapy is the cornerstone for the treatment of NHL. Chemotherapeutic options commonly used include the following:

The CHOP regimen is the standard treatment regimen for NHL. The components of CHOP include cyclophosphamide, doxorubicin, vincristine, and prednisone. Studies have shown an increased rate of remission and improved survival when CHOP is used with HAART.

Second, the components of the dose-adjusted (DA)–EPOCH regimen include etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin. These chemotherapeutic agents are used in low concentrations for prolonged periods and therefore are less toxic than the CHOP regimen. This regimen has shown complete remission in
more than 70 percent of patients and overall survival of up to 53 months. With the EPOCH regimen, due to the emetogenic potential of HAART therapy, the therapy stops until the cycles of chemotherapy are complete.

Third, CNS prophylaxis, as a prophylaxis in NHL, is the only intrathecal methotrexate administered, but if CNS involvement is already present, then combined treatment of intrathecal treatment of methotrexate, cytarabine, and hydrocortisone is recommended.

Fourth, the components of a CDE regimen are cyclophosphamide, doxorubicin, and etoposide. The CDE regimen is another well-tolerated and effective regimen that can be given concomitantly with HAART. The regimen is given by continuous infusion over four days. Complete response occurs in 44 percent of patients, with an overall survival of 43 percent at two years.

Fifth, the components of the CODOX-M/IVAC regimen are cyclophosphamide, doxorubicin, high-dose methotrexate or ifosfamide, etoposide, and high-dose cytarabine. It is given with HAART and given for the treatment of aggressive lymphomas like AIDS-related Burkitt’s lymphoma when the CD4 count is less than 100. This regimen has shown a two-year disease-free survival rate in 60 percent of patients. Finally, there is treatment of lymphomatous meningitis: This involves administration of intrathecal cytarabine, methotrexate with leucovorin rescue, and whole-brain irradiation.

**Primary Central Nervous System Lymphoma**

This is defined as lymphoma limited to the cranial–spinal axis with no systemic disease. It usually remains confined to the central nervous system and eye. Also known as primary cerebral lymphoma, it is a form of NHL that is very rare in immunocompetent people, but now its incidence is increasing in immunocompetent as well as immunocompromised people, also for unknown reasons. It constitutes 20 percent of all lymphomas seen in AIDS patients.

**Epidemiology.** Primary central nervous system lymphoma (PCNSL) has been decreasing in incidence since the advent of HAART. In general, its incidence is 1,000 times more in patients with AIDS as compared to immunocompetent individuals.

**Histology and Pathophysiology.** PCNSLs usually have immunoblastic histology with tumor cells having EBV infection along with expression of LMP-1 in almost all patients. Most of the patients with PCNSL also have BCL-6 mutation as well as high levels of the BCL-2 protein. It is usually seen in patients with very low CD4 counts and severe immunosuppression.

**Signs and Symptoms.** These include headache, diplopia, blurred vision, monocular vision loss, dysphagia, confusion, vertigo, progressive dementia, facial hypoesthesia, muscular weakness, altered mental status, personality changes, apathy, seizure, and stupor.

**Diagnosis.** In a CT scan in half of patients with AIDS, PCNSL shows ring enhancement after intravenous contrast administration. Due to the rapid growth of the tumor, there is central necrosis, which leads to irregularity of enhancement. CT scans of the chest, abdomen, and pelvis also are done to exclude systemic involvement. Magnetic resonance imaging (MRI) shows meningeal enhancement and gives the better diagnostic yield, especially when done with intravenous contrast. In polymerase chain reaction (PCR), the presence of EBV DNA in cerebrospinal fluid is highly suggestive of primary cerebral lymphoma.

**Treatment.** The main treatment of PCNSL is radiotherapy in combination with steroids, but tumors recur in more than 90 percent of patients. Still, median survival in patients with AIDS is around 3.5 months. Surgical resection of the tumor is usually ineffective because of its depth. The addition of methotrexate plus folic acid along with radiation has shown improvement in survival rates from four months up to more than three years. Combined use of methotrexate and radiation increases the risk of leukoencephalopathy and dementia in patients more than 60 years old. Newer treatments, such as high-dose chemotherapy combined with a stem cell transplant, are proving to increase survival by years.

**Prognosis.** This tumor has very bad prognosis with median survival of less than three months in untreated patients. Prognosis is better in patients with CD4 counts more than 200 and with no concurrent opportunistic infections.
Adherence to HAART therapy and response to treatment with methotrexate with or without radiation are also important factors. Poor prognosis is related to many other factors, including age more than 50 years; performance status greater than one or Karnofsky performance status less than 70; increased serum level of lactate dehydrogenase; high concentrations of protein in cerebrospinal fluid; and involvement of periventricular, basal ganglia, brain stem, and cerebellum, that is, parts other than the cerebellum.

**Primary Effusion Lymphoma**
This is a rare AIDS-related NHL as compared to systemic NHL and PCNSL. It constitutes about 4 percent of ARL. HHV-8 is found in all patients with EBV coinfection in 90 to 100 percent of patients. It involves body cavities such as the pleural space, pericardium, and peritoneum and spreads along the serous membrane.

Primary effusion lymphomas (PELs) are almost always seen in males.

**Histopathology and Pathophysiology.** PEL cells are morphologically variable with a null lymphocyte immunophenotype with human herpesvirus (HHV)-8.

It involves expression of p27K1P1 and a high proliferative index. HHV-8-encoded viral cyclins are important in the pathogenesis as they induce progression of cell cycle from G1 to S phase.

**Signs and Symptoms.** Patients typically present with fever, night sweats, weight loss, and hepatosplenomegaly.

**Treatment and Prognosis.** There are no specific guidelines for PEL treatment. It is usually treated with combination CHOP and HAART. It has a very bad prognosis, with a median survival of three to six months.

**Complications Related to AIDS-Related Lymphomas**
Patients may develop complications related to ARLs or as a result of treatment. These include the following: bone marrow suppression leading to anemia, neutropenia, or thrombocytopenia; repeated infections due to neutropenia; pleural and pericardial effusions; superior vena cava syndrome; tumor lysis syndrome; and focal neurologic signs secondary to PCNSL, vertebral, or spinal masses. Additionally, tumors in the gastrointestinal tract may cause bleeding, obstruction, or perforation.

**Lymphoma, Burkitt’s**

Lymphomas are malignancy of lymphocytes, which are immune cells resulting in impaired immunity and increased risk of infection as lymphocytes help the body to fight against infection. There are two types of lymphomas; Hodgkin's and non-Hodgkin's lymphoma, mainly differentiated from each other by the presence of Reed–Sternberg cells. Burkitt’s lymphoma is a form of non-Hodgkin's B-cell lymphoma and was first discovered in Africa in 1958 by a British surgeon, Denis Parsons Burkitt. It is
also known as small, noncleaved cell lymphoma. It is relatively rare but one of the most destructive of all human malignancies in most of the world. It develops very rapidly and becomes fatal within a few months; therefore, prompt diagnosis and treatment are very important.

**Epidemiology**
Burkitt’s lymphoma is most common in children living in sub-Saharan Africa, where it is related to the Epstein–Barr virus (EBV) infection and chronic malaria. Burkitt’s lymphoma is also seen elsewhere, including the United States, and in these places, it is most likely to occur in people who have a compromised immune system or chromosomal defects. Increase in age also has a negative impact on prognosis. Burkitt’s lymphoma is more common in people infected with human immunodeficiency virus (HIV), and before worldwide use of highly active antiretroviral therapy (HAART), the incidence of Burkitt’s lymphoma was around 1,000 times more in HIV-positive people than in the general population. The North American form of Burkitt’s lymphoma is not linked to EBV.

**Pathophysiology**
It is characterized by the translocation and deregulation of the c-myc gene on chromosome 8, resulting in uncontrolled growth of B lymphocytes.

**Types of Burkitt’s Lymphoma**
In the World Health Organization classification, there are three types of Burkitt’s lymphoma:

- **Endemic Burkitt’s lymphoma** primarily affects African children mostly of four to seven years and is twice as common in boys as in girls. It is common in malaria-endemic regions of the world (e.g., equatorial Africa, Brazil, and Papua New Guinea). EBV infection is present in nearly all patients with Burkitt’s lymphoma. It is believed that chronic malaria decreases resistance to EBV. The disease usually involves jaw or other facial bones but can also affect the distal ileum, cecum, ovaries, kidney, or breast.

- **Sporadic Burkitt’s lymphoma** occurs worldwide and is the most common variant found in places where malaria is not very common. Sporadic lymphomas are rarely associated with EBV infection. Globally, the sporadic variant is 1 to 2 percent of adult lymphoma cases, while in the United States and western Europe, it accounts for up to 40 percent of pediatric lymphoma cases. The tumor cells have a similar appearance to the cancer cells of classical endemic Burkitt’s lymphoma. The common site involved is the ileocecal region, whereas the jaw is less commonly affected.

- **Immunodeficiency-associated variant** of Burkitt’s lymphoma is more commonly found in people with HIV/autoimmune deficiency syndrome (AIDS). It accounts for 30 to 40 percent of non-Hodgkin’s lymphoma in HIV patients and may be an AIDS-defining disease. It also can occur in people with congenital conditions that cause immune deficiency and in the setting of post-transplant patients who are taking immunosuppressive drugs.

Compared to the endemic type, the incidence of EBV infection is considerably lower in the other two types of Burkitt’s lymphoma. In the sporadic disease, EBV infection occurs in about 20 percent of the patients, while in the immunodeficiency-associated type, it occurs in about 30 to 40 percent.

**Symptoms**
The symptoms of Burkitt’s lymphoma depend on the type. The endemic (African) variant usually starts as tumors of the jaw or other facial bones.
It also can affect body organs and can spread to the central nervous system, causing nerve damage, weakness, and leg paralysis. Burkitt’s lymphoma may be noticed first as a swelling of the lymph nodes (glands) in the neck, groin, or under the arm. These swollen lymph nodes are most of the time painless but can grow very quickly.

The types more frequently seen in the United States—sporadic and immunodeficiency-associated—typically start in the bowel and form a massive tumor bulk in the abdomen, often with enormous involvement of the liver, spleen, and bone marrow. Patients with more than 25 percent bone marrow involvement are usually said to have Burkitt’s leukemia. These variants also can start in the ovaries, testes, or other organs and spread to the brain and spinal fluid. Symptoms associated with Burkitt’s lymphoma include the following:

- Loss of appetite
- Unexplained weight loss
- Fatigue
- Night sweats
- Unexplained fever
- Nausea and vomiting
- Change in bowel habits
- Abdominal pain
- Gastrointestinal bleeding
- Mass in the upper or lower jaw
- Headaches
- Vision problems due to cranial nerve involvement
- Paralysis of the legs and lower half of the body
- Painless lymph node enlargement

**Diagnosis**

As Burkitt’s lymphoma spreads rapidly, immediate diagnosis is essential in case of a patient presenting with suspicious signs and symptoms. Whole or part of an enlarged lymph node or other disease site is biopsied, which usually confirms or rules out Burkitt’s lymphoma. Additional tests for staging of the disease are done quickly to look for any life-threatening complications from the rapid tumor growth, and these tests may include the following:

- Complete blood count (CBC) with differential
- Coagulation studies
- Serum levels of electrolytes and uric acid
- Serum creatinine, lactate dehydrogenase (LDH), and beta 2 microglobulin levels
- Chest X-ray
- Computed tomographic (CT) imaging of the chest, abdomen, and pelvis
- Magnetic resonance imaging (MRI) of the head and spinal cord
- Positron emission tomography (PET) or gallium scan
- Bone marrow aspiration and biopsy
- Echocardiogram
- Examination of spinal fluid
- Kidney function test
- Liver function test
- Testing for HIV disease and hepatitis B
- Cytogenic studies
- Flow cytometry

**Complications**

Complications of the disease include metastasis (spread of the cancer) to various body organs such as the liver, spleen, bone marrow, ovaries, testes, and spinal fluid. Bone marrow and the central nervous system are considered as medical emergencies and require immediate diagnostic and therapeutic intervention.

Renal failure due to retroperitoneal disease and renal involvement are also problems, sometimes as a result of tumor lysis syndrome. Intestinal perforation is another possible complication.

Complications and side effects of radiation therapy or chemotherapy include the following:

- Anorexia
- Aplastic anemia
- Low platelet count
- Low white blood cell count
- Increased risk of infection
- Constipation and diarrhea
- Hair loss
- Mouth sores (mucositis), nausea and vomiting
- Weakness and fatigue

**Treatment**

Burkitt’s lymphoma is treated mainly with chemotherapy, which can be high dose in a short duration or long duration or in combination with other therapeutic options.
For intensive intravenous chemotherapy treatment, it is preferred if the patient stays in the hospital. As Burkitt's lymphoma can spread to the fluid surrounding the brain and spinal cord, chemotherapeutic drugs also may be injected directly into the cerebrospinal fluid, a treatment known as intrathecal chemotherapy. Examples of chemotherapeutic medicines that may be used in various combinations for Burkitt's lymphoma include cyclophosphamide (Cytoxan), cytarabine (Cytosar-U of Tarabine PFS), doxorubican (Adriamycin), etoposide (Etopophos, Toposar, and VePesid), methotrexate (Rheumatrex), and vincristine (Oncovin).

**Combination Therapies**
Intensive chemotherapy is used in combination with the monoclonal antibody rituximab (Rituxan), which sticks to proteins on cancer cells, causing the immune system to attack cancer cells; urate-oxidase enzymes (e.g., rasburicase); autologous stem cell transplantation, in which the patient’s stem cells are removed, stored, and returned to the body; radiation therapy; and steroid therapy. In some cases, surgery may be needed to remove parts of the intestine that are blocked, bleeding, or ruptured.

**Supportive Therapies**
Intravenous antibiotics are used for the treatment of neutropenic fevers. Growth factors also are given like granulocyte-macrophage colony stimulating factor to help with neutropenia. Prophylactic allopurinol and aggressive hydration with urine alkalization may prevent tumor lysis syndrome and uric acid nephropathy during chemotherapy. Other supportive therapies include platelets transfusion in case of thrombocytopenia and irradiated and leukodepleted red cell transfusion.

**Prognosis**
In children, prompt intensive chemotherapy usually cures Burkitt’s lymphoma, leading to long-term survival rates of 60 to 90 percent. In adult patients, results are more variable. Overall, prompt treatment is associated with long-term survival rates of 70 to 80 percent.

Prognosis mainly depends on the spread of lymphoma, response to treatment, and incidence of relapse. Survival may be less if it has already involved bone marrow or spinal fluid. Most of the relapses occur during the first year of treatment, but in a few patients, especially those with HIV infection, delayed relapses have also been reported. Failure to achieve complete remission is the worst prognostic sign. Most of the patients with relapse are usually treated with salvage therapy involving chemotherapeutic agents named DHAP (dexamethasone, cytarabine, cisplatin). Very few patients show response to salvage therapy and, in them, it is followed by high-dose chemotherapy treatment and bone marrow transplantation or autologous stem cell transplantation. Patients with no response to chemotherapy are managed with supportive care.

**Lymphoma, Hodgkin’s, Adult**

More than half of the cases of Hodgkin’s lymphoma in the United States involve individuals below the age of 35, making it the most common neoplasm affecting young adults, and the third leading cancer with the highest mortality. Improvements in treatment
options have significantly decreased the mortality rate of Hodgkin's lymphoma, including the five-year survival rate, which has been estimated to be at least 80 percent, and the cure rate calculated as more than 75 percent. Hodgkin's lymphoma is considered as the most favorable malignancy because of the availability of effective treatment options and higher survival rates, although these outcomes also increase the risk of recurrence as these cancer survivors live longer.

Applying state-of-the-art therapy, as well as regularly monitoring the condition of the patient after treatment could decrease the risks of recurrence of Hodgkin's lymphoma. These activities entail hospital visits, which could vary in frequency depending on the details of the patient's socioeconomic status, educational background, and income. Previous reports have shown that the outcomes of Hodgkin's lymphoma patients after treatment are generally poorer among individuals of lower socioeconomic status or those of non-white ethnicity.

According to Simone Oerlemans and colleagues, survivors of Hodgkin's lymphoma are at a higher risk of experiencing severe physical as well as psychosocial effects after cancer treatment; this in turn influences their quality of life. Social factors include the development of fatigue and mental depression; these survivors could also experience problems with their marriage or infertility. In terms of financial problems, survivors of Hodgkin's lymphoma often have to face issues with insurance and mortgages after completing cancer treatment.

Interestingly, the report of Simone Oerlemans et al. described that survivors of Hodgkin's lymphoma who underwent a combination of chemotherapy and irradiation were at higher risk of experiencing a worse quality of life. Their report showed that these survivors often develop additional conditions that render their posttreatment lives less comfortable, which include dyspnea, diarrhea, pain, and emotional instability. In addition, their study also showed that older adults and female patients with Hodgkin's lymphoma are more likely to experience worse quality of life after cancer treatment.

A research team led by Erlyn Smith conducted a study that assessed the relationship between socioeconomic characteristics and the risk for advanced stages of Hodgkin's lymphoma among adolescents and young adults. By reviewing the cases listed in the California Cancer Registry, the study identified a total of 7,343 cases of Hodgkin's lymphoma among patients from 15 to 40 years old. The results of the study showed that advanced stages of Hodgkin's lymphoma were more common among male adolescents and young adults than their female counterparts. There was also a higher incidence of Hodgkin's lymphoma among foreign-born patients compared to those who were born and raised in the United States.

The study also showed that there were more Hodgkin's lymphoma patients who were single than those who were married. In terms of financial situation, individuals of lower socioeconomic status were more likely to present with advanced stages of the malignancy upon medical consultation. There were also more Hodgkin's lymphoma patients without insurance coverage than those with insurance coverage. These findings thus indicate that insurance and other cost-related issues played critical roles in the frequency and likelihood that an individual would undergo screening for Hodgkin's lymphoma at an earlier time.

For individuals who have no insurance coverage, visiting a physician or requesting a screening test for Hodgkin's lymphoma was therefore highly unlikely because of the expenditures that these entail. Further delay in screening thus results in a later diagnosis of Hodgkin's disease at a more advanced stage. It is also important to note that when a patient is diagnosed with an advanced stage of Hodgkin's lymphoma, the treatment scheme that would be utilized for this particular patient would be more intense and aggressive than patients with early stages of the disease. In addition, more intense and aggressive treatments are much more expensive than the simpler treatment regimens for early stages of Hodgkin's lymphoma.

Socioeconomic profiling of Hodgkin's lymphoma in adults often identifies the major issues that need to be resolved in terms of providing health care to the general public. Previous reports have shown that age range of 18 to 34 years is associated with the highest number of individuals who have no health insurance. This finding supports the idea that better health plans need to be developed for this particular age-group in order to help decrease the risk of having Hodgkin's lymphoma that goes undetected.

Another possible explanation for the correlation between advanced Hodgkin's lymphoma and the age range of 18 to 34 years is that these individuals might have health insurance, yet screening tests
for this specific neoplasm or possibly any other type of cancer may not be covered by their insurance. This scenario is therefore as serious as not having health insurance because it still prevents an adult from seeking medical attention at a time when the first few symptoms appear. For example, individuals with Medicaid coverage generally experience the same financial difficulty in getting support to undergo various screening tests for Hodgkin’s lymphoma as the uninsured. These individuals therefore hesitate in consulting a physician because of their inability to pay the corresponding medical fees. There are also some analysts who wonder whether being uninsured and underinsured are the same in terms of receiving coverage for chronic diseases such as Hodgkin’s lymphoma.

An inverse correlation between socioeconomic status and the risk for receiving a diagnosis of Hodgkin’s lymphoma has been reported by several independent research studies. Individuals of low socioeconomic status are thus more likely to develop Hodgkin’s lymphoma, and by the time they have undergone testing, a more advanced stage of the malignancy is often detected. A similar correlation has also been reported between the survival of patients diagnosed with Hodgkin’s lymphoma, wherein individuals of higher socioeconomic levels have a greater chance of surviving the disease because they are well supported by their health insurance. These relationships may thus be useful in developing health care programs that would assist in conducting early diagnostic screening of patients as a preventive measure against Hodgkin’s lymphoma.

Lymphoma, Hodgkin’s, Childhood

The majority of Hodgkin’s lymphoma cases are curable, often achieving remission after receiving treatment with multi-agent chemotherapy either in combination with irradiation or not. In patients with recurrent or refractory Hodgkin’s lymphoma, the use of salvage therapy results in long-term survival, ranging from 25 percent to 90 percent, depending on the influence of a number of risk factors. According to the 2009 guidelines on surveillance imaging issued by the National Comprehensive Cancer Network (NCCN), routine monitoring of Hodgkin’s lymphoma patients should be conducted during their first remission. However, the optimal approach in conducting the surveillance to detect the recurrence of Hodgkin’s lymphoma has not been established.

The general procedure in staging and in assessing the response of a patient with Hodgkin’s lymphoma to treatment is by conducting positron emission tomography (PET) using F-18-fluorodeoxyglucose (FDG), which is then often coupled with computed tomography (CT). Although this approach has been performed for several decades, its role and significance in the surveillance of patients with Hodgkin’s lymphoma during complete remission remains uncertain. In response to this dilemma, the NCCN has recently opposed the application of PET scans in patient surveillance, particularly when a number of reports have described the occurrence of false-positive radiographic findings. Although further studies validating the use of PET scans in patient surveillance are
warranted, this technique remains very useful in identifying most diseases at their earliest stages of progression. Surveillance radiography also entails additional expenditures as well as further exposure to radiation, not to mention referrals to specialists and the induction of anxiety in the patient and his or her immediate family.

A similar dilemma is also affecting pediatric patients with Hodgkin's lymphoma. Although the majority of pediatric Hodgkin's lymphoma cases are also curable, there is a growing concern regarding the risks of developing cancer due to exposure to radiation during diagnosis and treatment of the disease. There are also reports that have assessed the risk of developing secondary malignancies due to irradiation treatment. The typical surveillance schedule for a pediatric patient with Hodgkin's lymphoma involves imaging every three to five months during the first two years of remission, followed by yearly imaging for the next three to four years, depending on the patient's risk of disease recurrence.

Given the intensity of the irradiation dose that is generally used for imaging, and the expected growth and development that a child would still have to go through, it is therefore imperative to determine whether multiple exposures to posttreatment irradiation for surveillance is worthwhile. For families of pediatric cases with limited financial resources, surveillance imaging can be both a health hazard and an economic burden.

To address the dilemma regarding the safety of irradiation during surveillance imaging of Hodgkin's lymphoma cases during complete remission, estimations of the applied irradiation dose on specific organs as well as tissues could be performed. This allows the generation of a weighted sum of irradiation disease based on the sensitivity of the target organ and the rest of the neighboring organs that could be incidentally exposed during imaging. In a study conducted by S. C. Chawla and colleagues, a total of 248 pediatric patients with Hodgkin's lymphoma were retrospectively assessed in terms of the effective dose of radiation that has been applied during surveillance imaging.

The study showed that each pediatric patient received an average of 3.2 PET/CT scans for the disease, starting from the diagnosis to treatment. In addition, the average effective dose of each pediatric patient during a CT scan was 20.3 mSv, whereas for PET, the effective dose was 4.6 mSv and for PET/CT, 24.8 mSv. The total radiation dose that each pediatric patient received from the entire treatment scheme was 64.4 mSv using CT imaging, 14.5 mSv using PT imaging, and 78.9 mSv using PET/CT scans. Although these values show that CT scans utilize higher doses of irradiation, be it used as a single technique or in combination with PET, it is still possible that these estimations might reflect uncertainties because of the inter-individual variations in response to irradiation and chemotherapeutic drugs.

In order to more extensively assess the impact of surveillance imaging on pediatric patients with Hodgkin's lymphoma, a study led by Neha Rathore et al. investigated the radiation dosage employed in monitoring tests at their institution from 2000 to 2010. This prospective study identified a total of 99 pediatric patients that underwent therapy for Hodgkin’s lymphoma. Their records showed that during the first two years after therapy, pediatric patients who were determined to be in remission were subjected to an average of 11 surveillance tests, which ranged from 0 to 26.

Of the 99 pediatric patients included in the study, 13 had relapses, 11 of which occurred during the first five months after completion of treatment. Interestingly, the use of chest radiographs and CT and PET scans of the abdomen and pelvic region did not result in the identification of relapsed cases among the pediatric patients with Hodgkin's lymphoma. On the other hand, chest and neck CT scans, as well as chest and neck PET/CT scans resulted in the detection of relapsed Hodgkin's lymphoma.

Their study thus showed that only 17 scans out of a total of 1,358 resulted in the detection of a relapse. Based on this data, the proponents of the study concluded that surveillance monitoring could be ineffective in detecting relapse in Hodgkin's lymphoma, thus requiring a new method of monitoring disease recurrence in patients who have achieved complete remission. The results of the study also indicated that pediatric patients might be spending more than what is necessary, based on the findings that only approximately 1 percent of the imaging tests positively detected the recurrence of the disease. It is also possible that the low rate of detection of relapse might be due to the high cure rate of the treatment regimens, thus requiring less
imaging after multi-agent chemotherapy and radiation treatment. If the number of surveillance imaging tests were decreased, patients with Hodgkin's lymphoma would have a lower risk of developing a secondary malignancy due to the constant exposure to ionizing radiation.

Lymphoma, Hodgkin’s, During Pregnancy

One of the most challenging scenarios involving Hodgkin’s lymphoma is defining the appropriate treatment regimen when the patient is pregnant. In past decades, Hodgkin’s lymphoma has been considered as a highly curable neoplasm that is generally treated using both chemotherapy and irradiation. Reports have shown that this treatment approach results in a high (approximately 87 percent) progression-free survival rate, even in the most unfavorable stages. The treatment also results in long-term survival, thus allowing young patients to experience and enjoy several more years of their lives, hopefully without having to deal with a relapse or recurrence of the disorder.

The optimal approach in treating a pregnant patient who has been diagnosed with Hodgkin’s lymphoma remains elusive, although some reports have been published in past decades that describe the effects of specific treatment settings on pregnancy and other pregnancy-related issues. To date, there are less than 20 reports that have specifically described the pregnancy outcomes and survival of pregnant Hodgkin’s lymphoma patients; these consist of case reports, case series, and case-controlled studies.

A review of the case reports shows that, as long as the treatment for Hodgkin’s lymphoma is conducted during the early stages of gestation, it is possible for the developing fetus to progress until full term and potentially be born without any gross morphological or anatomical abnormalities. These case reports describe pregnant patients who were diagnosed with Hodgkin’s lymphoma to have received either single-agent treatment or combination therapy. For single-agent treatment case reports, these generally involved the use of vinblastine during the first trimester, which resulted in either normal fetal development as well as a favorable response to the administered drug or the occurrence of fetal syndactyly or the fusion of two or more fingers or toes.

There are also case reports of combination therapies for pregnant women diagnosed with Hodgkin’s lymphoma. These treatments could consist of vinblastine that is administered in the second trimester (as Hodgkin’s lymphoma was diagnosed during that period) and subsequently with cyclophosphamide, which has been reported to result in a partial remission of Hodgkin’s lymphoma and the birth of a healthy full-term infant; however, the mother eventually progressed with the malignancy. Another case report has described the use of procarbazine and chlorambucil during the first trimester, which then resulted in normal fetal development. There is also another case report that utilized the combination of mechlorethamine, vincristine, procarbazine, and prednisone, which is collectively known as the MOPP treatment.

Case series reports generally present the findings of several cases that have been treated with the same medications for a specific disease. Hodgkin’s lymphoma case series reports show a spectrum of outcomes in relation to the options and outcomes of treatment for Hodgkin’s lymphoma during
pregnancy, ranging from a series showing spontaneous abortions and fetal malformations after MOPP treatment, or a combination of cyclophosphamide with irradiation, to normal, healthy infants after treatment with a combination of doxorubicin, bleomycin, vinblastine, and dacarbazine, which is also known as the ABVD treatment.

There are also case series reports that describe positive infant outcomes after treatment of pregnant Hodgkin’s lymphoma patients with COPP, MOPP, or a combination of MOPP and vinblastine during the last two trimesters. Another case series report that included newly diagnosed and relapsed pregnant patients with Hodgkin’s lymphoma of varying stages (stages I to III) showed complete remissions after irradiation during the 10th to the 30th week of gestation as well as patients that experienced a recurrence of the neoplasm after irradiation. Other pregnant patients decided on undergoing therapeutic abortion, whereas others deferred their therapy until their children were born. It is also possible for a pregnant patient with Hodgkin’s lymphoma to deliver a healthy infant while undergoing chemotherapy. Similarly, there are also case series reports that include patients who conceived while undergoing chemotherapy for Hodgkin’s lymphoma.

Unfortunately, there are very few case-controlled reports on concomitant pregnancy and Hodgkin’s lymphoma. One report consisted of a total of 21 patients that were treated with MOPP, irradiation, or both, which were then compared to 155 age-matched and stage-matched women who were not pregnant yet and were also diagnosed with Hodgkin’s lymphoma. Interestingly, the results showed that the long-term survival of patients belonging to both groups were similar. Another report that included 48 pregnant Hodgkin’s lymphoma patients and stage-matched, age-matched, and year of treatment-matched controls also showed similar long-term survival.

In a recent case-control study that investigated the fertility as well as gonadal function of female patients who underwent treatment for Hodgkin’s lymphoma, two cycles of ABVD in combination with gonadotropin-releasing hormone did not compromise the fertility of female patients of ages less than 45 years old. This finding was based on the observations gathered from measurements of hormone levels, symptoms of menopause, parameters that indicate the preservation of fertility, length and characteristics of the menstrual cycle, number of pregnancies, and number of children.

Based on this limited number of reports describing the outcomes of treatment of pregnant patients with Hodgkin’s lymphoma, it is therefore imperative that additional studies should be conducted to establish the effects of specific schemes on fetal development. Another component that also requires attention is whether a specific treatment for Hodgkin’s lymphoma remains as effective as that observed in a nonpregnant patient, be it a female or male. It is possible that other factors may also influence the success of every treatment plan, yet it is also important to determine the molecular mechanisms behind the success or failure of a specific treatment during pregnancy.

The ABVD treatment scheme seems to be safe when administered at any trimester, although the number of reports in the literature is limited, suggesting that moderate degrees of toxicity in the developing fetus might have gone undetected. It is therefore critical that additional data on patients with Hodgkin’s lymphoma who elected to proceed with their pregnancies be collected in order to generate more robust conclusions. It has been suggested that a central registry in which children who have been born to a parent with Hodgkin’s lymphoma be established to capture the details of the long-term effects of concomitant pregnancy and Hodgkin’s lymphoma.

Lymphoma, Non-Hodgkin’s, Adult

Non-Hodgkin's lymphomas (NHLs) are noncommunicable cancers of white blood cells (lymphocytes), affecting either B or T cells. These immune cells become abnormal, dividing uncontrollably, and fail to protect the body from disease. Eventually, these cells form tumors. Because lymphocytes are found throughout the body, NHL can start almost anywhere, especially in the lymph nodes. NHL can occur at any age and is often marked by enlarged lymph nodes, fever, and weight loss. NHLs are classified into fast-growing, aggressive types or slow-growing, indolent types. In 2014, the National Institutes of Health estimated 70,800 new cases and 18,990 deaths from NHL in the United States.

Types of NHL
NHLs are categorized by how quickly they grow. Indolent NHL grows slowly and tends to cause few symptoms. Aggressive NHL grows and spreads more quickly, and tends to cause severe symptoms. Over time, many indolent lymphomas become aggressive lymphomas. NHL starts in infection-fighting immune cells. B cell NHL includes Burkitt’s lymphoma, chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), diffuse large B cell lymphoma, follicular lymphoma, immunoblastic large cell lymphoma, mantle cell lymphoma, and precursor B lymphoblastic lymphoma. T cell NHL includes anaplastic large cell lymphoma, mycosis fungoides, and precursor T lymphoblastic lymphoma.

Risk Factors Associated With NHL
The specific causes of NHL are not completely clear and more research is needed. However, research shows that the following risk factors are associated with NHL: (1) a weakened immune system (such as an inherited immune disorder, an autoimmune disease, or use of immunosuppressive drugs following organ transplantation); (2) having certain types of infections such as human immunodeficiency virus (HIV), Epstein-Barr virus (EBV), Human T-cell leukemia/lymphoma virus type 1 (HTLV-1), hepatitis C virus (HCV), and the bacterium Helicobacter pylori; (3) celiac disease in which gluten intake results in an immune reaction; (4) age: although NHL can occur at any age, the propensity increases with age, with the majority affected being older than 60; (5) obesity; and (6) exposure to herbicides and other chemicals.

Signs and Symptoms of NHL
People affected by NHL might experience the following symptoms: coughing, trouble breathing, or chest pain; fever, pain, swelling, or abdominal feeling of fullness; soaking night sweats; swollen, painless lymph nodes in the neck, armpits, or groin; unexplained weight loss; and weakness and tiredness that do not go away. People experiencing these symptoms for longer than two weeks should see a doctor.

Diagnosis of NHL
A person with swollen lymph nodes or other symptoms associated with NHL should seek medical care immediately. A doctor can assess your personal and family medical history as well as perform the following exams and tests: (a) a physical exam for swollen lymph nodes, spleen, and/or liver; (b) blood or urine tests for presence and amounts of certain antibodies and number of white blood cells, as well as check for other cells and substances, such as lactate dehydrogenase (LDH); (c) chest X-rays or computerized tomography (CT scan) to search for signs of cancer; and (d) lymph node biopsy, performed by removing either an entire lymph node (excisional biopsy) or part of a lymph node (incisional biopsy). Since NHL usually starts in a lymph node, a lymph node biopsy is a significant conclusive way to diagnose it. From the lymph nodes, NHL can spread to other organs (such as the liver, lungs, bone, and bone marrow).

Staging of Non-Hodgkin’s Lymphoma
To establish the best treatment, a doctor determines NHL disease stage and severity. Such determinations may require a bone marrow biopsy or a spinal tap, tests that will identify potential presence of lymphoma cells in these tissues. Medical imaging technology (such as a CT scan, a magnetic resonance imaging [MRI] scan, ultrasound, or a positron-emission tomography [PET] scan) allows doctors to visualize a person's head, neck, chest, abdomen, or pelvis as well as lymph nodes, spleen, and liver for nucleus lentiformis mesencephali (nLM) cells. The prognostic group depends on which tissues contain cancer cells and how many different types of tissues are affected. If NHL is found outside the lymph nodes, the letter E (for extranodal disease)
is added. Additional notation is included if specific sites appear to be affected (such as H for liver, M for bone marrow, and others).

- **Stage I**: The NHL is in one lymph node group (Stage I), or is found only in one area of a single organ outside of the lymph system (Stage IE).
- **Stage II**: The NHL is found in two lymph node groups on the same side of the diaphragm (Stage II), or extends from a single group of lymph nodes into a nearby organ (Stage IIE).
- **Stage III**: The NHL is found in lymph nodes above and below the diaphragm (Stage III) or it may also have spread into an area or organ next to the lymph nodes (Stage IIIIE), into the spleen (Stage IIIS), or both (Stage IIISE).
- **Stage IV**: NHL is found in several parts of one or more organs or tissues, including lymph nodes, the liver, blood, or bone marrow.

The letters A or B are also added to describe disease symptoms.

- A: the patient does not have drenching night sweats, fevers, or weight loss.
- B: the patient has drenching night sweats, fevers, or weight loss.

**Prognosis and Treatment Strategies**
Immediate treatment is recommended because delay in treatment decreases prognosis. Chance of survival and treatment options mainly depends on the type of NHL, its stage, age and general health of the patient, growth, amount of LDH in the blood, or whether NHL is initially or recurrently diagnosed. Asymptomatic patients with indolent NHL may not require immediate treatment. Health is closely monitored (watchful waiting) and treatment is initiated when symptoms begin. A symptomatic patient with indolent NHL receives chemotherapy and biological therapy. Radiation therapy may be used for patients with Stage I or Stage II NHL. A patient with aggressive NHL is treated with chemotherapy and biological therapy. Radiation therapy may be used too. NHL that returns after treatment is relapse or recurrence. Relapse patients are treated with high doses of chemotherapy, radiation therapy, or both, followed by stem cell transplantation.

**Lymphoma, Non-Hodgkin’s, Childhood**

Non-Hodgkin’s lymphoma (NHL), or lymphoma in children, is a term for cancers of the lymphatic or lymphoid system. The lymphoid system is part of the immune system that protects the body from infections. B and T lymphocyte cells are found in lymph glands, the spleen, the tonsils, adenoids, and many other organs and tissues. In lymphoma it is B and T lymphocyte cells that are malignant.

There are more than a dozen types of NHL. The four most common types in children are Burkitt’s lymphoma, and diffuse large B-cell lymphoma, lymphoblastic lymphoma, and anaplastic large cell
Lymphoma, Non-Hodgkin’s, Childhood

There are other types of lymphoma that occur in children, which include lymphoproliferative disease and rare NHL. NHL accounts for about 7 percent of childhood cancer, with about 800 children and adolescents diagnosed in the United States every year. About twice as many boys as girls are diagnosed with a type of NHL.

Most causes of NHL are unknown, but it is known that B and T lymphocytes are prone to making mistakes or developing variations or mutations. Sometimes mutations can lead to new cells multiplying without older cells dying off, as is the normal process. These lymphocytes can grow locally in lymph nodes or tonsils or spread to distant sites in the body through the bloodstream or lymph vessels.

The following symptoms and signs may be caused by childhood NHL: trouble breathing; wheezing; coughing; high-pitched breathing sounds; swelling of the head, neck, upper body, or arms; trouble swallowing; painless swelling of the lymph nodes in the neck, underarms, stomach, or groin; a painless lump or swelling in the testicles; fever for no known reason; and weight loss for no known reason; and night sweats.

Clinicians use several tests to determine if a child has lymphoma. These tests include a physical and history, and biopsy. Biopsy may include an excisional biopsy for removal of an entire lymph node or lump of tissue, an incisional biopsy for removal of part of a lump, lymph node, or sample of tissue, a core biopsy with a wide needle or a fine-needle aspiration (FNA) biopsy. Also common is a bone marrow aspiration and biopsy or the removal of bone marrow, blood, and a small piece of bone by inserting a hollow needle. In children the needle is usually inserted in the hipbone rather than the breastbone.

Several factors affect prognosis and treatment options in childhood NHL. These factors include the age of the child, the type of lymphoma, the stage of the cancer, the number of places outside of the lymph nodes to which the cancer has spread, and whether the lymphoma has spread to the bone marrow or central nervous system. Other key factors include whether there are certain changes in the chromosomes, the type of initial treatment, whether the lymphoma responds to the initial treatment, and the child’s overall health.

After childhood NHL as been diagnosed, other tests are done to determine the stage of the disease. Stages I through IV, as in other cancers, are used as a determination. Childhood NHL is also described as either low-stage or high-stage. Treatment for childhood NHL is based on whether the cancer is low-stage or high-stage. Low-stage childhood NHL has not spread beyond the area in which it began. High-stage lymphoma has spread beyond the area in which it began. Stage I and stage II are usually considered low-stage and stage III and stage IV are usually considered high-stage.

Today referring pediatricians usually counsel parents to enroll their child in a clinical trial in which the standard treatment is one arm of a trial randomized with one to three arms which have different combinations or dose schedules. Most children are first enrolled in a phase III trial as part of the Children’s Oncology Group. A team of doctors and medical social staff are crucial as a team in treating a child or adolescent with childhood NHL. These team members usually include a pediatric hematologist/oncologist, a radiation oncologist, a pediatric surgeon, pediatric oncology nurses, social workers, and psychologists.

Four types of standard treatment are currently used in childhood NHL: chemotherapy, radiation therapy (in some patients), high-dose chemotherapy with stem cell transplant, and targeted therapy.

Cancer treatments for childhood NHL cause side effects months or even years after treatment has ended. These include physical problems, changes in learning, memory, thinking, and second or new types of cancers. In particular, girls who received radiation to the chest for childhood NHL are at much greater risk for breast cancer at an earlier age. For children with recurrent childhood NHL there is no standard treatment. Options usually include a different combination of chemotherapy, target therapy (kinase inhibitor or tyrosine kinase inhibitor), or high-dose chemotherapy with stem cell transplant.

The history of treatment of non-Hodgkin’s lymphoma in children has benefitted from the development of treatment of childhood acute lymphoblastic leukemia, which it is somewhat related. Some of the same chemotherapy drugs are used although surgery and radiation are usually key elements of treatment. Because it is a rare cancer among childhood cancers in general, it has been difficult to accrue many patients into clinical trials to test therapies. In the last 40 years the survival rate has increased over time for NHL in children from 45 percent to 88 percent in children younger than 15 years, and from 47 percent
Lymphoma, Non-Hodgkin’s, During Pregnancy

Hodgkin’s lymphoma is considered the most common hematologic neoplasm that occurs in pregnant women; reports show that its incidence rate ranges from 1:1,000 to 1:6,000. On the other hand, non-Hodgkin’s lymphoma rarely occurs during pregnancy, and its incidence has been estimated at 0.8 cases in every 100,000. This significantly low rate of occurrence when compared to females in the general population could be attributable to the hormone therapy conducted in the treatment of this particular disease. The exposure of a non-Hodgkin’s lymphoma patient to reproductive hormones in the course of gestation may enhance the immune system’s responses, which in turn decreases the risk of developing non-Hodgkin’s lymphoma.

Lymphoma development during pregnancy often occurs at an average of 24 weeks during gestation, and this has generally resulted in positive patient outcomes, with very small chances of experiencing maternal, as well as fetal complications. A variant of diffuse large B-cell lymphoma and accounting for approximately 2.5 percent of non-Hodgkin’s lymphomas is primary mediastinal large B-cell lymphoma. Interestingly, this condition occurs at a higher rate in young female adults, often close to the average age of 37 years. On the other hand, diffuse large B-cell lymphoma usually develops in the elderly population, more frequently in males.

Primary mediastinal large B-cell lymphoma initially occurs as a bulky tumor within the region of the mediastinum, thus resulting in signs of compression in the patient such as dyspnea and the superior vena cava syndrome. Half of the patients with primary mediastinal large B-cell lymphoma also present with pleural or pericardial effusion. In other cases of non-Hodgkin’s lymphoma occurring during pregnancy, other symptoms initially develop such as exudative pericarditis, which might have resulted from a connective tissue disorder, or possibly a metabolic disorder. It is also possible that exudative pericarditis might have been induced by myocarditis or a malignancy. Subsequent to the testing and the generation of a diagnosis of exudative pericarditis, a patient could then undergo an enlargement of lymph nodes, which also results in the compression of the neighboring organs. Previous studies have shown that rare cases involving primary cardiac lymphomas initially present as exudative pericarditis.

Based on these unique accounts of non-Hodgkin’s lymphoma during pregnancy, it is thus interesting to examine the factors that trigger its development during gestation. It has long been recognized that non-Hodgkin’s lymphoma is a complex, as well as heterogeneous group of lymphomas that are characterized by variations in etiology. Some non-Hodgkin’s lymphomas may thus develop as an indolent follicular type of lymphoma, whereas others would be characterized with aggressiveness such as that observed in diffuse large-cell lymphoma.

The overall incidence of non-Hodgkin’s lymphoma among women is approximately 30 percent lower than that observed in men. It has been suggested that estrogen, together with other reproductive hormones, might have played a role in reducing the risk of certain subtypes of non-Hodgkin’s lymphoma, including diffuse large-cell lymphoma. Aside from enhancing the immune response of
women, the production and/or exposure to reproductive hormones may increase the secretion of cytokines, triggering B cells to undergo differentiation, as well as proliferation. Exposure to reproductive hormones may include factors that are related to menstrual periods, pregnancy, and the application of exogenous hormones, including oral contraceptives and hormonal replacements for menopausal women.

A study that investigated the relationship between non-Hodgkin’s lymphoma and female reproductive factors showed that certain subtypes are more frequently observed in women as compared to men. For example, follicular lymphoma occurs at a similar frequency in both males and females, whereas diffuse large-cell lymphoma has a propensity for occurring in males. The mechanism behind this sex-related discrepancy in the incidence of diffuse large-cell lymphoma may be due to the higher levels of reproductive hormones in women as compared to men. It should also be noted that women have the capacity to undergo multiple pregnancies in their lifetimes and thus the reproductive hormones associated with gestation may have primed the cells of the body to be more resistant to changes in rates of proliferation.

The extended presence of reproductive hormones might have also induced cells to undergo cellular differentiation, thus preventing the accumulation of undifferentiated B cells, which is a hallmark feature of non-Hodgkin’s lymphomas. Research has also shown that the risk of developing non-Hodgkin’s lymphoma is influenced by the age at which the female patient reached menarche, or the actual age of the female patient at diagnosis, or the age of the female patient when she delivered her first child. The incidence of non-Hodgkin’s lymphoma is also influenced by the duration of hormone replacement...
therapy, wherein a female patient who received the synthetic hormone for a long period is less likely to develop the neoplasm, as compared to a woman that underwent hormone replacement therapy for a short period of time. The dosage of oral contraceptives utilized during therapy is, on the other hand, more strongly associated with the risk for developing non-Hodgkin's lymphoma. Unfortunately, the relationship between the incidence of follicular lymphoma and oral contraceptives has not been established; therefore, additional investigations on this correlation are warranted.

Previous studies have also looked into the effects of various reproduction-related physiological processes with the risk of developing non-Hodgkin's lymphoma. For example, one study examined if breastfeeding altered the propensity of women in developing this particular neoplasm. By conducting case-control studies, it has been established that women who had previously breastfed three or more children had a significantly lower chance of developing non-Hodgkin's lymphoma.

To better understand the inhibitory mechanism of reproductive hormones on the pathogenesis of non-Hodgkin's lymphoma, studies have assessed the immunologic status of female patients during pregnancy and compared these with non-pregnant patients, as well as their male counterparts. The results of these studies showed that an immunologic shift is essential in promoting the implantation of the developing embryo.

Furthermore, this enhanced immunologic capacity also helps in protecting the fetus from tissue rejection, as it acts as an additional allograft within the system of the female non-Hodgkin's patient. It has been postulated that this immunologic shift might have been induced by a continuous increase in the level of progesterone during pregnancy. Progesterone has the capacity of inhibiting helper T cells, which are responsible for eliciting a cell-mediated immune response that in turn activates the machinery for cell-mediated immune responses.

Lymphoma, Primary Central Nervous System

Primary central nervous system lymphoma pertains to a subtype of non-Hodgkin's lymphoma that does not occur within the lymph nodes (extranodal) and thus develops within the components of the central nervous system, including the brain or eyes. Primary central nervous system lymphomas account for around 3 percent of reported primary tumors of the brain. In the case of immunocompetent patients, most of the primary central nervous system lymphomas are categorized as diffuse, large B-cell lymphomas, in accordance with the criteria established by the World Health Organization. The standard of care for patients diagnosed with primary central nervous system lymphoma consists of high doses of methotrexate or methotrexate-based formulations, administered either alone or in combination with whole-brain irradiation. Despite the established protocol in treating patients with this specific neoplasm, information on the molecular details of its pathogenesis is limited.

One of the major reasons for the scarcity of information on the molecular biology and genetics of primary central nervous system lymphoma is the difficulty in collecting tissue specimens that could be used in the analysis. The majority of the tissue samples from patients diagnosed with primary central nervous system lymphoma are derived from stereotactic biopsies. Another reason for the
limited knowledge on the molecular biology of primary central nervous system lymphomas is the short overall survival of patients, which, on average, ranges from two to five years. This average survival time is relatively short when compared to other subtypes of lymphomas. Clinicians have also speculated whether this characteristically short survival time is a reflection of the complexity of the molecular mechanisms involved in the development of primary central nervous system lymphomas. The detected MYD88 mutation represents the most common polymorphism in primary central nervous system lymphomas to date. The MYD88 gene encodes for a protein that acts as a signaling adaptor that is responsible for the activation of the NF-κB pathway, once the Toll-like receptor and interleukin-1 and interleukin-18 receptors have been activated. This genetic mutation results in an amino acid known as L265P, which involves the substitution of the amino acid lysine to the amino acid proline at position 265. Further analysis by independent researchers showed that this specific variant occurs at a lower frequency in other hematopoietic cancers, including chronic lymphocytic leukemia and lymphoid tissue lymphoma.

The identification of the MYD88 mutation in future cases will therefore assist in the diagnostic evaluation of patients and this will be very useful when a case presents symptoms that are highly similar to those of other lymphoid malignancies. The mutation involving the TBL1XR1 gene results in an amino acid change in the transducin-β-like 1 X-linked receptor 1, a regulatory protein that controls transcriptional activity and directly interacts with the corepressors of nuclear hormone receptors. The mutation in the TBL1XR1 gene could therefore result in the inhibition of specific pathways such as the Wnt pathway, although additional studies regarding this relationship are warranted.

A more recent study conducted by the same team reported additional mutations in primary central nervous system lymphoma specimens. These mutations were detected in a total of 37 genes, in which some played a major role in signaling pathways, in differentiation of the B cell lineage, and in the control of the cell cycle. The observation of novel mutations involving additional genes that were not reported in their previous study suggests that primary central nervous system lymphomas are a genetically heterogeneous group of neoplasms that also show similarities with other lymphoma subtypes. It appears that prior to the development of the tumor itself, the tissues involved in the pathogenesis of primary central nervous system lymphoma accrued single nucleotide mutations that altered specific cellular activities, including
cellular differentiation, proliferation, and signaling. The combination of mutations in various genes thus orchestrate a specific genomic scenario that triggers the cells to transform into the malignant type, which is then eventually detected using the clinical, histological, and biochemical diagnostic assays. The use of genetic screening, particularly using exome sequencing followed by Sanger sequencing, may thus help in the early detection of hallmark aberrations that commonly occur in primary central nervous system lymphomas and in the design and development of appropriate treatment regimens.

Lymphoma Research Foundation of America

The Lymphoma Research Foundation (LRF), currently headed by Steven J. Prince, the chair of the LRF board of directors, was formed in November 2001 after a merger between two independent organizations—the Cure for Lymphoma Foundation (CFL) in 1994 in New York to provide funding for research leading to treatments for patients suffering from various forms of lymphomas. The aim of the CFL foundation was to provide reliable support and educational materials to patients in order to access the available treatment options as electronic media was not widespread and the information resources for patients seeking support were limited. Jerry Freundlich served as the CFL president and on the LRF board of directors through 2003. He is presently an executive committee member. Barbara Freundlich served as the executive director of CFL for the first four years and is currently an active member of the board of directors.

The Lymphoma Research Foundation of America (LRFA) was founded in 1991 by Ellen Glesby Cohen, a sufferer of non-Hodgkin's lymphoma. As a patient, she was discouraged by the limited amount of information available on the disease and decided to start the LRFA to serve the needs of lymphoma patients and to create materials to educate newly diagnosed patients. The LRFA funded lymphoma-specific projects and awarded nearly $3 million to this cause. The LFRA also created a network of physicians and researchers who have made valuable contributions to this project. The Ellen Glesby Cohen Award is granted every year to an outstanding volunteer for public service in the lymphoma community.

The LRF is the largest nonprofit organization devoted exclusively to funding innovative treatments against lymphoma as well as promoting lymphoma research in the United States. The LRF also provides up-to-date information about the current research and treatment options on lymphomas to people and health care professionals. The mission of the LRF is to eradicate lymphoma and serve those touched by this disease. The LRF is dedicated to providing funds for biomedical research focusing on the origins of lymphomas, treatment methods, and identification of cures for lymphomas and to raising public awareness about the disease.

Since 1992, the LRF has awarded more than $50 million in the form of more than 300 grants, fellowships, and clinical development awards to understand, treat, and cure lymphomas. John P. Leonard, M.D., currently chairs the Scientific...
Advisory Board (SAB) of the LRF, which also includes 45 senior researchers with established leadership in the field of lymphoma research and patient care in the United States and Canada.

Research supported by the LRF, as stated in the research strategy, covers 67 forms of lymphomas. The LRF not only provides research grants but also supports young investigators undertaking important research projects. The LRF advances the development of therapeutics against lymphomas and funds translational research projects, applying knowledge gained from the basic sciences in clinical settings.

The foundation has a provision to fund a broad spectrum of grants supporting postdoctoral fellows, young investigators, and clinical career development awards, specifically targeting physician researchers. Apart from these, the LRF also supports key focused areas of lymphoma research through Disease Focus Area awards. These include senior investigator awards, correlative grants, planning grants, and experimental or developmental grants to explore novel scientific ideas targeting translational research. The LRF also provides grant funding for basic, translational, and early clinical research. Grants are selected for funding twice a year after a review by a panel of grant application reviewers made up of SAB members, who are experts in lymphoma research. The panel recommends the applications to the LRF board of directors for funding.

Another major important aspect of the LRF is to develop activities and resources to support and enhance the research focus on lymphomas. The LRF provides comprehensive service to lymphoma patients and information on disease-specific programs to more than 60,000 people each year. This information includes focused publications and Web sites dedicated to creating awareness about the disease, information on workshops, help lines, patient aid grants, podcasts, and conferences, as well as public policy and advocacy. The Clinical Trials Information Service initiated by the LRF provides up-to-date information to lymphoma patients on the investigational new treatments for lymphoma at cancer treatment centers across the United States.

The LRF also fosters collaborations and sharing of research ideas and knowledge by supporting meetings, workshops, and conferences. It extends its support via in-person meetings for physicians and health care professionals through the Lymphoma Rounds program, which provides a platform for local health care professionals to regularly meet to address issues related to the diagnosis and treatment of their lymphoma patients. Participants network, share best practices, and learn the latest information on new therapies and advances in the management of lymphoma through interactive case studies presented by lymphoma experts in their local areas. In addition, the LRF provides special in-person meetings of nurses caring for lymphoma patients to learn from the experiences of lymphoma experts.

The LRF offers a financial assistance program to help with the quality-of-life expenses for people undergoing lymphoma treatment. As an initiative to raise awareness about lymphomas and to generate funds, the LRF organizes the Lymphomathon program across the United States, which is a noncompetitive 5K walk, where survivors, family, friends, community members, and corporate teams walk to honor those who have suffered from lymphomas. The funds raised during the Lymphomathons are dedicated to the mission of the LRF.

Since 2003, the LRF has raised almost $11.7 million through Lymphomathons. The LRF also raises funds for research through donations and research rides. It encourages volunteers to communicate the voice of the lymphoma community to policy makers through its advocacy program. In July 2014, the LRF announced the launch of the Lymphoma Education and Advocacy Partners (LEAP), which is a coalition of foundations involved with funding in lymphoma research. LEAP includes the Cutaneous Lymphoma Foundation (CLF), the International Waldenstrom’s Macroglobulinemia Foundation (IWMF), the T-Cell Leukemia Lymphoma Foundation (TCLLF), and The Double Hit Lymphoma Foundation (TDHLF). LEAP will focus on public policies impacting health care and treatment options for lymphoma patients.

Madagascar

Madagascar is an island nation located in the Indian Ocean off of the southeast coast of Africa. The island of Madagascar separated from the Indian subcontinent 88 million years ago, which allowed native flora and fauna to develop there in a state of relative isolation from the rest of the globe. Madagascar’s unique biodiversity makes it a popular destination for ecotourism. The island is the home of the Madagascar periwinkle, a native plant species with anticancer medicinal uses. Like many African nations, Madagascar has no cancer registry. Widespread poverty and ongoing political instability create obstacles for cancer diagnosis and treatment among the Malagasy population.

Madagascar is the fourth-largest island in the world with a population of 20 million people. It ranks among the poorest nations in the world, with two-thirds of the population living in poverty. The Madagascar economy consists largely of subsistence farming. Cash crops of vanilla, coffee, cocoa, sugarcane, and cloves are grown for export. Industries include meat and sugar processing, mining, and tourism.

People from Africa and Southeast Asia settled on the island of Madagascar between 400 B.C.E. and 1000 C.E. In the 19th century, the island was united under the Kingdom of Madagascar. Prior this monarchy, no government ruled the entire island. The monarchy ended in 1897 when Madagascar became a French colony, and the island became an independent nation in 1960.

Following independence from France, Madagascar retained the centralized French model of administration for its national health system. The new Malagasy constitution laid out a plan to decentralize the system, handing funding and decision-making power over to regional health centers. Health care in Madagascar is provided by the public and private sectors as well as traditional healers. The majority of health care facilities are publicly operated, and people choose providers based on the perception of quality, availability of medicines, the cost of care, and the proximity of health centers.

Historically, cancer rates in Madagascar have tended to be lower than those in developed countries because of the relative lack of lifestyle-related cancers. Smoking and alcohol use are less common in Madagascar than in Western countries, making alcohol-related and tobacco-related cancers less common as well. The traditional Malagasy diet is low in meat and animal fat and high in fruits and fiber, contributing to the relatively low incidence of colon and rectal cancers. However, these are on the rise as alcohol, tobacco, and processed foods become more widespread across Africa.

Prostate and lung cancers constitute the majority of cancer mortalities among men in Madagascar. Childhood hepatitis B infections are widespread
among the Malagasy population, and carriers can develop liver cancer later in life. There is also a significant incidence of urinary bladder cancer related to *Schistosoma haematobium* infections. Additional cancer mortalities among Malagasy men are attributable to esophagus, oral cavity, and colorectal cancers.

For Malagasy women, cancer mortalities are most often due to cervical cancer or breast cancer. Mortality rates for cervical cancer in Madagascar are inversely proportional to social status. Cancer mortalities are more common among lower-class women and rarer for the upper classes. The more affluent Malagasy women have better access to health care and can afford to travel to receive treatment, lowering their general risk of mortality from these cancers. Social barriers prevent access to cancer treatment among the population of Madagascar. With 50 percent of the population living below the poverty line, very few Malagasy citizens can afford access to cancer treatment. As a result, cancers tend to be both underdiagnosed and underreported in Madagascar. In 2012, GLOBOCAN estimated approximately 18,000 new cancer cases and approximately 13,000 cancer deaths. According to the indigenous form of Christianity in Madagascar, cancer and other diseases are often considered to be preordained by fate. Preventative measures can be considered both ineffectual and to go against the will of God.

The government of Madagascar considers malnutrition and human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS; only 1 percent of the population is infected, a very low rate for Africa) to be the primary threats to public health on the island, and there is no comprehensive national strategy for treating cancer. The Madagascar Action Plan (MAP) set goals to improve health and nutrition in order to reduce poverty. A military coup jeopardized these plans in 2009. The international community refused to recognize the new government and has suspended aid to the country. This political crisis has contributed to sluggish economic growth, further reducing the average Malagasy citizen’s access to health care in the country.

Since 2009, the government has reduced its contribution to national health care, and the global economic crisis has lowered most family incomes. As of 2011, Madagascar had only one cancer treatment ward located in Joseph Ravoahangy Andrianavalona Hospital in the capital of Antananarivo. This cancer ward consists of 60 beds intended to serve the entire population of the island. If they can afford treatment, the largely rural agricultural Malagasy population must travel to the capital to see an oncologist.

In the 1950s, scientists discovered that the Madagascar periwinkle (*Catharanthus roseus*) produced anticancer substances. Established by the United States government, the Cancer Chemotherapy National Service Center (CCNSC) discovered the medicinal uses of the Madagascar periwinkle. This member of the dogbane family is native to Madagascar, and the medicines vinblastine and vincristine are derived from it. Vinblastine is used in the treatment of childhood leukemia, and vincristine is used to treat Hodgkin’s disease. Malagasy folk healers have used it to treat diabetes, dysentery, menstrual disorders, and toothaches.

Malawi

The majority of cancers and deaths associated with cancer occur in developing countries. A 2030 global cancer death rate projection is estimated to reach 13.2 million as compared to 12.7 million in 2008. Many factors exist that make screening, diagnosis, treatment, surveillance, and follow-up of various cancers difficult in poor, underdeveloped countries in sub-Saharan Africa. With only two pathology laboratories in the entire country of Malawi, underreporting and misdiagnosis are major clinical barriers for adequate cancer care.

Annually, it is estimated that more than 8,000 new cases of cancer occur in Malawi. From 2007 to 2010, there were 18,946 new cancer cases registered. The majority were females and adults between the ages of 15 and 59. However, less than 18 percent of the cases had been confirmed with histology, about 33 percent were diagnosed clinically, and slightly less than 50 percent of the cases were based on minimal investigations and the clinical exam. Cervical cancer was the most common cancer among the females. Kaposi’s sarcoma comprised 50.7 percent of the cancer cases in males.

The leading risk factor for cancer deaths worldwide is tobacco use. About 25 percent of men smoke tobacco in sub-Saharan Africa. Seventy-one percent of global lung cancer deaths can be linked to smoking, yet lung cancer is less common in this region. Possible explanations for the surprising low rates of lung cancer could be the result of underreporting, misdiagnosis, or lack of affordability.

Most countries rely heavily on tobacco imports. However, Malawi’s economy is heavily supported by its tobacco exports and is one of the world’s most tobacco-dependent economies. A large percentage of Malawi’s total workforce is employed in tobacco farming or tobacco processing. Because of this reliance on tobacco, antismoking campaigns often are targeted by the large tobacco companies who effectively influence the population at large and the government about the potential loss of jobs and revenue.

As a result of the numerous studies connecting tobacco use with a multitude of diseases, tobacco advertisement and public use are more regulated in the United States than they are in Malawi. The Malawi government does not mandate that cigarette packages contain health warnings nor is tobacco use prohibited in government buildings, restaurants, and health care facilities. Furthermore, as of 2012, nicotine replacement products were not legally sold in Malawi.

In most developed nations, there are established cancer screening protocols for breast and colon cancers. Cervical cancer, however, is the only malignancy in Malawi for which a screening program exists. Approximately 1,600 women die each year from cervical cancer. In 2004, the Malawi Ministry of Health implemented recommendations for women age 30 to 50 that consisted of a screen and treat program for cervical cancer utilizing acetic acid visual inspection. Roughly 80 centers in Malawi now offer some type of treatment for cervical cancer that includes visual inspection, cryotherapy, loop electrosurgical excision, major surgery, or any combination of the above.

Even so, few women take advantage of the cervical cancer screenings, and when they do present for care, the cancer is usually too far advanced for surgical intervention. Knowledge of the perceived benefit and poor health literacy are possible explanations for this obvious disparity of cancer screening as proposed by a study done by Victoria Fort and colleagues. Per the study, women were more likely to get screened if they were seeking care for something else.

Although human papillomavirus (HPV) types 16 and 18 cause 70 percent of cervical cancers, little is known about the types affecting Malawi women. Though there are two vaccines available for cervical cancer prevention, the vaccines are not readily available in Malawi. The vaccines are indicated for girls and boys ages 9 to 26. Even though the two manufacturers that developed the HPV vaccine, Merck and Company and GlaxoSmithKline, have lowered the costs of the vaccine for developing countries, Malawi has yet to include the vaccine in its national immunization program. Malawi has only recently begun pilot programs to administer the vaccine to a small minority of girls between the ages of 9 and 13.

Per Katie Ports and her colleagues, lack of information regarding HPV vaccines and their relationship with preventing cervical cancer were barriers noted within their small study, yet the women were receptive to the idea of HPV vaccination once educated about its benefit. Women reported previous positive experiences with vaccines and expressed...
willingness and a sense of responsibility to keep their babies healthy from preventable diseases. Women were also more likely to accept recommendations if they were suggested by their doctor.

It is not known if antiretroviral therapy has helped to decrease the prevalence of acquired immune deficiency syndrome (AIDS)-linked cancers such as Kaposi's sarcoma, but this could be related to lack of access to widespread medication and treatment. In regard to esophageal cancers, it is believed that the cause arises from a mycotoxin found in maize and fumonisin along with smoking and alcohol consumption. Future studies are needed to determine how eliminating these possible contributors will affect the prevalence of cancer in Malawi.

Furthermore, lack of resources, access to care, and human immunodeficiency virus (HIV) burden are instrumental to the cancer devastation to the citizens of Malawi. Global aid, physician and community worker training, and education materials are needed to help improve outcomes. History has shown how nationwide immunization programs have affected disease outbreaks such as measles. This same public health module could be utilized in Malawi in regard to the HPV vaccine and cervical cancer prevention. The vaccine would be most beneficial if it were disseminated and advertised widely throughout the country and given at every potential opportunity.

The future health of Malawi in regard to cancer will depend upon specific improvements in screening, tissue sampling, and prevention. Infrastructure changes that include additional pathology labs and cytotechnologists are desperately needed to improve accuracy and resultant outcomes of cervical cancer, for example. Adopting other worldwide-accepted screening recommendations for disease entities such as breast and colon cancer are also logical next steps in improving cancer outcomes in Malawi.

Malaysia

The southeastern Asian nation officially termed Malaysia was composed in 1974 out of the federation of the three territories of Labuan, Kuala Lumpur, and Putrajaya. The modern Malaysian state is a constitutional monarchy composed of the three federal territories as well as 13 other Malaysian states. With regard to population, Malaysia is currently in the top 30 largest nations in the world with more than 30 million citizens.

Unlike many other nations who currently do not have national cancer registries, Malaysia has one of the most expansive and well-maintained cancer registry systems in the world. Whenever a cancer incidence is initially observed, Malaysian clinicians, hospitals, and laboratories quickly will send that information off to a national database where domestic trends and incidence rates can be studied by researchers. Such excellent cancer registries have proved invaluable in that nation’s battle against cancer, giving researchers the capability to track every single cancer case that is observed within any given year. For instance, researchers were able to use the data in Malaysia’s national cancer registry to deduce that there were approximately 46,048 incidences of cancer in the country in the year 2005.

Cancer is certainly a mounting problem for Malaysian society as nearly 8 million Malaysian citizens died in 2005 as a result of various cancer incidences. Cancer is currently in the top five leading causes of death for Malaysian citizens, and scientists expect this trend to increase consistently in the coming years. Public awareness in Malaysia regarding cancer, its symptoms, and risk factors is regarded as
Poor. In the small, nonurban villages that make up the nation’s countryside, Malaysian citizens know virtually nothing about the disease and what causes it. This lack of awareness extends even to urban communities in the country, however. In a recent study, undergraduate-level Malaysian university students were surveyed in an attempt to gauge their awareness and knowledge regarding cancer. The results of the study conveyed that nearly 95 percent of all students surveyed had what could be considered poor awareness regarding cancer, while 65 percent of all students surveyed had what could be considered poor knowledge concerning the disease.

Such poor public awareness leads to consistent increases in annual cancer incidences as a large portion of the Malaysian population is totally unaware of what behaviors to avoid in order to prevent the disease. If cancer risk behaviors such as smoking or heavy alcohol consumption cannot be adjusted in the Malaysian population due to lack of public awareness, then cancer incidence rates will continue to climb in the coming years.

However, there are other obstacles to cancer treatment in Malaysia besides a mere lack of public awareness, which include emotional obstacles, practical obstacles, and service obstacles. In a recent study that was conducted, researchers found that many Malaysians had emotional obstacles in the way of cancer screening and treatment, such as them being too afraid to go to the hospital or being too concerned that the doctor might find something that is seriously wrong. Other Malaysians explained they would be too shy to talk to a doctor regarding such matters. Related to practical obstacles, many Malaysians described not having enough time to go to the hospital, and with regard to service obstacles, many Malaysians avoid care facilities because they are concerned about being able to afford the costs of a medical visit.

Presently, the most prevalent forms of cancer in Malaysia are breast, bowel, cervical, liver, and prostate cancer. Bowel, lung, and prostate cancers are the most prevalent forms of cancer incidences in males in the country, while breast, cervical, and bowel
cancers are the most common incidences of cancer in females here. Current Malaysian cancer registry data reveals that, in general, cancer incidences are tangibly decreasing in the nation. For example, there were 46,048 cases of cancer diagnosed in Malaysia in 2005, while there were only 18,219 cases diagnosed only two years later in 2007. However, certain cancers are consistently gaining traction in the nation; incidences of breast and bowel cancer have been increasing steadily in the country over the past several years and are set to continue this trend.

Malaysia has several facilities in the country that can provide cancer treatment services, but the country is in need of more highly trained oncologists in order to better cope with the nation’s current incidences of cancer. It is currently estimated that there are just over 30 practicing oncologists operating in the entire nation, and this number will need to increase if the country is to adequately meet the needs of its cancer patients in the coming decades.

Mali

The Republic of Mali is situated in west Africa. It is bordered on the north by Mauritania, on the north and east by Algeria, on the east by Niger, and on the south by Burkina Faso, Côte d’Ivoire, and Guinea. It is the 19th-most populous country in Africa and the 69th in the world, with an estimated population of 13.5 million. The official national language is French, and there are 66 living indigenous languages still spoken by respective ethnic groups. The most widely spoken ethnic languages include Bambara, Fula, Jula, and Senoufo. Each ethnic group has its own rich traditions of ethnomedicine. For example, a traditional healer who uses medicinal plants for treating cancers and other ailments is known as furakeland in Bambara, chafrrowo in Fula, and fi la-cha in Jula. The Department of Traditional Medicine in Mali has led research to develop improved traditional medicines that are sold in pharmacies alongside conventional medicines.

There are many traditional medicinal preparations used in Mali for treating cancers and associated conditions. Most of these incorporate the use of myriad local plant materials, many of which have shown medicinal properties in laboratory studies. For example, an aqueous extract of Ximenia americana, a medicinal plant used in Mali, demonstrated significant anticancer activity. Research also suggests that use of certain plants may actually help protect against cancers by reducing oxidative stress and stimulating enzymes and other processes that help the body fight carcinogens. For example, extracts from Malian medicinal plants such as Cussonia barteri, Glinus oppositifolius, and Lannea velutina demonstrated substantial antioxidant as well as antifungal, larvicidal, and molluscicidal
activities. Many other medicinal plants traditionally used in Mali, such as *Diospyros abyssinica*, *Crossopteryx febrifuga*, and *Parkia biglobosa*, also have demonstrated good antioxidant potential.

Medicinal plants are used traditionally in Mali to treat many health problems associated with cancers. For example, powdered *Biophytum petersianum* is used traditionally for treating different types of pain, as is *Cola cordifolia* and *Combretum molle*. *Opilia celtidifolia* is used traditionally for treating varied skin disorders.

There are serious deficiencies of modern pharmaceutical supplies, as opposed to traditional preparations, and in modern medical services for cancer and similar conditions in Mali. There is a relative shortage of doctors, with about 1,291, at a density of 0.889 per 10,000 population, and there are also about 1,067 licensed pharmacists in Mali, with a density of 0.74 per 10,000 population. Furthermore, according to the World Health Organization’s Health System Response and Capacity, as of 2010, there was no general availability of radiotherapy in the public health system in Mali, although chemotherapy was generally available.

Mali is a signatory to the Single Convention on Narcotic Drugs, Convention on Psychotropic Substances, and the United Nations Convention Against the Illicit Traffic in Narcotic Drugs and Psychotropic Substances; consequently, laws exist to control narcotic and psychotropic substances and precursors. Accordingly, the annual consumption of controlled substances is highly regulated to curtail abuse. Therefore, the annual consumption of morphine in 2010 was 0.011237 milligrams per capita (mg/capita), fentanyl was 0.021693 mg/capita, and phenobarbital was 7.044131 mg/capita. This creates a serious lack of access to basic pain relief that makes cancer experiences in Mali, particularly living with and dying from cancers, very different from elsewhere in the world.

Due, in part, to the shortage of medical services and supplies, health problems are endemic in Mali. The 10 leading causes of mortality, in rank order, are malaria, malnutrition, hypertension, trauma and accidents, human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS), anemia, pneumonia, postpartum complications, pregnancy complications, and diarrhea. The average number of cancer cases annually are 120 per 100,000 of the population.

Cancers account for a substantial amount of disability and suffering among impacted populations. According to the World Health Organization’s disease and injury country estimates, according to the age-standardized, disability-adjusted life-year estimates for 2004, the ten most prevalent cancers in Mali were led by liver cancer at 395 per 100,000 of the population; stomach cancer at 318 per 100,000; cervical and uterine cancers at 200 per 100,000; breast cancer at 133 per 100,000; bladder cancer at 105 per 100,000; lymphomas at 81 per 100,000; colon and rectal cancers at 72 per 100,000; esophageal cancer at 44 per 100,000; leukemia at 40 per 100,000; and trachea, bronchial, and lung cancers at 33 per 100,000.

Modern medical supplies and services are generally, if available at all, in short supply in Mali. Both prescription and over-the-counter products are often unavailable. Consequently, health problems are endemic and limit development. For example, an estimated 140,000 people live with HIV in Mali, which ranks the country 27th highest in Africa and 40th highest in the world. In 2007, the mortality rate for HIV/AIDS was 47 per 100,000 of the population. Debate continues on the relative risks in Africa for respective cancer types for those infected with HIV. The mortality rate for tuberculosis was 81 per 100,000 population, and that for malaria was 201 per 100,000 of the population, while the mortality rate for cancers in 2009 was 166 per 100,000 of the population. Furthermore, according to the World Health Organization’s Global Health Observatory Data Repository, in 2008, the age-standardized estimates of deaths from all cancers were 106 per 100,000 of the population for males and 124 per 100,000 of the population for females. As a consequence, life expectancy is only 45.28 years, which ranks Mali as the 37th-highest country in Africa and the 208th in the world. There is a clear and urgent need for improved cancer awareness, early detection programs, and health services infrastructure in Mali.

Diallo, D., A. Marston, C. Terreaux, Y. Toure, B. Smestad Paulsen, and K. Hostettmann. “Screening of
Malignant Fibrous Histiocytoma of Bone/Osteosarcoma

Osteosarcoma ranks as the most common malignancy involving bones and more frequently affects children and adolescents. However, osteosarcoma is generally considered as a rare cancer, accounting for less than 1 percent of all neoplasms occurring in the United States. Unfortunately, population-based information on the incidence of osteosarcoma and patient outcomes for this specific disorder is limited. Osteosarcoma in young individuals usually emerges in the metaphyses of the major bones of the lower limbs, including the femur, tibia, and humerus. Although this bone cancer most frequently affects adolescents, the elderly, particularly those within the age range of 70 to 80 years, are also often afflicted with this malignancy. Osteosarcoma of the elderly generally involves the axial bones or areas that were previously exposed to irradiation or harbored congenital bone abnormalities. Males also are more frequently affected by osteosarcoma than females.

Based on the information on the incidence of this neoplasm, it is therefore interesting to know whether there are other factors that are strongly associated with its occurrence in specific subpopulations. The first epidemiologic study on the incidence of osteosarcoma was conducted by the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute of the National Institutes of Health in Bethesda, Maryland. The program reviewed case reports of osteosarcoma from 1973 to 2004, from 17 cancer registries located around the United States. The incidence of osteosarcoma was also further classified into three age-groups, namely zero to 24, 25 to 59, and 60 years of age and greater, as well as according to sex, race or ethnicity, disease stage, pathological or histological subtype, and anatomical area involved. The races or ethnicities of the patients were classified into any of the following groups: white, black, American Indian, Alaskan Native, or Asian or Pacific Islander. In terms of pathological or histological subtype, the cases were categorized according to neoplasm occurrence in the patient (i.e., first, second, or third neoplasm) and the presence or absence of Paget’s disease.

The SEER study reviewed a total of 3,482 patients who had been diagnosed with osteosarcoma between 1973 and 2004. Interestingly, significant differences in the incidence as well as the survival rates of the osteosarcoma patients were observed. For example, the highest incidence of osteosarcoma in the youngest age interval (i.e., 0–24 years) was observed in the non-American races or ethnicities, which included the American Indians, Alaskan Natives, and Asian or Pacific Islanders. On the other hand, the highest incidence of osteosarcoma with Paget’s disease occurred in the elderly age-groups. Differences in the site of tumor occurrence also varied among the different age-groups. In addition, the survival rates of the patients diagnosed with osteosarcoma varied according to the anatomic site as well as the disease stage of the patient.

Despite the extensive information that was generated by the SEER program, additional issues emerged in the incidence, prognoses, and survival
rates in osteosarcoma. For example, despite the improvements in the treatment strategies for osteosarcoma, the survival rate of this malignancy remained at 70 percent for several years. This dilemma thus prompted analysts to further examine the details of the osteosarcoma cases, including the characteristics of the patients who developed this disorder. Saminathan Nathan and John Healey embarked on two major epidemiological studies on this rare bone malignancy by evaluating patient records on osteosarcoma from two national health registries of two countries. Furthermore, these records were also compared to those previously gathered from the SEER study.

The results of the study showed that survival rates were more reliable when gathered from a specific institution and not from a national health registry because it is possible that other critical data might have been left out during the collection of information. The investigation also showed that patients of Oriental descent (i.e., those coming from China, the Philippines, Japan, Kampuchea, Korea, and Vietnam) were strongly associated with good disease prognoses. The type of treatment applied to the osteosarcoma patient also influences the success in the therapeutic regimen as well as the survival rate. Interestingly, women are more likely to survive or show good prognoses than men. Elderly individuals within the 90-year age interval also have been associated with better treatment outcomes. Tumor characteristics such as being low grade, small sized, and intra-compartmentalized have also been strongly correlated with higher survival rates among osteosarcoma patients. Last, patients who underwent large resections were more likely to survive this bone malignancy compared to smaller-sized resections, such as forequarter or, in other cases, hindquarter amputations. Patients who developed single primary tumors were also associated with higher survival rates than patients who were observed to harbor several primary neoplasms.

In terms of socioeconomic and sociodemographic features, black patients showed a higher frequency of large neoplasms compared to the other ethnicities, although this specific subpopulation presented with similar survival rates as those of the Caucasians. The Oriental populations showed a higher propensity of developing osteosarcoma in their 90s, which then required wider resections despite the smaller size of their tumors. Interestingly, patients of Oriental background residing in the United States or in Singapore showed similar survival rates. In addition, the survival rate of patients with an Oriental background and residing in Singapore did not significantly vary from that of other ethnicities. One significant difference that was noted in the study was that the health care of the United States extensively varied among the states, whereas that of Singapore was uniform regardless of the site of medical consult within the country. Based on this observation, it is thus possible that the discrepancies in the survival rates and patient outcomes of osteosarcoma patients in the United States were due to differences in socioeconomic parameters. The prognosis of osteosarcoma patients is therefore affected by the ethnicity and the socioeconomic status of the patient. Furthermore, the observation that the patients of Oriental background showed similar survival rates in Singapore and the United States thus suggests that patients of Oriental background in the United States are more likely to show a more superior rate of survival.

Although these demographic studies have generated highly significant findings, it is also possible that genetic variations among ethnic groups also might have played a role in the discrepancies in survival rates of osteosarcoma patients. For example, the level of the enzyme alcohol dehydrogenase is significantly higher among individuals of Oriental background compared to Caucasians. This may in turn influence the metabolism of cyclophosphamide, which is the major chemotherapeutic drug administered to osteosarcoma patients, thus resulting in higher bioavailability in the tissues of the body. Additional studies relating to these discrepancies could further resolve the variations in survival rates and prognoses among osteosarcoma patients of various sociodemographic backgrounds.

Further Readings
Cancer drug marketing is becoming more common. Marketing may include anything from news releases to public service announcements to industry-sponsored health fairs, but advertisements are the mainstay of every campaign. Cancer patients are increasingly exposed to direct-to-consumer advertising (DTCA). While DTCA may educate patients about new treatments, critics argue misleading ads highlight benefits and downplay risks. This type of marketing also can negatively impact patients’ relationships with their physicians: Studies show 80 percent of physicians feel pressured to write prescriptions for advertised drugs, and 39 percent believe DTCA damages the physician–patient relationship. Physicians themselves are also targets of pharmaceutical industry-sponsored marketing and sales calls. Drug reps promote cancer treatments for off-label use; while marketing an off-label use to physicians is illegal, educating them about it is not. The practice is controversial and can harm patients. The World Health Organization has predicted a 50 percent increase in global cancer rates by 2020, and the Federal Drug Administration (FDA) has expedited the approval process for new cancer drugs. Together, growing need and increased treatment options will spawn even more advertisements as pharmaceutical companies compete for market share.

Patient-focused drug advertising is a long-contested marketing practice. DTCA, legal only in the United States and New Zealand, is any unsolicited promotional message appearing in popular media (television, print, or radio) informing audiences about prescription drugs. Direct mailings, brochures, and billboards are also considered DTCA. Drug ads have been appearing in newspapers since the 1700s, but they were largely unregulated. In 1906, Congress passed the Pure Food and Drug Act, which established truth in labeling and purity standards. The FDA was formed in 1938 and given authority over drugs, but the Federal Trade Commission regulated advertising. Oversight was transferred to the FDA in 1962, and a fair balance approach was adopted: Ads had to balance drugs’ benefits and risks. Most ads were physician directed until 1981, when a pneumonia vaccine ad ran in Reader’s Digest. Two years later, the first television commercial appeared. Following a brief moratorium to study DTCA’s potential ramifications, the FDA upheld the 1962 fair balance guidelines, requiring a full statement of risks and side effects. In 1997, the FDA relaxed the television ad rules. Now, DTCA only mentions a drug’s major side effects, while viewers are referred to other sources for additional information (Web site or toll-free number). While the FDA is supposed to review ads for accuracy and balance, it lacks the resources to do so. In 2001, the agency had only 30 people to review 34,000 ads. As a result, the pharmaceutical industry is largely self-regulating. It adheres to the rules established by its own trade group, the Pharmaceutical Research and Manufacturers of America (PhRMA). PhRMA maintains DTCA is educational, designed to stimulate conversation between patients and physicians, but a 2010 National Institute of Health report concluded DTCA is not an effective educational tool because it typically emphasizes benefit over risk.

Numerous studies have shown DTCA impacts physician prescribing behavior and physician–patient relationships, but few studies have focused exclusively on ads for cancer drugs. A survey of oncology nurse practitioners found 94 percent reported their patients had requested advertised drugs, with 40 percent experiencing up to five requests per week. A 2009 survey of cancer patients found 86 percent had seen DTCA. The majority of respondents believed ads presented information in a balanced fashion, were educational, and helped them have better discussions with their physicians, but 11 percent reported the ads made them less confident in their physicians’ clinical judgment. Perceptions were more favorable among those who had not gone to college. A 2000 study concluded cancer drug ads were the hardest to understand and had the least educational value. Similar results were reported in 2007: Researchers analyzing magazine ads for cancer drugs found them incredibly
difficult to read. The ads were also biased: Side effects were printed in a font size several millimeters smaller than benefit text. Misleading ads are common. AstraZeneca and TAP Pharmaceuticals violated the Prescription Drug Marketing Act while promoting their prostate cancer drugs (both companies pled guilty in 2005 and paid fines). In 2010, Dendreon was criticized for its Provenge marketing. The Center for Biologics Evaluation and Research argued ads overstated the efficacy of the prostate cancer drug and minimized its risk; the ads also distorted survival rates by failing to present them in context.

While DTCA has been studied extensively, direct-to-physician pharmaceutical marketing has received comparatively little attention even though it accounts for 80 percent of all drug promotion costs. Most marketing campaigns include drug ads in medical journals. A 2009 study found 21 percent of journal editors do not review ads before publication. Half of ads cite industry-sponsored research, failing to mention side effects or warnings. Researchers found journal ads were the third-most trusted source of drug information among physicians after drug reps and drug samples.

Physicians increasingly rely on drug reps for information about new treatments, drug interactions, and new uses for existing medicines. While it is illegal for drug companies to market medications for uses other than those approved by the FDA, physicians are not constrained by this law and can write prescriptions for any use they wish. Drug reps, however, need to educate physicians about off-label uses. In 2004 and 2006, Genentech was cited for inappropriate off-label promotion of Rituxan to treat cancers other than non-Hodgkin’s lymphoma, for which it had been approved. A 2007 lawsuit filed against Celgene Corporation charged the company with illegally promoting off-label use of two of its cancer drugs. A 2011 study found 75 percent of off-label recommendations lack evidence of benefit and expose patients to harm. Drug rep visits and education programs constitute the majority of physician-focused marketing costs, about $7 billion a year.

Marketing cancer drugs ensures that both patients and physicians learn about new treatments and new uses for existing drugs, but advertisements can be misleading. Many campaigns emphasize benefits but downplay risks. Sources other than industry-sponsored marketing materials should be consulted for balanced information about cancer drugs.

Marketing, Hospitals and Clinics

Cancer care marketing takes many forms. Hospitals and clinics endeavor to promote their services through a broad range of marketing activities including issuing news releases, producing public service announcements, staging health fairs, hosting educational forums, and advertising. Marketing efforts target several different audiences: patients and their families, physicians who refer patients for cancer care, and purchasing agents for managed care companies. Marketing cancer care to rural populations is particularly challenging. Partnering with local media to produce stories, while sometimes blurring the lines between news and promotion, is a common marketing tactic. Traditional advertising (television, radio, and print ads) is ubiquitous, but many campaigns have been criticized for misleading patients. Advertising is not stringently regulated, and emotional appeals often
promote unproven interventions, lack scientific evidence to support claims, misrepresent survival data, and downplay risks.

Marketing cancer care services is difficult for many reasons. The product is something no one wants: Most consumers ignore the topic of cancer unless they are personally impacted. This creates a barrier for marketers trying to reach potential customers, requiring multifaceted and multichannel campaigns. Messages must also be tailored for specific audiences: Referring physicians and patients, for example, have different information needs and evaluate messages differently. Research has shown physicians respond to messages communicating information about a hospital’s or clinic’s type and number of specialists, available nursing support, and new technologies or equipment. Physicians also value information about administration's responsiveness to requests or suggestions.

Patients, however, are attracted to hopeful messages that promote an attentive and caring medical staff, new treatments, and the possibility of a cure. Campaigns featuring cancer survivors’ testimonials are particularly effective. Patient-targeted media promotions often coincide with nationally recognized events like the Great American Smokeout and Breast Cancer Awareness Month. Other public relations activities include organizing health fairs and screenings, staging community education sessions, staffing cancer information hotlines, and hosting survivors’ celebrations. Rural populations, however, are not as responsive to mass-media campaigns. Research has shown generalized messages about cancer prevention and screening are not as effective as more personal, tailored communications. Campaigns employing local community leaders, business owners, and clergy carry more weight with this audience. This type of marketing is important because Americans living in rural communities underutilize screening services, delay seeking care, and suffer a disproportionate number of cancer deaths when compared with urban populations.

Many hospitals and clinics form partnerships with local media, ensuring important cancer stories get press coverage, but the distinction between marketing and news is often blurred. Press releases announcing new equipment or treatment options often run in local newspapers in their entirety. Critics argue press releases are positively skewed advertisements masquerading as news unless journalists balance claims with independently gathered information. Because press releases are not advertisements per se, the claims in them are not subject to regulatory oversight. Video news releases (VNRs) can also be misleading. A VNR is crafted to look like a television news story, but it promotes the services of a single hospital or clinic. Some hospitals pay for airtime, and their sponsorships guarantee a certain number of stories or VNRs will air on local newscasts each month.

While many hospital public relations departments produce VNRs in-house, some contract with news stations to provide video production services. Local reporters sometimes appear in the VNRs; while the reporters lend journalistic credibility, the marketers write and control the stories. VNRs’ sources are rarely disclosed, so viewers think they are watching real news. VNRs can increase awareness for a service or treatment that may be beneficial for cancer patients, especially in smaller media markets where television stations lack the resources to cover major events. Nonetheless, VNRs are marketing tools designed to win customers and seldom balance benefits with potential risks.

Traditional advertising is a key factor in most marketing campaigns. One of the most heavily
advertised service providers is Cancer Treatment Centers of America (CTCA). CTCA is a network of five for-profit hospitals with a strong media presence. Media kits with ready-made stories, interviews, and photos are regularly circulated to national publications like *Reader’s Digest* and *Newsweek*. Marketing also includes public radio underwriting, television commercials, and a strong Web presence. Emotionally poignant ads target audiences segmented by type of cancer, age, race, and gender. While the ads tout impressive survival rates, critics have claimed the numbers are misleading. In 1996, the Federal Trade Commission alleged CTCA made false claims in promotional materials and required disclaimers and scientific evidence to substantiate its claims in future advertisements.

A 2013 investigative report found CTCA used questionable statistics in its ads: Its better-than-average survival rates were compared with national figures; however, CTCA treats a very small subset of cancer patients and only includes survival rates for patients whose entire course of treatment was administered at CTCA. While national figures report survival at five years, most of CTCA’s statistics report survival up to four years; at five years, CTCA’s survival rates are no better than the national average. Critics have also complained ads promote therapies like acupuncture that have no scientifically proven benefit for cancer patients. Consumers expect bias in advertising, but critics decry selling hope to desperate patients with false claims and misleading statistics. One of the major challenges in marketing cancer care is maintaining sensitivity to the concept of promise: Marketers cannot promise a cure, and promotional materials should balance hope with realistic expectations.

Marketing cancer care ensures both patients and physicians learn about new treatment options and support services, but advertisements can be misleading. Campaigns often emphasize the benefits of new treatments and technologies while downplaying risks. Care should be taken to differentiate marketing tools, like press releases and VNRs, from actual news. Sources other than marketing materials should be consulted for balanced information about the range of cancer care services available at hospitals and clinics.

Massachusetts Medical Society

The Massachusetts Medical Society (MMS) is the state of Massachusetts’s professional association for physicians and medical students. In addition to its long history of sponsoring cancer-related screenings and promoting awareness of the disease, the MMS also remains one of the state’s staunchest advocates against tobacco use, notably through the efforts of its Committee on Student Health and Sports Medicine. Membership in the MMS is available to both doctors of medicine and doctors of osteopathy practice in the state of Massachusetts and to those who are presently medical students in the state.

The MMS also is internationally renowned for the publication and evaluation of cancer-related research through its two flagship publications: the *New England Journal of Medicine* and the *Journal Watch* series of newsletters.

History

The MMS was founded in 1781 and is today headquartered in the city of Waltham, Massachusetts. The society is the oldest continuously operating organization of its kind active in the United States.
The MMS was originally founded as a state-sponsored body that could offer official licensure to doctors and surgeons. The organization’s founding also aimed to promote medical and surgical knowledge throughout the state while advocating the effects of hygiene, sanitary living and working conditions, and preventative care.

By the mid-19th century the MMS had established itself as a national model for other, similar state organizations. It was the first such organization to create a statewide system with which to collect medical statistics from its citizenry, the results and study of which were ultimately published for use by the general public and medical schools. The society’s broad findings led to changes in both medical practice and statewide public health legislation, including the establishment of the State Board of Health.

Today, the society is active in legislation surrounding health topics such as medical marijuana, health care reform, and Medicare, as well as with the monitoring of state and federal regulations affecting Massachusetts physicians.

Organizational Structure and Resources
The official policies of the MMS are created by the body’s House of Delegates, which convenes biannually to discuss recent state and national developments in health policy, public health legislation, and administration. The MMS House of Delegates is also responsible for the election of the society’s rotating panel of officers, comprised of society president and roles such as speaker and treasurer. Its board of trustees, comprised of medical professionals and students who can serve a maximum of two three-year terms, operates the society’s administrative management.

The MMS is also home to numerous committees comprised of medical professionals dedicated to particular health-related issues. Prominent MMS subcommittees include the Committee on Global Health, the Committee on Violence Intervention and Prevention, and the Committee on Nutrition and Physical Activity.

Publications
The society’s flagship medical journal, the New England Journal of Medicine (NEJM), is widely recognized as one of the most prestigious peer-reviewed medical journals in the world and has been the source of several groundbreaking articles outlining research dedicated to cancer prevention and treatment.

First published in 1914 as the Boston Medical and Surgical Journal, the publication became the New England Journal of Medicine in 1928.

In 1973, a study published in the journal illustrated the importance of the removal of colorectal polyps as a method in preventing colorectal cancer. In 2004, the NEJM was the source of a groundbreaking new study outlining molecular advances in the treatment of advanced lung cancer.

The MMS also owns and publishes Journal Watch, a medical journal review series for doctors and health professionals. Several Journal Watch newsletters offer coverage of cancer-related research, including topics such as oncology and hematology, breast cancer, and skin cancer.

The NEJM Journal Watch Oncology and Hematology newsletter offers medical scholars and doctors a monthly survey of key research developments and findings derived from several prominent, cancer-related medical journals, including the Annals of Oncology, Journal of Clinical Oncology, the Journal of Clinical Cancer Research, and the Journal of the National Cancer Institute.

Antitobacco Efforts
The MMS has been one of the most active state medical boards in the United States in combatting the use of tobacco among both adults and children. In 1992, the society joined with the American Cancer Society and Blue Cross and Blue Shield of Massachusetts to form Tobacco Free Mass, a nonprofit coalition aimed at promoting legislation to reduce and ban the use of tobacco in public spaces.

Many MMS-backed antitobacco programs are conducted in alliance with the Massachusetts Medical Society Alliance, the society’s sister organization, which is comprised of MMS members and aims at promoting good health among Massachusetts citizens.

The society’s Committee on Student Health and Sports Medicine leads and advises members on issues pertaining to the health of Massachusetts schoolchildren and sports medicine, most notably through its promotion and support of scholastic health education programs.

Student Advocacy
Another paramount function of the MMS is acting as an important resource to the 2,500 students
who study medicine in the state each year. MMS has in place a variety of scholarship, loan, and grant programs aimed at offsetting the cost of medical training.

The MMS also provides both career advancement and networking seminars that assist medical students in issues related to licensing exams, residency applications, and mentorship programs.

The society’s Waltham, Massachusetts, headquarters is also home to the Boston Medical Library, which offers a myriad of scholarly and academic resources to the state’s medical student population. In addition to expansive selections of medical journals and publications, the MMS’s Boston Medical Library also assists students in research and offers tutorials that assist students in identifying materials for both course work and thesis writing.

Massey Cancer Center

Cancer centers exist to develop more efficacious methods to prevent, diagnose, and treat cancer patients. These programs use multidisciplinary teams to provide state-of-the-art treatments to cancer patients. The Virginia Commonwealth University Massey Cancer Center happens to be one of the world-class centers offering the latest range of treatments for all types of cancer.

The Virginia Commonwealth University (VCU) Medical Center opened the VCU Massey Cancer Center in 1974 to become one of only 68 facilities out of 1,500 cancer centers in the United States designated by the National Cancer Institute (NCI). The nonprofit VCU Medical Centers program ranks in the top 4 percent of cancer centers in the nation.

The VCU Massey Cancer Center grew in leaps and bounds from its initiation in 1974. Some of the key high points in the history of the Cancer Center include the following:

- 1974: VCU board of visitors established a cancer center on the MCV campus (health science campus of VCU), and NCI provided a planning grant to the University.
- 1975: NCI funded the first cancer center support grant (CCSG).
- 1983: Because William and Evan Massey gave a major gift to the cancer center, the name VCU Massey Cancer Center came from their involvement with the center.
- 1986: VCU Massey Cancer Center’s Dalton Oncology Clinic, BMT inpatient and outpatient clinics, and Thomas Palliative Care Unit moved into North Hospital (a renovated former E. G. Williams Hospital).
- 1987: VCU Massey Cancer Center established the Department of Radiation Oncology.
- 2006: An 80,000-square-foot, state-of-the-art cancer research facility opened at VCU Massey Cancer Center with funding from the NCI.
- 2008: The VCU Medical Center opened the Critical Care Hospital that houses the VCU Massey Cancer Center’s inpatient oncology care unit.

VCU Massey Cancer Center grew steadily over a few decades and put a solid scientific base in place, perfecting its cancer focus and shifting to concentrate on translational research. VCU Massey Cancer Center aspires to serve Virginia and the nation in a role of superior quality in cancer research, prevention and control, patient care, and education. Their overarching mission strives to uncover crucial discoveries about cancer and
to rapidly translate the findings into care for individuals with cancer.

VCU Massey Cancer Center emphasizes patient-centered care with 12 convenient clinical locations in Richmond and surrounding areas in the state of Virginia. The cancer center brings together the most comprehensive multidisciplinary team to provide highly coordinated care. Unified teams of practitioners include medical and radiation oncologists, surgeons, pathologists, genetic counselors, clinical research nurses, physical therapists, and social workers, to name a few. Each patient receives customized and personalized care. The VCU Massey Cancer Center stands out in treating not just the usual cancers of breast, colon, prostate, and lung but also complicated and atypical cancers like acute leukemia, esophageal, gastric, head and neck, liver, myelomas, pancreatic, and primary brain cancers.

The physicians at VCU Massey Cancer Center offer a variety of treatments based on multiple factors including type, location, and stage of the cancer and the patient’s age, health, and lifestyle. The patient plays an integral part in his or her treatment process and receives a great deal of information about the treatment options for the cancer. The variety of treatment options can vary from chemotherapy, radiation therapy, immunotherapy, nutrition, surgery, and biological therapy to bone marrow transplant.

The cancer patients at VCU Massey Cancer Center obtain holistic care with services other than the treatment for just their disease. These support services consist of resources in the areas of lodging, pharmacy services, wig salon, rehabilitation services, pain and symptom management, employee rights and workplace issues, alternative and complementary therapies, legal and financial issues, support groups, and survivor health. These resources go hand in hand with the principal mission to heal the person with cancer.

VCU Massey Cancer Center offers cancer patients the opportunity to participate in clinical trials as a way to uncover novel and improved methods to treat and prevent cancer. The research studies from clinical trials assess innovative medical therapies and novel devices along with expanding the scientific knowledge of a broad range of diseases. Massey proffers more than 150 clinical trials to cancer patients at any point in time.

The cancer center continuously develops novel research in both laboratory and clinical studies. Steven Grant and colleagues, using laboratory studies, uncovered a favorable treatment approach for multiple myeloma that couples two targeted agents to destroy cancer cells. The group of scientists showed the novel effect of combining the two to kill the myeloma cancer cells. In clinical research, Thomas Smith and colleagues tested a device for pain management while patients receive chemotherapy treatment. By applying electrodes to the skin of the cancer patient, the Calmare pain device effectively treated chemotherapy-generated peripheral neuropathy. Peripheral neuropathy causes pain in the nerves in the body brought on by the chemotherapy.

VCU Massey Cancer Center remains active on social media (Facebook, YouTube, and Twitter) and on major television news channels to share progress occurring in cancer treatment. The cancer statistics described on an ABC Twitter chat with Steven Grossman, MD, a deputy director at Massey, indicated that more than 1.6 million people in the United States alone will receive a diagnosis of cancer in a year, with a cost of approximately $216.6 billion. The deputy director detailed the major progress made recently in cancer immunotherapy and new knowledge about the function of cancer stem cells in resistance to treatment. Research at Massey also shows that, for cancer treatment to produce meaningful results, treatment must be directed to at least three distinct pathways to destroy the cancer cells. The cancer center does extremely well in continuously delivering the latest messages about all-around cancer care and cancer cures.

In conclusion, VCU Massey Cancer Center offers a phenomenally comprehensive program for cancer patients. Massey actively works at conquering the scourge of cancer, from education to research. Using state-of-the-art interdisciplinary teams and treatments, the cancer center helps all patients in a holistic manner to heal or to assist in the end-of-life processes. As an NCI-approved center, Massey excels at every stage of the process in cancer management.

Mayo Clinic Cancer Center

The Mayo Clinic Cancer Center (MCCC) is a service of the Mayo Clinic, and it is spread over three locations: Rochester, Minnesota; Scottsdale, Arizona; and Jacksonville, Florida. The clinic employs approximately 350 physicians and engages in patient care, administering radiation, chemotherapy, and surgery. The clinic serves more than 135,000 cancer patients per year. The clinic also conducts extensive research via clinical trials. In addition, the clinic provides cancer education, which benefits patients and cancer caregivers. The MCCC developed a system, now used worldwide, for grading cancer on a numerical basis. The MCCC is the only cancer treatment facility in the United States with three sites.

The MCCC has been recognized for its high level of patient care and research. It is one of 67 cancer treatment centers to earn the National Cancer Institute (NCI) cancer center designation. The NCI recognizes cancer treatment facilities that have achieved scientific excellence and diverse research approaches to dealing with cancer. The NCI designation places the clinic in the top 4 percent of approximately 1,500 cancer treatment facilities in the United States.

The clinic is also a member of the National Comprehensive Cancer Network, which inducted the MCCC into its ranks because of the clinic's expertise and potential to improve the lives of patients.

*U.S. News and World Report* ranked 900 cancer treatment centers. In this review, the Rochester campus of the Mayo Cancer Clinic ranked third in the nation. *U.S. News and World Report* based this rating in part on patient survival rate, which is much higher than expected at the Rochester MCCC. The Rochester campus also received the highest possible scores in patient safety, patient volume, and the ratio of nurses to patients. The Phoenix, Arizona, campus ranked 26 on the same report, and the Jacksonville, Florida, campus was not ranked.

The MCCC maintains 10 research programs: women's cancer, neuro-oncology, hematologic malignancies, genetic epidemiology and risk assessment, gene and virus therapy, gastrointestinal cancer, development therapeutics, cell biology, cancer prevention and control, and cancer immunology and immunotherapy.

The clinic runs approximately 900 clinical trials at a time. Trial subjects are recruited from all parts of the world, with populations that are underserved in cancer care, including Hispanics, African Americans, Alaska Natives, and American Indians. Participants in the clinic's trials do not necessarily travel to one of the three clinic locations. Instead, the MCCC has many off-campus sites, approximately one per state, where patients can be studied. Data is then collected at these sites and sent to the clinic. In these off-campus studies, the clinic follows protocols developed by the Alliance for Clinical Trials in Oncology. The Cancer Prevention Network is a clinical trial study group that is based at the clinic.

Clinical trials at the MCCC have resulted in important scientific breakthroughs in the understanding of and treatment of cancer. Among its achievements, the clinic has found ways to stimulate the body's immune system so that it can better fight cancer; identified types of breast cancer tumors and treatments; developed new drugs, gene therapies, and immunological therapies; and performed a groundbreaking genetic study of lymphoma cells.

The clinic developed and refined a computer-assisted method of performing brain surgery to remove deep-seated brain neoplasms (abnormal growths). It also developed an effective surgery for high-risk rectal cancer. And the MCCC was the first
research institute to test the use of the oncolytic measles virus in treating cancer.

In 2001, a team of researchers led by the clinic’s S. K. McDonnell conducted a study of 745 women who were treated for breast cancer at the Mayo Clinic for 30 years prior to 1993. The study found that, in the case of women diagnosed with breast cancer who also had family histories of breast cancer, survival rates were higher for women who had contralateral prophylactic mastectomies, that is, surgical removal of both breasts.

In 2006, a clinic study found that a combination of medications, paclitaxel and carboplatin, may be effective in treating malignant metastatic melanoma.

In 2013, two clinic scientists, Winston Tan and John Copland, identified a specific protein called stearoyl-CoA, which occurs more often in cancerous kidney cells than in healthy ones. This discovery led to more research aimed at developing an effective drug to suppress stearoyl-CoA. Because many cancers start in the kidneys and spread, this research has the potential to help many people. Tan and Copland have also identified 30 genes that promote growth of cancerous tumors.

In 2014, C. C. Chini, a physician at the clinic’s Rochester campus, led a team of scientists in isolating nampt, an enzyme linked to pancreatic cancer. The team found that targeting nampt with medications and gene therapy could slow the growth and limit the survival of pancreatic cancer cells. The scientists believe that their research has the potential to lead to new therapies in the treatment of pancreatic cancer.

The MCCC publishes an online magazine titled Forefront, which provides general information on cancer treatment as well as articles that distill the clinic’s research for a general audience of readers.

The clinic receives funding from many sources including the United States federal government, individual state governments, and private foundations. The clinic receives $140 million in competitive peer review grants, including the NCI’s Specialized Programs of Research Excellence (SPORE) grants. In 2014, the clinic received $28.6 million in federal funding in the form of a five-year federal cancer center support grant.

Further Readings

Mayo Clinic Cancer Center, Jacksonville

The Mayo Clinic Cancer Center is a cancer treatment service provider that has a multisite presence in three states: Scottsdale, Arizona; Jacksonville, Florida; and Rochester, Minnesota. This multilocation gives the center access to broad geographical research for wide and diverse service to patient populations around the world.

Mayo Clinic Cancer Center campuses have some of the best and internationally recognized scientists and physicians, and they collaborate across the spectrum of cancer research, starting from basic biology to treatment of the diseases,
and seek to establish ways in which to reduce the burden of cancer.

Mayo Clinic Cancer Center Jacksonville campus is a general medical and surgical hospital. It is categorized as a not-for-profit, and it is at the level of a nationally ranked *U.S. News* best hospital in 12 adult specialties. The Jacksonville campus is ranked number eight in Florida and ranks second in the Jacksonville, Florida, metro area as per *U.S. News* best hospitals. The center has 214 beds and, as of June 2014, the Jacksonville campus alone had 12,547 admissions, backtracking for one year. During the same year, the center successfully performed 5,853 inpatient and 6,505 outpatient surgeries. Its emergency room had 27,500 visits. In addition to treatment services, the campus does offer educational and training services; hence, it is also a teaching hospital.

The center is ranked as having high performance in adult service and also as a specialist in some adult health services including cancer; heart surgery; diabetes treatment; ear, nose, and throat solutions; gastrointestinal surgery; gynecology; and orthopedics, among several other solutions and specialties for the needs that patients often have.

For hospitals operating in the United States, there is a federal program in which hospitals are required to sample recently discharged patients and get their opinions about their stays. The survey’s purpose is to essentially get a measure of patient satisfaction on the services offered by the hospital. For the last year, the survey showered encouraging responses for some of the key questions at both state and national levels; for whether patients would recommend the hospital to friends and family, 90 percent of the patients responded definitely yes, with an average of 68 percent at the state level and 71 percent at the national level. For the same questions, 2 percent of the respondents indicated probably or definitely not, with an average of 8 percent at the state level and 5 percent at the national level.

As per the statistics from the American Hospital Association (AHA), which compiles data on all U.S. hospitals through an annual survey and from other sources (some of the details that AHA shows include hospital ownership, number of doctors and nurses, volume of births and emergency room visits, and available services such as sports medicine), Mayo Clinic Cancer Center Jacksonville inpatient has a wide range of services for cancer patients. Heart catheterization is available as well as palliative care solutions, infection isolation assistance, rehabilitation, chemotherapy, breast cancer testing, geriatric support, antismoking programs, and even sleep study spaces. All sorts of solutions are offered to patients who have various critical needs with regard to the many health issues that they may have over time.

For patient or family support services, Jacksonville center has the Alzheimer center and offers services through help with government services, chaplaincy and pastoral care services, cancer services, patient support groups, patient representatives or ombudsmen, and translation services. In addition to support services, the center undertakes community outreach programs, which include health fairs and health screenings.

Mayo Clinic Cancer Center also offers imaging services of both a diagnostic and therapeutic nature. These include computed tomography (CT) scanning and radioisotope studies plus magnetic resonance imaging (MRI), multislice CT, and ultrasound exams for all patients who require assistance. The center has staff members who are under full employment terms and others under part-time employment terms. Employees under full-time terms include 390 physicians and dentists, 405 registered nurses, and a single licensed practical nurse. Under part-time employment terms, the center has 19 physicians and dentists, 182 registered nurses, and one licensed practical nurse.

According to hospital statistics, each year, thousands of patients who have any of more than 200 kinds of cancer seek treatment at Mayo Clinic in Florida. For treatment of these patients, professionals who work in the Division of Hematology/Oncology will help all cancer patients as needed. To ensure effective and optimized health care service to their patients, the Mayo Clinic in Jacksonville, Florida, works in conjunction with the entire Mayo Clinic Cancer Center. Actually, to foster this initiative, division staff in Mayo Clinic Jacksonville work within the Mayo Clinic Cancer Center.

At the center, new drugs, biological targeted therapies, and immunology and gene therapies are studied to determine their potential for preventing and treating cancers. This research opportunity means the right facilities are available at the center; therefore, it allows qualified patients to enroll in cutting-edge clinical cancer research studies and receive the most advanced treatments. For a patient
who seeks medical help at the center, they have an opportunity to participate in the clinic’s exceptional research programs; this enables patients to learn about their condition and helps them become active participants in their cancer care.

As per Mayo Clinic Jacksonville’s records, the most common cancers seen are cancer of the colon, breast, prostate, and lung. However, Mayo Clinic’s oncologists have extensive experience in the diagnosis and treatment of every kind of cancer. The center has innovative and advanced cancer care available not only in the Jacksonville center but throughout the entire Mayo Clinic Cancer Center.

Further Readings

Mayo Clinic Cancer Center, Scottsdale

The Mayo Clinic Cancer Center is a National Cancer Institute (NCI)-designated comprehensive cancer care and research center. In addition to the center’s Arizona site, the center has sites in Rochester, Minnesota, and Jacksonville, Florida. The three sites collaborate to improve cancer patients’ care and quality of life.

The centers also cooperate on some research projects. The focus is on better understanding cancer biology and discovering new ways to diagnose, treat, predict, and prevent cancer. All Mayo cancer centers meet NCI standards for cancer care and research, including basic laboratory research, participation in high-priority NCI clinical studies, cancer prevention and control programs, education and training of health care professionals, public information services, and community service and outreach.

As part the Mayo Clinic Cancer Center, the Arizona center is affiliated with numerous cancer programs and institutions. In addition to NCI, these include the North Central Cancer Treatment Group (NCCTG), the Cancer Prevention Network (CPN), and the Coalition of National Cancer Cooperative Groups, Inc. The center also participates in 11 major cancer research programs: cell biology, developmental therapeutics, gastrointestinal cancer, gene and virus therapy, genetic epidemiology and risk assessment, hematologic malignancies, immunology and immunotherapy, neuro-oncology, prostate cancer, women’s cancer, and cancer prevention and control.

The Arizona center conducts numerous clinical trials focusing on cancer. It has conducted or has ongoing clinical trials focusing on patients with previously treated multiple myeloma, hematologic malignancies, small cell and non–small cell lung cancers, and breast cancer. Other clinical trials include a focus on acute myeloid leukemia, esophagus cancer, acute lymphoblastic leukemia, chronic myeloid leukemia, oropharynx cancer, and melanoma.

The three Mayo Clinic Cancer Centers, including the Arizona center, received a Clinical and Translational Science Award from the National Institutes of Health (NIH) in 2006. The $72.5 million grant was for five years and focused on the translation of basic science discoveries into effective clinical care approaches. In 2011, the centers were awarded a five-year extension of the grant amounting to $64.6 million.

Oncologists at the Phoenix center treat more than 100 different types of cancer. These include acute lymphocytic leukemia, anal cancer, melanoma, mesothelioma, ovarian cancer, pancreatic cancer, stomach cancer, throat cancer, uterine cancer, and vaginal cancer, to name a few. As of 2014, the Mayo Clinic included three hospital facilities: a five-story,
240-exam room outpatient clinic in Scottsdale; the Mayo Clinic Specialty Building, an outpatient clinic located in Phoenix; and Mayo Clinic Hospital, a 268-bed facility in Phoenix, which opened in 1998.

The cancer center in Arizona treats more than 90,000 cancer patients each year. These patients are seen by disease-oriented treatment groups featuring collaboration among oncologists, hematologists, surgeons, radiation oncologists, and other specialists. Individualized treatments feature surgery, chemotherapy, radiation therapy, and supportive care. Clinical care at the center also includes a multimodal treatment approach for lung cancer and asbestos-related cancers such as mesothelioma.

The Phoenix center includes various cancer education initiatives designed to help patients learn more about their cancer and cancer treatments. These initiatives provide information on cancer prevention, diagnosis, and complementary medicines and strategies. An important part of the education initiative is to help patients and families learn about coping strategies and caregiving.

The clinic provides cancer-related classes covering chemotherapy treatments and radiation treatments. It is also part of the American Cancer Navigator Program. The program provides information on cancer resources in the community, such as how to find assistance for financial and lodging needs, wigs from the American Cancer Society, and support groups. The Arizona clinic includes a Patient and Health Education Library, where patients and families can find cancer-related resources from books to DVDs. The library also features an interactive cancer education resource and a program to help cancer patients keep in touch with family and friends.

Consolidation
The Mayo Clinic Cancer Center first opened in Scottsdale in 1987. In 2012, the Mayo Clinic announced that it was building a new cancer center in Phoenix, Arizona, scheduled to open in 2015. The center in Phoenix is designed to create a single-center site to consolidate operations of the Mayo Clinic Cancer Center in Arizona. The facility is to include a $130 million, 217,200-square-foot facility featuring clinical and office space.

The idea behind the creation of the new facility was partially to provide convenience for cancer patients and their families. As a part of this effort,

The Mayo Clinic building in Scottsdale, Arizona. In 2012 the Mayo Clinic announced plans to build a new cancer center in Phoenix to create a single-center site and consolidate the operations in Arizona; the site was scheduled to open in 2015. The Arizona cancer center treats more than 90,000 patients each year. (Flickr/Mayo Clinic)
the Hematology/Oncology Department located on the Scottsdale campus is being moved to the Phoenix location. In addition, various other cancer-related units will be transferred to the new Phoenix location, including chemotherapy, bone marrow transplant, and research efforts.

The consolidation also features relocation of 32 chemotherapy infusion stations from Scottsdale to Phoenix, with an additional 18 more infusion stations planned. Exam rooms for cancer patients at the new site feature a new design concept that allows for more integrated team care of patients. The facility also features kiosks for virtual check-in and access to information.

The Phoenix facility features a $181.5 million proton-beam therapy program that represents the only one of its kind in the American Southwest. Scheduled for completion in 2016, the proton-beam therapy pinpoints tiny tumors hidden away deep inside the body and then destroys tumor tissues with large doses of radiation. These large doses can be used because the technology spares more healthy tissue surrounding the tumor, which is especially important when the tumors are located near major organs. Traditional radiation therapy has been known to cause future cancers.

The proton-beam facility is being built on the bottom floors of Mayo's six-story facility in Phoenix and will feature four treatment rooms. The overall space includes enough room for a three-story, 190-ton mechanical apparatus needed for the proton beam as well as a 20-ton magnet to guide the beam. The cancer center in Arizona will be the only facility of its kind in the state and one of less than 20 such facilities in the United States, one of which is in the Mayo Clinic Cancer Center in Rochester, Minnesota.

Meat, Cooking

Meat, the cooking process, can be described as transforming raw animal muscles into an edible product by adding high temperature and different spices such as salt, pepper, and herbs to improve the taste. This practice emerged several thousand years ago. However, the exact date and time is not yet clearly established. According to the literature, humans cook food to increase nutritive values such as protein and other essential nutrients. Choice of cooking methods sometimes depends on cultural norms, religious beliefs, and personal preference. For example, traditional ancient Romans cooked their meat with salt, smoke, and honey. Similarly, Jewish culture prohibits their meats from being cooked with other animal products; for example, fish should be cooked separately from beef. This means that at no time can the meat or the utensils be combined.

History of Meat Cooking
Historically, farm animals were used for textile and edible products such as milk and eggs. Overused animals that were unable to fulfill these purposes were eventually slaughtered and served for domestic cooking and eating. Today, numerous animal products are sold in grocery stores and food markets. The type, quality, and size vary according to economic demands. Some of the most common ones are processed meats, which contain a significant amount of sodium and sugar preservatives. These meats include pork bacon and sausages, roasted beef ready prepared, chicken nuggets and strips, and processed fish patties and sticks.

Interestingly, other meat products are available to consumers in different packages. For example,
some meats are raw and seasoned, ready to be cooked. These packages provide ease and convenient cooking methods. In contrast, other raw meats are available to be cooked and require more labor to prepare. Meats also are available in a complete package with other food groups ready to be placed in the microwave. Whichever way meats are purchased or obtained, some form of heating must be applied before humans can actually consume them.

**Meat Cooking Methods**

There are many different methods for cooking meats, whether they are purchased already prepared, seasoned, or raw. Meat cooking decisions are based on the animal muscle type, meat cut size, and tenderness. The most frequent cooking methods include grilling, smoking, frying, stewing, and baking. Grilling and smoking are used on all types of meats, particularly on tender cuts. This involves applying direct intense heat to the meat (beef, pork, chicken, etc.) over a pit or rack.

The cooking time depends on the age of the animal. Older animals usually take a longer time to cook, while meats high in fat content cook more quickly. Frying methods refer to cooking meat in fat at very high temperature. This process contributes flavor and a crispy texture outside the meat. Tender cuts of meats (breast and thighs) are often fried. Stewing is also another way of cooking meats. This is done by adding a small amount of liquid to the meat and allowing it to simmer until cooked. Baked meats are done in the oven with a temperature above 350 degrees Fahrenheit.

The internal temperature of the meat determines how well the meat is cooked. According to the U.S. Department of Agriculture (USDA), beef, veal, and lamb should be cooked to an internal temperature of 145 degrees F or 63 degrees C in order to prevent food-borne illness. It is well documented that one out of every seven hospital cases is caused from food-borne illness. Most times, the insides of meats that are prepared rare appear pink in color. This is associated with myoglobin and hemoglobin (iron) content of the meat. Medium-rare meat has an internal cooking temperature between 140 degrees F and 150 degrees F. During this level of meat cooking, the pink color changes to a gray color. The fully cooked or well-done meat has a brown color. This change in the meat is called oxidation.

Throughout the meat cooking process, raw meat constantly changes its physical and chemical structure. Raw muscle fibers are straight and connect with other muscle tissues. Once heat is applied to the meat fiber, it begins to change shape and produces fluid. During cooking, the meat becomes dry, and fluid excretion intensifies. The well-done cooked meat cell molecules are broken apart and recombine to give the meat a distinctive aroma.

**Reasons for Cooking Meat**

There are many reasons people cook meats. Three of these reasons are for personal preferences, to destroy food-borne pathogens, and to preserve the quality of the meat. First, meats are cooked based on personal preferences. For example, an individual may prefer grilled beef when compared to stewed beef. Studies have documented that raw meats are very tasty, but cooking increases flavor. Secondly, meats are cooked to prevent food-borne illness. Recently, the Centers for Disease Control and Prevention (CDC) reported between 1998 and 2008 approximately 9.6 million cases of food-borne illness, with more than 46 percent of the cases linked to animal products. The most frequent pathogens identified were *Escherichia coli* O157:H7, *Campylobacter jejuni*, salmonella, and *Listeria monocytogenes*. Third, meats are cooked to preserve shelf life and denature the long chain protein found in meats. Extending meat shelf life helps manufacturers to maintain the meat market. The protein denaturation promotes easy digestion in the human gastrointestinal tract.

**The Link Between Meat Cooking and Cancer**

Recently, many researchers have linked meat cooking to several types of cancers such as breast, pancreatic, colon, and prostate. The science illustrated that, during meat cooking, some meats produce carcinogens that interfere with human cell division.
When meats are cooked on high heat (above 350 degrees Fahrenheit), the animal muscle produces by-products called heterocyclic amines and polycyclic aromatic hydrocarbons (PAHs). These two chemicals are known to be carcinogenic in the human body and can cause change in the human DNA structure. Heterocyclic amine is a special protein that is combined with sugar and reacts at extremely high temperatures. On the other hand, PAH is produced when the juice of the meat escapes into the fire and fat from the meat begins to blaze. This example is quite obvious during grilled or barbeque cooking methods. The cancer prevalence is high in both males and females who consume a large amount of well-cooked meats and meats cooked with direct smoke.

**Meat Cooking Recommendations and Cancer**

Presently, there is no policy that governs meat cooking. However, in 2007, the World Cancer Research Institute and other collaborating cancer agencies recommended that red meat processed with high temperature should be consumed in moderation, especially if a person is diagnosed with cancer. Meats like bacon, salami, sausage, hotdogs, and ham should be avoided because of the high exposure to cancer-causing substances and excessive preservatives. The Delaney Clause prohibits the use of cyclamates and saccharin on human food.

In addition, the American Academy for Nutrition and Dietetics encourages patients who are diagnosed with any form of cancer and undergoing chemotherapy to eliminate raw and rare-cooked meats from their diets. Raw and rare-cooked meats not only contribute cancer-causing agents but promote possible stress on the immune system. Cancer patients have a very weak immune system, and animal products should be consumed with caution. The body has low white blood cells called neutrophils. The association recommends a neutropenic diet for cancer patients. The word *neutropenic* refers to a weak immune system. Most times, the diet is free from bacteria and harmful organisms. Foods in this diet include animal products like cheese, milk, and yogurt.

**The Importance of Meat in the Diet**

Animal protein is very crucial to human growth and development. When meat is digested, it is broken down into amino acids. These amino acids play a role with wound healing, growth, biological processes, and muscle structure. Poor meat intake can cause protein deficiencies and death if the body is deprived for a very long time. Individuals with cancer can prevent protein deficiencies by consuming meats that are well cooked, thus preparation should be done in a sterile environment. This is to ensure the meat is bacteria free.

According to the CDC, cancer is the second-leading causes of death in the United States. More than 575,743 people died from cancer in 2011. Because cooked meat consumption is linked highly to the growing cancer prevalence, it is pertinent that individuals control the amount and type of meat consumed. For example, many epidemiologists suggest that red meats are associated with certain breast, colorectal, and prostate cancers, and limiting the amount of this product can help reduce cancer rates. In addition, meat that is burned or gets a dark color during cooking should be avoided. Most times, these foods are high in heterocyclic amine and PAH, which can be detrimental to the human body.

One recommendation is to eat less cooked meats and increase plant-based proteins that are high in antioxidants and phytochemicals. These foods include legumes, fruits, and vegetables. This will help fight and reduce cancer-causing cells.

**Meat Processing**

Processed meat includes meat that is treated in some way for long-term preservation other than simply freezing. This includes prepared meat-heavy foods that may be canned, like stews or chili, as well as cured meats (which are treated with salt for a period of time to transform their proteins), smoked meats (usually salted or cured, as with bacon), dried meats (not just jerky but the more finely textured dried meats of Asian cuisines, jarred dried beef, and freeze-dried meats), and pickled meats (nearly always cured first). Cooking itself originated as a form of short-term preservation—it may not seem like it to us in the age of refrigeration, but the difference in shelf life between raw meat and cooked meat is profound and life changing to a premodern civilization, particularly as cooking was discovered before salt curing or smoking—but meat processing is a longer-term preservation method, especially with the use of salt.

Specifically, sodium nitrite and potassium nitrate are salts commonly used to preserve meat. Potassium nitrate or saltpeter has been produced from cave deposits, bat guano, and urine since the Middle Ages and was used in gunpowder both in early Chinese fireworks and in 19th-century firearms. In west Africa, it is used to thicken soups and soften beans and tough meat, while in the West, it has long been used to cure meat. Less used as a preservative today, it is still often used for specific, traditional cured meats, such as corned beef and French sausages.

When it is used to cure meat rather than simply to help preserve canned, jarred, smoked, or dried meat, salt has four functions. It partially dehydrates meat by pulling excess water out of the protein, which inhibits bacterial growth by providing a less-suitable environment for it. (Salt’s inhospitability to bacteria is key in its ancient use as a preservative.) It halts the fermentation process, which would otherwise result in the meat breaking down. (Though in southeast Asia, pork is salted and fermented in a wet environment with the addition of rice rather than being brined in a strong salted solution or cured in a dry preparation; this ferments the meat via lactobacillus bacteria, much as kimchi and sauerkraut are made, allowing friendly bacteria to grow, while harmful bacteria are killed off. The final product is often eaten raw.) It induces cellular osmosis, in which water is drawn outside the cellular membrane before being absorbed back in, bringing the salt with it. And it denatures the proteins, tenderizing them and changing the texture and flavor of the meat. These changes are seen both before and after cooking: Even without additional seasonings, the flavor and texture of corned beef brisket are distinct from those of untreated brisket. And dry salami starts out the same as fresh sausage but over time develops a much different flavor due to the salt, the behavior of the seasonings interacting with fat and salt over a long period of time, and the growth of healthy bacteria during the dry aging process, resulting in a tanginess similar to sourdough bread (and derived from the same bacteria).

The late 19th century brought new scientific sensibility to meat processing and curing, and potassium nitrate was mostly phased out in favor of sodium nitrite and sodium nitrate, usually in combination with sodium chloride (table salt). During the curing process, some of the nitrates are converted into nitrites by healthy bacteria. They are generally used in meats that are cured or stored for long periods of time, including prosciutto (which, like the Southeast Asia fermented pork, is eaten uncooked), country ham, dry salami, and some bacons. Meats that will be cured for a shorter period of time and...
cooked before eating, like most mass-produced bacons and cold cuts, city ham, and hot dogs, favor the use of nitrates.

Nitrates, nitrites, and the nitrosamines formed by interactions between the meat and the nitrites are all implicated in increased risk of chronic obstructive pulmonary disease and gastric cancer. Nitrosamines are believed to be the primary factor here, though the role of nitrates and nitrites on their own is not fully understood yet. Nitrosamines are formed from nitrites interacting with amines in the meat’s protein but can only form in specific conditions like high temperatures (the frying of bacon) or highly acidic environments, like the human stomach. Ascorbic acid and other compounds can minimize their formation.

There are a number of different nitrosamines, some of which are probable carcinogens, some of which are possible carcinogens, and some of which have no known carcinogenicity. The mechanism by which they are carcinogenic has not been shown. Gastric cancer is the strongest correlation, but there is also evidence of an esophageal cancer risk. Nitrosamines also are present in preserved fish and some cheeses as well as tobacco smoke, smokeless tobacco, and e-cigarette vapor.

Media

Media content is paramount to our personal and societal understanding and conceptualization of cancer. Most individuals in developed countries have ample general media exposure and media use. Individuals often cite news media as important sources of health information, including cancer information.

Media campaigns are at the forefront of many public health efforts to educate about, portray, and fight against cancer. Indeed, media messages may influence health-related behaviors, including those associated with cancer prevention, detection, treatment, and recovery.

Media also contribute to individuals’ narratives, myths, images, and beliefs about cancer. It is possible that media coverage of cancer has unintended effects as well as intended effects that should be taken into consideration when examining media’s impact on cancer in society. Media content, characters, and stories also feature images, behaviors, and messages that intensify the cancer epidemic.

Exposure and Attention
As information moves online (and mobile), certain groups may be marginalized due to occupation (e.g., a construction worker who cannot check his or her news feed during the day), geography (e.g., an individual in a rural location without access to broadband Internet), or income. Issues like the digital divide and the knowledge gap must be recognized at the intersection of media and cancer. If news organizations and public health campaigns focus primarily on multimedia and online information dissemination, there may be deleterious health consequences for those without access to important cancer information.

Individual-level factors also contribute to different types of media experiences. Factors such as personality, individual motivation, and personal values as well as whether the user is engaged in multitasking can potentially influence message effectiveness at the time of processing.

Conflicting messages in the news about cancer prevention and screening may lead to greater individual uncertainty about the effectiveness of cancer prevention efforts (e.g., proper nutrition) and cancer screening guidelines (e.g., age for mammography screening). For example, consumers may read
an article about how increased consumption of tofu and soy products increases risk of breast cancer but read another article about incorporating a reduced-meat diet for overall health and weight loss (which is also encouraged to reduce risk of cancer).

Exposure and attention to media content may also not accurately reflect epidemiologic trends for specific types of cancer. There are many types of cancer, and media sometimes disproportionately portray their incidence, prevalence, and severity. Breast cancer images, references, organizations, and news often outweigh other types of cancer with higher mortality rates (e.g., lung).

Additionally, media content that may seem desirable (e.g., prominence of tan skin in models or popular movie stars smoking) may serve to perpetuate some of the risky habits that contribute to greater risk of cancer. In this way, media content sends a different message from public health efforts to alert the public of the lifestyle changes society can make to prevent cancer.

**Information Seeking**

A prominent question about cancer in the media is what catalyzes individuals to seek out cancer information. Individuals may have discomfort or notice visible changes in their bodies and, subsequently, turn to media resources in an effort to understand a symptom and diagnose. On the other hand, individuals without particular symptoms may actively seek out additional cancer information after hearing a particular news story on cancer. Research indicates that individuals who pay close attention to health news and those with a family history of cancer are more likely to seek out cancer information.

Regardless of the exact rationale for paying particular attention to cancer in the media, the action of information seeking often makes the information obtained more effective and memorable. These media messages may prompt individuals to take action, encouraging them to engage with cancer communication sources: primary care providers, support groups, families, and social networks. Cancer prevention researchers point to active information seeking as a major precursor to reducing risky behaviors known to be associated with cancer diagnoses.

In order to increase the likelihood of high-risk individuals seeking out cancer information in the media, cancer messages must be appropriately tailored for channel effectiveness and the content tailored and made salient for the specific audience segments.

**Community and Social Media**

Media also allow society to join the cancer conversation by accessing support groups, asking questions, sharing cancer-related media links, posting personal content on social networking sites, and making online contributions and donations to cancer-related causes and organizations. This user-generated content is therefore part of cancer’s landscape in the media. It has both enriched the amount and diversity of cancer information available in the media and contributed to disproportionate coverage of cancer information noted previously.

Humorous or lighthearted cancer content may dominate media attention. For example, Facebook status updates about bra color status have dominated news feeds around the world in an effort to raise breast cancer awareness. In another example, “hashtag mamming,” which was introduced in the fall of 2013 for breast cancer awareness month,
encouraged women to post a picture on Instagram showing their cleavage in order to show solidarity with women getting mammograms. In another example, Movember is a new global charity that encourages men to grow a moustache in November and post pictures of their mustaches online in order to raise awareness about prostate and testicular cancer. These examples demonstrate the integration of user-generated content into the media environment. It is clear that these social media efforts create a larger sense of a cancer community, especially highlighting the ability for social media to intermingle support from cancer-free and cancer-affected voices.

Social media also has contributed to a more serious cancer community and greater understanding of the realities of cancer diagnosis. For example, Twitter has been utilized by individuals undergoing cancer treatment to detail their experiences or, as noted by journalist Bill Keller of the New York Times, to “live cancer onstage.” Lisa Boncheck Adams made national news as she live Tweeted and blogged about her experience living with stage 4 breast cancer. Although Adams’s decision to make public a very personal experience caused a large debate about what was appropriate for social media, she has approximately 14,000 followers at the time of this writing, demonstrating a larger community interested in her well-being through the cancer process.

The community aspect of cancer also can be understood by looking at philanthropic content. The social understanding and production of cancer is bound to symbols and events like the pink ribbon and Race for the Cure. Media coverage contributes to the culture and experience of cancer and allows community to be a part of the cancer experience, even if it is not firsthand.

Studies and Impact
Direct effects of media are varied, but the preponderance of evidence supports an association between exposure to risky health habits in the media and initiation of those same habits (e.g., smoking). Media advertisements, sponsorship, and promotional events play a health advocate role as well as showcase companies and behaviors that may contribute to greater cancer incidence. Media studies on the influence of media on cancer-related knowledge and behaviors have recently emphasized the processes by which media influences individuals’ health behaviors. This type of influence is called an indirect influence and asserts that media affects individuals’ beliefs and cognitions. Thus, strategies at improving health outcomes focus on how media affect these internal processing factors.

Conclusion
Media messages related to cancer, risky behaviors associated with cancer, and cancer information may be positive or negative and may have intended and unintended consequences. Individuals often seek out or encounter cancer information in the media, although it is likely that they will encounter ambiguous or conflicting information that may cause uncertainty or further information avoidance. Widespread media consumption and daily routines filled with mobile devices accessing information and sharing information via social media necessarily affects our societies’ understanding, knowledge, and decision making surrounding cancer, which may be vital to public health efforts to ease individual and societal cancer burdens.

Medicare and Medicaid
Medicare and Medicaid are public insurance programs in the United States. Medicare provides insurance for Americans based on being elderly or having
Medicare and Medicaid

Medicare

Medicare recipients mainly have disabilities or are elderly. Medicare recipients must be 65 years old or older, disabled, or with permanent kidney failure that necessitates transplant or dialysis. Medicare is a federal insurance program that has four parts: A, B, C, and D. Parts A and B are for hospital and medical insurance. Parts C and D are for flexibility and prescription drugs. A variety of hospital and outpatient services are covered, at least partially, by Medicare Part A, or hospital insurance: semiprivate room, meals, testing, and supplies. Home health care is also covered under Part A, which includes various forms of therapy, such as occupational and physical therapies. Payroll taxes fund Medicare's expenditures; the recipient does not have to pay premiums. Payroll taxes are gained through the Federal Insurance Contributions Act (FICA) and Self-Employment Contributions Act. For every $100 a worker earns, $2.90 is paid to the FICA account. For workers who are not self-employed, they pay $1.45 to FICA for $100 earned, and their bosses pay the same amount. Money earned through self-employments is taxed the same amount, but the workers themselves have to pay the full amount of $2.90 per $100 earned.

Medicare Part B, also called Supplementary Medical Insurance, is completely voluntarily. In 2014, monthly premiums were nearly $104 with a $147 deductible. Medicare Part B pays for outpatient physician treatment and home health care services. Part B covers a variety of services such as eyeglasses, blood transfusions, vaccinations, physician and nursing services, and diagnostic tests. Medicare Part C is an attempt to allow users to more specifically design their treatment services to the recipient’s needs. Medicare Part D offers prescription drug coverage and is voluntary, but enrolling at any time after the Initial Enrollment Period may carry a late enrollment penalty. Medicare Part D is offered by private companies, and the premium and coverage offered varies by plan, within boundaries set by the federal government.

Medicaid

Each state must set the specific conditions that recipients must meet to be eligible for Medicaid benefits. In general, young children (those under 6 years old) and pregnant women whose families earn less than 133 percent of the federal poverty level qualify. Those who receive supplemental security income also qualify. Certain adopted children and foster children and Medicare beneficiaries qualify also. States may also extend coverage to those who are low-income, institutionalized people, those with tuberculosis, those who are medically needy, and those who qualify at a higher percentage level of the federal poverty level (at 250 percent instead of 133 percent). Fees are paid directly to the health care provider on a fee-for-service basis. States may have a nominal deductible for services but may not create deductibles for pregnant women or children under 18. In addition, deductibles may not be charged for family planning or emergency services. States receive a varying amount of finances from the federal government depending on the financial resources that that state currently has. The range of federal funding for state Medicaid services ranges from 50 to 83 percent.

Medicaid is administered by the states. Each state establishes specific Medicaid eligibility. States determine the nature and scope of the services and how much each of the services will be reimbursed. Medicaid pays for inpatient and outpatient services, prenatal care, vaccines for kids, nursing home care, physician services, and rural health care. In addition, states may provide funds for diagnostic tests, transportation, pharmaceuticals, and rehabilitation services.

Medicaid and Medicare Fraud

Given that nearly $900 billion annually is spent on Medicaid and Medicare, it is easy to believe that white-collar criminals would be attracted to Medicaid and Medicare as a way to make money. In fact, a great deal of money could be made through Medicaid and Medicare fraud without the government even knowing about it. Medicaid and Medicare fraud comes in several different forms. One estimate of Medicaid and Medicare fraud is 8 to 10 percent. The first is phantom billing, which bills the federal government for unnecessary procedures and tests that were never performed. The fraud may also include equipment that is billed as new but is actually used. Patient billing fraud happens when a health care provider gets the necessary billing information from a client, who is a
confederate who receives a kickback, and then bills for a series of procedures that have not been provided. Upcoding is an additional fraudulent scheme by which the federal government is billed for more procedures or more serious procedures than what was necessary. This causes the bill to be larger than what it should be, thereby causing fraud and waste for taxpayers, not to mention depleting resources needed by those on Medicare and Medicaid.

There have been large Medicare arrests across the United States. In 2012, 91 doctors, nurses, and other health care providers were arrested nationwide and found to be responsible for about $430 million of fraudulent expenditures. Other raids have shown that foreign mobsters have become involved with Medicare fraud schemes because of the amount of money to be made. To combat this fraud, a Medicare Fraud Strike Force was developed. This task force has made large, nationwide arrests for fraud and regularly makes spot checks of health care organizations to make sure that fraudulent charges are not being made.

Cancer

Medicaid is operated jointly between the federal government and state governments. Medicaid benefits, therefore, will vary by state. In this section on cancer, Medicare benefits only will be examined. Medicare will cover certain things when it comes to different types of cancers. For breast cancer, one screening mammogram every 12 months is fully covered for all women with Medicare age 40 and older. One baseline mammogram between ages 35 and 39 is also covered. Medicare also covers newer digital mammograms. Medicare pays for a clinical breast cancer exam once every 24 months for women at average risk of breast cancer. A clinical breast exam (CBE) is covered once every 12 months for women at high risk and those of childbearing age who have had an exam that showed cancer or other changes in the past three years. Medicare’s cancer screening coverage information does not include magnetic resonance imaging (MRI) along with a mammogram as a screening method for women who are at high risk for breast cancer. And if a mammogram shows a change that requires more pictures, the patient might have to pay the deductible and co-pay for a diagnostic mammogram.

Medicare covers one Pap test and pelvic exam every 24 months if the patient is at average risk for cervical cancer. If a patient is at high risk for cervical or vaginal cancer or is of childbearing age and has had an abnormal Pap test in the last three years, the tests are covered every 12 months. The patient pays nothing for the Pap test or for collecting the Pap test and the pelvic exam. As part of the pelvic exam, Medicare covers a clinical breast exam to check for breast cancer. As of 2014, Medicare’s cancer screening coverage information does not list human papillomavirus (HPV) testing as a covered screening test for cervical cancer.

Medicare covers colorectal screening tests in people 50 and over to help find colorectal cancer or precancerous polyps, so they can be removed before they turn into cancer. Coverage for these tests depends on the person’s risk for colorectal cancer, when he or she had the last test, and whether something is found that needs to be removed during the test.

For men over age 50 with Medicare, one digital rectal exam (DRE) and one prostate-specific antigen (PSA) blood test are covered every 12 months. This coverage starts the day after the 50th birthday. The patient pays nothing for the PSA test, but the patient must pay 20 percent of the Medicare-approved amount for the DRE, and the yearly Part B deductible applies for the DRE. Medicare does not cover lung cancer screening tests at this time, even in people with a high risk of lung cancer.

MedImmune (United States)

MedImmune, with headquarters in Gaithersburg, Maryland, creates, produces, and sells preparations of biologicals and live-virus vaccines. This company began as Molecular Vaccines, Inc., an establishment started by Wayne T. Hockmeyer in 1988, and the name changed to MedImmune, Inc., in 1990. MedImmune spent the next two decades developing innovative biological and viral therapies.

The University of Rochester cultivated the human papilloma virus (HPV) technology. In October 1995, MedImmune gained sole rights to the HPV technology for further growth in the HPV methodology. The company’s interest lies with developing this type of virus technology. By June 1996, MedImmune acquired the license of the HPV intellectual property from the German Cancer Research Center.

The company then obtained approval from the U.S. Food and Drug Administration (FDA) in January 1996 to sell RespiGam, an immune globulin given by intravenous injections, for children at high risk of contracting serious lower respiratory tract infections precipitated by Respiratory Syncytial Virus (RSV). RSV remains the most common germ to trigger lung and airway infections in infants and young children. RespiGam went off the market in 2004.

After approval by the FDA, MedImmune sent Synagis (palivizumab) to market for the prevention of serious lower pulmonary tract infections in June 1998. Synagis is a human monoclonal antibody used to prevent RSV in children. In July 2004, MedImmune placed a liquid version of Synagis on the market.

MedImmune acquired U.S. Bioscience in November 1999. The attainment of U.S. Bioscience gave the company three oncology and infectious disease products. The merger increased expansion capabilities for the promotion of oncology products. Next, MedImmune secured the rights to the drug amifostine from ALZA Corporation. Ethyol (amifostine), an oncology drug, with an action of a cytoprotective adjuvant mediator, is used in cancer patients receiving radiotherapy or chemotherapy involving DNA-binding chemotherapeutic agents. Amifostine reduces neutropenia-related fever and infection triggered by DNA-binding chemotherapy agents (e.g., alkylating agents and platinum-containing agents like cisplatin). The drug also decreases xerostomia in patients receiving radiation to the head and neck for cancer.

In January 2002, MedImmune acquired Aviron, a company with research compiled in the area of infectious diseases. The Aviron Company completed research trials on the product FluMist (Influenza Vaccine Live, Intranasal), and the FDA continued to review it at that time. The product entailed a novel method of flu vaccine delivery by nasal mist administration. It took another year and a half (June 2003) before the FDA approved FluMist. FluMist became the first nasally administered vaccine for healthy people age five to 49 years in the United States. In 2007, the FDA expanded the age range from age two to 49 years.

MedImmune announced its collaboration with the National Institute of Health to develop pandemic flu vaccines in July 2005. The plans for a flu vaccine helped MedImmune to receive $170 million for a five-year contract under the Department of U.S. Health and Human Services for a cell-based vaccine. MedImmune initiated the building of a biologics manufacturing facility in Frederick, Maryland, in September 2006 to move forward with a cell-culture-based industry.

AstraZeneca purchased MedImmune in June 2007 and merged MedImmune with Cambridge Antibody Technology by December 2007 but maintained the MedImmune name. The MedImmune name remained because AstraZeneca envisioned a worldwide biologics business.

MedImmune forged a relationship with Inserm and Inserm Transfert in February 2011 in an effort to expand research across a variety of therapeutic venues. Research moved more into the areas of oncology, respiratory, inflammation, and autoimmunity. The year 2011 also saw MedImmune’s Frederick Manufacturing Center receiving the International Society for Pharmaceutical Engineering’s 2011 Facility of the Year Award.

In April 2012, MedImmune established an affiliation with Amgen to collaborate on creating and commercializing a respiratory, inflammation, and autoimmunity (RIA) portfolio. The current work focuses on systemic lupus erythematosus (SLE), asthma, idiopathic pulmonary fibrosis (IPF), psoriasis, chronic obstructive pulmonary disease, multiple sclerosis, and rheumatoid arthritis (RA).
Oncology represents just one of the five areas of main concentration for the MedImmune Company. The oncology research aims to study solid tumors (e.g., breast or lung cancers) and hematologic cancers (e.g., lymphoma or leukemia). This research probes novel technology designed to destroy cancer cells in more efficacious and directed ways (e.g., effector-enhanced, polyspecific, and toxin-carrying antibodies). The scientists study strategic biologic capacities crucial to the initiation and progression of cancer. The areas of biologics include immune-mediated cancer therapy, tumor-associated antigens, cancer stem cells, growth factor signaling, and survival and oncolytic viruses.

MedImmune’s work on immune-mediated therapies represents a thriving field of cancer research. These therapies strive to restore and strengthen a patient’s immune system so it is able to intensify the recognition of cancer and then be able to attack the cancer. With the enhanced ability of the immune system, the body is able to respond to treatment and to prolong survival. One of the immune-mediated therapies happens to be Tremelimumab, a CTLA-4 blocking immunotherapy that remains under study in melanoma and other solid tumors. R. W. Georgantas and colleagues published results demonstrating tumor suppression in melanoma.

Immunotoxins represent a second example of promising research in oncology at MedImmune. Referred to as the Trojan horse of cancer therapies, scientists cleverly linked a toxin to an antibody. The goal is to deliver a toxin directly into a tumor cell without injury to the normal cells near it. Research by D. Bannister and colleagues demonstrates early research on monoclonal antibodies linking to toxic payloads and resulting in clinical efficacy in cancer treatment.

In conclusion, MedImmune, Inc., represents an extraordinarily innovative drug company working in the field of biologics and vaccines for treatment of diseases like cancer. Biologics and vaccines embody new areas in the last two decades to be added to the treatment regimens in cancer. The company focuses on these areas of oncology: infectious disease and vaccines, cardiovascular and metabolic diseases, neuroscience, and respiratory, inflammation, and autoimmunity (RIA). MedImmune presently conducts more than 120 research projects with the hope of coming up with breakthroughs and improvements for treatment in many diseases.

Melanoma

Melanoma, also known as malignant melanoma and cutaneous melanoma, is a skin cancer originating from melanocytes, the melanin pigment-producing cells in the basal layer of the epidermis. Melanoma is the most lethal form of skin cancer because it has a higher potential for metastasis (i.e., spreading to other tissues). The primary cause of melanomas is overexposure to ultraviolet (UV) light either from direct exposure to sunlight (UVA and UVB) or from tanning beds (UVA), which is absorbed by the skin and results in DNA damage. This DNA damage causes aberrant gene expression in multiple genes and can lead to malignant tumor formation. Minimizing one’s exposure to these harmful UV rays by avoiding tanning beds and applying sunblock cream to any potentially exposed skin prior to outdoor activity as well as wearing protective clothing (such as wide-brimmed hats and long-sleeved shirts and pants) can greatly reduce susceptibility to melanoma.

Melanomas usually develop from existing moles (nevi). The first signs of melanoma are changes in the color, size, shape, or surface texture of an area of skin or existing mole. The majority of melanomas are usually either black or brown; however, other colors have been observed such as red, blue,
Melanoma may develop anywhere on the body, but are more likely to be found on the torso, head, or neck in men and on the arms or legs of women. Less-common melanomas have been found under nails and on the palms of hands, soles of feet, eyes, mouth, genitals, and the anal area.

Due to the fact that melanomas occur on the skin, the changes in shape and coloration of existing moles as well as abnormal growth of melanomas usually can be readily seen by the patient. In fact, patients are frequently the first to notice early-stage melanomas. If diagnosed early enough, most melanomas can be cured and excised with minor surgery. Early detection and treatment are key because, once the cancer has metastasized to other parts of the body, no reliably effective therapy is available and the chances of the patient succumbing to the disease are therefore high.

Melanoma progression can be characterized by five stages (stages 0–IV) where stage 0 indicates the melanoma to be in situ, meaning that abnormal melanocytes are located only in the epidermis, while stage IV is the most advanced, where the melanoma has metastasized to other parts of the body. Surgery is the first treatment of all stages of melanoma. After stage 0, other therapies besides surgery may be necessary to cure or remove the skin cancer.

Types of Melanoma

There are four main types of melanoma. Three of these—superficial spreading melanoma, lentigo maligna melanoma, and nodular melanoma—comprise 90 percent of malignant melanoma, while acral lentiginous melanoma and some other rare types make up the remaining 10 percent.

Superficial spreading melanoma is the most common type of melanoma, accounting for approximately 70 percent of all diagnosed melanomas. True to its name, this melanoma spreads along the surface layer of the skin for an extended period of time before penetrating more deeply. This type of melanoma can form from preexisting, benign moles. The first signs are darkened, flat, barely-raised lesions with irregular borders and color variations (black, brown, red, tan, or white). This melanoma can be found anywhere on the body. It is found most commonly on the backs of men, the legs of women, and the upper backs of both sexes.

Lentigo maligna melanoma arises from lentigos, which are flat, brown spots that are associated with aging or sun-damaged skin rather than moles. For this reason, this type of melanoma is found commonly among the elderly in chronically sun-exposed areas, such as the face, ears, arms, and upper torso. Because this melanoma arises from lentigos, it closely resembles lentigos but may contain different shades of brown and other color variations of black, blue, red, gray, or white.

Nodular melanoma is the most aggressive of the four main melanoma types because it grows more deeply and more quickly compared to the other three types. The melanoma appears as a blue-black, dome-shaped nodule, but as with most melanomas, color variations of blue, gray, white, brown, tan, red, or even flesh tones can be possible. This type of melanoma is invasive when it is first diagnosed, and malignancy is recognized when the damaged area becomes a bump or a highly raised area on the skin. This type of melanoma may not necessarily form from an existing mole and often occurs in areas of the body that only receive intermittent sun exposure (e.g., the chest).

Acral lentiginous melanoma is the most common melanoma among African Americans and Asians and the least common among light-skinned individuals. This melanoma appears as tan, black, or brown discoloration with irregular borders on the palms of hands, soles of the feet, or under nails, particularly the big toenail. The specific causes for this type of melanoma are unknown and unrelated to sun exposure, so the cancer cannot be attributed to UV radiation.

Treatment

Treatment strategies for malignant melanoma depend on several parameters, including histological classification and stage of the disease. Standard treatment for primary melanoma is wide excision of the primary tumor through surgery. Excision margins are based on the thickness of primary melanoma; wider excision margins are needed for the removal of a melanoma as its thickness increases. Due to the potential of metastases of melanomas to the lymph nodes, excision of the draining lymph node (or sentinel lymph nodes) is considered critical because this is most likely to be the first lymph node to which a melanoma will metastasize. Currently, sentinel lymph node biopsies (SLNB) are sensitive
enough to evaluate metastasis to the first draining lymph node. If lymph node metastasis is detected in the sentinel lymph node, then other lymph nodes in the area of the primary melanoma may also be removed surgically. When surgery of the tumor or metastatic lymph nodes is impossible or unreasonable, radiation therapy of the primary tumor or the regional lymph nodes is a viable option. Both types of therapy are appropriate for solitary or localized lesions but are not sufficient for patients diagnosed with metastatic disease. Adjuvant therapy (i.e., additional treatment provided after surgery or radiation) is recommended to patients with potential for recurrence (stages II and III) and may include immunotherapy, radiotherapy, or even the testing of a new treatment in a clinical trial. However, adjuvant therapies may reduce the quality of life for the patient without extending survival. Because there is no effective treatment for the most advanced form of melanoma (stage IV), many treatment options may be offered to the patient, which include participation in a clinical trial, chemotherapy, or immunotherapy.

**Follow-Up**
People who have been treated for, or with a family history of, melanoma should be monitored frequently to ensure an early diagnosis. For patients with melanoma thickness of less than one millimeter, less-intensive follow-ups are necessary. However, patients with high melanoma thickness (greater than one millimeter) will need more intensive checkups, that is, every three months for the first five years followed by every six months for a 10-year period.

**Melanoma, Intraocular (Eye)**

Intraocular melanoma is a disease in which cancer cells arise from melanin-producing cells of the eye (melanocytes). The most common type of intraocular melanoma is uveal melanoma, where the cancerous cells arise from the uvea. The uvea is the middle layer of the wall of the human eye and is composed of three main parts—iris, ciliary body, and choroid. Depending on the primary site of development, the tumor may be called an iris melanoma, ciliary body melanoma, or choroidal melanoma. Eye melanoma can occur on the conjunctiva or in the eye socket, but these types of eye melanoma are very uncommon. Although the incidence of intraocular melanoma is rare—only six per million—this cancer is noteworthy as it is the most common malignant tumor arising in the eye, and the second-most common type of melanoma after cutaneous. Unlike most cancers, the survival rate of intraocular melanoma has not improved despite the newer treatment options, and currently, there is no effective systemic therapy available once the cancer spreads to the other organs. Nearly half of all patients diagnosed with uveal melanoma will develop metastases, and the estimated five- and 10-year survival rates from the diagnosis of uveal melanoma are 75 and 60 percent, respectively. Hence, prevention and early identification are critical for individuals at risk of developing intraocular melanoma metastasis.

**Symptoms**
Symptoms of intraocular melanoma can include decreased peripheral vision, blurred vision, changes in the shape of the pupil, irritation, redness, the sensation of flashing lights, and specks of dust...
or floaters in vision. However, up to one-third of patients are completely asymptomatic at the time of diagnosis. Additionally, these symptoms are not unique to intraocular melanoma. Individuals experiencing any of these symptoms should be evaluated by an ophthalmologist for an appropriate examination and workup.

Complications
Growing tumors can impinge on adjacent structures within the eye and can lead to increasing pressure within the eye, causing glaucoma. It can also lead to vision loss or spread to adjacent organs—such as the liver, lungs, and bones.

Causes
There are no known causes for the development of intraocular melanoma. Exposure to ultraviolet (UV) radiation has been studied as a possible cause of intraocular melanoma. Although excess UV radiation is known to cause skin melanoma, it has not conclusively been shown to cause intraocular melanoma and is likely noncausal. Genetic risk factors, such as mutation of the BAP1 gene, are currently being studied as a cause of uveal melanoma.

Risk Factors
Known risk factors for intraocular melanoma include light eye color, white ethnicity, older age, and certain inherited skin disorders, such as dysplastic nevus syndrome. Studies have shown that intraocular melanoma rates are eight to 10 times higher in whites compared to blacks, and that the peak incidence is the seventh and eighth decades of life.

Diagnosis
Multiple methods exist for diagnosis; however, in 99 percent of cases, noninvasive indirect procedures such as ophthalmoscopy, slit lamp biomicroscopy, and ultrasonography are used. Invasive procedures, such as an angiogram or biopsy (removing a sample), are sometimes required to examine the suspicious tissue.

Prognosis and Prevention
Currently, there are no treatments for intraocular melanoma post metastasis. Although cutaneous melanoma (skin cancer) is related to intraocular melanoma, medications used to treat cutaneous melanoma, such as decarbazine and temozolomide, are not effective for treating intraocular melanoma. Naturally, this has put the emphasis on prevention and identification of individuals at risk of intraocular melanoma metastasis.

One way patients with intraocular melanoma may be monitored for metastasis is through liver function tests as uveal melanoma has a high propensity for metastasis to the liver. Liver metastasis makes up 93 percent of uveal metastasis, followed by 24 percent for lung and 16 percent for bones. It can also spread to the brain, skin, or any other organ of the body, so imaging tests, such as X-ray, computed tomography (CT), and magnetic resonance imaging (MRI), are also used to monitor whether the melanoma has metastasized systemically.

Tumor location, size, histology, or mitotic index (growth potential) all can be used to predict metastasis. These features are helpful in counseling the patient; however, they are not absolutely predictive for the progression of intraocular melanoma. Recently, chromosome analysis and gene expression profiles have been used to predict metastasis. Monosomy 3 and duplication of chromosome 8 are two examples of chromosomal anomalies associated with increased risk of metastasis.

In gene expression profiling, a patient’s gene expression profile is compared to the gene expression patterns from more than 40,000 cancer-related genes of other intraocular melanoma patients who
had either survived or died from the disease. The closer the genetic expression is to those who died from their disease, the worse the prognosis; the closer the genetic expression is to those who survived the disease, the better the prognosis. The genetic profile can be used to classify intraocular melanoma as either class 1 (unlikely to metastasize) or class 2 (very likely to metastasize).

**Treatment**

It is important to consider the size of the tumor when looking at treatment options. A small intraocular melanoma may not require immediate treatment, whereas a large melanoma may require a more aggressive treatment. Treatment options include surgery, radiation therapy, laser therapy, and cold treatments. Surgery can be done to remove a part of the eye that has the melanoma, or the entire eye can be removed if the tumor is large. Radiation therapy uses high-power protons or gamma rays to kill the cancer cells. Laser treatment involves the use of infrared laser, and cold treatment uses extreme cold (cryotherapy) to kill the melanoma cells.

**Drugs in Clinical Trial**

In June 2013, Carvajal and colleagues presented a study on the experimental drug selumetinib. Treatment of metastatic uveal melanoma with selumetinib was shown to shrink the tumor size, making selumetinib the first systemic therapy ever to treat patients with systemic ocular melanoma effectively. With selumetinib, 50 percent of patients experienced tumor shrinkage, with 15 percent achieving major shrinkage.

**Memorial Sloan Kettering Cancer Center**

The Memorial Sloan Kettering Cancer Center (MSKCC) in New York City is the oldest and largest private cancer center and hospital in the United States. MSKCC was founded in 1884 as the New York Cancer Hospital by a group of people that included John Jacob Astor and his wife Charlotte. The name of the hospital was changed in 1899 to General Memorial Hospital for the Treatment of Cancer and Allied Diseases. In 1936, the hospital was relocated on land donated by John D. Rockefeller Jr. and the new Memorial Hospital opened in 1939.

The Sloan Kettering Institute was established in the 1940s by Alfred P. Sloan and Charles F. Kettering, former executives of General Motors. Today, the institute is one of the leading biomedical research centers in the United States. The Memorial Sloan Kettering Cancer Center was established in 1960 to coordinate and oversee the policies of the Memorial Hospital and the Sloan Kettering Institute. In 1980, the two combined to form a single institution headed by a president and chief executive officer.

MSKCC is one of 41 institutes designated by the National Cancer Institute as a comprehensive cancer center because of their excellence in basic research, clinical science, and cancer treatment. MSKCC has 471 inpatient beds and a surgical area covering 72,000 square feet. MSKCC physicians work in close collaboration with research scientists to make the highest-quality care available to cancer patients and to develop effective strategies for cancer prevention, control, and cure. MSKCC also offers specialized training for physicians and scientists. The center...
provides care to patients with all types of cancer and allied diseases through professional counselling, patient information, and education.

The research programs at MSKCC are divided into eight categories, including cancer biology and genetics, cell biology, computational biology, developmental biology, immunology, molecular biology, molecular pharmacology, and chemistry. In 2014, MSKCC's research division was under the leadership of Joan Massagué and comprised more than 100 laboratory investigators, 400 research fellows, and about 200 doctoral students. Many members of both the National Academy of Sciences and the Howard Hughes Medical Institute are affiliated with the Sloan Kettering Institute. The research activities at MSKCC are spread across three buildings—the Rockefeller Research Laboratories, Schwartz Research Building, and Zuckerman Research Center.

The Sloan Kettering Institute offers a range of training programs, including a tri-institutional M.D.-Ph.D. program, doctoral programs, and summer internships. In 2004, the Louis V. Gerstner Jr. Graduate School of Biomedical Sciences was established at MSKCC and offers a doctoral program for laboratory scientists in the field of cancer biology. The primary aim of this program is to train the next generation of researchers, clinicians, scientists, physicians, and other allied health care professionals to assume leadership roles in the life sciences and medicine, with a special emphasis on cancer treatment, prevention, and care.

The education and training programs at MSKCC form a vital and integral part of the center's mission. These programs include graduate training, post-doctoral training, and continuing education to prepare the next generation of physicians, scientists, nurses, and technicians.

MSKCC awards the Paul Marks Prize for Cancer Research, named after Paul A. Marks, the center's president emeritus, to recognize young leaders making significant contributions to the understanding and development of new cancer treatments. The prize encourages researchers to create novel cancer therapies and to better understand the mechanisms of cancer development and progression. The prize is awarded to a maximum of three investigators every alternate year, and nominees for the award have to be 45 years old or younger. Prize winners are selected by a panel of cancer research investigators from leading research institutions, and the winners share a cash award of $150,000 and present their work at a scientific symposium at MSKCC.

Fred's Team is the athletic fund-raising program at MSKCC, named in honor of running legend and New York City (NYC) marathon cofounder Fred Lebow. Fred's Team participates in the TCS NYC Marathon, the Boston Marathon, and other events, raising money to support more than 50 areas of cancer research. Fred's Team has raised more than $59 million since its founding in 1995. The Society of Memorial Sloan Kettering Cancer Center, a volunteer organization, also plays an important role at the center. Founded in 1946, the society develops and funds programs to enhance patient care and provides public education materials on cancer prevention, early detection, and treatment.

Further Readings
Menarche is a woman's first menstrual cycle; the age at which it begins can vary considerably. Of both social and medical significance, menarche is the principal event of female puberty, signaling the entrance into adolescence as the result of becoming potentially fertile. The age of 13 is a traditional estimate given as an average or typical start time, but the average age in the United States is closer to 12, while in general, Asian women experience menarche later than Western women do.

Menarche requires a certain set of biological events as prerequisites: the release of estrogen by the ovaries in response to signaling from pituitary hormones; the growth of the uterus, widening of the pelvis, increase of fatty tissue, development of the breasts, and height growth, all in response to estrogen; the estrogen-driven growth of the uterine lining, the endometrium; and the accumulation of sufficient body mass (which results in delayed menarche among the malnourished). There is no one specific signal in the body that causes menarche to occur; rather, these many physiological changes lead up to it. Menarche often differs from later menstruation: While also accompanied by abdominal cramps (typically less severe than in a postadolescent woman), the flow is usually scantier, sometimes limited to brief spotting, and is visually brighter. Menarche does not always indicate that ovulation has occurred; studies indicate that most women's cycles remain anovulatory (without ovulation) as much as three years after menarche and six years for about 10 percent of women. Thus, although menarche is commonly taken as a sign of fertility, this is true for only a minority of women, for whom there is no clear external sign indicating their first ovulation. A small number of women ovulate before their first menarche, and can conceivably become pregnant from a conception that precedes menarche, which further demonstrates the error of the commonly assumed conflation of menarche and the ability to conceive and carry a child.

While the amount of time, if any, between menarche and first ovulation varies from woman to woman, studies have established that early menarche correlates with early onset of ovulatory cycles. D. A. N. Apter and Reijo Vihko, for instance, established that not only does early menarche lead to early onset of ovulatory cycles but that earlier menarche also correlates with a shorter span of time between menarche and ovulatory cycles. For instance, in their study, the time from menarche until half of the woman's cycles were ovulatory was only one year among girls whose menarche came before age 12, but 4.5 years for girls whose menarche came at or after age 13. This is of particular concern for girls whose menarche is unusually early.

Environmental factors are known to impact the timing of menarche. Malnutrition was already mentioned as a delaying factor. Studies have identified the following as factors associated with early menarche: childhood obesity (due to its impact on estrogen), low birth weight, being a single child, experiencing preeclampsia in the womb, not having been breast-fed, insufficient exercise as a child, high-conflict family relationships, and nonwhiteness. In light of the fact that menarche is later in Asia than in the West, nonwhiteness is an especially complex factor and is attested in a study of early menarche in the United Kingdom; here, it should be assumed that the relevance of nonwhiteness to early menarche in the UK is due not to genetic factors, or at least not to genetic factors alone, but to some social or environmental factor that is demographically correlated with being a nonwhite citizen or resident of the UK.

Childhood stress in general has an impact on the onset of puberty, which seems to be more pronounced in girls. Stress that threatens physical survival or introduces sufficient uncertainty—such as being a war refugee—is more likely to delay menarche than bring it about early. While the reasoning, such as it is, behind this delay makes sense—if the individual's own survival is uncertain, the survival of potential children is more likely if their conception can be delayed—the mechanism by which social effects impact the timing of menarche is not understood. In animal research, pheromones have been implicated as influencing hormonal release. As with nonwhiteness in the previous paragraph, it is likely that many social factors are correlations rather than causes; many young women whose physical survival is in chronic jeopardy also face malnutrition, for instance, and so many social factors simply indicate a greater chance of the presence of a specific physical factor, the mechanism of which is much better understood.

Malnutrition may also explain why the average age of menarche in the West declined significantly.
Menarche, Early

in the 20th century. As late as 1850, average age of menarche in Europe was 17, and 110 years later, it had declined to 13. (The fact that menarche used to come later in the West is likely reflected in the fact that American girls celebrate their sweet sixteen as a sort of coming of age ritual, as Latin American girls celebrate their quinceanera on their 15th birthdays.) It remains significantly close to that number more than 50 years later. The late 19th and early 20th centuries included many developments that impacted famine and nutrition, from the development of modern fertilizers and agricultural science to improved crop yields to the science of nutrition and a better understanding of what nutrients children and pregnant women require, to the introduction of modern canning and preservation, rapid transportation, and refrigeration—all of which made it comparatively easy to have fresh food year round, a challenge that northern climates had struggled with for all of human history. It is not too much of an exaggeration to say that, until the 19th or 20th centuries, in much of the world, some level of malnutrition was the norm for a large percentage of children a large percentage of the time.

Menarche is important not only for its cultural significance but because early menarche is correlated with a higher risk of breast cancer. Breast cancer risk is higher in three relevant groups: women whose breast development began at a younger age; women who experience early menarche (with risk increasing by 5 percent for each year, according to one analysis); and women with the BRCA1 gene who experience early menarche—who face an increased risk relative to the general population that is greater than the cumulative risks of BRCA1 carriers and women with early menarche. (BRCA2 carriers, on the other hand, face only that cumulative risk.) This risk is largely faced in the form of an increased risk of estrogen-receptor-positive tumors. The source of the risk is believed to be the exposure to ovarian hormones; thus, while menarche is taken as the indicator, the risk actually refers to the woman's lifetime number of ovulatory cycles. (Late menopause is similarly tied to breast cancer risk, though not as strongly as early menarche.)

However, for many women, the risk of early menarche is significant in another sense as well. Age at first birth is a risk factor, with higher ages carrying higher risk. While that risk is usually expressed in terms of absolute age—with a woman bringing her first child to term at 30 facing a higher risk than a first-time mother at 25—at least one study suggests that the relevant figure to consider is not absolute age but the interval between menarche and first full-term birth. Assuming, then, that a given population of women has their first children at the same age, the greater risk of breast cancer is faced by those of them with the earliest menarche.

In the last 30 years, precocious puberty—a term encompassing both early menarche in girls and early development in boys—has been on the rise in the United States, disproportionately affecting African American and Hispanic girls, though the most rapid increase was seen in white girls. (Precocious puberty is 10 times more common in girls than boys.) Environmental chemicals, whether in the atmosphere, drinking water, beauty products (including body soap, toothpaste, sunscreen, and children's shampoo), or food, are sometimes suspected as being culprits; the industrial petrochemical bisphenol A, used in many plastics and food can linings, is known to mimic estrogen, and chemicals like polyvinyl chloride act as endocrine disrupters.

Merck (Germany)

Merck Germany, or Merck KGaA, was founded in Darmstadt, Germany, in 1668 by pharmacist Friedrich Jacob Merck and is the oldest pharmaceutical and chemical company in the world. The establishment of Merck and company as a subsidiary in the United States took place in 1887 in New York. Merck & Co. was expropriated in 1917 after World War I and has since been an independent company based in the United States. Since its inception as a pharmaceutical company, Merck Germany has expanded into a world leader for innovative and high-tech products in the pharmaceutical and chemical industry. In 2013, Merck Germany had total revenues to the tune of €11,095 million. Merck of Darmstadt, Germany, holds the global rights to the name and the trademark MERCK, with headquarters in Darmstadt, and is presently headed by Karl Ludwig Kley, who holds the position of chair of the executive board.

Merck Germany operates the key businesses of the Merck Group. Darmstadt houses the research and development (R&D) units, production plants for pharmaceuticals and chemicals, and the departments of human resources, patents and scientific information, procurement, sales, and accounting. The headquarters at Darmstadt are expected to expand over the next years to convert the site into a global headquarters with a new innovation center promoting innovative interdisciplinary projects. Merck Germany group has an approximate head count of 38,000 employees in 66 countries. Merck Germany introduced a strategic change in management in 2007 and refocused on the product portfolio. This change was followed by a number of acquisitions and portfolio realignments for a sustainable business development model.

Although a leading global corporation, Merck Germany remains a family owned company. Shareholders own 30 percent of the total capital of Merck Germany, and the rest is held by the Merck family. Merck Germany is a corporation with general partners (Kommanditgesellschaft auf Aktien [KGaA]), where at least one partner has unlimited liability for the company’s creditors (general partner). The shareholders hold an interest in the share capital without any personal liability for debts. It is a combination of a German stock corporation (Aktiengesellschaft) and a limited partnership business (Kommanditgesellschaft). The company has no management board, and the business is carried on by the personally liable partners with limited rights and obligations of the supervisory board.

Merck Germany operates in Europe, Africa, Asia, Oceania, and Latin America. The pharmaceutical and chemical businesses of Merck are divided into four major divisions:

Merck Serono—Biopharmaceuticals, which is the largest division of Merck focusing on specialized therapeutics for neurodegenerative diseases, oncology, immune-oncology, fertility, cardiovascular diseases, endocrinology, and biosimilar business. Merck Serono was founded in 2007 when Merck acquired the Swiss biotechnology leader Serono, merging the two companies. Merck Serono has a present head count of 14,600 employees and a presence in 150 countries. Merck Serono has four R&D hubs, one each in Boston (United States), Darmstadt (Germany), Beijing (China), and Tokyo (Japan), representing the strategic business regions for Merck Serono. Merck Serono invests heavily in R&D activities, amounting to approximately 20 percent of total sales. Merck Serono also has smaller R&D laboratories in Italy and Israel. Merck Serono also has strategic research partnerships.
with biotech companies, clinical research groups, and academic institutions and universities. In September 2014, Merck Germany announced that the biopharmaceutical division Merck Serono was on track for the expected transformation and growth program, reflected by the successful execution of growth initiatives as well as progress of pipeline drugs, most importantly in the immuno-oncology and biosimilars arena. Merck Serono plans to invest 130 million to 50 million euros, in addition to the already committed 100 million euros, in biosimilars by 2015, depending on the outcome of phase I studies.

The consumer health division of Merck Germany offers over-the-counter pharmaceuticals and products and has a presence in 100 countries with approximately 1,600 employees. The division includes multivitamin supplements, cold remedies, and women’s and children’s health supplements. As of 2013, Europe accounted for 65 percent of the total sales in the consumer health care division, and emerging markets accounting for 32 percent of total sales. The consumer health division business was worth 477 million euros in 2013. The consumer health division has the strongest presence in Europe, but it is rapidly expanding into emerging markets in Asia and South America.

The performance materials division focuses on advanced-technology chemicals and covers six areas that include display materials and lighting materials needed for liquid crystal display and organic light emitting diodes (OLEDs); the solar and energy division develops novel photovoltaic materials that are supplemented with process chemicals for printing technologies. The division also works on the chemical coating processes used for solar cell manufacturing. The cosmetics division concentrates on the development of active ingredients for light protection, insect repellents, and skin perfection. The performance materials division also produces specialized fillers and active ingredients for the foods and cosmetic industry. The coatings division produces specialized paints and coatings for architecture, the automobile industry, and electronics. The printing and plastics division manufactures pigments for screen printing, offset printing, and offset coating as well as pigments for soft-touch plastic drinking bottles, food-grade plastics, and various automotive components.

Merck Millipore is the division for chemicals and tools for life science research. Millipore Corporation of the United States was acquired by Merck Germany in 2010 and became part of the company’s life science tools division. Merck Millipore is headquartered in Billerica, Massachusetts, and offers more than 60,000 products with a global presence in 66 countries. Merck Millipore offers a broad range of products and services for the high-growth, high-margin market segments, such as bioresearch and bio-production.

In September 2014, Merck Germany signed a definitive agreement for the acquisition of U.S. Company Sigma Aldrich for 13.1 billion euros, establishing it as one of the leading players in the life science industry. The transaction has been unanimously approved by the board of directors of Sigma Aldrich. The acquisition of Sigma Aldrich expands the global reach of Merck and increases its presence in North America as well as the fast-developing Asian markets. The acquisition of Sigma Aldrich will support the delivery of more than 300,000 products and will offer a complementary range of products to research laboratories and academia business. Sigma Aldrich would also complement the products of Merck Millipore in pharmaceutical and biopharmaceutical production.

The Merck group focuses on innovation and spent 1.5 billion euros for research and development in the year 2013 and plans to continue the trend in coming years.

Further Readings
Merck and Co., known as Merck Sharp and Dohme outside the United States, is an American pharmaceutical company based in New Jersey. Originally established as the American subsidiary of the Germany pharmaceutical company Merck, it was seized by the federal government during World War I and established as an independent American company.

Today, it is the seventh-largest pharmaceutical company in the world and the publisher of the Merck Manuals, a best-selling series of medical reference books that includes the best-selling medical textbook in the world, the Merck Manual of Diagnosis and Therapy. It operates in 120 countries with about 76,000 employees, though between 2011 and 2015, it cut its workforce by about 20 percent in an effort to cut costs.

In the past, Merck developed the first vaccines for mumps and rubella, Vioxx for the treatment of arthritis, and Mevacor, the first statin. It has also developed a number of treatments for cancer and cancer-related side effects. Fosamax, for instance, is the trade name for alendronate, developed to treat postmenopausal osteoporosis and later applied as a preventative of bone problems as a result of certain cancers.

Fosamax is a bosphophonate, which is absorbed by the bone with a terminal elimination half-life of 10 years. The absorbed drug binds to exposed bone surfaces and inhibits osteoclast-mediated bone resorption. This results in a reduction of fractures as a result of osteoporosis and helps prevent osteoporosis induced by corticosteroid usage. However, side effects include osteonecrosis of the jaw in a
small number of patients, especially cancer patients given intravenous Fosamax. In 2013, Merck agreed to a $27.7 million settlement in a class action lawsuit over the side effect.

Merck produces Gardasil, a vaccine that prevents many strains of human papillomavirus (HPV). HPV causes 70 percent of cervical cancers and many anal, vulvar, vaginal, and penile cancers, making Gardasil a cancer vaccine of considerable efficacy against those cancers. HPV infections also contribute to about a third of head and neck squamous cell carcinomas, so although it has not been clinically proven for this purpose, in theory, Gardasil reduces the incidence of those cancers. Gardasil was approved by the Food and Drug Administration (FDA) in 2006 and by 41 states by 2008 and is approved for use in 120 other countries. The FDA specifically recommends the vaccination before adolescence or sexual activity. In men, Gardasil is expected to protect against penile and anal cancer and should also help curtail the spread of HPV in order to reduce cervical cancers in women.

Gardasil became politicized when it was revealed that Merck was lobbying state legislatures to make vaccination compulsory as a requirement for public school attendance for young girls. Despite the medical sense of the requirement, even before the issue of vaccination as a personal choice became politicized by the anti-vaccination movement, the HPV vaccine specifically was controversial because of its association with a sexually transmitted disease (STD) rather than a disease spread through casual contact, like measles and mumps. Surprisingly perhaps, Texas governor Rick Perry, a Republican who later ran for president, made Gardasil a mandatory school vaccination in the state; his order was overturned by the legislature, which in Texas wields more power than the governor. Conservative groups opposing compulsory vaccination suggested that being vaccinated against an STD would lead to girls being more promiscuous.

Merck manufactures Keytruda, the trade name for pembrolizumab, which was approved by the FDA in 2014 as a breakthrough therapy for metastatic melanoma. Keytruda targets programmed cell death (PD-1) receptors and is used following treatment with the monoclonal antibody ipilimumab. The drug is an early example of what promises to be a vibrant class of cancer drugs that boost the immune system's ability to fight cancer and has shown potential to treat stomach cancer in initial studies. Merck beat out Bristol-Myers Squibb, Roche, and AstraZeneca in the race to develop the first PD-1 receptor blocker. A Bloomberg report extrapolated likely sales of $1.5 billion for Keytruda alone in 2017.

Emend is the trade name of aprepitant, Merck's antiemetic approved by the FDA in 2003 to prevent nausea and vomiting induced by surgery or chemotherapy. It is also available as an intravenous drug. Merck's Intron A is an antiviral drug used to treat chronic hepatitis C and B, hairy cell leukemia, chronic myelogenous leukemia, multiple myeloma, follicular lymphoma, carcinoid tumor, and malignant melanoma.

Sylatron is Merck's trade name for pegylated interferon alfa-2b, a hepatitis C treatment that has been approved to treat melanoma with nodal involvement after surgical resection. It is on the list of the World Health Organization's essential medicines.

Temodar is Merck's brand name for an oral chemotherapy drug, temozolomide, an alkylating agent used to treat the aggressive brain tumor glioblastoma multiforme, as well as melanoma, relapsed anaplastic astrocytoma, and as an off-label use, oligodendroglioma brain tumors.

Zolinza is Merck's trade name for vorinostat, an inhibitor of histone deacetylases, used to treat cutaneous T-cell lymphoma.

Like many pharmaceutical companies, Merck's ethical record is not spotless. In 2009, it was revealed that it had sponsored the Australasian Journal of Bone and Joint Medicine, a medical journal that reprinted from other journals articles that portrayed Merck's products favorably. The relationship was not disclosed, and the journal was published by Elsevier under the guides of a normal independent peer-reviewed scholarly publication. Merck has also been investigated for routine overbilling to Medicaid and other health care programs and for compensating health care professionals in return for prescribing Merck products.

Merkel Cell Carcinoma

Merkel cell carcinoma pertains to a rapidly progressing neuroendocrine skin cancer that is thought to have arisen from the Merkel cells that line the basal layer of the epidermis. The concept of its origin is based on the presence of neuroendocrine granules in the cytoplasm as well as keratin filaments, which are also observed in skin cells. It also has been suggested that Merkel cells might have emerged from pluripotent stem cells that are programmed to differentiate into dermal cells. Since its first historical description in 1972, information on Merkel cell carcinoma has significantly increased with the development of immunohistochemical detection techniques and improvements in electron microscopy. Interestingly, the incidence of Merkel cell carcinoma has also increased markedly in the past few decades, possibly due to improvements in detection methods. It is thus timely that biologic updates on this malignancy be presented in this entry.

In 2008, a novel human polyomavirus known as Merkel cell polyomavirus was described in the literature and was identified as a contributing factor in the etiology of Merkel cell carcinoma. The Merkel cell polyomavirus is a tiny, circular virus that harbors double-stranded DNA and belongs to the family Polyomaviridae. The genome of the Merkel cell polyomavirus is 5.3 kilobases in length and encodes for the major components of polyomaviruses, such as the large tumor antigen (LT-Ag) and the small T antigen (ST-Ag). These components are encoded in the early region and induce cells to enter the cell cycle and initiate viral DNA replication. The late region is a distinct region from the T antigens and encodes for the structural VP capsid proteins through the action of a noncoding region. This particular noncoding sequence acts as the promoter or origin for viral replication.

Genomic studies have shown that mutations alter the function of the LT-Ag of the Merkel cell polyomavirus, which inhibits viral DNA replication and eventually results in cell death. On the other hand, studies have indicated that ST-Ag is a distinct oncoprotein that imparts its effects in downstream activities, including that of the mammalian target of rapamycin (mTOR) pathway. Recent studies have shown that 80 percent of Merkel cell carcinoma samples harbored Merkel cell polyomavirus sequences, whereas normal skin samples presented only a 16 percent detection rate for the same viral sequences. A mouse-derived monoclonal antibody has also been described to possess a high level of sensitivity in detecting a segment of the LT-Ag of the Merkel cell polyomavirus. Knowledge on the DNA sequence of the LT as well as ST-Ag regions also has facilitated the design of primers for polymerase chain reaction (PCR) analysis of Merkel cell carcinoma tissue samples.

In terms of clinical management of Merkel cell carcinoma, a four-level staging system was proposed in 2010, which was based on the results of assessments of a total of 5,823 cases of Merkel cell carcinoma submitted to the National Cancer Database registry. The National Cancer Database later adopted this staging system for Merkel cell carcinoma. The

Further Readings
current staging system consists of two groups of stages; one group comprises stages I and II, whereas the other groups comprise stages III and IV. These are further classified according to the nodal features, including histological findings after biopsy and the clinical stage based on analysis of images.

Several factors have been identified as predictors of Merkel cell carcinoma, which include invasion into the lymphovascular regions of the primary tumor, advanced stages of the disease, and the occurrence of immunosuppression. The overexpression of specific proteins such as survivin and VEGFR2 also has been associated with a highly aggressive form of Merkel cell carcinoma. These recent findings on molecular markers may be used eventually as tools in predicting treatment outcomes of patients diagnosed with Merkel cell carcinoma.

Unfortunately, the relevance of imaging in analyzing and staging Merkel cell carcinoma has not been fully established. However, recent studies have suggested that positron emission tomography and computed tomography (PET and CT) be used as the first-line methods of imaging instead of CT alone or magnetic resonance imaging (MRI). The use of PET and CT is most appreciated in cases of Merkel cell carcinoma that do not present with palpable adenopathy; thus regional screening of nodes using PET and CT may further assist in the diagnosis of Merkel cell carcinoma. Several studies also have reported that the chances of patient survival are lower when only clinical exams to detect nodes were performed, without the application of PET and CT.

Recent studies also have shown that a multidisciplinary approach is the best treatment of Merkel cell carcinoma. Primary Merkel cell carcinoma generally is treated by surgical resection, which may or may not be coupled with irradiation. Resection should include approximately two-centimeter margins beyond the affected area, which in turn decreases the need to expose the patient to irradiation. When an adjuvant setting is required in a particular Merkel cell carcinoma case, then irradiation is recommended as the next treatment. Some reports have shown that irradiation of the surgical bed does not confer any direct benefits to the patient with Merkel cell carcinoma, thus indicating a need to conduct more extensive studies. A clinical trial was earlier launched, with a primary goal of determining the benefits of irradiation on the early stages of Merkel cell carcinoma. However, this clinical trial was prematurely terminated due to a sudden decrease in the number of recruited study participants when other novel treatment options were presented to potential treatment patients.

Malignant mesothelioma is a relatively rare and difficult-to-treat form of cancer that arises in the mesothelium, the thin layer of tissue covering the majority of organs inside the human body.

Mesothelioma is classified into types based on where in the mesothelium the cancer first emerges. Pleural mesothelioma is the most common type and affects the tissue known as pleura that surrounds the lungs. Less-common forms are peritoneal and pericardial mesothelioma, which arise in the lining of the abdomen (peritoneum) and the lining of the heart (pericardium), respectively. The signs and symptoms vary depending on the specific type of mesothelioma, but the underlying cause is almost always due to long-term exposure to asbestos.

Treatments are available to help improve quality and longevity of life for individuals with mesothelioma, but for most patients, a complete cure is not achievable.
Prevalence and Risk Factors
According to the American Cancer Society, approximately 3,000 new cases of mesothelioma are diagnosed annually in the United States, with the prevalence being among men aged 65 or older. Exposure to asbestos is considered to be the primary risk factor for developing mesothelioma.

Asbestos is a strong, heat-resistant mineral that is naturally present in the environment. Traditionally, it has been used as a component in a vast array of consumer products, from adhesives to oven mitts, and in all types of building materials, such as roofing shingles, insulation, and flooring. While asbestos is still used in some products, its widespread application ceased in the late 1980s in the United States after the link between the substance and the deadly cancer became known.

When asbestos fibers become disturbed during construction, installation, or removal of asbestos-containing products, a thick dust is created that can be harmful to health if inhaled or swallowed. The tiny asbestos fibers can get lodged in the mucus of the throat, windpipe, or airways and eventually settle in the lining of the lungs, chest wall, or abdomen, causing irritation that may injure the cells of the mesothelium and lead to mesothelioma. The time from asbestos intake to mesothelioma outbreak may span as much as three or four decades, although the disease can develop more rapidly in some individuals and not at all in others.

There are several factors that may increase the risk of developing mesothelioma. Individuals who were exposed to asbestos at an early age, for an extended period of time, and at higher levels are more likely to develop the cancer. In addition to anyone who has been directly exposed to asbestos fibers, there is a higher risk among individuals who live with someone who has been directly exposed, usually through work. Asbestos-exposed workers may inadvertently bring harmful asbestos dust into the home on their clothing and skin, putting everyone who lives in the home at higher risk for mesothelioma.

Another risk factor for mesothelioma may be linked to the polio vaccine given to millions of individuals between 1955 and 1963. The vaccine contained a virus known as SV40 that was derived from monkeys and is believed by some to have a link with mesothelioma. There also may be a link between mesothelioma and injections of a radioactive agent known as Thorotrast used in some X-ray tests until the 1950s.

Signs and Symptoms
The specific signs and symptoms of mesothelioma depend on where in the body the cancer originates. In pleural mesothelioma, which affects the lungs, early symptoms mimic minor common ailments, such as fatigue, cough, hoarseness, and fever. As a result, many individuals with mesothelioma ignore their symptoms until they progress to include other signs and symptoms, such as chest pain under the rib cage or in the lower back, shortness of breath, unusual lumps of tissue under the skin on the chest, swelling of the face and arms, excessive sweating, and unexplained weight loss. The majority of individuals with pleural mesothelioma have active symptoms for several months before being diagnosed with the cancer.

Some early indicators of peritoneal mesothelioma, which affects the abdomen, also can be confused with symptoms of less-serious conditions. For example, nausea, vomiting, and stomach pain can signal a host of illnesses and are not exclusive to mesothelioma. More-telling symptoms of peritoneal mesothelioma include the additional ailments of swelling or fluid buildup in the abdomen, lumps of tissue in the abdomen, and unexplained weight loss.

Diagnosis and Treatment
If symptoms and patient history—such as known exposure to asbestos—suggest a possibility of mesothelioma, a complete physician's exam would be performed to check for lumps, fluid, or other markers. Blood tests and imaging tests of the lungs or abdomen also might be ordered to help identify or rule out a potential diagnosis of likely mesothelioma. However, the only way to make a definitive diagnosis of mesothelioma is through a biopsy procedure in which a small portion of tissue is extracted from the affected area to be examined in a laboratory. The tissue sample is analyzed under a microscope to determine if the abnormal tissue is mesothelioma and, if so, what types of cells are involved. The cellular identification and involvement determines the definitive diagnosis, disease staging, and treatment options for the patient.

Once a diagnosis of mesothelioma is made, the cancer is staged into one of four categories based on its level of infiltration within the body. Using
peritoneal mesothelioma as an example, stage I is limited to a single portion of the mesothelium in the chest and is considered to be localized cancer. Stage II involves spread beyond the lining of the chest into the diaphragm or lungs. Stage III includes spread to other structures within the chest and possibly nearby lymph nodes. Stage IV mesothelioma is considered advanced cancer and typically has spread more extensively within the chest and potentially to distant sites within the body, such as the brain and liver.

The staging system helps determine an appropriate treatment plan. Generally, stage I, II, and III mesothelioma cancers have some potential to be surgically removed. However, the decision to remove the cancer is determined more by a combination of the patient’s overall health, the tumor’s location and infiltration pattern, and the cellular subtype of the tumor. Even when surgical resection is performed, in a majority of cases, damaging and aggressive mesothelioma cancer cells are left behind after surgery. As a result, chemotherapy and radiation often are used in conjunction with surgery in mesothelioma patients.

The survival outlook for individuals with mesothelioma is generally one to two years, depending on stage at diagnosis and other prognostic factors, such as age, blood cell count, and weight maintenance. Usually, mesothelioma is diagnosed at an advanced stage, and the only treatment option is palliative care, which focuses on making the patient as comfortable as possible while the cancer follows its course.

Further Readings

Mesothelioma, Childhood

Mesothelioma is a rare cancer that originates in the mesothelium, a membrane that lines many body cavities (including the thoracic cavity, abdominal cavity, and heart). Most mesothelioma originates in the thoracic or abdominal cavities (the pleura and the peritoneum). Nearly all mesothelioma is caused by exposure to asbestos. While this is commonly associated with workplace exposure, that obviously does not apply to childhood mesothelioma, which more often originates as a result of asbestos being present in the home, school, or child-care facility. It also can develop in children of workers who are exposed to asbestos dust in the workplace and bring it home on their clothes. In a small number of cases—less than 10 percent—the environmental factor may be something other than asbestos, such as radiation or inhalation of fibrous silicates.

Symptoms of mesothelioma usually begin with pain in the chest wall or respiratory problems, including shortness of breath, a feeling of tightness that may be caused by pleural effusion (fluid surrounding and constricting the lung), wheezing, coughing, hoarse voice, persistent irritation in the throat or chest, or coughing up blood. Mesothelioma in the abdominal cavity can cause a buildup of fluid in the cavity, weight loss, bowel obstruction, and abdominal swelling. Often, abdominal mesothelioma is discovered later than thoracic cavity mesothelioma. Either mesothelioma can result in anemia or fever, and if the cancer has spread beyond the mesothelium, pain, swelling in the neck and face, and difficulty swallowing are common. Advanced cases can result in blood clots, jaundice, low blood sugar, and severe bleeding in the organs, a condition called disseminated vascular coagulation.

Asbestos was used widely in the industrial ramp-up during and following World War II, when its toxicity was not well understood (though concerns had been raised in the previous decades due to health
Mesothelioma, Childhood

problems with miners and shipyard workers). It was used commonly as both building insulation and electrical insulation in construction not only of residences but of workplaces, warehouses, and factories, which introduced a secondary problem once its dangers were understood: the danger of being exposed to, and aerating, the asbestos while removing it in order to replace it with a safer insulation. Indeed, this is the very manner by which many children were exposed to asbestos. Mesothelioma also can develop as a result of exposure to naturally occurring asbestos in the environment. This led to a widely studied epidemic of mesothelioma in several Turkish villages, for instance, where asbestos was present in both the air and the water supply. Mesothelioma can be caused by asbestos exposure of as little as one month, and it can take as long as 40 years to manifest in adults.

Despite efforts in 1989 by the Environmental Protection Agency (EPA), asbestos is not banned in the United States, one of the few developed countries to permit its use. Asbestos content is regulated in most products, and consumer products can contain only trace elements (resulting from airborne asbestos in the factories where they are made, usually). The Occupational Safety and Health Administration (OSHA) has limited the density of asbestos presence in workplaces. Asbestos continues to be used in vinyl floor tiles and sheet flooring, cement board, window putty, stucco, furnace tape, cement pipes and flues, the stipple used to texture walls and ceilings, and drywall joint filler compound and in fireproofing, acoustic, and roofing materials.

Asbestos seems to lead to mesothelioma as a result of mechanical damage, not chemical reactions. The small fibers of asbestos may interfere with chromosomes and disrupt mitosis, leading to the development of cancer. Smaller particles, which can be absorbed deep into the lung tissue, are believed to be more harmful and carcinogenic than larger particles. The incidence of World Trade Center syndrome, in which severe respiratory ailments have developed among workers who had exposure of only a day or two to the airborne particulates of the collapsed World Trade Center buildings after 9/11, has shed some insight on the mechanisms by which asbestos and other small particles can cause cancer.

Mesothelioma is difficult to diagnose. Chest X-rays often offer the first hints, especially in children, who do not have jobs exposing them to asbestos, in order to suggest that diagnosis to the physician. Pleural thickening may be visible on the X-ray, and if there is fluid buildup, it may appear on a computed axial tomography (CAT) scan or magnetic resonance imaging (MRI). Cytopathology can investigate the fluid—a syringe is inserted through various means depending on the location, and fluid is extracted for analysis. Even this method makes malignancy difficult to determine. A biopsy is almost always necessary, the method for which depends on where the mesothelioma has manifested. It may be necessary to open the chest to obtain a tissue sample, or a thoracoscopy may be performed, in which a small cut through the chest is made, and a thin, lighted tube is inserted between two ribs. In abdominal mesothelioma, the biopsy often may be performed laparoscopically.

The prognosis for mesothelioma is poor. Surgery does not offer good, long-term survival rates. Radiation can be used to relieve symptoms caused by tumor growth or as adjuvant therapy with surgery, but chemotherapy is the only mesothelioma treatment modality that has been proven to increase survival rates in controlled randomized trials.

Further Readings
The United Mexican States is a democratic republic encompassing 31 states and a Federal District. Mexico is the world’s fifth-largest country by area and the third largest in the Americas. The Mexican Consejo Nacional de Población (National Census Bureau of Mexico) estimates Mexico’s population at 119,713,203 people, ranking the country as the 11th-most populous in the world. The International Union Against Cancer reports that cancer is the third-leading cause of death in the country. Because Mexico is known for its traditional and nontraditional approaches to cancer prevention and treatment, the country is of relevance to the oncological community worldwide.

History
In the Mexican culture, the treatment of conditions consistent with the symptomatology of cancer (e.g., abscesses, hard swellings, polyps, tumors, and warts) dates back to the Mayan period, but historic records from the Mexican Society of Oncology trace the contemporary treatment of cancer to the first decade of the 20th century. This is when the Federal District of Mexico acquired the country’s first order of radium. The records report that, in the 1920s, Mexico’s General Hospital was the first medical institution to acquire equipment for the administration of deep radiotherapy treatments. By the 1930s, both radiotherapy and Wertheim-style hysterectomies were used for the routine treatments of uterine carcinomas. Wertheim surgeries required the removal of cervical cancer through abdominal incisions. During the same period, Mexican physicians began to treat malign neoplastic diseases—masses of tissues that experience abnormal growth. In 1940, Mexico’s General Hospital acquired the first radon plant in Latin America. This technological addition, together with the appointments of several Mexican physicians and surgeons trained abroad, marked Mexico’s General Hospital as the birthplace of Mexican oncology. An institute for cancer studies was soon established in 1946 to serve oncology patients, most of whom were affected by gynecologic tumors. Soon, the institute was overrun with patients and struggled to meet patient demand. Due to this rapid growth and the need for specialized medical care, the government established the Instituto Nacional de Cancerología. The institute later housed the first cobalt therapy unit in Mexico and the third in Latin America. Cobalt-60 allowed Mexican oncologists to use gamma rays for cancer treatment. Today, Mexico is recognized as a Latin American leader in cancer prevention and treatment, and the country collaborates with various international research institutions, including the United States–Latin American Research Network (US-LA CRN) and the Union for International Cancer Control (UICC).

Cancer Incidence and Mortality
Mexico has experienced demographic transitions accompanied by changes in its epidemiological profile. The country’s health concerns, for example, have shifted from communicable to noncommunicable diseases. Cardiovascular disease, diabetes, and cancer currently are the three leading causes of death in the nation. The World Health Organization reports that approximately 57,000 people die of cancer every year, accounting for 13 percent of all deaths due to noncommunicable diseases in the country. Furthermore, statistics by Mexico’s Sistema Nacional de Información de Salud (The National System of Health Information) show that prostate; lung, bronchial, and larynx; and stomach and gastric cancers cause the highest mortality rates for males; while breast, cervical, and liver cancer comprise the highest mortality rates for Mexican females; and leukemia, lymphoma, and sarcoma are the most common forms of cancer in children and adolescents.

Prostate cancer incidence in Mexico is largely attributed to age, with the majority of males affected by the disease being 50 years of age or older. The Instituto Nacional de Estadísticas y Geografía/INEG (The National Institute of Statistics and Geography) reports that prostate cancer mortality rates vary greatly by federal districts, with Quintana Roo having a death rate of 9.4 percent and Nayarit a death rate of 33.2 percent.

The high prevalence of lung cancer in Mexico has been linked to various factors, including second-hand smoke, the exposure of mine workers to radon, and the increase in teenage smokers. INECT statistics indicate that 12.3 percent (i.e., 1.7 million) of adolescents in Mexico are active smokers. These statistics place adolescents at higher risk of developing lung cancer, given that many begin smoking at 14 years of age.
The third-most frequent cancer in Mexican men, stomach and gastric cancer, has been associated with dietary patterns. Research studies have linked stomach cancer in Mexico with a diet high in salted, dried meats, such as chorizo and other sausages, as well as a high intake of fresh meats, dairy products, and fresh fish. In addition, studies have associated the disease with the consumption of chili peppers and chili powder.

Research studies associate the incidence of breast cancer in Mexico with an underutilization of early detection techniques, such as self-exam and mammography. Underutilization has been attributed in part to cultural beliefs about the causes and treatments of the disease. In addition, the breast cancer rate has been associated with an increase in alcohol intake and a folate and vitamin B12 deficiency.

Although cervical cancer is responsible for 3,900 deaths a year in Mexico, the incidence and mortality have decreased during the past decade. Scientists attribute the improved incidence and mortality rates to Pap smear screenings and lower birthrates. Nonetheless, Mexican women are still at risk, especially those living in the central and southern parts of Mexico.

Statistics from a Mexico Cancer Profile issued by the Pan American Health Organization indicate that liver cancer killed approximately 2,500 Mexican males and approximately 2,700 Mexican females per year during the past decade. Hepatocellular carcinoma is the most common form of liver cancer, with higher mortality rates found in individuals 60 years of age or older. Alcohol consumption and hepatitis C virus (HCV) infections are linked to the incidence of the disease in the country.

Cancer Institute and Research
The Secretaría de Salud de México (Mexico's Health Ministry) is the government institution in charge of social assistance programs, medical services, and public health issues. The ministry supports initiatives for cancer prevention, treatment, and care, and most of them are coordinated through the National Center of Cancerology. The center is dedicated to provide specialized medical care to cancer patients and oversees 25 cancer centers around the nation. The administration works on developing common national programs and strategic plans that focus on cancer prevention, detection, and treatment.
The national programs center on five main topics: early detection and prevention, development of health education materials concerning the 10 most-common forms of cancer in the country, palliative care, medical infrastructure, and tobacco control. To disseminate information about the disease, the institute launched InfoCancer, a resource available online and on the phone to cancer patients and their families, friends, and caretakers.

In addition to providing information and services to cancer patients, Mexico also works with the scientific community to support cancer research. The Consejo Nacional de Ciencia y Tecnología (National Council of Sciences and Technology), for example, oversees the promotion of scientific and technological agency. The organization also works with other institutes and academic institutions and offers a wide range of grants to support scientific research. In addition, the National Council offers a wide range of opportunities for postgraduate studies at home and abroad.

**Nontraditional Treatment**

In addition to the traditional medical approach, Mexico is known for its alternative approaches to cancer treatment. Cancer patients from around the world visit the country, seeking to ingress in its many facilities centering on holistic methods. Alternative cancer treatment facilities are more common along the U.S.–Mexico border, where dozens of clinics have opened to serve patients from the United States. Alternative methods offered at the border clinics can be divided into two main groups: metabolic therapy and antitumor treatments. Metabolic therapy focuses on improving body function rather than on specific ways to treat the disease. The metabolic approach includes chelation, colon therapy, nutritional therapy, and immune system support. Antitumor treatments are designed to specifically target the cancer. Some of these treatments offered at the Mexican clinics include oxygen therapy, electromagnetic therapy, hydrotherapy, hyperthermia, antineoplaston therapy, and cell therapy. The use of these alternative methods is not regulated, but the Mexican government investigates and closes clinics operating illegally in the country.

The scientific community in Mexico is actively engaged in national and international efforts to prevent, detect, diagnose, and treat cancer in the country and abroad. Their efforts and initiatives provide the oncological community with material for further inquiry into the disease and its impact around the globe.

**MIT Center for Cancer Research**

The David H. Koch Institute for Integrative Cancer Research (Koch Institute), which upon its opening in 2010 replaced the Massachusetts Institute of Technology (MIT) Center for Cancer Research, is one of eight National Cancer Institute
(NCI)-selected basic research centers. Founded in 1969, the Koch Institute conducts research on cancer, with a special emphasis upon the genetic and molecular bases of cancer, how changes in cellular processes affect cell growth and behavior, and how the immune system develops and recognizes antigens. In addition to its research efforts, the Koch Institute serves as an organizational body for researchers across the MIT community with an interest in cancer research.

Founded in 1861 in response to the increasing industrialization of the United States, MIT is a private research university located in Cambridge, Massachusetts, with a stellar international reputation for excellence. Unlike many other colleges and universities of the time, which had the classics as the central focus of their undergraduate educational experience, MIT concentrated on technology and collaboration with industry. With an $11 billion endowment and traditional strengths in engineering, the physical sciences, economics, biology, and other areas, MIT is one of the most highly regarded universities in the world and has been affiliated with more than 80 Nobel Prize winners, 50 National Medal of Science recipients, and two field medalists. As medical research has grown as a field, MIT has sought to increase its involvement in this area of study.

In 1974, Nobel laureate Salvador Luria, known for his work with the replication mechanism and the genetic structure of viruses, founded what was then known as the MIT Center for Cancer Research. Under Luria’s leadership, the MIT Center for Cancer Research was organized to study basic biological processes as these related to cancer. MIT viewed the Center for Cancer Research as having a twofold purpose. First, the MIT Center for Cancer Research served as a much-needed physical research center where studies regarding cancer could be undertaken. Second, it also served as an organizational mechanism for the larger MIT cancer research community, one that could foster the exchange of information and collaboration. Initially funded with a National Cancer Institute Center Core grant, the MIT Center for Cancer Research relied upon funding from a variety of sources, including the Howard Hughes Medical Institute and the National Institutes of Health. The MIT Center for Cancer Research quickly gained a reputation for excellence, producing four Nobel laureates, including David Baltimore, Susumu Tonegawa, Phillip Sharp, and H. Robert Horvitz.

In 2006, then-MIT president Susan Hockfield announced plans for a new building for the MIT Center for Cancer Research in an effort to build upon the prior accomplishments of the group and to provide state-of-the-art facilities for the scientists and researchers who worked there. In 2007, the Ludwig Fund announced a $20 million gift that would allow the founding of a Center for Molecular Oncology at the new facility. This grant was joined by a $100 million gift from industrialist David H. Koch. Part of Koch’s gift was devoted to the new building, which was estimated to cost approximately $250 million, and half was dedicated to research endeavors. In response to Koch’s gift, the MIT Center for Cancer Research was renamed in his honor.

Cancer Research

One of eight NCI-designated basic research centers, the Koch Institute differs from the other such centers insofar as it does not provide medical care to patients or conduct clinical research. Instead, the Koch Institute has partnered with a variety of oncology centers that do this work. The new facility permitted the MIT Center for Cancer Research’s existing faculty to be joined with an equivalent number of engineering faculty. This was seen as crucial in promoting interdisciplinary approaches to diagnosing, monitoring, and treating cancer. The Koch Institute is comprised of faculty members from various MIT departments, including biology, biological engineering, chemistry, and mechanical engineering. In all, the Koch Institute is comprised of more than 40 laboratories and 500 researchers spread across the MIT campus.

The Koch Institute has identified five discrete areas that it has chosen to focus upon in an effort to control cancer. These five areas include developing nanotechnology-based therapies; creating devices that will permit better cancer detection and monitoring; exploring the molecular and cellular bases of metastasis; advancing personalized medicine through analysis of cancer pathways and drug resistance; and engineering patients’ immune systems to combat cancer. To this end, the Koch Institute remains funded by an NCI center grant and is also the home to more than 100 fully funded studies.
Researchers at the Koch Institute are engaged in an ongoing series of studies to address the five areas of research it has focused upon. Darrell J. Irvine, for example, has worked to help patients' immune systems to recognize cells that have undergone changes as a result of cancer and then to destroy them. Matthew Vander Heiden and his team of researchers have worked to better understand cancer cell metabolism and how small molecules might be used to activate enzymes that might help to restore the normal state of cells with cancer. Jacqueline A. Lees, who also serves as associate director of the Koch Institute, has investigated how proteins and pathways are mutated in cancer as well. It is hoped that further knowledge regarding these mutations will allow advances in detecting and hopefully treating osteosarcoma.

Michael J. Cima and his laboratory are working to create tiny nanosensors that are chemically sensitive to different molecules. It is hoped that these sensors will be able to be used to help determine proper dosage for chemotherapy. Sangeeta N. Bhatia and her team are working to engineer new therapeutic agents that can home in on cancer cells and selectively destroy them, while leaving surrounding healthy cells alone. This type of therapy will permit stronger pharmaceuticals to be used to fight cancer and increase patient well-being. Together, these and other efforts are revolutionizing research that addresses cancer as it focuses on using approaches that are tailored to a specific patient's condition and health. Over time, the Koch Institute will undoubtedly continue to produce further research that will affect how cancer patients are treated.

Moldova

Moldova is a country located in eastern Europe between Romania to the west and Ukraine to the north, south, and east. Historically known as Moldavia, it is officially known as the Republic of Moldova, with its capital city being Chisinau. The republic declared its independence in 1991 but had the same boundaries as the Moldavian Soviet Socialist Republic as part of the dissolutions of the Soviet Union. A new constitution for the country was adopted on July 29, 1994.

Health care in Moldova has known dynamic development in the past years. The development has seen the country's hospitals being equipped with ultramodern equipment, especially the new surgical blocks and general medical departments being built in Chisinau, the capital city. The country's number of physicians is about 264 per 100,000 people. In 2004, health expenditure was $138 per capita, and as per statistics from the World Bank, the health expenditures per capita was at about $223.

The health sector in Moldova is under the health ministry. According to the health ministry, for the period before 2011, the number of people living with cancer in the country was 42,000. Per year, cancer caused about 5,600 deaths in the country. Given these statistics, cancer was the second-most dreaded disease in the country based on the number of deaths, the first cause of deaths being cardiovascular diseases. Narrowing down to cancer, the type of cancer that has the most number of deaths is lung cancer. The second is stomach cancer, the fourth liver, and the fifth colorectal cancer. The number of cancer-related deaths is higher than in most other European countries. Of the persons who are diagnosed with cancer, less than half survive. Based on the five-year survival record, the survival rates for persons with cancer are well below that of the countries in the European Union. According to the Moldovan health ministry, these damning results are as a result of late diagnosis of the disease.
The Moldovan government has, for the first time, allocated 80 million lei ($5,400,000) to acquire medication for cancer patients. It is the first time that the executive arm of the country is spending such an amount of money for cancer treatment. A donation by the Norwegian charity organization under the initiative Help Moldova saw the Oncology Institute from Chisinau receive 25 medical beds, special clothes, and other much-needed products. This donation was made during the World Cancer Day that is marked on February 4. After the completion and the opening of the cancer facility in Chisinau, data from the ministry of health indicates that, in 2012, the number of patients with cancer was 8,204, and these patients were taken on primary evidence in Moldova. The data shows that 5,734 people with cancer died in 2012, which is a slight increase compared to a year before.

The only specialized center for cancer diagnosis and treatment in the country is the Oncology Institute of Moldova, where help will come to patients who need help. It was founded in 1964 and has long since been upgraded to include a series of surgery, radiotherapy, and chemotherapy departments. The breast cancer unit in the institution has two branches and offers surgical treatments for many forms of cancer, with breast cancer being the most critical aspect. According to data from the institution, every year, more than 1,000 breast cancer patients are treated and surgery performed for about 2,500 patients. Of these patients, 600 have breast cancer and the others have benign diseases of the breast.

Just like every other country, Moldova has almost all types of cancer diagnosis among its citizens. However, some are more prevalent than others and consequently cause more deaths than others. The top type of cancer as per deaths is lung cancer, with a rate of 21.24, breast cancer is second with a rate of 20.93, colon—rectum cancers are third with a rate of 17.97, stomach cancer is fourth with a rate of 12.53, liver cancer is fifth with a rate of 9.83, oral cancer is sixth with a rate of 6.95, pancreas cancer is seventh with a rate of 6.31, lymphomas are eighth with a rate of 4.44, cervical cancer is ninth with a rate of 4.13, and at the tenth place is prostate cancer with a rate of 3.22. Other types of cancer that have high rates in the country are ovary cancer, bladder cancer, skin cancer, leukemia, and uterine cancer, among others.

As earlier stated, coronary heart disease and cancer predominate as the main causes of death in the Republic of Moldova for both men and women, according to research by nongovernment organizations in the country; this fact can be attributed to very heavy alcohol and tobacco consumption among both men and women. According to statistics from the research, in 2010, most mortality issues can be attributed to smoking-related actions, while about 18 percent for men and 14 percent for women were related to alcohol use.

In 2007, the government of Moldova approved the Unified Program, which was modified in January 2009 (Government Decision No. 44). The program includes the cervical smear test as part of the family planning services provided within the specialized ambulatory care and a series of other prophylactic checkups for cervical and breast cancer. However, even though this might qualify as a worthy cause against cancer deaths through early diagnosis, the program could not be treated as screening as it is not based on clear criteria for enrollment of target groups presenting no clinical signs.

Policy recommendations for the development of national screening programs for cervical and breast cancer were made in 2007 based on international experience and cost–benefit analyses within a project supported by the Department for International Development of the United Kingdom. However, they have not yet been put into practice. In 2011 and 2012, the 90 health systems in transition in the Republic of Moldova National Health Insurance Company provided financial support for pilot screening programs for cervical and breast cancer in some territories, but this is still far from nationwide coverage.

Morocco

Cancer in the north African nation of Morocco is one of the country’s leading causes of mortality and morbidity, with roughly 35,000 new cases of cancer reported annually. The International Agency for Research on Cancer and the World Health Organization (WHO) GLOBOCAN 2012 project reported 16,829 cases of cancer in men and 18,189 cases of cancer in women annually. The overall world age-standardized rate (ASR) for all sites combined was 136.6 per 100,000 for men and 114.5 per 100,000 for women. The most frequently diagnosed cancers in the nation for men are lung (19.0 percent, ASR 24.8/10[5], 3,497 cases), prostate (15.5 percent, ASR 22.9/10[5], 2,332 cases), colorectum (8.8 percent, ASR 12.0/10[5], 1,358 cases), bladder (6.9 percent, ASR 9.7/10[5], 1,429 cases), and non-Hodgkin’s lymphoma (6.0 percent, ASR 8.2/10[5], 1,089 cases). The most common cancers for women in Morocco are breast (39.9 percent, ASR 43.4/10[5], 6,650 cases), cervix uteri (11.4 percent, ASR 13.0/10[5], 2,258 cases), colorectum (7.5 percent, ASR 9.0/10[5], 1,126 cases), thyroid (3.4 percent, ASR 3.9/10[5], 929 cases), and ovarian (735 cases). Of all cancers, 2 percent are observed in childhood (0–14 years), and approximately 43 percent of them are malignant hemopathies. The incidence of cancer is increasing due to growth of the population in the country, population aging, and the pervasiveness of tobacco smoking.

Health Care Infrastructural Challenges

At the time of independence following French colonial rule (1877–1956), there were only 33 qualified doctors in Morocco. In the decades since independence, the government embarked upon a long series of health care reforms and implemented plans to build new hospitals and update and undertake repairs on existing health care facilities built during the French protectorate.

Much remains to be done to expand both health care infrastructure and practitioners, particularly in the public sector, although there does exist growing nonprofit and for-profit private sectors. In 2006, the World Health Report indicated Morocco was one of 57 countries with a severe lack of health personnel to serve the nation’s population of 32.52 million through its network of 2,626 health care bodies, 1,731 of which are located in rural areas. Further, Morocco is vulnerable to an exodus of medical practitioners to other nations. The WHO in 2008 reported that the global expenditure for the Moroccan health care system totaled $4.3 billion, or 5.6 percent of the gross domestic product (GDP). Compared to other nations at Morocco’s level of development, these figures are low given the needs of modernizing health care infrastructure and given that the epidemiological profile of Morocco is changing with increases in noncommunicable diseases such as cardiovascular diseases, diabetes, and cancer.

National Cancer Control Plan

The Ministère de la Santé of Morocco established its Plan National de Prévention et de Contrôle du Cancer 2010–2019. The plan has supported more than 80 cancer research projects by 135 cancer researchers from 20 institutions across 32 research teams. It also established regional cancer registries. However, there remains a need for further research, better primary prevention activities, increased programs for early detection, specialized infrastructures and human resources, enhanced management of available oncological resources, establishment of standards for diagnosis and
treatment management, policies regulating generic drugs in addition to a cancer communication strategy, and increased palliative care and psychosocial support. Further, increased funding is needed for the thousands of Moroccans for whom cost of treatment exceeds financial capabilities; fewer than one-third of the Moroccan population has adequate medical insurance.

Additional development needs include the epidemiology of cancer through the establishment of more cancer registries in Morocco. The National Center for Biotechnology Information recently reported that there has been no population-based data of cancer incidence in Morocco. At present, the only sources of epidemiological information currently deemed valid on the epidemiology of cancer in Morocco are, first, the Rabat Cancer Registry, which registered 2,473 new cancer diagnoses in the nation’s capital city in 2008 and, second, the Grand-Casablanca-Region Cancer Register (GCRCR), which is based on a population sample accounting for 10 percent of the overall Moroccan population. The GCRCR has recorded 3,336 cases of cancer, including 1,833 in women and 1,503 in men. The standardized incidence was slightly higher in females (104.2 for 100,000 females per year versus 100.3 for 100,000 males per year).

Noteworthy research centers in oncology and radiotherapy include la Laboratoire d’Onco-virologie, Institut Pasteur du Maroc in Casablanca, Morocco, Service de Radiothérapie, Institut National d’Oncologie in Rabat, the Al Azhar Oncology Center in Rabat, and the Laboratory of Genetics and Biometry, Faculty of Science, Ibn Tofail University, in Kenitra, Morocco. HRH Princess Lalla Salma, president of the Lalla Salma Foundation for Cancer Prevention and Treatment, has led an effort to establish resources to support cancer diagnosis, treatment, education, and prevention throughout Morocco. The Lalla Salma Foundation funded the construction of a regional oncology center situated in the Moulay Ismail hospital in the Moroccan city of Meknes, which is aligned with the Plan National de Prévention et de Contrôle du Cancer 2010–2019. Another newly developed regional oncology center and host facility for cancer patients, located in the northeastern city of Al Hoceima, allows for providing care and treatment to cancer patients living below the poverty level. Such patients often experience additional challenges of extensive travel and lack of family support if they are forced to relocate to a distant location for cancer treatment.

Health Partnerships
The Moroccan government established collaborative partnerships with a number of Jordanian and Gulf nations, the United States, and European organizations for health care generally and cancer research and care specifically. The Cancer Prevention & Control Research Training Program of Morocco (CPCRT) is a five-year (2010–2015) public health research and training program supported by the U.S. National Institutes of Health that has established a partnership among the University of Rabat Medical and Pharmacy School, the Moffitt Cancer Center in Tampa, Florida, and the CoEmpower organization in Bethesda, Maryland, to train Moroccan mid-career professionals and support existing Moroccan public health research infrastructures in cancer prevention and control.

Other research collaborations include Cancer Research Morocco (CRM), a group that links Moroccan clinical and basic research cancer groups to collectively develop strategies for prevention, diagnosis, treatments, and cures. Cancer specialists are members of international organizations such as the Middle-Eastern Association for Cancer Research, the Arab Medical Association of Cancer, l’Association Internationale des Registres du Cancer, la Société Internationale de Chirurgie Hépatopancréato-Biliaire, la Fédération Pan-Arabe de Chirurgie, la Fondation Française de Carcinologie Digestive, and la Société Française de Cancérologie.

Specific Contexts
Domestic cooking fumes intake in Morocco by using a compact charcoal oven known as a kanoun, particularly during childhood, has increased the risk of nasopharyngeal carcinoma (NPC). Among adults across north Africa, NPC rates are at the level of 5.4 in men and 1.9 in women, 10 times higher than that in Europe.

One unique cancer risk in Fez, Morocco, is found in the Leather Souq, the oldest leather tannery in the world, which dates back at least nine centuries. While ancient practices in the tanneries used natural dyes, more current practices may be using synthetic dyes. Environmental impact assessments have been made to evaluate the potentially carcinogenic metabolites of dyes. In addition, Moroccan
environmental activists contest that the contemporary textile and leather industries use chemicals such as chromium 3, widely known to be lethal.

Tobacco use continues to be an important risk factor for lung cancer in Morocco and its north African neighbors. A World Health Organization study reported that 29 percent of adult men and 0.2 percent of women in Morocco use tobacco. Ministères de la Santé et de l'Éducation Nationale have partnered with Lalla Salma Foundation for a nationwide antismoking campaign in a range of public places, including hospitals, schools, and universities.

Mozambique

The Republic of Mozambique is a southeastern African country, whose coastline directly faces Madagascar island. Originally inhabited by the Swahili, Arabs, and Persians, Mozambique was colonized and conquered in the 1500s by the Portuguese, who ruled the country for more than 400 years. The Portuguese held their grasp over Mozambique’s rich natural resources (such as aluminum, gold, gemstones, and petroleum) up until the end of the 19th century, when other European powers (mostly British and French) started to siphon its economic power through various private companies’ administrations. Similar to the apartheid system in neighboring South Africa, in Mozambique, a small white Portuguese minority concentrated much of the overall country’s wealth in their hands, possessing far better education and skill than the black indigenous majority. This situation evolved into significant social tensions, giving birth to a guerrilla movement called the Front for the Liberation of Mozambique (FRELIMO), which in 1964, initiated a military campaign against the Portuguese army. In 1974, the FRELIMO took control of the territory, forcing the expulsion of the entire Portuguese population and establishing a one-party communist regime. After only three years of peace, in 1977, the Mozambican Civil War erupted, when the Anti-Communist Mozambican National Resistance (RENAMO) militia started an armed opposition to the new government. This civil war plagued the country with violence and the destruction of its infrastructures, causing the nation’s economy...
to collapse until the declaration of peace in 1992, when a new democratic constitution was enacted, bringing back to Mozambique more than 1.5 million refugees who had left the country in the last 15 years.

During the 1970s, the primary health care system in Mozambique was quite developed, and the government invested significant resources in vast vaccination programs that covered more than 90 percent of the population. During the civil war, though, severe budget cuts were made to public health care expenditures, and many mass human rights violations, including terror strategies such as isolation or deliberate destruction of medical facilities, caused a large setback to this country’s health services. Corruption is also a significant issue in Mozambique, and the public health sector is rife with it: Many doctors or nurses ask for bribes, further reducing the opportunity for patient equality, especially as the country is plagued by poverty. Today, Mozambique is facing many severe challenges, such as high infant mortality and child malnutrition rates (up to 53 percent), a significant human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS) prevalence in both adult and child populations (11.5 percent), malaria still being largely endemic in many territories, and natural disaster emergencies such as flooding and cyclones. HIV constitutes a risk factor for cancer (mostly for Kaposi’s sarcoma), while malaria is a risk factor for children’s Burkitt’s lymphoma. Like many other underdeveloped, developing countries, many nongovernmental organizations (NGOs), such as the United Nations Children’s Fund (UNICEF) and Save the Children, operate in the territory, supporting primary health care by funding hygiene awareness campaigns, building modern clinical facilities, and employing the expertise of expatriate medical personnel.

The largest hospital in Mozambique is the Hospital Central de Maputo, which was built in 1976, has a total of six departments, 1,500 beds for inpatients, and serves an average of 700 outpatients every day. Nonetheless, no radiation therapy (RT) centers are available in Mozambique, and very few patients can afford to receive proper RT in overseas clinics. Many of the most common cancer types in this country (cervix, breast, and prostate) would greatly benefit from this treatment modality, with a potential reduction of mortality for up to two-thirds of

*Image: The skyline of Maputo, capital of Mozambique and home of the country’s largest hospital. The Hospital Central de Maputo has six departments, 1,500 beds for inpatients, and serves an average of 700 outpatients every day. the patients affected. In Mozambique, there is only one national cancer registry, the Registro de Cancro de Beira, within the pathology department of the Hospital Central in Beira. It was established in 2005 to collect and provide data on all cancer cases in the Beira region, but it has very limited resources: There is only one staff member paid by the International Agency for Research on Cancer (IARC) and just a single computer. Although due to the lack of data still available, the overall picture is probably incomplete, some early assessment on the actual cancer burden in Mozambique was made. The most common sites for cancer are cervical cancer, with an age-standardized incidence rate (ASIR) of 50.6 and the highest age-standardized mortality rate (ASMR) of 34.5, prostate cancer (ASIR: 16.1, ASMR: 12.9), followed by Kaposi’s sarcoma (ASIR: 15.5, ASMR: 13.2), breast cancer (ASIR: 13.1, ASMR: 7.5), and esophagus cancer (ASIR: 12.8, ASMR: 12.4).

Due to the high HIV prevalence in the Mozambique population, the risk of persistent human papillomavirus (HPV) infections is significantly increased. HPV constitutes by itself an important risk factor for cervical cancer, especially when both viruses are combined, a situation further aggravated by the overall lack of screening tests (Pap tests) for early detection and proper prevention. For these reasons, Mozambique has the second-highest incidence (42–60 per 100,000 women each year) and mortality rate for cervical cancer in all Africa, after Malawi. In order to address this major health issue, the Mozambique Ministry of Health, together with the GAVI Vaccine Alliance, decided in 2013 to start a massive vaccination campaign against HPV and a parallel PapVac study project to assess a proper strategy of implementation of vaccination programs for about 8,300 preadolescent girls throughout the country.

Other risk factors for cancers include tobacco use, which in turn may explain the higher rate of esophageal cancer in South African men. To address this problem, Mozambique authorities implemented moderate public smoking bans, although they are not very strongly enforced, and thus cancer prevention is still lagging behind.

**Multiple Endocrine Neoplasia Syndrome, Childhood**

Multiple endocrine neoplasia type 2b (MEN2B), also known as multiple endocrine neoplasia type 3, Williams-Pollock syndrome, Gorlin–Vickers Syndrome.
syndrome, and multiple endocrine neoplasia syndrome, is a genetic disease that causes the development of multiple tumors, nearly always including one or more cancers in childhood. MEN2B is caused by variations in the RET proto-oncogene, with the M918T variation accounting for 95 percent of cases. About half of MEN2B patients inherited the variant gene from a parent, but the other half are spontaneous mutations. Older fathers are more likely to conceive children with MEN2B, and boys are twice as likely as girls to have it.

Signs of MEN2B may occur in infancy and are nearly always present before age 10. Children with MEN2B are tall with long limbs, an elongated face, and protruding lips—sometimes called a Marfanoid build because of its similarity to the features of Marfan syndrome—and benign tumors develop in the submucosa of most or all organs as well as in the mouth and eyes. Most patients develop medullary thyroid cancer; at least half develop pheochromocytoma, a cancer of the adrenal glands. Other symptoms include a lack of tears when crying and uncomfortably dry eyes—often an early sign detected in infants—as well as low muscle mass, gastrointestinal problems, delayed puberty, and craniosynostosis, a fusion of sutures in the skull that results in changes to the skull's growth pattern and a swelled-seeming head as the child gets older. Though MEN2B children often look the same as children with Marfan syndrome, they lack the cardiovascular complaints of that disease.

Depending on the child's age at onset, any number of the above symptoms may suggest the MEN2B diagnosis, which can be confirmed with a nearly 100 percent accurate DNA test. Older tests relied on serum calcitonin levels. Medullary thyroid carcinoma and pheochromocytoma are rare enough cancers that the question of MEN2B is always raised when they are diagnosed.

The thyroid is one of the largest endocrine glands and is located in the neck below the Adam's apple. The thyroid makes proteins, produces hormones, and influences how the body reacts to other hormones. Most thyroid cancers have a high survival rate. Medullary thyroid carcinoma originates in the parafollicular cells, neuroendocrine cells in the thyroid that secrete calcitonin, a hormone that reduces blood calcium. The importance of calcitonin in the human body is not well understood as it does not appear to be a significant part of the body's regulation of calcium homeostasis. Medullary thyroid carcinoma accounts for only about 3 percent of thyroid cancers, and 25 percent of medullary thyroid tumors are found in MEN2B patients. The most common symptom is diarrhea, but the tumor may also cause periodic flushing of the face, sometimes accompanied by hot, itchy skin. When medullary thyroid carcinoma symptoms are the first presented, they may be mistaken for carcinoid syndrome, which causes the same symptoms because of elevated serotonin; in this case, the symptoms result from elevated calcitonin.

If detected early enough, medullary thyroid cancer can be surgically removed with little complication, though there is always a chance of recurrence. In MEN2B patients, early detection is highly dependent on age; the older the child when they develop medullary thyroid cancer, the more likely they have already presented some other MEN2B symptoms. In the non-MEN2B population, on the other hand, half of medullary thyroid cancer cases have metastasized (spread to other parts of the body, usually the lymph nodes) before diagnosis. When there is a high risk of recurrence, radiation therapy is recommended. Though Caprelsa has been approved for metastatic medullary thyroid cancer in adults, it has not been trialed for children or MEN2B patients.

Pheochromocytoma is a neuroendocrine cancer of the adrenal glands, developing in the chromaffin cells. It develops in about half of MEN2B children. Early symptoms are those of sympathetic nervous system hyperactivity, including elevated blood pressure and heart rate, palpitations, panic attacks, excessive perspiration, headaches, flank pain, unexplained weight loss, and elevated blood glucose levels. The most common symptom is an attack lasting up to an hour and consisting of elevated heart rate, sweating, headache, and sometimes panic or anxiety. In non-MEN2B patients, pheochromocytoma usually goes undiagnosed and is easy to mistake for anxiety disorder; often, the real cause is not discovered until an autopsy. In MEN2B patients, however, the link with pheochromocytoma is well-known, and the patient's pediatric oncologist will know to look for it. Blood tests give a reasonable indication of pheochromocytoma's presence. The preferred treatment is surgical resection by laparotomy or laparoscopy, a complicated procedure undertaken...
only at surgical and cancer centers with appropriately specialized surgical staff. Sometimes a complete removal of the adrenal gland is necessary to prevent recurrence.

Without intervention, children with MEN2B will not likely survive their 30s, though a few cases of untreated individuals have been diagnosed in their 50s—likely with late-onset MEN2B, however. Because thyroid cancer is nearly universal in MEN2B patients, even children who have not yet developed medullary thyroid carcinoma may be given a prophylactic thyroidectomy, ideally before age four. Benign mucosal tumors need not be removed but can be if they are the source of pain or for cosmetic reasons.

Abraham Lincoln has been proposed as a possible late-survivor of MEN2B, due to his Marfan-like syndromes, history of constipation, bumpy lips, and family history of a similar disorder. However, Lincoln lived, apparently fairly healthily, much longer than a MEN2B patient is expected to live without surgery.

Multiple Myeloma/Plasma Cell Neoplasm

The application of novel therapeutic agents in the treatment of multiple myeloma has changed the notion that this malignancy is incurable and, instead, has suggested that it is a chronic disease that someday would have a cure. The backbone of the new therapies for multiple myeloma consist of proteasome inhibitors as well as immunomodulatory agents that play an important role in reducing the occurrence of relapses. Most of the patients diagnosed with multiple myeloma undergo a relapse during the course of the entire disease. The recent findings of clinical trials using proteasome inhibitors as well as immunomodulatory agents could help clinicians in designing and developing new treatment strategies for multiple myeloma. Information generated from studies using these novel agents may also improve the clinical effectiveness and safety of treatment schemes for multiple myeloma patients.

Multiple myeloma comprises 1 percent of all hematologic malignancies and is recognized as the second most frequent cancer involving the hematopoietic system. Almost 22,000 new cases are diagnosed each year, and more than 10,000 deaths due to multiple myeloma were reported in the United States for 2013 alone. The average age of patients at diagnosis is 69 years. The average duration of overall survival of multiple myeloma patients has markedly increased in the past several years due to the identification of novel drugs and their subsequent inclusion in clinical trials for the treatment of various stages of multiple myeloma. Clinical trials using novel agents against multiple myeloma have improved the basic knowledge on its pathogenesis, as well as facilitated in distinguishing malignant clones, thus serving as potential therapeutic strategies. The aim of clinical trials is to identify a novel agent that would result in the sustained toxicity of tumor cells, thus resulting in the control of multiple myeloma and an improvement in the overall long-term survival of patients.

Proteasome inhibitors are protein complexes located within the cell and are responsible for the destruction of regulatory proteins, including those that control the cell cycle, cell death or apoptosis, and DNA repair. Proteolytic breakdown of ubiquitinated proteins inside a proteasome core can occur
Multiple Myeloma/Plasma Cell Neoplasm

in at least one of its subunits, including a1 that has a caspase-like activity, a2 that presents a trypsin-like activity, and a5 that provides a chymotrypsin-like activity. Inhibition of the activity of proteasomes results in cell cycle arrest and cell death, two activities that do not occur in cancer cells because these inherently possess elevated levels of proteasome activity that effectively detect any impending inhibitory effects in their immediate microenvironment.

One of the most recognized proteasome inhibitors is bortezomib, a novel drug that received accelerated assessment and review by the U.S. Food and Drug Administration due to the results of Phase II clinical trials that established its safety and efficacy compared to dexamethasone in the treatment of patients with relapsed multiple myeloma who have earlier received at least one treatment regimen. The initial findings of the clinical trial showed that the administration of bortezomib resulted in a significant improvement in the survival of the patient, as well as in generating a response from the drug. The subsequent trials resulted in a six-month improvement in rates of patient survival and in generating a response to the drug. The depth of response to the drug also improved from 1 percent to 9 percent, and a 2.7-month improvement in the time for disease progression.

Another proteasome inhibitor is carfilzomib, which has been recently approved as a treatment drug for multiple myeloma. The ideal candidates for carfilzomib are patients who have undergone at least two therapies that used bortezomib as well as an immunomodulatory drug and have shown relapse. The term relapse, which is used interchangeably with refractory disease, pertains to the progression of the disease within 60 days after the administration of the last therapy.

A Phase II clinical trial involving carfilzomib showed that the proteasome inhibitor also caused thrombocytopenia as a side effect, which was also observed with bortezomib. The clinical trial also showed that carfilzomib did not cause severe renal impairment, and that only 1.5 percent of the patients had to be discontinued from the study because of the development of renal dysfunction. More clinical studies are currently being conducted on carfilzomib. These trials include the identification of the optimal dose for the treatment of multiple myeloma that results in an improvement of the disease yet shows the lowest incidence of severe adverse reactions or side effects to the drug.

In addition to bortezomib and carfilzomib, other novel proteasome inhibitors are in the pipeline for the treatment of multiple myeloma. These new batches of inhibitors will have to undergo screening for safety and efficacy using a study population of patients of varying stages and responses to previous therapies. Marizomib is an intravenous, irreversible proteasome inhibitor that has been assessed for its safety and overall response rate. Toxicities caused by marizomib include transient hallucinations, changes in cognition, and physical imbalance. As of 2014 the drug was being evaluated based on a dose frequency of twice a week, using a dose of 0.5 mg/m² IV for a total of 120 minutes. Thus, the treatment schedule would include the administration of the drug on days 1, 4, 8, and 11, with the entire cycle lasting for a total of 21 days. Marizomib is administered as a single agent or in combination with a low dose of dexamethasone, which is orally administered at a dose of 20 mg one day before and one day after receiving marizomib.

Another novel proteasome inhibitor in the pipeline is ixazomib, an oral drug that was being assessed in a 2014 Phase I clinical study using a dosing schedule of weekly and biweekly and involving relapsed multiple myeloma patients. Initial results have shown that ixazomib causes various adverse events in 91 percent of the patients; these include thrombocytopenia, diarrhea, fatigue, rashes, and nausea. Approximately 10 percent of the study population developed mild peripheral neuropathy. Based on the promising results of proteasome inhibitors in the treatment of multiple myeloma, these novel drugs may assist in improving the conditions of patients. It is thus essential that additional clinical trials be performed to determine the extent of efficacy and safety of these novel drugs.

Mycosis Fungoides

Though the name means mushroom fungus disease, mycosis fungoides, granuloma fungoides, or Alibert–Bazin syndrome is a type of cutaneous T-cell lymphoma, a non-Hodgkin’s lymphoma. Lymphomas are cancers of the immune system, originating in white blood cells called lymphocytes. Traditionally, they are divided into Hodgkin’s lymphoma, which is more responsive to radiation therapy, and all others. However, in the last decade, this distinction has fallen out of favor, given the extreme variation among different non-Hodgkin’s lymphomas, some of which are caused by infectious agents, while others result from genetic diseases, autoimmune diseases, or chemical exposure. Some are associated with haemophilus influenzae type B (HIB), some are not, and their aggressiveness varies considerably.

Cutaneous T-cell lymphomas begin with a mutation of T cells, a lymphocyte that matures in the thymus or tonsils and is key in cell-mediated immunity.

Mycosis fungoides does not seem to be hereditary or genetic in origin, and it is much more common in men than women. The rate of incidence is highest over age 50 and very low under age 20. It is related to Sézary syndrome, a leukemic form of the disease.

The first symptom of mycosis fungoides is the skin condition that gives it its name, a patchy rash of plaque that may have reddened lesions or bumpy tumors surrounded by patches of rough skin. Itching is not uncommon but present in only about a quarter of cases. Otherwise, it often resembles psoriasis, eczema, and other less-serious skin conditions. Usually, it is not identified as a cancer until a skin biopsy is performed. Usually, several biopsies are performed in different spots as not all of the rash tissue is malignant.

Mycosis fungoides has three stages: premycotic, which looks like other skin conditions; mycotic, in which infiltrative plaques begin to appear and atypical lymphoid cells can be found microscopically; and tumorous, which is malignant, with medium-sized lymphocytes infiltrating. Premycotic fungoides may last for decades before progressing. Untreated mycosis fungoides may metastasize to lymph nodes or blood and internal organs or develop into a higher-grade lymphoma.

Treatment varies. Naloxone, an opioid antagonist used since the 1960s to counteract opioid overdose, was approved in 2010 to treat pruritus resulting from all cutaneous T-cell lymphomas. Although mycosis fungoides is considered incurable like other cutaneous T-cell lymphomas, it may go into indefinite remission. Treatments include local radiation therapy and either topical chemotherapy (applied like an ointment) or conventional systemic chemotherapy and photopheresis, a photodynamic therapy in which the patient’s blood is treated with a photosensitizing agent and irradiated with ultraviolet light (UVA) before being returned to the patient. Other photodynamic therapies are possible as well, including the use of topical photosensitizers before exposing the skin to sunlight or ultraviolet light. Other treatments like topical steroids help to treat the rash and itching and may be sufficient in premycotic or mycotic cases.

Mycosis fungoides can also be treated with Ontak, an antineoplastic agent that binds to interleukin-2 receptors and kills the cells, which can cause remission if other treatments have been ineffective; Tar-gretin, an anticancer treatment approved in 1999; Zolinza, a compound that inhibits histone deacetylases, is used to treat persistent cutaneous T-cell lymphomas that do not respond to or recur after other medications, and which is often used to treat Sézary syndrome; and Istodax, which was approved for cutaneous T-cell lymphomas in 2009. Clinical trials are exploring the use of Panobinostat, an experimental drug developed by Novartis as an on-selective histone deacetylase inhibitor, and Resimmune, an anti-T-cell immunotoxin developed by the National Institutes of Health and trialed by Angimmune.

Further Readings

Myelodysplastic Syndromes

Myelodysplastic syndromes (MDS) are a heterogeneous group of blood cancers arising from the early death of hematologic cells derived from bone marrow (BM). The death of these cells can lead to severe fatigue, infections, bleeding, and more, causing significant impairment in daily functioning or even death. Though the incidence is low relative to many other cancers, the burden is large on patients and families due to extended periods of suffering and financial hardship, with many having no hope for a cure at this time. However, many advancements in research and therapy are being made to improve life for people with MDS.

Epidemiology and Prognosis

Myelodysplastic syndromes generally affect elderly men and women, with more than 85 percent of cases occurring after age 60. There are up to 75 cases diagnosed per 100,000 people over age 65. Up to 15,000 people are diagnosed with MDS each year in the United States alone, and it is estimated that more than 60,000 people are living with MDS in the United States. Worldwide, MDS is grossly underdiagnosed, and thus the global disease burden is unknown at this time. Studies have shown that MDS seems to occur at a younger age in Asia, independent of race, but strong evidence is lacking.

MDS is sporadic with no identifiable causative factor in almost all cases. However, some cases may be initiated by chemotherapy or radiation from prior cancer therapy or an environmental radiation exposure. Additionally, high levels of benzene exposure can cause MDS. This is generally seen in chemical plant workers that manufacture benzene, often in China, and is also thought to occur from tobacco use or high levels of industrial emissions or hazardous waste, though significant data for the latter three is poor at this time.

Approximately one-third of MDS cases progress to acute myeloid leukemia (AML), most often those considered high risk due to certain clinical and genetic abnormalities. Patients who develop this secondary AML generally have a poorer prognosis than those with primary AML (no prior predisposing disease) and often do not respond as well to chemotherapy. In the two-thirds who do not develop AML, prognosis is still generally poor, and predicted survival (based on the median survival data of a large cohort) can range from less than a year to more than seven years, though the prognosis is impossible to determine exactly for any given individual. Predicted survival for a particular patient is based on disease subtype and risk category as defined by French-American-British (FAB) classification and the
Myelodysplastic Syndromes

Revised International Prognostic Scoring (IPSS-R) scoring system, respectively.

Disease Mechanisms and Clinical Characteristics
MDS is caused by the early death of cells in the BM that become red and white blood cells and platelets. The combination of cells affected, severity of the illness, and response to treatment is variable and gives each patient a distinctive disease presentation, determined by their unique signature of abnormal processes in cancer cells compared to normal cells.

The three cell types affected lead to characteristic symptoms with decreased levels of the corresponding cells, and patients may have only one or any combination of deficiencies in these cells. Low red blood cells (anemia) are the most commonly decreased cell type in MDS, leading to chronic fatigue and low tolerance to exertion, so patients have extremely limited daily functioning compared to baseline. This fatigue can be emotional or mental as well as physical, affecting a patient’s mood and ability to perform routine tasks. This anemia often leads to blood transfusion dependence when untreated. Chronic transfusion therapy has many potential side effects, such as an immune attack of transfused cells (the likelihood increases proportionally with higher numbers of transfusions), liver and heart disease, arthritis, infections, and more.

The frequency of transfusions required by a patient is a commonly used marker for worsening disease and increased resistance to treatment.

Low white blood cells (leukopenia) can lead to severe, life-threatening infections due to inability of the immune system to respond to certain pathogens. Minor infections occur frequently in patients with leukopenia, including mucosal yeast infections (commonly in the mouth), skin infections, and pneumonias. However if levels decline significantly, more severe infections may occur and can lead to death.

A low platelet level (thrombocytopenia) leads to poor blood clotting, which causes easy bruising and can lead to spontaneous bleeding if levels drop too low. These bleeds can lead to worsening anemia, stroke, or a multitude of other effects depending on the location of the bleed within the body.

Treatment
MDS is incurable with medical therapy alone, and the only curative treatment is with a BM transplant. However, this treatment is not ideal for all patients; only some are eligible, fewer find a matched donor, and the risks of transplant are high. There are supportive and medical therapies available that slow the progression of the disease and can significantly alleviate symptoms. Because the vast majority of MDS patients are anemic, red blood cell (RBC) transfusions and erythropoiesis-stimulating agents (ESAs, which increase RBCs by BM stimulation) are often a mainstay of therapy.

The three Food and Drug Administration (FDA)-approved drugs at this time that have proven to be effective for prolonged medical therapy are lenalidomide, azacytidine, and decitibine. All have certain indications depending on the subtype of the patient's disease. While not curative, response to these therapies can lead to significant improvement in quality of life by increasing blood cell counts and corresponding improvement of symptoms. This can lead to higher energy and return to daily functioning as well as decreased risk of infections and bleeding. If the anemia improves (the patient achieves transfusion independence), this is a sign that the drug will give him or her clinical resolution for some time. However, not all patients respond to the recommended therapies, and even if they do, the dysplastic cells often become resistant to these therapies over time, and symptoms again worsen. In this case, other approved therapies may be tried, or the patients can be put on clinical trials for treatments under study. Patients receiving frequent transfusions are also usually started on an iron-chelating agent, like deferasirox, to reduce the risk of iron overload.

Other treatments are not currently FDA approved but are frequently used due to high rates of resistance to approved drugs. One such drug is rigosertib, which has been shown to give significant clinical improvement in patients with high-risk disease in clinical trials. Clinical trials for rigosertib are currently under way in low-risk patients, with promising results so far. High-dose all-trans retinoic acid (ATRA, a vitamin A derivative) therapy also has been shown to have a significant positive effect in some patients. The subset of patients these drugs work best on has yet to be completely identified, though genetic and epigenetic studies are currently under way to better understand their mechanisms at a biochemical level. Other medications currently being studied are DNA deacetylase and methyltransferase (HDAC and DNMT) inhibitors, isocitrate dehydrogenase 2 (IDH2) inhibitors,
and transforming growth factor-β (TGF-β) pathway inhibitors, as well as many others in early stages with only preliminary data.

BM or umbilical cord blood transplant is ideal for younger patients who are otherwise healthy and have high-risk disease or are progressing to AML. BM transplants can significantly improve life expectancy by eliminating all MDS and return a patient’s quality of life to a healthy state. However, many risks come with BM transplant, including a high risk of infection and death, ranging from 20 to 40 percent survival in most studies, though some have reported a higher survival rate. The patient’s oncologist and BM transplant physician must be consulted to decide if this procedure is right for him or her if significant quality of life and life expectancy improvement may be achieved in persons with a poor prognosis.

Looking to the Future

Advancements in drug design, clinical genetic and epigenetic testing, and research on the driving mechanisms of MDS are rapidly progressing. Many experimental therapies are entering clinical trials, though they are still in the early phases. Our understanding of the underlying drivers of MDS is leading to personalization of therapy, something that exists for many other cancers but thus far has not existed in MDS therapy. Curative therapy for all MDS patients is far from ready for clinical practice, but improvement of therapy targeting symptoms and improved life expectancy is imminent, and huge advances will be seen in the next five to 10 years, leading to improved quality of life in all people who develop this disease. MDS patients and their families should be hopeful for significant advances in the coming years.

Myelodysplastic/Myeloproliferative Diseases

Myelodysplastic and myeloproliferative neoplasms (MDS/MPNs) are a group of disorders that do not have the characteristic unique features to be classified as an MDS or an MPN alone but instead have features of both. These disorders are characterized by simultaneous low levels of some types of blood cells and elevated levels of other types, with abnormal growth patterns seen on bone marrow biopsy.

MDSs are a heterogeneous group of blood cancers characterized by early death of more mature blood cells exiting the bone marrow. The three types of blood cells that can be affected are red blood cells (RBCs), white blood cells (WBCs), or platelets and are collectively called myeloid cells. Any one of these or a combination may be affected in a particular patient. The cell types affected, severity of disease, age of the patient, and genetic changes observed are just a few of the factors that contribute to an individual’s prognosis and clinical presentation. Low RBCs lead to anemia, causing debilitating fatigue that can be emotional, mental, or physical, as well as dependency on blood transfusions (which has its own complications). Anemia is present in the vast majority of patients with MDS. Low WBCs, termed leukopenia, lead to infections. These infections may be minor, such as mucosal yeast infections or skin infections.
However, when WBCs are severely low, the infections can be systemic and life threatening. Low platelets cause thrombocytopenia, a disorder that leads to poor blood clotting. This can cause a range of complications depending on severity, from easy bruising if mildly decreased to spontaneous internal bleeding if severely decreased, leading to hemorrhagic stroke, gastrointestinal bleeding, or even death.

On the other hand, MPNs are a group of blood cancers characterized by uncontrolled cell replication of myeloid cells in the bone marrow, leading to elevated levels of RBCs, WBCs, or platelets. These patients are often asymptomatic. If symptoms are present, they can lead to a large range of minor, nonspecific symptoms or symptoms as severe as blood clots, stroke, ulcers, heart attack, and gout, among others.

The combined MDS/MPNs are a collection of four categories of poorly understood disorders, all having a cancerous stem cell expansion in the bone marrow and some abnormal combination of low and high levels of various mature blood cells in circulation. These disorders are chronic myelomonocytic leukemia (CMML), atypical chronic myeloid leukemia (aCML), and myelodysplastic and myeloproliferative neoplasms—unclassifiable (MDS/MPN-U). The frequency of these disorders is very rare independently, combining for an incidence of up to six new cases per million people per year in one study, much less than that of MDS or MPNs. These diseases present many challenges for the people who are afflicted and for their physicians due to lack of understanding of the disease processes and poor treatment options. However, research is ongoing, and clinical drug trials continue to improve care. Here the current standing of the knowledge of these four disorders and future directions for research and therapy are presented.

**Chronic Myelomonocytic Leukemia**
CMML is a disease of the elderly and occurs more often in males (up to 3:1), with a median age of onset of approximately 70 years old. It is characterized by persistent elevation of a type of WBC called monocytes in the bloodstream. To make the diagnosis, chronic myeloid leukemia (CML) and acute myeloid leukemia (AML) must be ruled out, and another bone marrow abnormality must be detected. These patients usually present with bone marrow failure and corresponding symptoms, which mirror the symptoms seen in MDS with low blood cell levels. Nonspecific symptoms that frequently occur include fever, night sweats, enlargement of the liver or spleen, and weight loss. Approximately 15 to 20 percent of patients progress to secondary AML. Median survival in patients with CMML is between one and two years, with various clinical and genetic factors affecting an individual’s prognosis. The International Prognostic Scoring System (IPSS) can be used for calculating prognosis in a subset of CMML patients, and the subtypes CMML-1 and CMML-2 further categorizes a patient’s risk based on the extent of abnormal immature cell expansion in the blood and bone marrow.

**Atypical Chronic Myeloid Leukemia**
ACML presents very similarly to CMML, with bone marrow failure symptoms, nonspecific systemic symptoms like fever and weight loss, and an enlarged spleen. The diagnosis of this disease involves ruling out a few others, including primary myelofibrosis and chronic neutrophilic leukemia, and the criteria that differentiate this disease from...
others are defined but shaky as this disease has such close resemblance to others. It can be differentiated mainly by the high proportion of WBCs called neutrophils in the blood and by ruling out the classic CML mutation BCR-ABL1 fusion in addition to other genetic and blood cell-level studies. Median survival is less than two years, and this disease also puts patients at risk for progression to AML.

**Myelodysplastic and Myeloproliferative Neoplasms—Unclassifiable**

MDS/MPN-U is a group of disorders that do not meet the criteria for MDS or MPN and also do not fit into one of the other MDS/MPN overlap syndromes. The best-characterized disorder in this group is termed *refractory anemia*, with ringed sideroblasts and thrombocytosis (RARS-T), also generally found in the elderly population. RARS is an MDS that leads to anemia with abnormal blood cell maturation, and thrombocytosis is an elevated platelet count that often is asymptomatic but can lead to increased risk of blood clots forming in the patient’s blood vessels. This also can be accompanied by nonspecific symptoms. The median overall survival is good compared to other MDS/MPNs, at nearly six years, and is similar to RARS. Though RARS-T is clinically similar to RARS in that the bone marrow findings and prognosis are similar and symptoms of anemia are the most common features, it is important to distinguish this disorder from RARS because they respond to different types of medical therapy. Other MDS/MPN-Us (non-RARS-T) are associated with a poorer prognosis, with median overall survival just longer than one year. These unclassifiable disorders may have no defining diagnostic features other than not meeting the requirements for another category and have very limited treatment options compared to RARS-T. MDS/MPN-U also may lead to secondary AML, though the rate of conversion is not well documented.

**Juvenile Myelomonocytic Leukemia**

In contrast to the other overlap syndromes, JMML is a disease of the young. It is a rare disorder, causing only 2 percent of childhood leukemias, and occurs in individuals (more often males) at a median age of just one year. Though risk factors are not well established for the other overlap syndromes, JMML is known to occur with much higher frequency in patients who have neurofibromatosis type 1 (NF1). Diagnosis requires increased monocytes in the blood, as in CMML. Additionally, CML and AML must be ruled out, and two other characteristic findings must be documented, as denoted by the World Health Organization (WHO) diagnostic criteria. Affected individuals usually have nonspecific symptoms (as in the other disorders) and commonly have a bronchitis or tonsillitis-like illness. It often leads to a predisposition to easy bleeding, rash, enlarged lymph nodes, and enlargement of the liver and spleen. The easy bruising and bleeding are due to a low platelet level, which is very common in these patients. Unfortunately, the prognosis for JMML is poor, with median overall survival between 10 months and four years, depending on age at diagnosis (younger patients tend to have a better prognosis) and features of the blood, such as platelet level (lower platelets are associated with worse prognosis). Between 10 and 20 percent of patients progress to AML.

**Diagnostics and Treatment**

Diagnosis of these disorders involves drawing a blood sample to assess levels of RBCs, WBCs, and platelets as well as taking a bone marrow biopsy and aspiration to assess for abnormal-looking, immature, or cancerous cells and for genetic abnormalities. All of these disorders are diagnoses of exclusion, and other blood cancers must be ruled out before a diagnosis can be made. All can be treated partially with supportive therapy (i.e., without chemotherapeutic drugs) depending on the type of low blood cell count the patient has. This includes blood transfusions and bone marrow-stimulating agents (termed ESAs) to increase production of RBCs for anemia and antibiotics to treat infections when they occur due to low WBCs. Bone marrow transplant is also an option for some people, and each disorder has a corresponding therapy plan that generally works best for the individual.

Once a diagnosis is established, treatment options for these disorders are unfortunately very limited. For CMML, medical therapies include azacitidine and decitabine, which are more effective in higher-risk patients (an overall response rate of about 25 percent is seen), as well as hydroxyurea, especially in patients with elevated WBCs. Resistance to these therapies is common and may develop later on in patients who initially saw improvement. The only curative therapy is bone marrow stem cell transplant. This is by far the best option for some patients, especially those who are younger than these patients. Unfortunately, the prognosis for JMML is poor, with median overall survival between 10 months and four years, depending on age at diagnosis (younger patients tend to have a better prognosis) and features of the blood, such as platelet level (lower platelets are associated with worse prognosis). Between 10 and 20 percent of patients progress to AML.

Between 10 and 20 percent of patients progress to AML.
(generally up to age 70), high risk, resistant to available medications, and in whom the treatment will significantly prolong the life span. However, bone marrow transplant is a dangerous procedure with a high risk of infection and death, in up to 60 to 80 percent of patients in some studies. However, when the transplant goes well, the treatment can completely restore daily functioning, totally alleviate symptoms, and significantly prolong life. Affected individuals and their families should talk to an oncologist and bone marrow transplant physician to decide if this procedure is right for them.

For aCML, there has been no effective medical treatment so far, and diagnosis is associated with a poor prognosis. Hydroxyurea is effective in some patients for symptom alleviation, but the only real therapy is bone marrow stem cell transplant. Though transplant is a high-risk procedure, because of the lethal nature of this disorder, patients who are eligible and have a matched donor should be considered strongly for transplant.

In RARS-T, though the prognosis is better than that of other MDS/MPN overlap syndromes, the treatment options remain limited. Because of the similarity to RARS, therapies used for MDS have been tried in small studies with some success. Lenalidomide is one such drug, which led to transfusion independence in two patients, one of whom also went into remission. Because RARS-T is associated with a better prognosis in elderly patients, bone marrow transplant is not recommended for most patients but is at the discretion of the patient’s physician as to whether an individual is a good candidate. Some patients also have responded to an MPN therapy called ruxolitinib, which inhibits a protein called Jak2. Other MDS/MPN-Us are treated with similar methods, but none have proven to be very effective at this time, and prognosis is poor. Additionally, patients with a platelet-derived growth factor receptor (PDGFR) gene abnormality are candidates for imatinib therapy, a drug that was initially designed for CML treatment.

JMML therapy is not well established and even with chemotherapy has had less than a 10 percent survival rate. Patients rarely have long-term survival, but it can occur more frequently in patients who have undergone bone marrow transplant. There was greater than 50 percent survival after four years in one study of patients with bone marrow transplant. Additionally, experimental therapies such as vitamin A derivatives (13-cis retinoic acid) have shown some success as well.

Looking to the Future
As these disorders are so rare, studies to find appropriate therapies for each one have been small and often anecdotal. Some therapies have proven effective in a limited number of patients, and multicenter efforts to create larger-scale studies are under way, integrating knowledge of MDS, MPN, and clinical and basic science research of the overlap syndromes to develop new therapies. One such target is the Ras gene, which is known to be involved in many cancer types and has been shown to be involved in all of these disease categories. Additionally, combination therapies are being tried to see if they improve outcomes over a single chemotherapeutic agent alone. For example, a phase II trial is under way for combination therapy with ruxolitinib (as described previously as commonly used in MPNs) and azacitidine (a drug commonly used in MDS). Further research is required to discover the causal genetic mutations that lead to development of these syndromes. Once more candidate targets have been identified, therapies can be applied or developed to target those mutations in each patient, leading to personalized therapy in MDS/MPNs with increased efficacy. Bone marrow transplant remains a good option for many patients, and studies are ongoing to increase the efficiency of transplant and survival.

As it stands now, prognosis and treatment options for these disorders remain poor. However, the rapid expansion of our knowledge about the molecular mechanisms of these disorders will certainly lead to improved therapy and survival for patients affected with these devastating disorders in the next few years.

Further Readings
Multiple myeloma (MM) is a hematologic cancer, or cancer of the blood, that develops in plasma cells of bone marrow. Plasma cells, also known as B cells, are normally responsible for producing antibodies that provide long-term protection against foreign antigens. MM develops when a single mutated, or cancerous, plasma cell proliferates uncontrollably, known as monoclonal proliferation. Collections of these cancerous plasma cells form tumors within the bone that interfere with normal blood cell production. Plasma cell tumors crowd out the production of other blood cells, leading to bone lesions and abnormally low numbers of red blood cells, white blood cells, and platelets. Additionally, cancerous plasma cells produce abnormal antibodies that damage the body and, in particular, the kidneys. MM is considered incurable but treatable, and the introduction of stem cell transplantation and the development of more effective therapies have improved management of the disease and extended patient survival.

Risk Factors
MM is noncontagious, and although most people who develop the disease have no clearly identifiable risk factors, there are several factors that may increase a person's risk for the disease:

- **Age**: The risk for MM increases with age. Less than 1 percent of cases are diagnosed in people younger than 35, and the majority of people who develop MM are older than 50, with the median age of diagnosis at 69.
- **Gender**: Men are at a slightly greater risk for developing MM than women.
- **Race**: African Americans are twice as likely to develop MM as are white Americans. The disease shows the lowest prevalence in Asians.
- **Family History**: MM appears to run in families. According to the National Cancer Society, someone who has a sibling or parent with the disease is four times more likely to develop the disease than would be expected otherwise.
- **Radiation**: People who have been exposed to radiation are at an increased risk for MM.
- **Workplace Exposure**: Although no clear link has been identified, the prevalence of MM is higher among agricultural and petroleum workers.
- **Obesity**: Risk for MM increases slightly if an individual is obese, although the mechanism is not well understood.

Prevalence
After non-Hodgkin’s lymphoma, MM is the second-most common blood cancer and represents 1 percent of all cancers in white individuals and 2 percent of all cancers in black individuals. According to the National Cancer Association, in the United States in 2014, 24,050 new cases will be diagnosed (13,500 men and 10,550 women), and 11,090 deaths are expected to occur (6,110 men and 4,980 women) as a result of MM. This translates into a lifetime risk of one in 143 for the disease.

Disease Presentation and Symptoms
Many organs can be affected by MM, but most individuals (70 percent) present with bone pain. The source of this pain is usually lesions, or tumors, within the spine or ribs, but persistent, intense pain can reveal a pathological bone fracture. In addition to forming tumors within the bone, cancerous plasma cells release factors that lead to bone breakdown and elevated blood calcium levels. The crowding out of normal red blood cell production by overproliferative plasma cells can cause anemia, wherein decreased red blood cell production impairs oxygen delivery to the body's tissues.

Anemia can be asymptomatic or cause feelings of fatigue, weakness, and shortness of breath on exertion. Additionally, the cancerous plasma cells
produce paraprotein, an abnormal, nonfunctional antibody fragment that impairs the body’s defenses and damages the kidneys. The weakened immune system, lacking the ability to produce functional antibodies, puts patients at risk for infection. Kidney damage can lead to a decrease in urine production, blood in the urine, and eventual complete kidney failure.

**Diagnosis and Staging**

It is important to note that, in all patients, MM is preceded by a monoclonal gammopathy of undetermined significance (MGUS). MGUS is a benign condition in which paraprotein is found in the blood but in lower levels than with MM. MGUS can then progress into a range of blood diseases, with MM developing at a rate of 1 to 2 percent per year. MM is diagnosed based on the finding of bone marrow that is at least 10 percent monoclonal plasma cells and monoclonal protein in the blood or urine. In patients with less-common, nonsecretory MM, the diagnosis is based on the presence of at least 30 percent monoclonal plasma cells in the bone marrow.

The recommended tests if MM is suspected include a detailed medical history and physical examination, laboratory testing of blood and urine to characterize and quantify abnormal blood cell counts and protein production, and bone marrow examination. To identify bone lesions, X-ray and magnetic resonance imaging (MRI) of the spine, skull, chest, pelvis, and legs is recommended.

According to the International Staging System (ISS), staging the progression of the disease places the individual into one of three escalating risk groups that are defined by the levels of $\beta_2$-microglobulin and albumin in the blood. Further staging is determined by genetic analysis of the plasma cells to detect the presence of specific genetic or chromosomal abnormalities that are associated with a worse outcome.

**Treatment and Prognosis**

Treatment of MM is dependent on the stage of the disease and the health of the individual. Asymptomatic (smoldering) MM requires only close monitoring. Symptomatic (active) MM is treated immediately with high-dose chemotherapy and with stem cell transplantation depending on the age of the patient. The standard chemotherapy regimens—thalidomide-dexamethasone, bortezomib-based regimens, and lenalidomide-dexamethasone—are employed to eliminate rapidly dividing, cancerous cells. Following the elimination of the individual’s bone marrow cells with chemotherapy (and radiation if necessary), in patients under 65 years of age, transplantation of healthy, blood-forming stem cells gives the individual an opportunity to reestablish their blood system free of cancer. Unfortunately, the MM tends to relapse, and the cancerous cells can become treatment resistant.

While there is no cure for MM, effective management of the disease can significantly extend survival. ISS stage I patients have a median survival of 62 months. ISS stage II patients have a median survival of 44 months. ISS stage III patients have a median survival of 29 months. These survival times are measured from the point that treatment is started, and many patients, especially those with smoldering MM, begin treatment months or years following diagnosis. Of patients diagnosed with MM, 44.9 percent survive for longer than five years.

**Further Readings**

A group of oncologists have recently expressed their concern regarding the price of cancer drugs, particularly those for the treatment of chronic myelogenous leukemia.

First, they point out the doctrine of just price, in which a fair value should be given to any kind of commodity, based on the price and the worth of the product. Thus, the higher-priced drugs should reflect higher levels of efficacy and safety. However, these clinicians are also aware of the doctrine of free market economy, wherein the prices of the cancer drugs are representative of what the customer is willing to pay in order to receive the product. These clinicians therefore want to identify which doctrine is better and which offers a morally and medically acceptable concept of marketing cancer drugs.

One argument for this dilemma could be based on the impact of the cancer drug on the lives of the patients, particularly in curing them and improving their medical conditions. In this scenario, the just price should prevail based on the moral implications of the treatment outcome. Prime examples of this scenario include the cost of bread in situations afflicted by famine, the price of polio vaccines, and the drugs employed for the treatment of various chronic conditions such as diabetes, hypertension, and multiple sclerosis. When an item does not save lives or is not critical in alleviating the suffering of an individual, then the market inherently controls the price of the product because it is highly likely that the item is not restrained by matters involving ethics. For example, buying an original painting by Picasso, embarking on a luxury cruise, and spending a two-week vacation in New York are all very expensive activities yet are not products that are essential to life.

In the case of chronic myelogenous leukemia, three drugs have been approved by the U.S. Food and Drug Administration (FDA) a couple of years ago, namely, bosutinib, ponatinib, and oxacetaxine. These most recent drugs were then included in the list of drugs that are commonly used for the treatment of chronic myelogenous leukemia, which include imatinib, nilotinib, and dasatinib. The latest three drugs may be as effective or more effective than the older drugs, yet their prices have been described to be astronomically high. The price of using ponatinib for the treatment of chronic myelogenous leukemia for one year is estimated to be at $138,000. On the other hand, oxacetaxine, which is recommended for induction, could cost approximately $28,000; ponatinib also could be employed in the maintenance course of the treatment, and this may cost $14,000. The cost of bosutinib has been estimated to be at around $118,000 each year.

Financial analysts, together with clinicians, have assessed and discussed the prices of the recently released drugs for cancer treatment. This collaborative effect unanimously expressed that the current market prices of drugs for the treatment of chronic myelogenous leukemia are way too high, and that these prices are unsustainable. Based on this consensus, the group of analysts feels that this situation can compromise the patients’ need for highly effective and safe therapies for their health conditions. The group also expressed their concern that, if the prices of these cancer drugs are not controlled very soon, the health care system of the United States might also be compromised, particularly losing its capacity in sustaining itself using the revenue that it receives from drug sales.

An extensive assessment of the prices of cancer drugs resulted in serious discoveries—11 of the 12 most commonly used FDA-approved drugs cost at least $100,000 each. Furthermore, the prices of these drugs have increased by at least 200 percent in the past decade; the average cost of cancer drugs each month used to be $5,000, whereas this currently costs more than $10,000 every month. Both financial analysts and clinicians recognize the fact that innovative methods and new discoveries in any field of practice should be appropriately rewarded. The efforts of pharmaceutical companies in conducting research and developing new drugs are therefore very tedious, time-consuming, and challenging, with the aim of developing better and safer drugs that the public could use in the treatment of specific medical disorders. The average cost of developing a new drug has been estimated at $1 billion; this price thus somehow dictates that the market value of the new drug should be high enough to compensate for the investment that the pharmaceutical company made.

Analysts should understand that the cost of developing a new drug does not only entail expenses in buying reagents and equipment in the
laboratory as well as paying highly trained scientists to conduct these investigations in drug development. There are also ancillary expenses that go with the cost of developing a new drug, including the amount required to conduct a clinical trial, which is a requirement for all drugs prior to their approval for sales in the market. Advertising the new drug on television and other forms of mass media also requires a considerable amount of money. Thus, for a pharmaceutical company to generate a new drug, it has to be ready to spend close to $1 billion, and more importantly, it has to generate sales revenue greater than $1 billion in order to compensate for the initial costs that they spent in its development, testing, and marketing. Analysts from various fields are currently assessing the value of each new drug that has been released in the market. Are these drugs being sold at the right price based on their value? The answer to this question may be released in the near future and may cause further dismay, particularly when drug development is now considered as another marketing arena.

Nasopharyngeal Cancer

The global impact of nasopharyngeal cancer has not been established due to the scarcity in the number of studies that investigate the epidemiology of this disease. Nasopharyngeal cancer is considered as a malignancy that is strongly influenced by ethnicity as well as geographic distribution. Based on the limiting feature of this malignancy, the details of its etiology have remained uncertain. The incidence of nasopharyngeal cancer around the world is generally very low; also certain parts of the world present relatively high rates of incidence. For example, in certain populations in southern China, north Africa, southeast Asia, and the Arctic region, nasopharyngeal cancer is recognized as the most common type of malignancy. The unique distribution of nasopharyngeal cancer in specific geographical areas around the world indicates that its development, occurrence, and transmission could be influenced by environmental and genetic factors.

To determine the impact of environmental and genetic factors on the incidence of nasopharyngeal cancer, it is essential to initially establish the global incidence rate of this malignancy. However, previous reports have shown that nasopharyngeal cancer is associated with variations in rates of incidence because of a lack of integration in conducting epidemiological studies. Furthermore, the mortality data of nasopharyngeal cancer has not been established as most of the areas afflicted by this malignancy do not have a disease database that registers every case that develops in the country. The only organization that might probably have the most comprehensive information on the incidence of nasopharyngeal cancer at the global scale or at a country-by-country level is the International Agency for Research on Cancer (IARC).

The IARC was established by the World Health Organization (WHO) as an agency that would collect information on various cancers at the global scale. The section of Cancer Information maintains a large database that holds specific information on various aspects of different cancers. Aside from the incidence of each type and subtype of cancer, the IARC also collects information on the mortality rate of various cancers and lists international and national cancer registries. Unfortunately, information on mortality rates of specific cancers only represents those of selected countries. It is thus possible that certain countries have not been assessed in terms of the incidence and mortality of rare malignancies, including that of nasopharyngeal cancer.

In order to generate a useful database that documents various types of information on nasopharyngeal cancer, scientists have embarked on integrating the data from various countries and reviewing these in terms of accuracy. Through this approach, misinterpretations of the data could be avoided, and further research studies could be
developed based on the information provided by this database. One of the major contributions of the IARC is GLOBOCAN, which is a database on the incidence of cancer in five continents. For example, the GLOBOCAN2008 report contains the latest data as of the year 2008. Data on the incidence of various cancers are then compiled in this report, which is printed in several volumes and contains information collected from 300 registries located in a total of 61 countries around the world.

Epidemiologists utilize data from incidence and mortality rates in the design and development of preventive programs against a specific disease. In the case of cancer, these same sets of data are collected from each country and region around the world. Analysis of this data would then identify the top 20 countries that show the highest mortality for a specific cancer as well as determine the trends of each cancer in every country and on the global scale. For example, the incidence of one particular cancer is increasing in country X, whereas this has been observed as decreasing in country Y. Yet, on a global scale, the incidence of this specific cancer has remained the same in the past five years.

Assessment of the data on nasopharyngeal cancer showed that there were significant variations in the incidence of this specific malignancy around the world. Furthermore, the incidence of nasopharyngeal cancer between males and females varied per country. For example, the incidence of nasopharyngeal cancer in central America was estimated as 0.2 per 100,000 person-years, whereas that in southeast Asia was 6.5 per 100,000 person-years. On the other hand, the incidence rates for nasopharyngeal cancer were lowest in central America, as well as in South America and western Europe. At the national level, the incidence rates of nasopharyngeal cancer were highest among males from southeast Asian countries such as Malaysia, Indonesia, Singapore, Cambodia, and Brunei, as well as in Myanmar.

The incidence rates of nasopharyngeal cancer in females also varied per country. For example, the incidence rate of this malignancy in women in central America was 0.1, whereas that in southeast Asia was 2.8, reflecting at least a twofold increase in occurrence. The highest incidences of nasopharyngeal cancer at the national level were observed in the registries of southeast Asian countries such as Singapore, Myanmar, Indonesia, Bhutan, and Thailand. All these data indicate that nasopharyngeal cancer occurs at a higher rate among males than in females, reaching a 200 percent increase. On the other hand, the low incidence rate of nasopharyngeal cancer in both males and females in China were uniquely low, possibly reflecting a dilution in this specific population. However, in order to fully establish and validate this claim, additional investigations are warranted.

Another approach in studying the epidemiology of nasopharyngeal cancer is through mortality rates. By comparing mortality rates between that of the WHO and that collected by GLOBOCAN, it is possible to generate a more accurate estimate of this parameter within a five-year period. The mortality rates of nasopharyngeal cancer varied across the globe, ranging from 0.1 among males in central America to 4.2 among males in southeast Asia. Most of the registries showing the highest mortality rates involved males from counties in Asia, South Africa, and Micronesia. On the other hand, the lowest mortality rates were observed in countries of western and northern Europe, South Africa, central America, and Melanesia. The mortality rates of nasopharyngeal cancer in females ranged from 0.1 to 1.8 in central America and southeast Asia, respectively. The highest mortality rates in females were observed in countries from Asia, South Africa, and Micronesia. These variations in incidence and mortality rates thus make it more difficult to assess the severity of this particular malignancy at a global scale. Additional studies could possibly improve the statistics on this specific cancer.

Nasopharyngeal Cancer, Childhood

Nasopharyngeal cancer is a unique form of head and neck malignancy because it has a distinct epidemiological pattern by being prevalent in countries situated in southeast Asia. Nasopharyngeal tumors also have been reported to be radio sensitive, which brings hope to most clinicians as well as their patients. However, this therapeutic approach also has been associated with a higher risk for its recurrence, particularly in patients who are at the advanced stages of the disease. The five-year rate of cancer control among patients diagnosed with stages III and IV nasopharyngeal cancer ranges from 70 to 80 percent. Based on this trend, it is therefore also important to determine whether the same pattern occurs among pediatric patients who developed nasopharyngeal cancer.

Previous studies have shown that local control of nasopharyngeal cancer is strongly associated with the total dose and the duration of radiation that is directly delivered to the tumor. In the advent of two-dimensional radiotherapy, various strategies have been employed to improve the control of advanced stages of nasopharyngeal cancer. One approach would be to use higher amounts of radiation, which is the main principle behind stereotactic radiosurgery, whereas the other approach involves the application of an external beam of radiation, a technique employed in brachytherapy. The introduction of a higher radiation dose through accelerated fractionation has been utilized in the treatment of advanced cases of nasopharyngeal cancer. In this technique, several fractions of radiation are applied each day, whereas in other patients, around six smaller doses are administered within a span of one week. Unfortunately, these methodologies also can result in severe toxicity effects on the patient as well as a higher risk of developing late complications that are often fatal. Various other organs that are critical to the life of the patient also occupy the head and neck region, which includes the spinal cord, the brain stem, the parotid glands, and the orbits. Thus, administering higher doses of radiation may result in better control of the tumor yet would also result in the rapid deterioration of the quality of life of the patient due to the toxic and fatal effects of higher radiation doses on neighboring organs of the head and neck.

Intensity-modulated radiotherapy (IMRT) is a recent advancement that allows the delivery of higher dosages of irradiation to the target tissue or organ, thus sparing the adjacent and unaffected regions from the damaging effects of radiotherapy. The principle of IMRT is that the application of higher doses facilitates the local control of radiation, thus resulting in a higher survival rate for patients with nasopharyngeal cancer. Previous studies have shown that the effective IMRT dose for adult patients with nasopharyngeal cancer is 85 Gy. Furthermore, the application of IMRT is associated with a 95 percent local control rate. The five-year disease-free rate of nasopharyngeal cancer treated with IMRT was roughly 77 percent, whereas the overall survival rate was 75 percent. On the other hand, late toxicity effects due to IMRT were observed in 84 percent of the patients at a four-year follow-up, which included deafness, skin dystrophy, and subcutaneous fibrosis. Only 5 percent of the patients showed recurrence at the fifth year of follow-up.

Despite the extensive information on the effectiveness and side effects of IMRT on nasopharyngeal cancer, its actual effects on pediatric patients have not been fully assessed. Chang-Juan Tao and colleagues thus recently conducted a research study on the long-term toxicity effects of IMRT combined with chemotherapy on 34 pediatric and adolescent patients with nasopharyngeal cancer. The study population consisted of patients of ages ranging from eight to 20 years old who were histologically diagnosed with nasopharyngeal cancer. Patients who showed metastatic nasopharyngeal cancer were excluded from the study.

The effective IMRT dose for the pediatric and adolescent patients with nasopharyngeal cancer was 66 Gy, which was significantly lower than that applied to adult patients. The local control rate in this young population that received IMRT combined with chemotherapy was 97 percent, which was relatively similar to that reported in adult nasopharyngeal patients. The five-year disease-free
survival of the pediatric and adolescent patients was 85 percent, whereas the overall survival was 88 percent, which was significantly higher than that observed among adult patients with nasopharyngeal cancer. Among the 34 patients enrolled in the study, only 24 survived for at least two years; however, these patients showed side effects due to the treatment regimen that they received. Approximately 67 percent of the patients presented xerostomia of grades 1 and 2, whereas 63 percent of the same cohort developed deafness. The findings of the study thus showed that the combination of IMRT with chemotherapy resulted in a longer control of nasopharyngeal cancer in pediatric and adolescent patients. Furthermore, the application of IMRT in combination with chemotherapy resulted in a low number of cases of late toxicities, wherein an 84 percent incidence rate was observed in adult patients, whereas only 67 percent of the pediatric and adolescent patients showed the same response to the treatment.

A recent study led by Martina Buehrlen used another therapeutic regimen consisting of a combination of irradiation and chemotherapy using cisplatin, folinic acid, 5-fluorouracil, and finally, interferon beta. The study population included a total of 45 pediatric patients with ages ranging from eight to 20 years and positively diagnosed with nasopharyngeal cancer. The treatment design was based mainly on the cancer stage of each patient. For example, patients with stage II nasopharyngeal cancer underwent radiotherapy at a dose of 59.4 Gy, whereas those with stages III and IV underwent three courses of the three chemotherapeutic drugs. All patients were administered interferon beta for a period of six months. Patient outcome was determined by magnetic resonance imaging of the tumor to determine treatment response. The results showed that 43 of the 45 pediatric patients achieved complete remission using the combination therapy. In addition, only three patients developed metastases after treatment. The progression-free survival rate using the combination therapy was determined to be 92.4 percent, whereas the overall survival rate was 97.1 percent. Late toxicities among patients included deafness and hypothyroidism. These findings thus indicate that a combination therapy using irradiation, chemotherapy, and interferon beta was effective, well tolerated, and superior to earlier therapeutic regimens for nasopharyngeal cancer in pediatric patients.

National Alliance of Breast Cancer Organizations

The National Alliance of Breast Cancer Organizations (NABCO) was a leader in the field of health care advocacy from its founding as a nonprofit in 1986 until it closed its doors in 2004. It was cofounded by Nancy Brinker, Ruth Spear, Diane Blum, and Rose Kushner. During their tenure, NABCO’s mission was to advance knowledge by providing information and be the leading educational resource center available on breast cancer. It established a network of nearly 400 member organizations and agencies in the United States that provided education to the public as well as information, resources, and referrals to medical professionals and their organizations. All NABCO services were offered free of charge. NABCO also worked on the community, state, and federal levels for regulatory change and legislation to benefit those with breast cancer, breast cancer survivors, and those at risk of developing breast cancer.
Resources and Information
NABCO’s legacy included the NABCO Breast Cancer Resource list. This reference guide contained more than 3,000 breast cancer resources, including fact-based books, brochures, booklets, other breast cancer organizations, hotlines, and Web sites. This guide was made available to women and health care providers free of charge and covered a broad range of topics and useful information on treatment choices, insurance and financial issues, adjusting to the diagnosis, family support and care giver resources, hospice, and planning for the end of life. This comprehensive compilation of information was also made available online.

As a pioneer in providing breast cancer information, NABCO was the first organization to launch an extensive, disease-specific cancer site on the World Wide Web in 1995. This was instrumental in expanding their outreach in their ongoing efforts to educate both patients and health care providers about good breast health and to provide the latest breast cancer information and garner community support for the treatment and prevention of breast cancer. The Web site also featured an e-mail reminder system and an online calendar. The reminder system encouraged women to schedule breast exams and mammograms, and the calendar tracked breast cancer conferences, medical meetings, public policy and advocacy-related activities, outreach and fund-raising events, business or work-related health promotion activities, and locations for free and low-cost mammograms. NABCO was a one-stop shop for information and resources.

Research and Pharmaceutical Companies
NABCO was skilled in establishing working relationships and collaborations with government agencies, other nonprofit organizations, and corporations, particularly drug companies. Although some critics found the relationship with drug companies troublesome, these relationships funded the work and mission of NABCO. Examples of their collaborative efforts include projects with the National Cancer Institute (NCI) Board of Scientific Advisers (BSA), Breast Cancer Intergroup of North America (BCINA), Novartis, and Avon Products Foundation. The NCI collaboration worked to create plain-English summaries of clinical trials, which made it easier for breast cancer patients to find out about experimental treatments. This work was also undergirded by work with BCINA.

Another noteworthy project was the NABCO Recurrence Project, of which Novartis was a major sponsor. The NABCO Recurrence Project sought to fill in the gaps related to the lack of information regarding recurrent or advanced-stage breast cancer or metastasis. Current trends in research and public information are still lacking in this area. In addition, NABCO was the recipient of a $1 million unrestricted grant from the AVON Foundation to develop and provide continued breast health education.

It should be noted that NABCO was also aware of the needs of underrepresented populations of medically underserved women with breast cancer and launched the Within Our Reach program in 2001. This collaboration was funded by individuals, corporations, and foundations to provide focus and support to specific demographics of breast cancer patients, survivors, or those at higher risk. Special attention went to women of African American, Haitian, Native American, Latina, and Pacific Islander ethnicities; women located in rural areas; and disabled, homeless, lesbian, and bisexual women.

Coming to an End
As the landscape for funding changed, NABCO strategically closed its doors in 2004 with $2 million in the bank and a host of intellectual property. Part of its plan to close was to distribute its funds and intellectual property to other nonprofit organizations. The following 12 nonprofit cancer and health organizations received nonexclusive rights free of charge to NABCO’s educational materials, including its well-known Breast Cancer Resource List:

- American Cancer Society
- Breastcancer.org
- Cancer Care Inc.
- CDC Foundation
- Foundation for the National Institutes of Health
- National Coalition for Cancer Survivorship
- National Medical Association
- Oncology Nursing Foundation
- SistersNetworkInc.
- Susan G. Komen Breast Cancer Foundation
- Y-ME National Breast Cancer Organization (now defunct)
- Young Survival Coalition
It also should be noted that, in addition to using these resources to support their respective missions, the recipients agreed to make the educational materials available to other appropriate organizations to further benefit women with breast cancer and in essence continue what NABCO started.

The following eight nonprofit breast cancer education and service programs received NABCO cash grants:

- Northeast Medical Center in Concord, North Carolina
- Planned Parenthood of Cameron and Willacy Counties in Harlington, Texas
- The Rose in Houston, Texas
- Scripps Health in San Diego, California
- Southeast Mississippi Rural Health Initiative in Hattiesburg, Mississippi
- I. M. Sulzbacher Center for the Homeless in Jacksonville, Florida
- YWCA of Seattle, Washington
- YWCA of White Plains and central Westchester, New York

According to statements taken from an interview with Amy Langer, longtime executive director of NABCO, in the Harvard Business School online alumni magazine in 2013, “NABCO was instrumental in changing the course of breast cancer screening, treatment, and care. Our physician and corporate partnerships to educate women replaced fear with facts. We helped craft and implement laws and regulations, improving mammography’s quality and accuracy and making screening more accessible to poor and underserved groups. Our efforts started a movement that vastly escalated breast cancer research funding, and gave patients and survivors a permanent voice in medical decision making.”

Disorders (NIDCD); the National Institute on Drug Abuse (NIDA); and the National Institute of Diabetes on Digestive and Kidney Diseases (NIDDK).

The NCI was established as the principal agency within the NIH for conducting cancer-related research in the United States. This includes conducting clinical research on cancer diagnosis, detection, and innovative and promising new cancer therapies; examining the basic structures, mechanisms, biology, and chemistry of cancers to increase scientific understanding of this pervasive health threat; examining the best strategies for cancer prevention and control; and conducting research to develop best practices for the dissemination of relevant cancer information to key audiences. The development of the NCI was mandated and funded by the U.S. government through passage of the landmark National Cancer Acts of 1937 and 1971. These National Cancer Acts have spurred a major national investment in cancer research, treatment, and survivorship and have initiated a concerted program of research and intervention to reduce the nation's cancer burden. Publically, these cancer control efforts have become known popularly in the United States as the war against cancer.

The NCI is charged formally with coordinating the U.S. National Cancer Program action plan for eliminating cancer in the United States by confronting the threat of cancer, disseminating relevant information about cancer research, cancer prevention, and cancer treatment, and evaluating the use of state-of-the-art cancer treatments. The NCI receives funding to accomplish these goals through an NIH budget as well as through an additional direct bypass budget that comes straight to the NCI from the U.S. Congress. These federal government funds support research at NCI's headquarters in Bethesda, Maryland, and in laboratories and medical centers throughout the United States, as well as in many other countries around the globe. The NCI is the only NIH institute to receive a direct bypass budget from Congress, and it is also the only institute whose director is appointed directly by the president of the United States. These unique factors indicate the high priority for addressing cancer issues in the United States and the importance of the NCI. In 2014, the director of the NCI was Harold Varmus, MD, a prominent scientist, Nobel laureate, and former director of both the NIH and the prestigious Memorial Sloan Kettering Cancer Center in New York City.

The NCI's 2014 operating budget was $5.126 billion. This is the largest operating budget of any NIH unit, and it accounted for more than 17 percent of the total 2014 NIH operating budget of $29.925 billion. The NCI uses these federal funds to coordinate the National Cancer Program, including conducting its own research, training, infrastructure development, and health information dissemination programs (intramural activities) as well as supporting research, training, and health information dissemination about the causes, diagnoses, prevention, and treatment of cancer at many sites across the United States and internationally (extramural activities). The NCI supports a number of important cancer rehabilitation and treatment programs that provide care for cancer patients and their families. The intramural research supported by the NCI is generally conducted by NCI-employed scientists, and the extramural research supported by the NCI is generally conducted by outside scientists who are typically employed at major research universities and medical centers, including at NCI-designated cancer centers. However, there are some projects that involve collaborations between intramural and extramural scientists. The NCI also supports the Cancer Prevention Fellowship Program, a four-year postdoctoral training program that provides research and educational opportunities for scholars who have already received doctoral degrees (such as the MD, PhD, ScD, and DPH degrees) across different areas of the health sciences to enhance these postdoctoral fellows’ abilities to conduct important new research concerning cancer prevention and control and train the next generation of leading cancer prevention and control scientists.

Funding from the NCI supports the following important cancer research and control activities:

The NCI funds relevant cancer-related research projects conducted by universities, hospitals, foundations, and businesses throughout the United States and abroad that are funded through competitively selected research grants, contracts, and cooperative agreements. Research grants support investigator-initiated and NCI-designated research projects. The NCI-designated grant topics are introduced with targeted calls for applications such as requests for applications (RFAs) and program announcements (PAs) that are developed
by NCI scientific program staff. These calls for applications are designed to encourage intramural and extramural researchers to submit research grant applications that address critically important research topics that can advance cancer knowledge and applications. Grant applications submitted to the NCI are competitively evaluated for funding by standing NIH review groups (referred to as study sections) composed of leading cancer scientists or by specially established NCI review groups (referred to as special emphasis panels) also composed of leading cancer scientists to review grant applications for targeted calls that may fall outside of the scientific purview of the established NIH study sections. These standing grant review panels are rigorously administered to maintain high scientific integrity by the NIH Center for Scientific Review (CSR), and in the case of the special emphasis panels, they are supervised by the NCI Grants Administration Branch.

There are several different grant mechanisms that are supported by the NCI. Several of the major research grant mechanisms employed by the NCI include the R-01 Research Project grant (sometimes referred to as a program project grant), which is designed to support major, sophisticated, multiyear cancer research and intervention efforts conducted by leading cancer researchers; the R-21 Exploratory/Developmental grant, which is designed to support innovative new cancer research activities over a few years on a smaller scale than the R-01 research project grants but that might lead to larger R-01 investigations; the R-03 Small Research grant, which is designed to encourage less-experienced cancer researchers to test new techniques and pilot studies over just a few years that are likely to lead to successful applications for larger R-01 and R-21 grants; the P-50 Specialized Center grant, which is designed to support large-scale, multi-project research programs over a number of years conducted by the most experienced and sophisticated transdisciplinary research teams (composed of leading scholars from multiple disciplinary perspectives who coordinate efforts and expertise) to
significantly advance cancer science, lead to new cancer research programs and applications, spur new exploratory cancer research projects, and train the next generation of cancer scientists in targeted high priority areas; and the R-13 Conference grant, which is designed to support important scientific meetings and workshops that hold the promise to advance cancer science and applications.

Contracts funded by the NCI also support targeted research and application projects initiated by the NCI. Calls for contract proposals are designed by NCI program staff to address important cancer research topics and to provide work to enhance NCI programs and activities. Cooperative agreements are funded by the NCI to support collaborative research projects conducted jointly by NCI scientists and extramural investigators concerning NCI-initiated research topics. Cooperative agreements are developed by NCI program staff to address important cancer research topics and also are designed to enhance the research capabilities of NCI staff.

Research projects conducted in NCI's own intramural research laboratories and clinics are awarded funds through a competitive internal application and selection process. These intramural research projects generally are conducted at the NCI's extensive and state-of-the-art research laboratories in Bethesda, Maryland, the NCI Frederick National Laboratories for Cancer Research (located in Frederick, Maryland), and at the NIH Clinical Center (located on the NIH campus in Bethesda, Maryland).

Education and training programs in basic and clinical science disciplines are supported by career award grants (these are referred to as K grants, which are designed to support the career development of cancer researchers at different levels in their careers and in different areas of cancer research (some of the major K awards that are most relevant to cancer and society include the K-01 Mentored Research Scientist Development grant to support career development in the biomedical, behavioral, or clinical cancer sciences, leading to research independence in one of these targeted areas; the K-05 Established Investigator grant in Cancer Prevention, Control, Behavioral, and Population Research, which is designed to support career development for research scientists who are already qualified to pursue independent research and will help to extend their relevant cancer research programs; and the K-07 Cancer Prevention, Control, Behavioral, and Population Sciences Career Development grant, which is designed to support junior candidates in developing their academic and research expertise or to support senior candidates with acknowledged scientific expertise to improve curricula and enhance the research capacity within an academic institution). The NCI also supports training grants and fellowships that are awarded through a competitive selection process. These training programs typically are conducted at major research universities and medical centers around the United States and internationally as well as on site at NCI offices and laboratories.

The NCI is the only institute or center within the NIH that supports a national network of major clinical and applied medical centers (referred to as NCI-designated cancer centers) that conduct cutting-edge cancer research, provide state-of-the-art cancer care, and collaborate with the NCI on important cancer research and outreach projects. Medical centers must meet stringent requirements and pass a competitive review to earn approval to become a designated NCI cancer center. There are two types of NCI-designated cancer centers: (1) an NCI-designated cancer center that must demonstrate scientific leadership, resources, and capabilities in laboratory, clinical, or population science or some combination of these three components. It must also demonstrate reasonable depth and breadth of research in the scientific areas it chooses and transdisciplinary (combining multiple scientific perspectives and expertise) research across these areas; and (2) an NCI-designated comprehensive cancer center that must demonstrate reasonable depth and breadth of research in each of three major areas: laboratory, clinical, and population-based research, as well as substantial transdisciplinary research that bridges these scientific areas. In addition, a comprehensive NCI-designated cancer center also must demonstrate professional and public education and outreach capabilities, including the dissemination of clinical and public health advances in the communities it serves. Of the 68 NCI-designated cancer centers, 41 have been designated as NCI comprehensive cancer centers. The comprehensive cancer centers receive higher levels of funding and are eligible to participate in a broader range of NCI-supported activities than the other designated cancer centers.

The NCI funds collaborations with voluntary organizations and other national and foreign institutions engaged in cancer research and training.
Because the NCI is widely recognized as the leading center for cancer science, it provides guidance and support to many other cancer research organizations around the globe.

Cancer research by industrial concerns, including collaborations with pharmaceutical and biotechnology organizations to develop new cancer treatments and equipment, are supported by the NCI. Many of the most successful NCI-funded cancer drug and biotechnology development clinical trials are eventually commercialized and brought to market by major pharmaceutical and biotechnology organizations. These collaborations with corporations enable the NCI to work with industrial partners to actively translate new research findings into health care practice.

The NCI funds collection and dissemination of relevant information on cancer through publications (scientific journals, monographs, and cancer information pamphlets); the cancer.gov Web site, which provides the latest information about cancer research and treatment; the Cancer Information Service (CIS), which operates a toll-free telephone hotline, 1-800-4-CANCER, and provides information via the Internet; and collaborations with media and news representatives about cancer research and treatment. The CIS also informs consumers about where they can seek cancer treatments and where they can apply to participate in cancer clinical research trials. One of the major mandates established in the National Cancer Act of 1971 was for the NCI not only to conduct cutting-edge cancer research but also to disseminate widely the latest information from this research about cancer prevention, treatment, and control to relevant public audiences.

The NCI also supports construction of laboratories, clinics, and related facilities for cancer research with construction grants. The NCI has an active program of expanding the national and international cancer research capabilities by expanding cancer research infrastructure and technologies.

The NCI is composed of the Office of the Director and seven major research units—two of these research units are intramural units, and the remaining five are extramural units. The intramural units are the Center for Research (CCR) and the Division of Cancer Epidemiology and Genetics (DCEG). CCR manages NCI’s basic and clinical intramural research program; DCEG conducts population and multidisciplinary research to examine genetic and environmental determinants of cancer and the best means for cancer prevention. The five extramural units are the (1) Division of Cancer Biology (DCB), supporting basic research in all areas of cancer biology; (2) Division of Cancer Control and Population Services (DCCPS), supporting genetic, epidemiologic, behavioral, social, and surveillance cancer research; (3) Division of Cancer Prevention (DCP), supporting research to determine and reduce a person’s risk of developing cancer as well as research to develop and evaluate cancer screening procedures; (4) Division of Cancer Treatment and Diagnosis (DCTD), supporting the translation of promising research into improved diagnostic and therapeutic cancer treatments; and (5) Division of Extramural Activities (DEA), coordinating scientific review of extramural research before funding and providing systematic surveillance of that research after awards are made. There are also a number of units coordinated by the Office of the Director, including the Office of Communication and Education that oversees NCI’s communication with key publics.

The DCCPS is the NCI division that conducts research and applications programs that are most relevant to cancer and society issues, including promoting cancer prevention activities, screening and early detection of cancers, adoption of the best cancer diagnosis and treatment strategies, successful cancer survivorship, and competent end-of-life care. The DCCPS hosts the innovative and active Behavioral Research Program (BRP), which includes major research branches concerning important cancer and society issues: the Basic Biobehavioral and Psychological Sciences Branch (BBPSB), the Health Behaviors Research Branch (HBRB), the Health Communication and Informatics Research Branch (HCIRB), the Process of Care Research Branch (PCRB), the Science of Research & Technology Branch (SRTB), and the Tobacco Control Research Branch (TCRB).

HCIRB advances research on the processes and effects of communication and informatics in modern society across the cancer control continuum, including the development of a communication and technology infrastructure that increases access to and use of cancer information, improves public understanding of cancer information, enhances consumer–provider interaction, and translates research discoveries into clinical and public health practices. The HCIRB’s two major research priorities are (1) communication science research,
improving the interactions between science, media, journalism, and clinical care; raising cancer control awareness and knowledge by improving access to and understanding of relevant cancer information; investigating influences of the changing media environment on knowledge and attitudes toward cancer prevention and control; and evaluating communication processes for effective patient-centered cancer care; and (2) technology-mediated communication research, supporting development and adoption of innovative, evidence-based, multilevel information technology interventions, including Web, mobile, and social media technologies; improving communication and care coordination for patients and caregivers; and encouraging evidence-based, translational health communication technology intervention research for cancer control.

HCIRB conducts the important biennial representative Health Information National Trends Survey (HINTS) about public access, use, and preferences for health information, providing important data about national health information needs and opportunities for guiding health communication interventions. The HCIRB also coordinates the extramural Centers of Excellence in Cancer Communication Research at five major research centers across the United States to conduct innovative and far-reaching health communication research as well as training the next generation of cancer communication researchers. The NCI has been and continues to be a major facilitator of advanced health communication research and practices.

The DCCPS also supports the important Office of Cancer Survivorship (OCS) that promotes research and applications concerning helping the growing number of cancer survivors in society to adjust effectively to living with cancer. The OCS works to enhance the quality and length of survival of all persons diagnosed with cancer and to minimize or stabilize adverse effects experienced during cancer survivorship. The office supports research that both examines and addresses the long- and short-term physical, psychological, social, and economic effects of cancer and its treatment among pediatric and adult survivors of cancer and their families.

National Cancer Policy Board

In March of 1997, the Institute of Medicine (IOM) and National Research Council (NRC) established the National Cancer Policy Board (NCPB). The NCPB tackled major U.S. cancer policy issues by drawing together leading cancer experts to research, workshop, and disseminate information with the goal of cancer prevention, treatment, and awareness. Under the IOM, the NCPB conducted studies and created advisory reports on several aspects of cancer policy relating to prevention, treatment (physical, psychological, and social), survivorship, and palliation. Recommendations made in the studies and reports of the NCPB have been addressed and implemented by organizations, the government, and health care providers. The NCPB lasted for eight years. In May 2005, the IOM created the National Cancer Policy Forum (NCPF) to replace the NCPB.

Funded primarily by the National Cancer Institute (NCI) and Centers for Disease Control and Prevention (CDC), the IOM created the NCPB to focus
on U.S. cancer policy concerns. Consumers’ declining confidence in the U.S. cancer care system led the NCPB to study the effectiveness of cancer services, quality assurance mechanisms used in cancer care, and barriers that block access to cancer care. Their report Ensuring Quality Cancer Care responds to five questions: What is the state of the cancer care system? What is quality cancer care, and how is it measured? What cancer care quality problems are evident, and what steps can be taken to improve care? How can we improve what we know about the quality of cancer care? What steps can be taken to overcome barriers to access to quality cancer care? The report provided 10 recommendations to improve cancer care quality, increase understanding of quality cancer care, and reduce or eliminate barriers to quality care. The report outlined a hoped-for ideal model for cancer care guided by standards with special attention to innovation and equal access. The report however did raise concerns about the safety and quality of U.S. cancer care at that time.

The NCPB had a 20-member board with wide representation including consumers, health care providers, and investigators across disciplines for a total of three chairs and 52 members over the board’s lifetime. This scope of membership is reflected in the diversity of cancer policy study produced in the board’s eight years of operation. The NCPB produced 28 peer-reviewed reports along with 21 additional studies of cancer care, science, and research, including two reports on palliative care, a nationally distributed report on survivors of childhood cancers, a report on the psychosocial needs of women with breast cancer, and an oncology report with 10 recommended changes to the U.S. response to the long-term effects of cancer and cancer treatment. Congress has worked to address many cancer issues raised by the NCPB, including survivorship (and children), data systems, health care costs, insurance coverage, and palliative care as have outside organizations, health care professionals, and scientists and researchers.

Through its published reports, workshops, and communications the NCPB helped draw vital attention to overlooked issues relating to U.S. cancer care. In the late 1990s, it drew public attention to questions relating to the quality of U.S. cancer care. In the early 2000s, the board raised the issue of palliative care and advocated for supports for palliative patients (e.g., providing sufficient insurance compensation for end-of-life care). Additionally, the NCPB highlighted the long-term effects of childhood cancer (e.g., impairments in learning, growth, and maturation) that at that time had not been documented sufficiently. Other important policy issues that the NCPB addressed included preventative medicine, health care coverage for the poor and underinsured, regional health care quality (e.g., Georgia), evaluating treatment approaches (e.g., colorectal screenings, magnetic resonance imaging (MRI) versus mammography), and state and federal legislation and support in reaching these goals and answering these questions.

On May 1, 2005, the IOM created the NCPF to replace the NCPB. Different reasons are suggested in the discourse for this change (i.e., narrower work focus, changes in funding, and seeking partnerships with representatives of governmental agencies).

Sponsors first promised two years of funding for the forum. Funding for the NCPB initially came from the NCI (75–80 percent) and the CDC (20–25 percent). In contrast, initial funding of the NCPF came from the NCI (38 percent), CDC (26 percent), other agencies (6 percent), and the private sector (30 percent). Both the NCPB and the NCPF raised additional monies to fund their work, but total annual funding for the forum provided for fewer staff and narrower work focus than the board had previously.

Participants in the forum include clinicians, patients, researchers, professional and advocacy organizations, pharmaceutical manufacturers, and policy makers. The forum identifies high-priority cancer policy issues and examines them via discussion-promoting activities. All forum members can identify and debate cancer care and research policy issues and study ways to improve these areas. Like the NCPB, the NCPF produces publicly available reports and sponsors of the forum work to implement its recommendations.

The National Cancer Registrars Association (NCRA) represents thousands of figures in the cancer registry field and has been in operation since 1974. The mission of the organization is to serve as the key group for educating and certifying cancer treatment professionals. The organization played a vital part in the professional development of cancer registrars. For effective and efficient registration, it could be done best by professionals; therefore, NCRA developed and maintained a variety of programs for training cancer registrars. Toward this end, in 1983, the first series of exams, a group known as the CTR, for registrars began. In 2003, NCRA began administering exams for prospective professionals. In addition to the ongoing training program for cancer registry staff, NCRA provides mechanisms for communication between registry staff and other standard-setting organizations through its workshops, annual conferences, publications, and continuing education credit program. Recently, the organization has expanded its scope to include development of registries of diseases other than cancer.

The organization was founded in 1974 in Dallas, Texas, after years of attempts to get it started. This was created off of a strong committee to review the feasibility of a national organization devoted to the subject. Through the help of the American College of Surgeons, the committee conducted a mail survey of cancer registrars in all facilities with approved cancer programs and with the CEOs of these facilities to determine if an organization was needed and, if established, whether it would be supported. The results of the survey indicated that there was a need for a national organization and the required support to maintain the organization was available.

The formation of NCRA began with the ad-hoc committee drafting bylaws and other required documents. For effective planning, the committee was expanded to include additional members to help plan a formal organizational meeting. The first meeting was scheduled for May 13 and 14, 1974, in Dallas. Invitations were extended to cancer registrars across the United States, and those who attended reviewed and edited the committee's drafts of the bylaws and other formal documents. The final versions were voted on by those in attendance, and the National Tumor Registrars Association (NTRA) was formed.

The elected officers of the NTRA featured Tim Richardson of Ohio as the president; Barbara Lord from California as the president elect; Vida Peterson from Pennsylvania as the vice president; Frances Wedge from Washington, D.C., as the secretary; Jeanne Ratti from New Jersey as the corresponding secretary; and Marie Maxfield from Texas as the treasurer. President Richardson contacted Barbara Wade from California to be the organizational parliamentarian.

According to the bylaws of the final accepted version, the aims of NTRA were to promote tumor studies and reporting functions so registrars could help cancer patients, create educational standards, establish a regulated system for tumor registration functions, and enhance the knowledge of tumor functions as needed while also administering information on more functions within the organization as they came about. The purpose was to ensure that...
all members would be fully educated and understand the needs they may have at any given moment. In 1993, the organization rebranded to the NCRA. The organization is governed by the elected board of directors. In running the affairs of the organization, the board of directors follows the procedure prescribed in the adopted bylaws, code of ethics, policy and procedure manuals, and strategic management plan (SMP) and ensures legal and ethical integrity while maintaining the accountability of the committees, liaisons, and task forces. To ensure quality services and up-to-date procedures, these documents are reviewed periodically to ensure they continue to meet the needs of the association and the profession.

The current leadership of NCRA is made up of Terri M. Richardson as the president, Leah Kiesow as the president elect and secretary, Shirley Jordan as the immediate past president, Janet Reynolds as the senior treasurer, Kathleen Hess as the junior treasurer, Paulette Zinkanna as the educational director, Sharmen Dye as the professional development director, Kyle L. Ziegler as the public relations director, Linda Corrigan as the recruitment and retention director, Pamela Moats as the advocacy technical and practice board director–east, Mindy Young as the advocacy technical and practice board director–midwest, and Kendra Hayes as the advocacy technical and practice board director–west.

After training of the registrars, the organization offers accreditations. The NCRA Council on Certification promotes standardization in the collection and use of cancer data through examination and certification of cancer registrars and other cancer data specialists. The organization examination CTR credential system marks achievement, fosters professional pride, and is nationally recognized in recruitment and retention of registry personnel.

NCRA provides awards to support the efforts that its members undertake. These awards relate to educational achievements and the literary developments that members in the organization have worked for over the years.

National Childhood Cancer Foundation

Childhood cancer remains the leading cause of death by disease among children in the United States. Childhood cancers include many common and uncommon cancers including brain tumors, hepatoblastoma, and Hodgkin’s disease. Every day, 42 children are diagnosed with cancer. Cancer affects everyone regardless of socioeconomic status. Unfortunately, more than 40,000 children undergo treatment for cancer each year.

Headquartered in Bethesda, Maryland, since 1987, CureSearch has facilitated research to help find a cure for childhood cancers. CureSearch National Childhood Cancer Foundation (NCCF) is the education, advocacy, and fund-raising arm of the Children’s Oncology Group (COG), the world’s foremost pediatric cancer research collaborative. COG includes more than 8,000 experts at more than 200 leading children’s hospitals, universities, and cancer treatment centers around the world. Together they treat more than 90 percent of all children diagnosed with cancer.

CureSearch NCCF is a nonprofit, public charity, 501(c)(3) organization that accepts tax-deductible donations. CureSearch’s mission is to secure needed resources that will enable the COG to conduct research and clinical trials in pediatric cancer and
to find a cure. CureSearch NCCF supports these efforts by raising public awareness, bringing in donations and funds from government agencies, and serving as the grantee organization to COG. They raise awareness of childhood cancer and the funding needs of those affected and their families through community events and fund-raisers, publications, and educational resources. They provide information to patients, families, and professionals on all aspects of childhood cancers including the various types of cancer, treatments, tests, and procedures and supports available to patients and families. This information is provided face-to-face through webinars and printed materials. They support research by serving as the grantee organization to COG’s funded clinical research trials.

CureSearch provides opportunities for researchers to shake up the status quo by supporting work to solve the most challenging problems in childhood cancer research. This is done through promotion of collaboration by researchers and through clinical trials at hospitals throughout the nation. CureSearch sponsors the Clinical Trial Advancement Awards. These monies and in-kind support help with the delivery of new treatment to children with cancer. Another initiative, titled the Young Investigator program, identifies individuals with the potential to make advancements in childhood cancer research while building another generation of high-quality researchers. Early-stage researchers are located throughout the United States. CureSearch funds early-stage investigators for two years in areas of study that represent the highest risk with the poorest outcomes for children with cancer. The board of directors provides executive leadership, experience, and expertise from business, economics, and medicine. Many directors have personal experience with childhood cancer, and they understand the challenges facing patients, families, and professionals. The scientific advisory council plans, develops, and implements the organization’s scientific strategy agenda and grants program. With the assistance of the scientific advisory council, CureSearch funds laboratory research. The annual symposium focuses on emerging themes in laboratory science with the potential for early implementation and offers special networking opportunities for young investigators seeking careers in clinical and translational investigation.

National Marrow Donor Program

A cord blood or bone marrow transplant may be the only hope for patients diagnosed with lymphoma,
leukemia, and other diseases. Up to 70 percent of patients who need cord blood or bone marrow do not have a matching family member who can donate. The National Marrow Donor Program (NMDP) sponsors the Be the Match registry for just such a need. Matches are made from the registry approximately 76 to 97 percent of the time, depending upon race and ethnicity. The NMDP also provides continuing medical education, resources, and guidelines, sponsors research, and offers support to patients and their families.

The NMDP registry has greater than 11 million volunteers who are on standby to provide bone marrow. Included in the registry are 193,000 umbilical cord blood units that have been donated by parents. One person is diagnosed with a blood cancer every four minutes. Someone dies from a blood cancer every 10 minutes. The NMDP registry is the largest in the world. Partnerships with other registries, including internationally, increases potential matches to 22.5 million donors and 601,000 cord blood units. The NMDP encourages joining the registry as there are still situations when an appropriate match cannot be identified. From the time physicians contact and search the registry to the delivery of the donation, the NMDP is there to support with technology, logistics, and expertise.

Patient support is of primary importance to the NMDP. Service coordinators assist patients and their families with answering questions regarding disease, transplants, the donor process, insurance, financial options, and life following a transplant. These services are free and confidential and are offered nationally and internationally by phone and by e-mail. There are multiple costs associated with treatment, including the search for a donor, travel and lodging, uninsured transplant costs, post-transplant needs, and prescriptions. The NMDP offers financial aid programs to help with these costs. More than 1,800 families received $3.2 million in 2013. Fund-raising eliminated barriers and provided financial relief so that the patients and their families could focus on recovery.

Research conducted by the NMDP has had a significant impact on cancer survival rates and has improved the quality of thousands of lives. They continue to search for answers regarding timely transplants, treatment, and better donor matching. Their research program, Center for International Blood and Marrow Transplant Program (CIBMTR), has published more than 700 research articles. They collaborate both nationally and internationally. Funds raised by the NMDP not only support research but contribute to reaching new donors and family assistance to ease the high costs associated with medical care.

Commitment to research by the NMDP has had a significant impact on the quality of life for patients and blood cancer survival. Leukemia, lymphoma, and other blood cancers are being cured by transplant science. Bone marrow transplants have moved from a new procedure 30 years ago to the current standard of care for multiple life-threatening diseases. Survival rates are increasing, complications are being reduced, and new science is exploring blood transplantation as treatment for other diseases. In the past five years, unrelated donor survival rates at one year are comparable to that of related donors, up from 42 to 60 percent. Survival outcomes also have improved with increased timeliness from diagnosis to transplantation.

The discovery and application of best treatment is a main goal of CIBMTR. More than 500 transplant centers nationally and internationally contribute to data collected by the CIBMTR, representing more than 330,000 transplant recipients. The research sample repository is a world-class leading resource for researchers. The repository inspects, processes, and stores 8 million DNA samples from donors, recipients, and research participants. A critical discovery from research identified a higher survival rate when transplant occurs earlier rather than later, even if there is not a close match. In other words, a close match transplant that occurs later in the disease stage does not increase survival rates. Bioinformatics scientists help develop the science of matching recipient and donor. They continue to develop strategies and models for selecting the best possible and timely match and less-toxic chemotherapy regimens. The Amy Strelzer Manasevit Research Program (and other programs) supports efforts to reduce serious complications that may arise after a transplant. The White House Office of Management and Budget’s Program Assessment Rating Tool rates NMDP above average.
The NMDP has met or exceeded the following goals: decreasing the cost of per-unit donor typing; increasing the number of cord blood units; increasing the number of transplants; improving patient outcomes post one year; and adding more than 2 million minority donor registrants. Fundraising remains an important part of these efforts. Be the Match Walk+Run events, for example, are now held in 17 cities.

To register with NMDP, donors submit a sample of cells usually collected from the inside of the cheek. The sample is then compared to specific markers for patients who need a transplant. Physicians access the registry every day. When a match is found, the donor is screened and approved for donation. Once approved, the patient’s doctor requests either peripheral blood stem cells or a bone marrow donation, whichever better suits the patient's needs. During the transplant, the donor's healthy cells are placed in the patient’s bloodstream, where they then settle in the bones. It is within the bones that the cells will produce new cells. Umbilical cord blood is increasingly available as parents have become more aware and want to donate. Blood is collected from the umbilical cord after birth, not from the baby. The blood is tested, frozen, and stored as a unit for future use. Donation and registry, in any of the above ways, is always free and anonymous.

Natural Causes of Cancer
There are approximately 200 types of cancer caused by multifactorial reasons. Cancer belongs to a disease classification that is characterized by out-of-control cell growth, and various cancer types are further classified based on the type of cell that has been affected by the disease. The cells damaged by cancer grow uncontrollably to form lumps or masses of tissues called tumors, except in leukemia, where cancer prohibits normal blood function by abnormal cell division in the bloodstream. The tumors grow and interfere with digestive, nervous, and circulatory systems, and they can release hormones that further alter body functions. The tumors that are restricted to one spot and have restricted growth are usually considered as benign. The malignant tumors are usually the cancerous cells that manage to move through the body using the blood or lymph systems. They usually destroy the healthy tissues. This process is called invasion, and these cells further divide and grow and make new blood vessels to feed themselves in a process called angiogenesis. Subsequently, the tumor spreads to other healthy cells in the body; the process is called metastasis, and it is most difficult to treat.

Nature Versus Environment
An estimated 5 to 10 percent of the cancer cases are caused by genes, and the remaining 90 percent are attributed to lifestyles and environmental factors. The etiological factors related to lifestyle include cigarette smoking, diet comprising fried foods and red meat or food additives, alcohol, excessive exposure to sun, pollutants in the environment, infections, stress, obesity, and physical inactivity. Existing evidence suggests that almost 25 to 30 percent of cancer deaths are due to tobacco, 30 to 35 percent are due to diet, 15 to 20 percent are due to infections, and the remaining deaths are due to radiation, stress, physical activity, environmental pollutants, and so on. Owing to these causal factors, several developed countries have shifted their focus to preventing cancer deaths through effective public health messages promoting smoking and tobacco control, increased ingestion of fruits and vegetables, limited use of alcohol, control of calorie
intake, increased physical exercise, avoiding direct sun exposure, minimal meat consumption, use of whole grains, and use of vaccinations and preventive checkups for cancer. In spite of these developments, cancer continues to be one of the chronic illnesses that are causing deaths in developed countries; in the United States, cancer accounts for 23 percent of deaths followed by heart disease, which has seen a steady decline in the last decade.

If exogenous risk factors such as smoking, chronic inflammation, and unbalanced diet are eliminated, then cancer is more likely to occur at a later age, and the influence of endogenous processes will start. Usually, age is one of the natural causes of cancer as cells take a long time to develop and several changes take place in the genes before they actually turn cancerous. These are caused while the cells are dividing or due to carcinogens. Some people are born with genetic mutations, and such individuals are more likely to develop cancer at later stages of life. For example, BRCA1 and BRCA2 are examples of breast cancer genes that genetically predispose some women to breast cancer. Research also has indicated that 3 percent of women suffering from breast cancer have these genes. Similarly, some people have a genetic predisposition to colon (large bowel) cancer. Cells experience uncontrolled growth when there are damages or mutations to deoxyribonucleic acid (DNA).

The genes that are responsible for cell division are first, oncogenes, which are altered forms of genes that are known as proto-oncogenes and are responsible for cell growth. When they are altered or mutated, they lead to tumor formation. Second, tumor suppressor genes are present in our cells and control cell growth and death, which is called apoptosis. They also suppress cell growth, and therefore are recessive in nature. When these cells are mutated, they cause cancer that is due to aging or environmental exposure, or it can be inherited. In mutations, due to inheritance, one copy of the tumor suppressor gene pair is inherited from a parent and is present in all cells in the body; the second copy is acquired and occurs in one cell or a handful of cells. Most genes associated with hereditary cancer are tumor suppressor genes, but most mutations in these cells are not inherited. Third, DNA repair genes are the ones that can be described as the mismatch-repair genes that correct the naturally occurring errors in the DNA. Mutations and alterations in these genes cause cancer. One of the major causal factors that affect DNA includes the carcinogens that are present in tobacco, asbestos, arsenic, radiation such as gamma and X-rays, the sun, and compounds in car exhaust fumes. Continued exposure to these carcinogens steals the electrons from the body, which leaves it vulnerable to cancer. Usually, several mutations take place before a person acquires cancer. In cancers that are inherited, one such mutation is passed on by the parent, and other mutations are acquired. Cancers that are inherited are classified into sporadic cancer, familial cancer, and inherited cancer. Sporadic cancer occurs by chance—one of the family members is affected by cancer at an older age; familial cancer is when several members of the family are affected by cancer. There is a cluster of cancer cases in the family but no clear inheritance trend, and it occurs at an average age of onset. It could be related to the lifestyle of the family or could occur due to single gene mutation that has reduced penetrance, a mutation associated with lower cancer risks. Inherited cancer refers to families having multiple members with the same or related cancers, and it impacts the younger than average ages. Often, families with inherited cancer have it for two or more generations, with cancer displaying an autosomal dominant pattern of inheritance. A child born to a parent with an inherited predisposition to cancer will have a 50 percent chance of inheriting cancer.

A weak immune system is also seen as a risk factor for certain types of cancer vulnerability. This has been linked specifically to people who have had organ transplants and take drugs to suppress their immune systems to avert organ rejection. People suffering from human immunodeficiency syndrome or acquired immunodeficiency syndrome are likely to suffer from Kaposi’s sarcoma, which causes lesions in one area of the body including skin. People born with rare medical conditions are more vulnerable to cancer as well. Cancer caused by viruses such as cervical cancer and other cancers in genital or anal areas and certain chronic illnesses can further stimulate cells to grow abnormally.

Epidemiological studies estimate that almost 15 percent of worldwide cancer incidences are associated with microbial infection. Viruses cause some forms of cancer by causing genetic changes in cells that could potentially make it cancerous. Through existing epidemiological and biological studies, the International Agency for Research on Cancer
has classified six viruses as Group 1 carcinogens, each associated with the origin of certain types of human cancers: Epstein–Barr virus (EBV), Kaposi’s sarcoma–associated herpes virus and human herpes virus B (KSHV/HHV8), human papilloma virus (HPV), hepatitis B virus (HBV), hepatitis C virus (HCV), and human T-lymphotropic virus type 1 (HTLV-1) as well as the bacterium Helicobacter pylori (H. pylori). The HPV types cause cervical cancer as well as a subset of ano-genital and head and neck cancers, which cause 5 percent of all virus-induced cancer. Recently, a new human polyomavirus, MCV, has been discovered, which causes a rare tumor, Merkel cell sarcoma, in people with weak immune systems. The development of cancers induced by infectious agents is intimately linked to their persistence in the host. In fact, pathological abnormalities are not usually observed when infections are rapidly cleared by the immune system, while cancer development risk dramatically increases after the establishment of a chronic infection. Cancer of the cervix, liver, oral cavity, and stomach have an infectious etiology.

Prevention Versus Treatment

Human genome solutions to diagnosis, prevention, and treatment of cancer are emphasized through several observational studies and point to contrary evidence. Studies on identical twins indicate that genes are not a source of chronic illnesses, and it is lifestyle and environment that account for most of the chronic illnesses.

The last decade has witnessed a shift away from treatment to more preventive aspects of cancer. A growing shift toward prevention is also related to costs as it is estimated that prevention is assumed to be 7 percent of the cost of treatment. The global treatment estimate is $163 billion; the cost of prevention of cancer is at $11.4 billion. Preventive aspects of cancer include promotion of increased intake of fresh fruits, vegetables, and cereal grains that might impact the development of cancer of the oral cavity, larynx, esophagus, stomach, colon, lung, prostate, and rectum. One of the examples is the five-a-day campaign by the National Health Service, United Kingdom. Even though research is still ongoing on various dimensions of cancer, some research indicates that a diet rich in phytochemicals, antioxidants, and omega-3 fatty acids prevents cancer. Phytochemicals are chemicals found in plants that protect plants against bacteria, viruses, and fungi, and consuming large amounts of brightly colored fruits and vegetables and cereals can decrease the probability of certain cancers from occurring. They usually prevent carcinogens from forming in the body by acting as antioxidants or nutrient protectors. Antioxidants include vitamin C (ascorbic acid), which can prevent the occurrence of rectum, pancreas, and cervix cancer. Beta-carotene is known as provitamin A and is known to prevent cancer by enhancing white blood cells in the immune system to block cell damage from cancerous cells. Rich portions of beta-carotene are present in dark green, leafy, and yellow-orange fruits and vegetables and are known to prevent stomach, lung, prostate, breast, and head and neck cancer. Vitamin E is known to prevent prostate and colorectal cancer. Omega 3 fatty acids inhibit tumor development in breast and prostate cancer. Fish such as salmon, mackerel, sardines, herring, halibut, striped bass, tuna, and lake trout, flax seed oil, and beans contain good proportions of omega 3.

Nepal

The Federal Democratic Republic of Nepal is a mountainous Asian country located in the Himalayan region. Nepal has been a monarchy up until very recent times and has always been a somewhat isolated Hindu country, partially because of its geographic features: Himalaya includes some of the highest mountains on Earth, such as Mount Everest, and most of its peaks are over 20,000 feet (6,000 meters) high. Various dynasties held their power through Nepal’s history, most notably the Malla kings, who ruled from the 12th to the later 15th century, and the Gorkhali, who unified the country in 1768 under the rule of King Prithvi Narayan Shah, who founded the Kingdom of Nepal. A brief war between the Kingdom of Nepal and the British East India Company was fought in 1815 and 1816, but a century later, in 1923, the English and Nepalese crowns signed an agreement of friendship that lasted through both world wars. During the Great Wars, Nepal helped the British army, fighting their enemies with the assistance of several units of Gurkha soldiers, and also supported the military effort with raw materials, guns, food, and equipment. In 1996, the Maoist Communist Party of Nepal tried to seize power by violent revolution, leading to the long and bloody Nepal Civil War that ended in 2008, with the abolition of the monarchy and the establishment of the federal republic. Today, political tensions do still exist, and many power-sharing struggles caused various governments to be toppled one after the other, negatively affecting the country’s economic growth, which still suffers from widespread poverty and illiteracy rates.

Health care services and public health care facilities in Nepal are of very poor quality compared to international standards. Lack of hygiene and health education, inadequate sanitation and transportation systems, geographical constraints, widespread poverty, low availability of medical facilities, minimal government expenditures on health care, and considerable inequality in wealth distribution are all contributing factors. Also, social marginalization and traditional beliefs further aggravate the situation, especially in rural and isolated areas. Some important awareness campaigns to sensitize public opinion on cancer prevention and encourage proper hygiene practices and healthy behavior were made in the last few years, mostly with the help of the many nongovernmental organizations (NGOs) that operate in the territory.

The major cancer treatment facility is the National Cancer Center, BP Koirala Memorial Cancer Hospital in Bharatpur. The hospital was built in...
1992 and got its name in memory of the first democratically elected prime minister of Nepal in 1959 and 1960, Bishweshwar Prasad Koirala, who died of throat cancer in 1982. Much of the funding and medical staff of this hospital come from China and provide the local population with modern technologies to treat cancer, with many specialized oncology and surgery departments, such as advanced reconstructive urologic surgery, neurosurgery, radiation oncology, and palliative care. The other comprehensive cancer treatment facility is Bhaktapur Cancer Hospital, located in the Kathmandu valley. The oldest and most famous cancer treatment facility in Nepal, though, is the Bir Hospital in Kathmandu, built in 1889 by the government and still administered by the National Academy of Medical Sciences.

In Nepal, the cancer registry system is very poorly implemented: A central agency that coordinates all national cancer data from public and private hospitals does not exist, and there is no national population-based cancer registry. In 2005, a hospital-based registry system was established with the support of the World Health Organization (WHO), pooling data from the seven largest cancer treatment facilities, but only one analysis study was published with the data coming from this database. An evaluation of the present data coming from Nepal's major hospitals tells us that approximately 10,000 new patients seek treatment for cancer every year.

In Nepal, the most common site for cancer in males was the lung, followed by the oral cavity and stomach, while the most common in females were cervix (middle-aged women), uterus (older women), breast (young women), and lung. Leukemias and lymphomas were the most common cancer forms in children and young people. Lung cancer is the most common cancer in both male and female individuals and is also the leading cause of cancer death for both genders. Tobacco smoking and chewing are among the most important risk factors for lung, oral cavity, and larynx cancer in the Nepalese population, together with occupational hazards and worker exposure to carcinogenic substances in middle- and large-scale manufacturing industries. Other common risk factors are poor awareness and education on unhealthy lifestyle habits, lack of prevention and screening programs for early detection and treatment, alcohol consumption, and infections such as human immunodeficiency virus (HIV), human papillomavirus (HPV), and malaria.

Precocious interruption of treatment regimen is also an issue in Nepal because of sudden drops in socioeconomic conditions, political instability leading to transport blockades and strikes, and fear from treatment toxicity related to lack of proper education on health topics.

Similar to Sri Lanka, in Nepal, many hospitals and clinics also offer Ayurvedic and traditional, herbal immune therapies as complementary cancer treatment. While Ayurvedic principles mostly focus on a spiritual and philosophical approach to heal mind and body together, some of the herbal remedies and detoxification methods proposed may possess some therapeutic value for oncologic patients. However, while Ayurveda therapy may improve immune response among cancer patients and reduce the side effects of chemotherapy, it still poses a risk for heavy metal poisoning due to the high concentration of the elements often used in Ayurvedic medicines.

Further Readings
in the Netherlands because of lung cancer. In the context of the Netherlands, lung cancer has a direct link to smoking and practically no connection to occupational or environmental agents. Nevertheless, according to statistical data from 2014, prostate cancer has climbed now to the top of the list in the case of men, and breast cancer became the main cancer in women.

Unlike other European countries, in the Netherlands, the second-most important cancer in the context of incidence is skin cancer in both men and women. But the second cancer causing more deaths among the female population is breast cancer (around 3,000 deaths in 2010; actually it is in the fourth position worldwide in terms of registration), and among the male population, it is intestinal cancer (also around 3,000 deaths in 2010). The five-year survival rate mainly depends on the kind of cancer, but in a general way, it increased to 60 percent in recent years.

It is estimated that one person in three suffers from cancer in the Netherlands. Two-thirds of the totality of new cases are people older than 60.

Risk Factors
One of the biggest problems in Western countries as a risk factor in the incidence of cancer is lifestyle and the habits it implies in terms of activity or nutrition. As an illustrative example, in the Netherlands, almost 50 percent of its population suffers from being overweight or obesity. In fact, its concerns in the field of health do not differ very much from the concerns of other Western countries. In such a way, a lot of cancer prevention campaigns try to make the population conscious of the danger of smoking, inactivity, sun exposure, alcohol, and the need of being attentive to any symptoms. National prevention programs emphasize that one-third of the cases of cancer can be reduced by a proper lifestyle and a balanced diet.

Because the incidence of breast cancer is one of the highest in Europe, special attention is paid to it. Although not all the risk factors for cancer are known, the Ministry of Public Health has considered it important to publish a complete list of risk factors (which include genetic factors, not having given birth or to give birth at an older age, early menstruation, late menopause, being overweight after menopause, hormonal treatment, and use of alcohol, among others).
Cancer Registries and Other Institutions
The Netherlands Cancer Registry intends to collect data on incidence, prevalence, survival, mortality, and risks in the country. It belongs to the International Association of Cancer Registries, and since 1989, it has offered data with reliable and objective information that contributes to epidemiological research, clinical studies, and determination of the quality of care. Simultaneously, it gives orientation in terms of trends and variations. It works, like similar institutions in the rest of Europe, through a regional network, collecting data from each patient who goes to a hospital for diagnosis or treatment. They also receive data from other sources, such as blood laboratories, pathological laboratories, or medical registries from clinics and hospitals. At the end of 2013, they implemented a new system that allowed specialists direct access to patients’ data and links to other databases, facilitating the possibility of controlling the quality of care.

The Netherlands Cancer Institute was created in 1913 by a group of pathologists with the main goal of offering the best treatments to patients suffering from malignant tumors. It had rooms for about 17 patients and a laboratory for its own scientists. Nowadays, it has places for 650 patients, and it is an important center of clinical and scientific expertise. In addition, the Dutch Cancer Society was founded in 1949, and its main goal is to collect donations to help people suffering from cancer. Actually, it has a regular base of 1 million donors, and it plays a fundamental role in cancer control policies and legislation to reduce the incidence of cancer and improve the quality of life of patients. In its programs of prevention experts from that society give priority to avoiding sun exposure as the Netherlands has an alarming increase in the number of skin cancer cases (particularly melanoma).

Netherlands Cancer Institute

Spanning more than a century, the history of the Netherlands Cancer Institute/Antoni van Leeuwenhoek Hospital (NKI/AvL, Nederlands Kanker Instituut/Antoni van Leeuwenhoek Ziekenhuis) in Amsterdam reflects groundbreaking developments in laboratory research, patient care, and the public’s perception of cancer as a disease. The often ambivalent—sometimes even openly strained—relations between laboratory and clinic, between doctor and patient, between specialist cancer treatment center and the relevant disciplines in university hospitals, and between incurable patients and hopeful relatives and citizens become evident from an analysis of the history of NKI/AvL. This history qualifies the idea of the war on cancer as a process of continuous progress and shows that scientific progress is inherently intertwined with prevailing ideas about diseases and their treatment.

In 1913, the publisher J. H. de Bussy approached a few Amsterdam professors and business acquaintances with the proposal to found a specialist cancer institute. A building that had formerly housed a bank was fitted out for the treatment of patients and for scientific research. International experts were contacted, and an association, the Van Leeuwenhoek Vereeniging, was established, which in 1933 developed into the International Association to Combat Cancer, or the Union Internationale Contre le Cancer (UICC). By the end of the 1920s, NKI moved to a building that had previously been the central depot for military uniforms on Sarphatistraat in Amsterdam. This new site provided enough space to house the large numbers of mice required as standardized
test animals, which were bred in collaboration with Clarence C. Little of the Jackson Memorial Laboratory (Bar Harbor, Maine). At the same time, it housed the gradually expanding specialist library on cancer research and treatment, which was to become world renowned. The institute also was able to specialize in radiation treatment as the Dutch electronics company Philips provided it with state-of-the-art equipment, including a machine known as the millionaire, with a theoretical maximum electrical potential of 1 million volts.

Shortly after World War II, Queen Wilhelmina celebrated her golden jubilee, and the Dutch people wanted to present her with a gift. This gift was the Koningin Wilhelmina Fonds (KWF) ter bevordering van de kankerbestrijding (Queen Wilhelmina Foundation to promote the fight against cancer), which was formally founded on March 14, 1949, with the aim of ensuring ongoing fund-raising efforts. Because NKI also had been engaged in fund-raising, it was decided that it would end these activities and would henceforth get an annual grant from KWF.

In its Sarphatistraat building, NKI was an independent institute, which by 1955 had nearly 200 employees, including 13 physicians and trainee physicians and 34 nurses. By this time, a new radiotherapy department had been established, again fitted out with the latest radiation equipment provided by Philips, including a machine that could produce beams of radiation with continuous motion.

One subject that was debated for many years was whether NKI/AvL should become part of the Amsterdam University Hospital. The hospital did not have enough space on its grounds, however, so it was decided to build a new facility in the Slotervaart district in the western part of Amsterdam. This also was where the central laboratory of the Dutch blood transfusion service was to be housed (and later the new municipal Slotervaart hospital).

By the mid-1960s, when NKI had been in existence for nearly half a century, its laboratory staff had made internationally respected discoveries. Three decades of research at the mouse laboratory had elucidated the nature of the mammary tumor virus (MTV), which caused breast cancer in mice. It turned out to be an RNA virus, which was converted to a DNA copy in mice, after which it was incorporated into the host animal’s DNA. This mechanism enabled oncogenic viruses to be transmitted to the progeny without infection. Such findings put Amsterdam at the forefront of international cancer research. The spectacular progress had been made possible by the decision to abandon the tradition of the lone wolf researcher and move toward more multidisciplinary research efforts. In fact, this fit in with a prevailing trend in life sciences in the 1960s, in response to the development of new branches of science such as biochemistry, biophysics, molecular biology, and so on. However, it sometimes proved difficult to tear down the barriers between the various disciplines at universities, whereas it proved easier to create a melting pot from departments such as biology, virology, immunology, and electron microscopy in a small and dedicated institute like NKI. As a result, scientific research at NKI developed into teamwork by specialists.

By contrast, the clinic, the AvL, was going through a more difficult time. Although its equipment included devices like an ultramodern cobalt irradiator, its therapeutic efficacy was limited by the fact that patients often were referred to this specialist clinic at a late stage of their disease. Van Lier’s book on the NKI concluded that this resulted in an image among the general public that radiation therapy was only for the hopeless cases, creating a kind of taboo on this form of treatment.

At its Sarphatistraat site, the NKI/AvL was a typical small-scale institute where everybody knew each other personally and where there was a high level of cross-fertilization between the laboratory and the clinic. This was to change when the clinic moved to the brand-new complex at Slotervaart in 1973. It took another five years before the laboratory also moved to its new building at the Slotervaart complex.

The specialist cancer hospital AvL would distinguish itself from the university hospitals in the Netherlands by integrating the various oncological subdisciplines. Another unusual characteristic was that all medical specialists at the new AvL were fully employed by the institute, a unique arrangement in the medical world. Another major break with past practices was to involve patients more closely in their treatment. For instance, library staff previously had been forbidden to provide patients with specialist literature on cancer as it was thought they would not be able to interpret it correctly. In the mid-1970s, the Radiotherapy Department became the first to start handing out patient information leaflets.

By this time, the laboratory had also moved to Slotervaart, but its reputation had deteriorated
considerably. This improved when the biochemist Piet Borst was appointed director of NKI/AvL in 1982, the first time a nonclinician was appointed head of the institute. Borst managed to breathe new life into the experimental work, based on the old mouse laboratory, for instance, by concentrating the research effort on genetically modified mouse models. As a result, the laboratory fully regained its former status as a state-of-the-art cancer laboratory.

Just as elsewhere in the world, however, the process of translating laboratory findings into clinical treatment remains difficult at NKI/AvL. Nevertheless, the AvL acquired a powerful position within the European Organization for Research and Treatment of Cancer (EORTC) by participating in clinical trials. Other landmarks in the institute’s history were the establishment of the Centrum voor Kwaliteit van Leven Studies (Center of Expertise on Quality of Life) of the World Health Organization and, in 1995, an outpatient clinic for familial tumors in cooperation with both of the Amsterdam university hospitals.

In the course of the 21st century, NKI/AvL has developed into a world-renowned comprehensive cancer care center characterized by the close interaction between the laboratory and the clinic, thanks to the short lines of communication between them. This means that the ideal that its founders had in mind in 1913 has been realized.

Further Readings
Both physicians and patients wanted to know more about the way patients and their relatives experienced hemophilia. In 1972, a joint research project was set up, titled Hemophilia in the Netherlands (the HIN study), to survey aspects like the occurrence of the disease, its treatment, school absenteeism, unemployment, stigmatization, and dependence on physicians.

The situation of hemophilia patients was greatly ameliorated in the 1970s. Boys with hemophilia were now able to go to summer camps and play sports (though not soccer) with a doctor in attendance. School absenteeism and hospitalizations were greatly reduced. Doctors also encouraged young patients to switch to treatment at home, with parents treating hemorrhages and providing prophylaxis with the missing coagulation factor. The use of self-treatment was also stimulated as many patients had developed a morbid fear of injections, which turned out to disappear when they started injecting themselves. At first, the implementation of this program was hampered by certain legal obstacles, but these eventually were solved jointly by the hemophilia experts and the NVHP.

Preparing the factor concentrates involved pooling the blood from many donors, which inevitably led to contaminated concentrates, even if just one of the donors had an infection like hepatitis. Naturally, there were international research efforts to try and solve this problem. One of the approaches was to heat the concentrates in order to inactivate the virus, but this had very limited success.

The close and institutionalized collaboration between hemophilia patients and the doctors treating them became greatly strained on the emergence of the acquired immune deficiency syndrome (AIDS) epidemic. Around 1980, a mysterious disease broke out in the United States, which was later proven to be caused by a virus, human immunodeficiency virus (HIV). On Sunday, January 30, 1983 (later referred to by those involved as Bloody Sunday), a meeting was held that was attended by all parties involved—patients, physicians, producers of blood products, and the authorities—to discuss what measures had to be taken to ensure the safety of donor blood and blood products. The relations between hemophilia patients and their doctors were severely shaken: Hemophilia once more became stigmatized, this time mostly through fear of HIV infection. The NVHP became a contributor to the process of restoring confidence and defending the interests of people infected with AIDS toward the authorities and insurance companies. Fortunately, the heat treatment of plasma products, which had proved insufficiently effective for hepatitis, was found to work well with the AIDS virus. Nevertheless, there was initially some reluctance in the Netherlands about introducing this heat treatment as doctors feared that the treated coagulation factors might induce antibodies. This problem was soon cleared and solved, however. In the 1980s and 1990s, the NVHP was very active in educating patients with hemophilia about the factor concentrates that were available internationally and the costs involved.

The HIV problem for patients needing treatment with coagulation factors was solved definitively in the 1990s as Factor VIII and Factor IX now could be produced using recombinant-DNA methods, making them completely free of viral contamination (whether HIV or hepatitis). However, the recombinant-DNA technology also created new problems. Although female relatives of patients had been able to voluntarily undergo genetic assessment since the 1960s, focusing on the identification of carriers of the hereditary trait for hemophilia, the new DNA technology also enabled doctors to diagnose children before birth (prenatal diagnostics) to assess whether they had the congenital predisposition for hemophilia. Once more, the NVHP became an important party in communications and discussions about the possibilities and limitations of this new technology.

The developments in hemophilia research over the last 50 years have been truly spectacular, despite the very serious setback caused by AIDS. As a result, there is now a large group of people in the Netherlands with severe hemophilia who have nevertheless survived beyond the age of 40, an age that they would not have attained half a century ago. As an organization, the NVHP has greatly influenced the development of a specialist branch of medical research into hemophilia, and it has contributed especially to the acceptance of new treatment approaches resulting from such research.

Neuroblastoma

Neuroblastoma is an embryonic cancer that occurs as a result of the improper development of immature nerve cells. These cells, named neuroblasts, experience the abnormal persistence of a developmental state, which then accumulates to build tumors in sites of the sympathetic nervous system tissues. About 50 percent of these masses originate in or around the adrenal glands. Other developmental sites include the abdomen, neck, chest, and pelvis.

This disease is most commonly experienced between one and two years of age, with 90 percent of cases being diagnosed before age five. With more than 600 cases diagnosed every year, neuroblastoma is the most common extracranial solid cancer experienced in children. It is responsible for 8 to 10 percent of childhood cancers and accounts for more than 15 percent of their cancer mortality. Neuroblastoma contributes to 33 percent of cancers experienced before age one, making it the highest malignancy expressed in infancy, according to Peter Zage and Joann Ater.

Experience of the disease varies widely. Neuroblastic tumors can be completely benign and even, in some cases, spontaneously regress. However, about 60 percent of diagnosed tumors already show signs of spreading. And, in many other cases, these tumors are malignant and demonstrate aggressive metastasis. This cancer's heterogeneous nature and tendency to spread create a diversity of symptomatic expressions as well as difficulties in etiologic research, diagnosis, and treatments.

Further Readings

Symptoms
General symptoms such as headache, fever, irritability, and fatigue all can be experienced in cases of neuroblastoma. However, a variety of specific symptoms may be expressed depending on the primary tumor location, metastasis, and hormone secretion, describes the American Cancer Society.

Concerning localized tumors, many complications arise from pressure against body structures. For instance, tumors localized in the abdomen often will show a large, painless lump of tissue under the surface of the skin, which could lead to stomach pain and diminished appetite. In some cases, these lumps grow against the child’s blood or lymph vessels, preventing fluids from getting back to the heart and causing abdominal swelling. Additional complications such as difficulty during bowel movements and urination can also occur if the mass presses against the child’s bladder. In other cases a tumor that develops in the chest or neck can put pressure on areas of the body such as the throat, windpipe, and important blood vessels. Some other manifestations of these include swelling in the face, neck, arms, and upper chest.

Symptoms also can be expressed differently depending on areas affected by metastatic spread. Areas that typically are affected include lymph nodes, skin, bones, and bone marrow. Lymph node tumors can produce swelling. Spread to the bones can cause bone pain and, in cases of paraspinal neuroblastoma, spinal cord and nerve root compression. When the disease is present in bone marrow, a shortage of blood cells can be experienced. Possible effects of this include tiredness, irritability, frequent infections, and excess bleeding from small cuts.

Paraneoplastic syndromes occur when tumors release hormones that create complications in tissues and organs. One rare example of this is opsoclonus-myoclonus-ataxia syndrome, which is exhibited by irregular and rapid eye movements, muscle spasms, and uncoordinated walking and standing. Other symptoms of paraneoplastic syndromes can include constant diarrhea, fever, and flushing of the skin.

Pathogenesis
Neuroblastoma is the result of genetic mutations in critical genes that lead to abnormal cell proliferation and differentiation of immature nerve cells named neuroblasts. Little is known about what actually causes the genetic mutations in these cells. In the
less-common cases of familial neuroblastoma, the cell mutations have been shown to be inherited in an autosomal dominant manner. Those with this disease typically are diagnosed at an earlier age and have multiple primary tumors. Mutations in the anaplastic lymphoma kinase (ALK) and Phox2b genes currently are noted as the major predictors of hereditary neuroblastomas, according to Y. P. Mossé and colleagues. However, familial neuroblastoma accounts for a small 1 to 2 percent of neuroblastic tumors. In the remaining sporadic cases, cell mutations are somatic, and in most cases, causes remain unknown. The influence of these genes is not limited to inherited cases of the disease. They are also shown to be a factor that predisposes an individual to having neuroblastoma, but additional somatic mutations are necessary to actually cause the disease.

Another gene that is highly associated but not considered a cause of neuroblastoma is the MYCN oncogene. Amplification of this gene is strongly associated with aggressive tumor stage and poor outcomes, Ravikanth Balaji reports.

**Diagnosis**

Initial discovery of neuroblastic tumors often arises from the discovery of a mass or masses on plain radiography, computed tomography (CT), or magnetic resonance imaging (MRI). Calcification and hemorrhage often are observed by radiography and CT scan. Accurate tumor information such as localization, size, and extent can be determined from MRI. A diagnosis of neuroblastoma can only be made if it fulfills at least one of the following requirements, according to G. M. Brodeur and colleagues: (1) unequivocal pathologic diagnosis supported by light microscopy and (2) bone marrow biopsy containing unequivocal tumor cells and increased levels of serum catecholamines or urinary catecholamine metabolites.

Tumor tissue obtained by biopsy provides much of the biological data needed for diagnosis. In the majority of tumors, particularly when neuronal differentiation is present, histological diagnoses can be made using a light microscope. In other cases, the tumor cells are densely packed, small, blue cells with little differentiation. Here, other immunologic methods such as electron microscopy are used. Similarly, identification of neuroblastic tumor clumps is also possible in bone marrow analysis. Catecholamine metabolites such as homovanillic acid (HVA), vanillylmandelic acid (VMA), and dopamine (DA) provide biochemical support for neuroblastic tumor diagnoses. Significantly elevated levels of these tumor markers can be found in 95 percent of cases.

**Classification**

The most commonly used classification of neuroblastoma cases is the International Neuroblastoma Staging System (INSS). The INSS is a postoperative system that relies on the extent of surgical resection, in addition to lymph node involvement and extent of metastatic disease, to stage patients. Because the INSS was designed around the extent of surgical resection, it is not fully compatible with the International Neuroblastoma Risk Group (INRG) pretreatment risk classification system.

For this reason, a new method is being adopted to classify the expression of this disease. The INGR Staging System (INGRSS) classifies tumors into L1, L2, M, or MS based on image-defined risk factors and metastatic disease, explains T. Monclair and colleagues. Built around tumor imaging rather than surgical resection, it has an enhanced pretreatment utility. The primary function of the INGRSS is as a component of the INGR, and it is intended as a system to be used in coordination with the INSS in order to improve the combination of disease-staging and risk stratification.
The International Neuroblastoma Pathology Classification (INPC) is a molecular classification of neuroblastic cells. Based on neuroblast pathology, age, and the mitosis-karyorrhexis index, this system classifies tumors as either favorable or unfavorable and has significant prognostic value, as described by H. Shimada and colleagues.

Treatment and Prognosis
Current treatments of neuroblastoma cancers are used in accordance with the Children’s Oncology Group (COG) risk-group assignment. Based on the INSS, INPC, tumor biology, and patient age, this system places patients into either low-risk, intermediate-risk, or high-risk groups, according to W. B. London and colleagues. Therapy generally is chosen based on the group in which a patient is placed. Options for low-risk patients include resection or observation and, in some cases, chemotherapy. Treatments for intermediate-risk patients involve chemotherapy, surgery, and radiation therapy. High-risk tumors require aggressive multimodal therapies, which may include chemotherapy, stem cell transplantation, radiation therapy, surgery, immunotherapy, and differentiation therapy.

Outcomes of children in the low- and intermediate-risk groups have improved significantly over the past few decades, with current survival rates being higher than 90 percent in both groups. Most research for these groups is now focused on reducing therapy and decreasing long-term treatments. However, even with intensified therapeutic techniques, prognosis for patients with high-risk tumors remains poor. Survival rates for these children are between 40 and 50 percent. Also, high-risk patients are very susceptible to recurrent neuroblastoma after initial treatment, which has a survival rate only slightly higher than 50 percent. Increased studies of the biologic influences of neuroblastoma eventually will lead to new molecular and genetics-based treatments.

Neutrons

Neutrons are vital in the diagnosis and treatment of cancer. They can be used to form radioisotopes or be applied in external neutron therapies. The two external neutron therapies are fast neutron therapy and boron neutron capture therapy. Fast neutron therapy is still considered by many scientists as mainly experimental and remains a highly controversial topic. The new, experimental form

of neutron therapy, called boron neutron capture therapy, is showing some promising preliminary results, especially in difficult-to-treat cancers like glioblastoma multiforme. American James Chadwick discovered the neutron in 1932. A neutron beam is generated using either a nuclear reactor or a particle accelerator.

**Nuclear Reactors**
The first nuclear reactor was built in 1942 during World War II as part of the Manhattan Project. After the war, these reactors were used to generate electricity. During the late 1950s, research reactors started producing radioisotopes for medical use. According to the World Nuclear Association, there were approximately 240 research reactors in operation in 56 countries in March 2014. This number changes regularly due to important upgrades or maintenance requirements. Nuclear reactors operate on the basis of nuclear fission. Uranium-235 or Plutonium-239 is used as fuel in these reactors.

**Particle Accelerators**
Most of the accelerators used today are either cyclotrons or synchrotrons. An accelerator can have a diameter of up to 18 meters. This enormous size is necessary to accelerate particles to the required speed. A radio frequency is used to accelerate protons from the center of the cyclotron in an outward spiral. It is possible to have one accelerator simultaneously delivering multiple proton beams to several treatment rooms. When the protons strike a beryllium target, a neutron beam is generated.

Gantries are used to direct the neutron beam toward the patient. These gantries can rotate 360 degrees around the patient. Patients are positioned on mobile couches, which can also turn 180 degrees. This allows the treatment beam to enter the patient at almost any angle, which helps spare normal, non-cancerous tissue. The emitted neutron beam can be shaped using different types of collimators to create a precise treatment field.

**Fast Neutron Therapy**
Scientists have tested fast neutrons on a variety of different cancers with mixed results. Due to the risk of serious normal tissue damage, only malignant conditions are considered for treatment. Tumors that respond to neutron therapy include the following:

- Salivary gland tumors
- Paranasal sinus tumors
- Head and neck tumors
- Soft tissue sarcomas
- Uterine sarcomas
- Melanomas
- Bone tumors
- Inoperable lesions
- Recurrent cancers
- Slow-growing tumors

**Advantages of Fast Neutron Therapy**
Cells that are actively dividing are more sensitive to radiation compared to cells in a resting phase. Fast-growing tumors are very sensitive to conventional radiation like X-ray or gamma radiation. Slow-growing tumors are more resistant to these types of radiation.

Radiation damages cells through either single or double stranded DNA breaks. Neutrons deliver high linear energy transfer (LET) radiation. The lack of electric charge also means that the neutrons can travel past the electrons on the outside of the atom to collide directly with the nucleus. When the neutrons are stopped by the nucleus, they emit protons with high-ionizing capabilities. The large amount of energy produced by the emitted protons causes a great amount of single-hit double-stranded DNA breaks. This type of DNA damage is irreparable, and the cell dies.

A very controversial topic in the fast neutron therapy debate is the oxygen enhancement ratio (OER). Oxygen acts as a radio sensitizer, making cells more sensitive to radiation-induced damage. Tumor cells tend to be hypoxic, especially at their centers. Some scientists believe that neutrons are less dependent on the OER than X-ray photons.

**Disadvantages of Fast Neutron Therapy**
Normal tissue damage is an important disadvantage of fast neutron therapy. Most tumors are situated behind or around normal healthy tissue. Because of its cell killing abilities, fast neutron therapy can cause serious damage to these healthy cells. This can lead to unpleasant, long-term side effects.

**Boron Neutron Capture Therapy**
Neutron radiation has recently received more attention in the form of boron neutron capture therapy
(BNCT), especially in the treatment of glioblastoma multiforme. Glioblastoma multiforme has a very poor prognosis with mean survival of nine to 12 months after the first diagnosis. Even though boron neutron capture therapy is still in the early stages of research, some studies are delivering promising results. Other cancers that are also treated with BNCT include recurrent head and neck cancers and primary and metastatic melanoma.

With this type of neutron treatment, a patient is administered a boron containing drug. The drug delivers boron to the tumor cells. Boron-10 is non-radioactive in itself. The tumor is then irradiated with a thermal neutron beam, which causes a fission reaction with the boron. Alpha particles with a high LET as well as multiple lithium nuclei are created. This causes significant damage to the tumor cells. Alpha particles do not travel long distances inside of tissue. The rationale behind this type of treatment is that it is possible to deliver a high tumor dose with a high LET, while at the same time sparing the surrounding normal tissue.

Fast Neutron Therapy and Society
There are only two neutron therapy centers operational in the United States and one in South Africa. A third neutron facility in America, Fermi Lab, stopped its neutron therapy due to a lack of funding. The facility has been in negotiations with a medical provider in the hope that it may continue its neutron treatment program.

The cost of setting up and running neutron therapy facilities is much higher compared to X-ray treatment facilities. Neutrons still are an experimental treatment option. Therefore, the centers offering this type of treatment are highly dependent on funding from nongovernment sources. People who do not have one of these treatment facilities in their own country would have to pay large amounts of money to travel abroad for treatment.

Many scientists question the relevance of fast neutron therapy as only a very small percentage of cancers justify this type of treatment. Because it is a very expensive treatment option, many feel that the same advantages can somehow be achieved at a lesser cost and with less-severe long-term side effects.

Radioisotopes
Isotopes are different atoms with an identical atomic number (determined by the number of protons inside the nucleus), same placement on the periodic table, and similar chemical attributes. The atomic mass and physical characteristics of isotopes are, however, different. There is at least one isotope for every chemical element. The atomic mass is determined by the amount of neutrons in an atom.

A radioisotope is an artificially altered isotope with an excess of either neutrons or protons inside of the nucleus. Neutrons are added to the nucleus in a process called neutron activation. This is done in a nuclear reactor. The chosen atom is bombarded with a neutron beam. The nucleus of the atom captures some of the neutrons in the beam, resulting in a neutron-enriched radioisotope, which is unstable. A radioisotope will return to a stable condition through radioactive decay. This type of decay is characterized by the emission of alpha or beta particles. Sometimes gamma rays are also emitted during radioactive decay. The time it takes for a radioisotope to become stable again is called the half-life of the isotope.

Neutron-Rich Radioisotopes for Cancer Therapy
Neutron-enriched radioisotopes tend to decay with a negatively charged beta particle emission. The radioisotope becomes more stable by changing a neutron into a proton. For this to happen, the neutrally charged neutron needs to become a positively charged proton. It releases its negative charge through a negatively charged beta particle. Beta particles can travel very far in air, but they are stopped over only a few millimeters inside of human tissue. Their negative charge causes large amounts of ionizing reactions to occur over a short distance in tissue. This characteristic makes them ideal for use in a therapy setting.

Iodide-131 is used in the treatment of thyroid cancers or hyperthyroidism. Strontium-89, samarium-153, phosphorus-32, phenium-186, rhenium-188, and radium-223 are effective in the treatment of painful bone metastasis.

Targeted alpha therapy (TAT) is a new type of treatment utilizing the body’s own antibodies to escort an alpha-emitting radioisotope directly to tumor cells. Actinium-225 is used in this type of treatment. The first radioisotope necessary for the production of actinium is uranium-233, which is formed by enriching thorium-232 with neutrons in a nuclear reactor.
Neutron-Rich Radioisotopes for the Diagnosis of Cancer

Technetium-99 is the daughter product of molybdenum-99. It is also the most widely used radioisotope in diagnostic nuclear medicine. Molybdenum-99 is created through the fission of uranium-235. Technetium-99 is very useful in detecting cancer in the brain, skeleton, and organs.

Radioisotopes and Society

Approximately 40 million technetium-99 diagnostic procedures are performed globally every year. According to the World Nuclear Organization, diagnostic radiopharmaceutical use increases by more than 10 percent per year.

There are five research reactors that produce most of the world’s molybdenum-99. These five reactors are all more than 40 years old and frequently need to be maintained. From 2007 to 2010, multiple maintenance issues created a significant shortage of molybdenum-99. Many patients had to cancel their diagnostic procedures, while others had no choice but to pay for more expensive diagnostic procedures like positron emission tomography (PET) scans. With the continuous, rapid increase in nuclear diagnostic imaging, a serious shortage of radioisotopes may exist in the future.

Neutron-enriched uranium plates are shipped from America to the different countries responsible for manufacturing molybdenum-99. Many governments are concerned about nuclear safety, especially with the rise in terrorist activities. Recently, there has been a call for research reactor facilities to change from using high-energy uranium (HEU) to low-energy uranium (LEU).

Whether they are used either in the production of diagnostically essential radioisotopes or for the treatment of cancer, neutrons and oncology are set to remain inseparable.

Further Readings

New Zealand

New Zealand is a country composed of two islands (North and South Island) situated in the southwestern Pacific Ocean. Originally inhabited by the Māori tribes, New Zealand was colonized by the British empire in 1840, two centuries after it was first discovered by a Dutch explorer in 1642. The vast majority of New Zealand’s 4.5 million population is of European descent, and it is for the most part concentrated in the urban areas of Auckland and Wellington, its capital. Due to its considerable autonomy and ability to self-govern, the British Crown gradually lost control over New Zealand’s parliament, up until 1947, when the country
New Zealand adopted the Statute of Westminster, effectively declaring its independent authority, even though it is still formally a monarchy with Elizabeth II of England as its Queen.

New Zealand fought alongside the British empire in World Wars I and II, playing key roles in various naval battles in the Pacific theater, and today, it is a very developed country with a solid economy, focused on foreign policies that benefit poorer nations among the Pacific islands, and is considered the second-most peaceful country in the world.

The health care system of New Zealand is a mixed public–private system, with a high-quality system of public hospitals and emergency services for its citizens, with a series of health insurance plans and co-payment methods to help cover the expenses, such as subsidies for paying for medications and primary care. Long waits to receive treatments are often an issue, often exceeding a year for nonurgent surgery, encouraging a significant market in private medical insurance that is mostly covered (up to 50 percent of the whole market) by the Southern Cross Health Insurance, which has its own hospital chain.

Cancer treatment in New Zealand is delivered from a network of six district health boards (DHBs) with the supervision of the Ministry of Health, which coordinates the approach to cancer control through a series of different programs that ensure patients the best treatment and support services. The six DHBs that provide cancer treatment in New Zealand are Auckland, Canterbury, Capital and Coast, MidCentral, Southern, and Waikato. Most cancer centers operate as departments integrated into major hospital complexes and are often linked to palliative care teams and facilities.

The public Regional Cancer Service at Auckland City Hospital is the largest cancer center in New Zealand, treating more than 3,000 patients per year with a very modern radiation oncology department, a hematology ward to treat hematological malignancies such as leukemia and lymphoma, and a palliative care service. Other centers like the Regional Cancer Centre located at Waikato Hospital, Hamilton, instead, offer extensive training programs in all oncology specialties: radiation, medical, hematology, and palliative care.

Many nongovernmental organizations (NGOs) operate to help increase public awareness of cancer prevention and screening, offer patient care and psychological support, and sponsor research projects and fund-raising campaigns. Among these, one of the oldest is the New Zealand Cancer Society, which was founded in 1929 by launching the New Zealand Branch of the British Empire Cancer Campaign.

In 1948, a national population-based register of all primary malignancies diagnosed, called New Zealand Cancer Registry (NZCR), was set up primarily using information sent by public hospitals to collect and store cancer incidence and mortality data. In 1993, the Cancer Registry Act made it compulsory for pathology laboratories to report every cancer diagnosed inside the register, and in 2011, plans to expand it were announced by the Ministry of Health. Also, a New Zealand Children's Cancer Registry (NZCCR) was set up in 2000, under the governance of the National Child Cancer Network.

Cancer is the leading cause of death in New Zealand, accounting for nearly a third of all deaths every year (29.4 percent), followed by ischemic heart disease (18.3 percent of deaths). Lung cancer reported the highest number of cancer deaths in 2011 (18.9 percent of total cases), followed by breast, prostate, and pancreatic cancer, and it is consistent with previous data from the last 10 years. Data from the New Zealand Cancer Registry accounts for 21,050 new cancer diagnoses and 8,891 cancer deaths in 2011.

Colorectal and prostate were the most common cancer registration sites in 2011, accounting for 28.8 percent of all registrations. The most common cancer sites for females are breast, colorectal, and melanoma (skin cancer). For males, the most common cancer sites are prostate, colorectal, and melanoma (skin cancer). The most common malignancies for children are leukemia and testis cancer. The highest incidence of new cancer diagnosis by age was for people age 65 and over (57.1 percent), followed by people between 45 and 64 years (34.7 percent).

Risk factors for cancer in New Zealand are those commonly found in other well-developed Western societies: high-fat diets, low vegetable consumptions, sedentary lifestyle, obesity, smoking, and high alcohol intake.

Inequalities in cancer survival between ethnic and socioeconomic groups are known to exist in New Zealand. Of the 21 cancer sites examined, 17 had an excess mortality rate that was higher for Māori compared to non-Māori by 10 percent or
more, from 1991 to 2004. However, more recent findings reveal that the Māori cancer mortality rate dropped by 10.3 percent between 2001 and 2011, showing a positive trend. The causes of these inequalities are still elusive and not well understood but may include disparities in health care access and the higher prevalence of comorbidities, such as diabetes or heart disease, that may restrict the ability of patients to tolerate radiotherapy or chemotherapy.

Further Readings

Nicaragua

Nicaragua is the largest country in the central American isthmus. Officially known as the Republic of Nicaragua, the country borders Honduras to the north and Costa Rica to the south, and the Pacific lies to the west and the Caribbean Sea to the east. The total population of Nicaragua as per 2012 estimates is 5.67 million, with 2.81 million of these being men and 2.86 million women. The average annual deaths related to cancer stand at approximately 27,500. The gross national income per capita is $1,000. The health situation in the country is divergent between the urban areas and the rural areas. While the urban areas have considerably better and advanced healthy facilities and services, the poverty-stricken rural areas lag behind.

It is estimated that the number of new cancer cases in Nicaragua for the year 2008, based on GLOBOCAN data for Nicaragua as a whole, was 5,591. This was as per the 2012 estimates, and of this total number, 2,351 of these cases were men and 3,240 women. The five most-common cancers in Nicaragua are gynecological issues relating to women, urological issues relating to the bowels and other problems, hematological cancers including lymphoma in many of its forms as well as multiple myeloma, stomach, and breast cancer. Statistically, the types of cancer are gynecological cancers with 1,062 recorded cases, urological-related cancer with 813 recorded cases, hematological malignancies with 567 recorded cases, stomach cancer with 527 recorded cases, breast cancer with 468 registered cases, liver cancer with 335 recorded cases, and colorectal cancer with 299 recorded cases.

For persons who have been diagnosed with cancer, they need pathology, surgery, and chemotherapy or radiation therapy; in Nicaragua, the total number of oncologists needed may be based on the number of people who need assistance in some way. Based on estimates in relation to the number of cancer incidences recorded, in Managua, new cancer cases per year based on 2012 estimates were 1,429 and, in Matagalpa, 536. Based on annual new cancer cases, the number of hematologist oncologists required in the two cities includes radiation clinical oncologists, two; urologic oncologists, eight in Managua and three in Matagalpa; gynecologic oncologists, two in both cities; and last, pathologists, three in Managua and two in Matagalpa.

These numbers for the professionals required to handle new cancer cases are based on the number of estimated annual cancer cases. For developing countries like Nicaragua, the International Atomic
Energy Agency (IAEA), of which Nicaragua is a member, supports oncology training for managing chemotherapy and radiation together instead of having to rely on two separate people for both solutions. All cities must have a minimum of two surgical oncologists, two radiation or clinical oncologists, and two hematologist oncologists.

In addition to the professionals listed above, support staff is necessary to aid in the delivery of services. Support staff required in the treatment of cancer in Nicaragua includes oncology-pharmacists plus nurses, technicians, and those who work with end-of-life procedures. Nicaragua cancer treatment and oncology nursing staff for each 24-bed oncology unit comprises one head nurse and a nurse specialist as well as 13 nurses working eight-hour shifts, five days per week (these oncology units are operating 24 hours a day, seven days a week). Because most of the Nicaragua cancer patients require special treatment options, many facilities have to be equipped with the best possible staff members. Professionals working in the radiation oncology units include many technicians, physicists, and engineers who can work with many radiation-based procedures as necessary.

To control management and treatment of cancer in Nicaragua, both government and nongovernmental organizations are involved. These include pilot projects that are used to determine the overall efficiency of many treatment options and to see if different treatment solutions may be utilized as a means of facilitating the basic health needs of all those who are asking for solutions and getting different treatment functions to meet demand. Based on the finding, the IAEA has brought in international partners, notably the World Health Organization (WHO) and the International Agency for Research on Cancer (IARC), to develop sustainable cancer control projects and donors to fund them in Nicaragua. In addition to Nicaragua, a similar initiative by IAEA is being conducted in Tanzania, Mongolia, Ghana, Yemen, Vietnam, Albania, and Sri Lanka.

Nickel Compounds

Nickel is a very abundant, naturally occurring chemical element, which is usually found combined in various forms with iron, sulfur, or arsenic on the Earth's surface and inside large meteorites. Earth's molten core is composed of a nickel–iron alloy known as NiFe. Some natural ores containing nickel include garnierite, pentlandite, limonite, nickeline, kamacite, and taenite.

From a chemical point of view, nickel is a metal in the group VIIIB of the periodic table that exists in the oxidation states of +2, +3, and +4. It is a silvery-white, hard, but ductile metal used in combination with other metals (especially iron, copper, and zinc) to form alloys and plating used in industrial manufacturing for electrical and magnetic properties, high resistance to corrosion, and production of magnets, rechargeable batteries, coins, ceramics, and jewelry. Nickel is an essential
element for many plants and bacteria, necessary for various biosynthetic processes, and is a constituent part of all organs of vertebrates. However, the nickel requirements for human beings and animals are so small that they are included among trace elements, and given its wide availability in the environment, there are actually no known cases of nickel deficiency.

Pure or metallic nickel is used in the chemical industry as a catalyst and for industrial purposes in the production of nickel steels and alloys, electroplating, electrical and sintered components, plumbing equipment, and batteries. Nickel alloys are appreciated for their ferromagnetic properties, high temperature resistance, and oxidation resistance against salts and are used for the production of heating elements, rocket engines, surgical implant prostheses, and storage of liquefied gases. A 75 percent nickel and 25 percent copper alloy called Monel is used for the production of naval parts, propeller shafts in boats, and desalination plants because of its great resistance to seawater corrosion.

Nickel oxides and hydroxides are finely divided powders used in the manufacture of nickel salts, specialty ceramics, alloy steels, and nickel catalysts such as those found in automobile exhaust control. Green nickel oxide is a component in the Edison battery and fuel cells, and it is often used as a porcelain, glass, and ceramics colorant.

Nickel sulfide and subsulfide are used as catalysts in the petrochemical industry, in the production of lithium batteries, as intermediates in the primary nickel industry, and in the hydrometallurgical processing of nickel ores. Together with nickel carbonyl, they are also by-products of mineral refining and metals processing.

Nickel salts are all used as intermediates in the manufacture of nickel catalysts and other nickel compounds, and many of them are also used as electrolytes in nickel electroplating. Nickel acetate, nickel ammonium sulfate, nickel titanate, and nickel carbonate also are used as dye mordant and pigments in the preparation of colored glass and ceramics. Nickel chloride is used in industrial gas masks to absorb ammonia, while nickel nitrate hexahydrate is used for the production of Ni–Cd batteries.

Nickel carbonyl is a yellow organonickel liquid compound and is one of the most toxic substances produced in industrial manufacturing, with a lethal concentration for humans as low as 30 parts per million (ppm; or three ppm for 30 minutes of exposure). It also poses additional safety risks as it is highly volatile, and its vapors can autoignite. It is used as an intermediate in the Mond process for the purification of nickel, vapor plating, and deposition of nickel in semiconductor manufacturing. Nickelocene is a paramagnetic solid metallocene, used as a catalyst and complexing agent.

Being a natural element of the Earth’s crust, small amounts of nickel are found in everyday food, water, soil, and air at very low levels. Natural emissions include volcanoes, windblown dust, forest fires, and dissolution of nickel-containing rocks in soil and water. Anthropogenic sources of nickel include oil and coal-burning power plants, steel-refining complexes, and trash incinerators’ finely pulverized emissions. Nickel usually requires a long time to be removed from air, either by solubilizing in raindrops or by slowly settling to the ground, where it ends up in soil or sediment, forming iron or manganese complexes.
The major source of nickel exposure is oral consumption as nickel is found in both food and water and may include human pollution, for example, nickel-plated faucets contaminating water and soil, mining or smelting waste-water production, cooking with nickel–steel alloy housewares, and eating in nickel-pigmented dishes. Other forms of exposure include breathing (polluted air from nickel metal refining, fossil fuel combustion, and tobacco smoking) and skin contact (through direct contact with jewelry, shampoos, detergents, and coins). A less-common form of chronic exposure is through hemodialysis as traces of nickel ions may be absorbed into the plasma because of the chelating action of albumin. The daily average amount of nickel to which most people are usually exposed does not pose a threat to human health. Most of the nickel absorbed every day by humans is removed by the kidneys and passed out of the body through urine or is eliminated through the gastrointestinal tract without getting absorbed. Nickel is not a cumulative toxicant; however, larger doses or chronic exposure may be dangerous for human health and may represent an occupational hazard due to their acute toxicity and carcinogenicity.

Acute toxicity to nickel may range from less-threatening effects such as allergic reactions, dermatitis, dizziness, and gastrointestinal discomfort to more severe effects such as potentially fatal lung and kidney damage, pulmonary fibrosis, heart failure, and renal edema, especially after exposure to nickel compounds. Workers exposed to airborne fumes, dusts, and mists containing finely pulverized nickel and nickel compounds, such as those working in nickel refineries, nickel processing plants, alloy and stainless steel manufacture, and other nickel-using processes (such as electroplating, smelting, and welding), are all considered at risk for developing cancer.

Many national and international organizations such as the United States Department of Health and Human Services (DHHS), the International Agency for Research on Cancer (IARC), and the U.S. Environmental Protection Agency (EPA) determined that nickel metal and nickel compounds range from those that could reasonably be anticipated to be a carcinogen up to known human carcinogens, and thus, exposure to these substances poses a risk for human health by causing lung cancer and cancer of the nasal cavity (sinus cancer). These claims were confirmed in recent years by numerous epidemiologic studies, cohort studies, and nested case-control studies in different industrial sites in Canada, Italy (Florence), Norway (Kristiansand), Finland, and the United Kingdom (Clydach).

Workers in smelters and refineries were exposed to metallic nickel, nickel oxides, nickel subsulfide, soluble nickel compounds, and nickel carbonyl in concentrations 100,000 to 1 million times greater than typical background levels found in the air and water. Nickel accumulated during daily work was also retained by the mucous membrane for years after retirement.

Other workers who may be exposed to nickel are spray painters, welders, battery makers, jewelers, painters, and varnish makers. Workers exposed to nickel and nickel compounds through inhalation or skin contact showed significantly increased risk (up to three times higher) for lung cancer and cancer of the nasal cavity (sinus cancer), but many recent studies showed a statistically elevated risk of developing other site-specific cancers, such as cancer of the buccal cavity and pharynx, laryngeal cancer, stomach cancer, and pancreatic cancer. Specifically, nickel may significantly increase risk for lung cancer in workers who smoke tobacco (up to five times higher) due to a multiplicative, synergistic effect, suggesting that the effects of nickel exposure and smoking may be additive.

Various forms of nickel and compound types show different potency in their carcinogenicity partly depending on their solubility and ability to reach high concentrations in target tissues. In particular, evidence demonstrated elevated risk of lung cancer and nasal sinus cancer in humans specifically for nickel chloride, nickel sulfate, insoluble and water-soluble nickel salts, nickel oxides, nickel sulfide, and nickel subsulfide.

Water-soluble nickel compounds and metallic nickel were also deemed as contributing to risk of carcinogenesis in humans. Many other nickel compounds such as nickel arsenide, nickel antimonide, nickelocene, and nickel carbonyl demonstrated carcinogenic activity in in-vivo and in-vitro animal studies.

Many studies on both human- and animal-cultured cells demonstrated that soluble nickel salts can be complete carcinogens or initiators of carcinogenesis at tissue sites distant from the site of administration. Nickel mechanisms of carcinogenesis
can be attributed to the production of 8-hydroxy-2'-deoxyguanosine in target sites (mostly lung and sinus cavity) and direct DNA attack by reactive oxygen species produced by nickel ion’s oxidoreductive activity (Fenton’s reaction). Those reactive species and nickel itself may cause chromosomal damage, inhibition of DNA repair activities, and genetic aberrations such as gene silencing that, in turn, may cause cancer. Nickel compounds also act as co-mutagens with a variety of other DNA-damaging agents and may cause oxidative stress and inflammation to tissues, indirectly contributing to carcinogenesis.

To address the human health and environmental hazards posed by nickel dust and nickel compounds, many significant improvements in the refining processes have been made in order to reduce exposure and dust emissions with complex filtration systems. Enclosed operational industrial water circulation systems, for example, greatly decreased the volume of wastewaters getting to water bodies. To protect workers, many governments published occupational safety guidelines and have set limits for metallic nickel and nickel compound concentrations in workplace air during working hours. Engineering controls reduced the environmental concentrations of toxic substances, and factory personnel are required to use personal protective equipment and follow strict sanitation procedures to reduce exposure.

Niger

The Republic of Niger (not to be confused with Nigeria) is an inland country in central-western Africa, named after the Niger River. Most of Niger’s population is composed of subsistence farmers who live off their land. Many of them are clustered along the more fertile river banks as around 80 percent of this country is covered by the Sahara desert. Through its history, many empires saw their rise and decline in Niger, such as the Songhai empire (600–1591), the Hausa kingdoms (mid-1350–1808), the Mali empire, and the Kanem–Bornu empire, and the first contacts with Western societies happened only much later at the beginning of the 19th century due to the landlocked nature of this country. After almost 40 years of war and bloodshed, in 1922, Niger was declared a French colony up until 1956, when it became an autonomous state within the French community. From 1958 to 2010, a series
Niger of seven republics alternated themselves with four different military regimes, following an interminable series of military coups that ended in 2010 with the election of the Seventh Republic.

Niger’s rural economy is very poor and underdeveloped, with soils degraded by over-extensive cultivation and often plagued by numerous droughts and locust infestations, although the country itself is rich in mineral deposits of uranium, gold, and coal, which comprise most of the national exports. The vast oil deposits in Niger always have been exploited by foreign countries (mainly the United States and China), and only in 2011 was its own petroleum industry born. Foreign and multinational oil corporations in the Niger delta often founded various repressive military dictatorships in Niger that showed no concern for environmental pollution or local populations’ human rights in order to better exploit the country’s oil basins. Thus, most of the Nigerien population lives in poverty conditions, with one of the lowest literacy rates in the world (especially for females), a life expectancy of just 54 years, and exceptionally high child mortality (124 per 1,000), according to the organization Save the Children.

Health care in general is very scarce in Niger, with a distinct lack of proper medical facilities and very limited resources such as medical equipment, staff, or supplies (especially drugs). The largest Nigerien medical facilities are the National Hospital in Niamey (with just 244 beds) and the Lamordé University Hospital, which is also a teaching hospital and a training center for new doctors. Many nongovernmental organizations (NGOs) such as the Red Cross and Save the Children operate in the territory, trying to guarantee some form of basic health care to the population and to promote awareness, sensitization, and cancer screening programs. Today, with the help of foreign international funds, the Nigerien Ministry of Health is trying to strengthen the quality of services provided.

The first national cancer registry, called Niger Cancer Registry, was established only in recent times (1992), and it is located in the Faculty of Health Sciences at the Abdou Moumouni University in Niamey to collect and analyze data on all cancer cases diagnosed among the population of the capital city. Despite the limitations of the available data, a total of 1,577 cancer cases were reported between 2006 and 2009. The most common cancer sites in Niger are breast, ovary, and cervical cancer in females and liver and colorectal cancer in males, followed by bone and non-Hodgkin’s lymphoma. Burkitt’s lymphoma is the most common childhood cancer because malaria is still endemic in many regions among the farming population. In Nigerien studies, the most frequent histology of breast cancers were carcinomas (46.17 percent). Thanks to the fiber-rich dietary habits of most rural Nigeriens, colorectal cancer incidence is significantly lower than in developed countries, but it is still increasing because of the recent urbanization process that has caused many Nigeriens to shift toward a high-fat and refined carbohydrates-rich diet. Liver cancer is the most common cause of cancer death in Niger with a lethality of 36.45 percent and often comes in association with liver cirrhosis, chronic hepatitis B and C virus infections, and histories of alcohol abuse or aflatoxin exposure, like in neighboring western African countries.

Ecological issues in the Niger delta related to petroleum spills and over-extensive environmental exploitation also may constitute additional risk factors for cancerous malignancies. Roughly 240,000 barrels of crude oil are spilled in the Niger delta every year, causing a vast contamination of soil, ground, air, and water, exposing the population to high levels of many known carcinogens such as benzene, dioxins, polycyclic aromatic hydrocarbons (PAHs), and benzo(a)pyrene. Benzene, for example, was found at levels more than 900 times above United Nations World Health Organization (WHO) guidelines. Gas flares often cause acid rain, which further pollutes the environment and forces rural populations to find shelter under asbestos roofing that protects their homes from corrosion but increases risk for lung cancer, asbestosis, and peritoneal mesothelioma. Oil spills reduced the ascorbic acid content of vegetables from crops by as much as 36 percent, thus reducing the daily intake of one of the most well-known natural antioxidants that help in dietary cancer prevention. Consumption of meat from oil-contaminated livestock also may increase the incidence of cancer of the digestive tract.

Nigeria

The territory that makes up the western African nation officially termed the Federal Republic of Nigeria has in times past been the location of countless cultures, civilizations, and peoples. The British protectorates of South Nigeria and North Nigeria were merged in 1960 after the Nigerian peoples gained independence from the British, and in the years that followed, several civil wars ensued. The modern Federal Republic of Nigeria was created in 1999 and has been in place since. The nation currently has one of the top 10 largest populations in the entire world with more than 170 million citizens comprise more than 500 different ethnic groups.

As the Nigerian population is quickly aging according to domestic statistics, incidences of cancer are set to surge in the coming years. As Nigeria is a developing nation that is currently struggling with several other health emergences like the spread of acquired immune deficiency syndrome (AIDS) and malaria, the increased incidence of cancers within the country will only further strain an already strained health care system. Nigeria does not have the screening, treatment, or registry capabilities that other more-developed countries have. The nation currently does not have a national cancer registry or a national treatment plan, which would prove invaluable in the nation’s fight against cancer. The nation’s 11 regional cancer registries are not well maintained due to lack of resources. Also, as in any emerging country, Nigeria currently lacks the funds, oncologists, and physical resources to institute a sustained effort to prevent and remedy its domestic cancer incidences.

Researchers estimate that Nigeria experiences more than 500,000 new cancer incidences and nearly 100,000 cancer fatalities per year. In the past few years, cancer mortalities have appeared to account for more than 5 percent of all mortalities within the country. Even in spite of these estimates, the presence of cancer in Nigeria is not well understood as a result of the general lack of data on the disease in the country. Cancer literature regarding Africa accounts for just 1 percent of the world’s literature on the subject, and the amount of literature regarding cancer in Nigeria is furthermore a fraction of that 1 percent. Many cancer patients in the Nigerian population will never experience or participate in cancer care, and so countless cases go unreported. Even the current population statistics for Nigerians are not considered to be accurate, so making effective inferences regarding trends in cancer cases in Nigeria is exceedingly difficult. When these notions are combined with the fact that Nigeria has only around 100 oncologists operating out of five cancer treatment centers, then it
can be understood how cancer is emerging as one of Nigeria's most pertinent health emergencies.

Childhood cancers are currently posing a large problem to the Nigerian medical community. The most prevalent forms of childhood cancer in Nigeria are incidences of Burkitt's lymphoma, retinoblastoma, nephroblastoma, sarcomas, and leukemia. Various data compiled from some of the nation's 11 regional cancer registries suggests that there are an unusually high amount of brain tumors and leukemias occurring in Nigeria's youth, though researchers are uncertain of the reasons for this. One of the most prevalent cancer incidences in Nigeria's youth, Burkitt's lymphoma, is correlated largely with malarial infections and emaciation, though incidences of Burkitt's lymphoma have been decreasing over the past several years as the nation's malaria problem is better contained. However, childhood cancer patients in Nigeria are faced with the same obstacles that adult cancer patients are faced with there, which is namely the near total lack of access to cancer care due to financial and geographical reasons. In spite of the fact that almost four-fifths of all childhood cancer cases can be remedied with contemporary treatment practices, most Nigerian children will never be able to afford even the most basic medical care.

Currently, the most prevalent forms of cancer incidences in Nigeria are breast cancer, cervical cancer, liver cancer, lymphomas, and prostate cancer. Prostate cancer accounts for the most common incidences in the male Nigerian population, followed by cases of liver cancer and incidences of lymphomas. With regard to Nigerian women, the leading form of cancer incidence of females in the nation is by and large breast cancer, followed by cases of cervical cancer and lymphomas. In the female Nigerian population, incidences of cervical cancer are quickly growing as a result of a consistently increasing amount of infections from the human papillomavirus within the country. In comparison to other nations, lung cancer prevalence is currently fairly low in Nigeria, but researchers believe that incidences may increase in the coming years as tobacco corporations have begun to expand their advertising campaigns in the country. Females account for well over half of all cancer incidences in the nation.

Sadly, many citizens of the Federal Republic of Nigeria have had cancer throughout its history. The critically acclaimed Nigerian academic, pharmacist, and politician Dora Akunyili passed away as a result of ovary cancer in June 2014. Furthermore, Maryam Babangida, who was the wife of Nigeria's infamous former head of state General Ibrahim Babangida, also lost her battle with ovary cancer in 2009. Sam Ojebode, who was once a player for the Nigerian national soccer team, lost his bout with lung cancer in 2012 at the age of 67.

As mentioned earlier, it is difficult if not impossible for the vast majority of Nigerians to receive or have access to basic cancer treatment facilities. As there are only five medical facilities in the entire country that are equipped with any kind of radiation treatment machinery, up to 40 million Nigerians are served by a single one of these facilities. In the coming years, more facilities will need to be created in Nigeria to lessen this statistic, and cancer treatment services will need to be provided in more-affordable ways in order to more adequately serve Nigeria's undertreated cancer patients.

Further Readings
Nixon, Richard (War on Cancer)

In 1971, President Richard Nixon declared war on cancer in his State of the Union address. Devoting a relatively small portion of his address, Nixon called for $100 million in additional funds. The State of the Union Address, building on existing support from activists and the U.S. Senate, helped result in the 1971 signing of the National Cancer Act. Since then, more than $100 billion has been spent on cancer research. While the cancer death rate has declined only marginally since 1950, there have been substantial gains in research funding, the development of treatment options, and changes in attitudes toward the disease.

Origins of the War on Cancer
At the time of the declaring of war on cancer in 1971, it was the second-leading cause of death. Cancer had a social stigma that prevented many from disclosing their illness. A philanthropist named Mary Lasker worked to change attitudes. The American Cancer Society also lobbied for increased funds and attention. Lasker conducted lobbying and advocacy efforts to bring cancer to the attention of lawmakers. She hoped to gain funding for increased research for cancer, helping to eventually find a cure for the disease.

Richard Nixon's 1971 State of the Union Address was partially directed toward declaring war on cancer. He stated, "I will also ask for an appropriation of an extra $100 million to launch an intensive campaign to find a cure for cancer, and I will ask later for whatever additional funds can effectively be used. The time has come in America when the same kind of concentrated effort that split the atom and took man to the moon should be turned toward conquering this dread disease. Let us make a total national commitment to achieve this goal."

The signing of the National Cancer Act in 1971 was a tangible result of Nixon's commitment. The act was signed on December 23, 1971. During the signing ceremony, Nixon declared, "I hope in the years ahead we will look back on this action today as the most significant action taken during my administration." Nixon's motivations for the war on cancer were mixed. The use of the war analogy also was applied to actions taken in the war on drugs. Nixon presided over unpopular actions in southeast Asia and looked for opportunities to shift attention. In 1971, wage and price controls were implemented, actions fairly surprising from a Republican president. Nixon's support for a war on cancer helped him to gain popular support as he prepared for his 1972 reelection campaign.

Cancer research was a priority of Massachusetts Senator Edward Kennedy, and the U.S. Senate had passed a resolution in 1970 that led to a study on cancer research. That research was conducted by

---

Ikawo, O. E. “A Literature Review on Cancer in Nigeria.” College of Medicine at the University of Lagos (May 2014).

what came to be known as the Yarborough Commission, which took its name from Senator Ralph Yarborough, who was defeated for reelection in 1970. Yarborough was targeted for defeat by Nixon, and Kennedy was seen as one of his key rivals. Nixon and the relatively liberal Democratic Senate each became champions of the war on cancer.

Implementation, Results, and Criticism of the War on Cancer

The war on cancer helped to result in substantially increased funding for research. Among the initial steps taken in 1971 was the conversion of the former biological warfare facility, Fort Frederick, into a cancer research center. The Frederick Cancer Research and Development Center became a major center to conduct research. The act also provided for collaborations with other federal agencies, state agencies, and the private sector. Educational campaigns such as antismoking campaigns were also promoted. The act was designed to foster research and to allow a focus on areas where there was the greatest potential for improvement.

The four decades after Nixon declared war on cancer and signed the National Cancer Act saw more than $100 billion being spent on cancer research. There were also the creation of cancer treatment centers and public health efforts throughout the nation. Some cancers such as leukemia have seen significant improvements in treatment. Other cancers such as lung cancer and breast cancer have seen changes from greater awareness as people quit smoking and obtained mammograms, which can prevent cancer from developing or allow for early detection. Another consequence of raised awareness is the banning of cigarette smoking from many public places.

Individual types of cancer also gained attention. In 1974, then First Lady Betty Ford underwent a mastectomy and helped to raise attention regarding breast cancer. That helped to gain attention for breast cancer, which impacts a huge number of women, and to encourage early screening.

There has been some criticism of the war on cancer, in terms of both the current state of the battle against cancer and the lack of initial improvement in mortality rates. There is much greater understanding of the wide variety of diseases that constitute what is commonly understood as cancer. Some note that the National Institute of Health’s (NIH’s) stringent requirements for funding have stymied further research. Strict constraints on the federal budget also may result in fewer resources available for future research as well. Research and medical and pharmaceutical treatment may be more difficult to conduct in the future.

Conclusion

More than four decades after the war on cancer, research and treatment efforts against cancer continue. Nixon called for greatly increased research, and that has certainly occurred, with more than $100 billion being spent. In addition, cancer no longer has a strong social stigma, and public health campaigns have helped to identify and reduce risks, particularly in areas such as tobacco smoking. The war on cancer has helped to create the impetus for other diseases and has provided a model for diseases such as human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS) and for recent calls for increased research for Alzheimer’s disease. While progress has been made, new public health dangers such as the increase in obesity.
and lingering high mortality rates represent contemporary challenges to the war on cancer.

North American Association of Central Cancer Registries

Established in 1987, the North American Association of Central Cancer Registries, Inc. (NAACCR) is a professional organization that develops and promotes uniform data standards for cancer registration, provides education and training, certifies population-based registries, aggregates and publishes data from central cancer registries, and promotes the use of cancer surveillance data and systems for cancer control and epidemiologic research, public health programs, and patient care to reduce the burden of cancer in North America.

NAACCR members consist primarily of population-based central cancer registries, and all such registries in the United States and Canada are members. In addition, major cancer surveillance organizations across North America are sponsoring members of NAACCR. The members work together to provide consensus standards for coding, editing, and data exchange and promote best practices for the collection and use of cancer information. NAACCR coordinates the implementation of standards to promote continuity in data collection, data exchange, and analysis. NAACCR offers a variety of high-quality educational opportunities throughout the year, covering fundamentals of cancer registry operations, data processing, and electronic data management tools.

Central cancer registries collect data on defined populations in a defined time period and strive to collect information on every cancer case in the catchment area so that accurate incidence, mortality, prevalence, and survival statistics can be calculated. Collecting complete, timely, high-quality cancer data is essential for central cancer registries. Additionally, it is imperative that central cancer registries follow the same data collection standards and rules so that valid comparisons can be made between different geographic areas. NAACCR provides the only independent, objective certification program to assess the quality of population-based cancer registry data. Registries must meet quantifiable data quality standards to be NAACCR certified. The criteria include measures of completeness of reporting, timeliness, and accuracy (less than 3 percent of cases may have missing values for age, sex, or state or province of residence; less than 5 percent may be missing race codes; all records must pass edit checks; and less than 5 percent of cases may have information derived solely from death certificates). NAACCR certification has demonstrated marked and measurable improvement in the quality of cancer surveillance data since the inception of the program 25 years ago. In the most recent certification year (2014), 45 U.S. state and regional registries along with eight Canadian provincial and territorial registries were certified at the Gold (highest) level, while nine additional U.S. and two additional Canadian registries were certified at the silver level.

Another priority of NAACCR is the evaluation and publication of data from member registries. In order to assure comparability of the aggregated data from population-based registries in different geopolitical areas, procedures and standards are in place to assure that the data are collected using a universal case definition (reportability standard); collected using uniform rules and standards; coded using a common set of rules and definitions; assessed for completeness within a geographic area; and are from the same time period, of similar quality, and adjusted to a common standard.
NAACCR produces an annual series of publications, “Cancer in North America” (www.naaccr.org/DataandPublications/CINAPubs.aspx), consisting of three separate volumes of data (Volume I: Combined Cancer Incidence for the United States, Canada, and North America; Volume II: Registry-Specific Cancer Incidence in the United States and Canada; and Volume III: Registry-Specific Cancer Mortality in the United States). Data on more than 7.7 million cancer cases in North America covering 98 percent of the population are included and represent the most comprehensive statistical data on cancer in North America. Data are presented for all cancer site groups by gender and, for the United States, by race and ethnicity. Rates of several cancers are presented by stage at diagnosis. NAACCR data contribute to the “Annual Report to the Nation on the Status of Cancer” prepared annually by a collaborative effort of NAACCR, the American Cancer Society, the Centers for Disease Control and Prevention, and the National Cancer Institute.

NAACCR has developed a series of standards for cancer registries to ensure the comparability and quality of cancer surveillance data in North America. NAACCR Standards Volume I details a standard data transmission file layout that is used by all cancer registries in North America and many registries around the world. The NAACCR data exchange record layouts were designed to facilitate electronic transmission of cancer registry data among registries for multiple purposes. The layouts can be used to provide standardized data from reporting sources to central registries; to share tumor reports on residents of other states or provinces from one central registry to another; or to report data from diverse facilities or states or provinces contributing to a combined study. Standards Volume II serves as a data dictionary and provides a comprehensive reference to ensure uniform data collection, reduce the need for redundant coding and data recording between agencies, facilitate the collection of comparable data among groups, and provide a resource document to help registries that are establishing or revising their databases. The document is used by new and existing facility-based and central cancer registries to ensure that their programs’ standard definitions and codes are consistent with those used by regional and national databases. NAACCR Standards Volume III provides standards for completeness, quality, analysis, management, security, and confidentiality of data, and Volume IV provides standardized electronic data edits that can be run on a standard NAACCR file. The final standards volume contains standards for reporting of data using electronic pathology reports.

Since 1987, NAACCR has provided valuable services and resources to central cancer registries and the entire cancer surveillance community. Relying on outstanding volunteers from this community who are willing to work collaboratively on areas of mutual interest, NAACCR has been able to make much progress on achieving its mission. Cancer surveillance personnel from across North America contribute knowledge and expertise for the benefit of all population-based registries, which strengthens the infrastructure and improves the quality of data. NAACCR will continue to focus on five major areas, including standardization and registry development, research and data use, professional development of members, communications, and strategic alliances.

North Korea

North Korea (NK) claims it has a universal health care system for all citizens. However, the reliability of that claim is suspect. Health professionals working with contacts in NK say that adequate health services exist only for those who can pay. Most of
the information on NK’s health care system is outdated as access to the country is almost unavailable, and what is shown visitors is only the cream of the crop, so to speak. The latest statistics available (2001) indicate that NK spent 3 percent of its gross domestic product (GDP) on health care.

By contrast, the United States spent nearly 18 percent in 2013. The number of hospitals increased from 285 to 2,401 in 1986 and clinics from 1,020 to 5,644. For the last 30 years, there has been a greater importance placed on traditional Korean medicine, based on holistic treatment with herbs and acupuncture. NK did initiate a national telemedicine TV network in 2010. It connects the Kim Man Yu hospital in Pyongyang with 10 medical facilities in other provinces. In the 1990s, NK’s health care system, because of natural disasters and economic problems, experienced a sharp drop in health care services. In 2001, hospitals and clinics in North Korea were suffering shortages in medicines, equipment, running water, and electricity.

Surprisingly, in 2010, the World Health Organization (the United Nations public health arm) touted NK’s health care system as “the envy of the developing world.” At the same time, they cited “remaining challenges including poor infrastructure, a lack of equipment, malnutrition, and a shortage of medicines.” The organization was critical of an Amnesty International report that described “barely functioning hospitals” as outdated.

In an article by Margie Mason of the Associated Press in 2013, she intimates, after a guided tour of NK’s health facilities, that it is a “rehearsed picture of health the reclusive government wants the outside world to see, complete with spotless, granite corridors. But the reality of that image is clouded every time Chairman Mun takes a breath that explodes into icy wisps.” The hospital is so cold during this February visit that patients remain bundled in thick coats, gloves, and scarves during exams, while nurses swish with every step as they hustle through the halls in white snow pants and matching puffer jackets. Mun himself wears big, furry, teddy bear slippers. She says, “Even in the gleaming capital, some health facilities appear to be a throwback to another time. Hulking machines and antiquated equipment in exam rooms could have arrived decades ago, when there was still a steady flow of medical supplies from the former Soviet Union.” Despite this, NK touts its new breast cancer Institute in Pyongyang, the capital. It seems all the health care money is spent in the capital. The center is stated to be for “the prevention and treatment of mammary gland diseases and scientific researches.” However, like many facilities in NK, the hospital appears devoid of patients. Defectors and aid workers say hospitals everywhere are often eerily vacant. Bad roads, a lack of transportation, and no money make it impossible for many to access health centers. Medicine and care are supposed to be free. But in reality, everything has a price.

There’s a saying in North Korea: “If your relative has cancer, then your entire family is ruined because everything will go to getting that medicine,” says Jeon, a 24-year-old defector in Seoul who fled North Korea five years ago. “Some families who cannot afford the medicine have no choice but to watch their loved ones die.” Despite the new center, breast cancer is far from the top of the list of health problems gripping the country, revealing a disconnect between where the government spends and what the people really need, Mason describes.

Beijing, China, reports that NK has claimed to have developed a highly effective injection to cure liver cancer. The Injection Gallium-66 Microspheres developed by the NK Academy of Medical Science is able to treat liver cancers smaller than five centimeters. The medicine is guided by ultrasonic waves only to cancer tissues. The gallium substance was available in the country, and proper doses were obtained for the injection. It is normally effective in 20 days and can be in five. Giving of the injection to 50 patients since 2002 shows that it is effective in as many as 90 percent of patients.

Medicine is not a prestigious occupation in NK. This is because of earlier communist denunciation of all intellectuals, including doctors. As a result, 75 percent of physicians in NK are women. The country is perhaps 15 to 20 years behind in medical research, including cancer research. Nurses often have only a high school education or less.

NK highlights preventative care above all else. They have adequate inoculations when serum is available. All children get mandatory exercise in schools. There is a variation in the quality of medical care in the country. The best hospitals are found in Pyongyang, where government officials are afforded the best care. The predominance of cancer specialists are in the capital. Some facilities in Pyongyang are the only hospitals where patients may obtain
advanced cancer care. Cancer is the leading cause of death in the country, ahead of heart disease.

Assessing cancer care or health care, for that matter, in North Korea is severely hampered by the overly reclusive nature of the government. Suffice it to say that the biggest problem in NK is shortage—shortage of advanced treatment facilities, shortage of medicines, shortage of people's access to quality facilities, and alas, a shortage of food. Malnutrition is probably the most important factor in incidence of disease. Without needed nutrients, the body opens itself up to all manner of unfriendly disease. Also, the shortage of health education for all but the elite is another cause of disease.

NK has the trained doctors to treat cancer so long as patients are elite, live in the capital city, or can afford to get to where the treatment is. Many outlying hospitals do not even have doctors but are run by midwives. Nursing training is lacking. It is good that NK focuses on preventative medicine, and they have managed to increase longevity in the country significantly. However, NK basically is a repressed country with a repressive government, which in turn represses health care.

Norway

The northeastern European nation officially termed the Kingdom of Norway is thought to have first been settled by humans as long ago as 10,000 B.C.E. From this era to contemporary times, Norway has experienced numerous political renditions, from being under Denmark’s dominion from 1523 to 1814 to being unified with Sweden from 1814 to 1905. The Norwegian Parliament declared the nation and its peoples independent from Sweden in 1905, and thus the country has been the sovereign Kingdom of Norway ever since.

There is hardly any concrete data regarding specific rates of cancer in Norway previous to the year 1952 as this was the year that the country enacted a mandatory nationwide cancer registry. Consequently, little tangible information is available regarding precise trends of the disease in the country prior to the 20th century. Nonetheless, some things about the disease in the country pre-1952 can be certain, such as the fact that, like the rest of the globe’s population, the citizens of Norway have been dealing with cancer for centuries. In 2008, researchers at the University of Oslo conducted tests on a female body that was found aboard an ancient and buried Viking ship. After the test results were ready, the researchers discerned that the woman had died around the year 830 C.E. and that she had specifically suffered from bone cancer during the final years of her life. Subsequently, this is the nation’s first confirmed cancer casualty.

More than a millennium later, Norway was occupied by foreign forces during World War II, from 1940 to 1945. As the realities of being an occupied nation led to many lifestyle changes for Norwegians,
so too did these lifestyle changes seemingly affect cancer rates within the country. For instance, as the war progressed throughout the continent, Norwegians were forced to ration their food as a result of large-scale food shortages. It came to be that the majority of the Norwegian population began to catch and grow their own food, and so a regular Norwegian diet during this time frame usually consisted of fresh fish and fresh vegetables. Also, it was extremely difficult during this time for the average Norwegian to come across alcohol or tobacco, so usage of these substances was largely nonexistent. When Norwegian cancer data was analyzed in the years after war, there was a tangible dip in cancer incidences in the generation that lived through the war. This fact has led researchers to believe that the shift in the average Norwegian’s diet and behavior during this period strongly correlated to lower rates of cancer in the nation’s population.

Since the country mandated a nationwide cancer registry in 1952, Norway’s specialists have been able to precisely observe six decades of shifts and progressions in the incidences of specific cancers. Cancer rates have more than tripled in the country since its registry began, but this can partially be attributed to various factors such as the nation’s large populace of elderly citizens and its overall and sustained population growth. It is an unavoidable fact, however, that, since 1953, cancer rates in males have increased by 120 percent, while in females rates have increased by 60 percent. Currently, the most prevalent forms of cancer in Norway are bowel cancer, breast cancer, lung cancer, malignant melanoma, and prostate cancer. In recent years, incidences of lung cancer, malignant melanoma, and prostate cancer have been quickly increasing in Norway’s male population, while incidences of bowel cancer, breast cancer, lung cancer, and malignant melanoma have been increasing regularly in the nation’s female population. In general, incidences of stomach cancer and cervical cancer have been steadily dropping in the nation over the past several years.

Though currently survival rates are high in the country, cancer has been increasing in incidence in Norway recently, and many Norwegian citizens have had cancer over the years. The historic Norwegian Olympian athlete Grete Waitz succumbed to an undisclosed cancer at her home in Oslo in 2011, and also during the same year, the beloved Norwegian actress Wenche Foss lost her battle to breast cancer. More historically, the eminent and critically acclaimed Norwegian opera singer Kirsten Malfrid Flagstad passed away after a short battle with bone marrow cancer in 1962.

Norway is regarded in the international community as having good cancer specialists but conversely of having too few of them. The relatively small amount of specialists that the nation has are forced to work up to 60 hours a week in order to try and see as many patients as possible, and the Norwegian health care system will only become further strained as cancer rates are projected to steadily increase here over the next decade. Nevertheless, there is promising cancer research being conducted in the country at places such as the Institute for Cancer Research at Oslo University Hospital in Oslo and the Department for Cancer Research and Molecular Medicine at the Norwegian University of Science and Technology in Trondheim.

Novartis Group
(Switzerland)

Novartis International is a leading Swiss multinational company with its headquarters in Basel, Switzerland. In 1996, after the merger of Ciba-Geigy and Sandoz businesses, Novartis was established, and in 2003, Novartis consolidated Sandoz’s generic drugs businesses into a single subsidiary and named it Sandoz.

Research and Development Focus

Novartis has almost 200 projects in clinical development, including 144 in its pharmaceutical division, and it has received three U.S. Food and Drug Administration (FDA) breakthrough therapy designations: LDK378 in lung cancer, RLX030 (serelaxin) in acute heart failure, and BYM338 (bimagrumab) in sporadic inclusion body myositis. Its portfolio includes a range of therapies for the treatment of cancer, hematology, pituitary, and other rare diseases. These include Afinitor/Votubia (everolimus); Exjade (deferasirox); Femara (letrozole); Gleevec/Glivec (imatinib mesylate/imatinib); Jakavi (ruxolitinib); Sandostatin LAR/Sandostatin SC (octreotide acetate for injectable suspension/octreotide acetate); Signifor (pasireotide); Tasigna (nilotinib); Zometa (zoledronic acid); and Zykadia (ceritinib). In 2014, the FDA approved the drug ceritinib from a new class of medicines known as anaplastic lymphoma kinase (ALK) inhibitors, which will be sold as Zykadia for non–small cell lung cancer patients who have a specific mutation of the ALK protein for which this drug will be used. The drug was developed based on the understanding of molecular pathways of a disease and its role in designing specific therapies.

In 2014, Novartis Group invested 17 percent of net sales or $9.9 billion in research and development. In pharmaceuticals, research and development investments were $7.2 billion or 22 percent of pharmaceutical net sales, focusing on the areas of greatest patient need and scientific promise. In 2013, Novartis has provided medicine worth $2.1 billion to more than 100 million patients and health education, infrastructure development, and other programs to another 8.1 million people worldwide. The company has 6,000 scientists working in the global research organization. The company recognizes that demographic transition affecting emerging countries and concerns around urbanization and high environmental pollution and chronic and age-related disorders are increasing along with cancer. This poses a serious challenge to public health resources, the economy, and the labor market.

Novartis's global research operations include the Novartis Institutes for Bio-Medical Research (NIBR), which has facilitated the development of the new products for the company. NIBR scientists collaborate with 300 academic and biotechnology partners worldwide to accelerate research and deliver the benefits of scientific progress to patients. Novartis Oncology of NIBR is a specialized part of the company that focuses on precision oncology treatment. Specifically, it aims to discern the genomic basis of cancer evolution and develop drugs to improve patient outcomes based on these
Novartis Group (Switzerland)

factors. They aim to provide precise cancer treatment by identifying pathways where cancer commonly occurs, screening compounds that can potentially impact the pathways, identify biomarkers, and create diagnostic tools that target patients most likely to benefit from therapy. Scientists at Novartis have gained insights into the complete genetic makeup of human cells, and the goal of functional genomics is to understand the function of each gene and its interaction with each of the nearly 30,000 others in the genome. Currently, several microexperiments have been undertaken to unravel each gene in the genome simultaneously. For instance, a single experiment can reveal the genes in high levels of lung tumors but not in healthy lung tissues. This research facilitates the identification of molecular targets and compounds to genetically profile tumors or patients and, in the future, to guide and customize therapeutic choices.

Novartis Oncology conducted a study titled Oncology Personalized Medicine: Global Professional Study (GPS) among 276 health care professionals (HCPs) in seven countries. Results indicated a positive attitude toward personalized medicine in oncology, and four key areas were narrowed down for successful implementation: professional capabilities to have data to support clinical decision-making, care processes that need to be improved with scientific advances in terms of clinicians being able to put them into practice while working with patients, systems and infrastructure in terms of lack of funding as a stumbling block for personalized care, and collaboration in terms of setting up of multisectoral teams vital for the delivery of personal care.

Dr. Ann Aerts was appointed head of the Novartis Foundation for Sustainable Development (NFSD) as of January 1, 2013, after Professor Klaus M. Leisinger, who led NFSD for more than 30 years. In India, the company has established its oldest social venture, Healthy Family (Arogya Parivar, in Hindi) that goes beyond its business interests toward developing a comprehensive approach to health care. Under this program, the company has increased available medicines from 28 to 109 to address the illnesses suffered by Indians living in rural areas. Under the Healthy Family initiative, the company organized 300,000 village health meetings and health camps attended by almost 11 million people.

The Access to Medicine Index, which ranks companies based on the accessibility of their products to the poor, ranked Novartis in 2012. In 2010, Novartis contributed $1.5 billion or 3 percent of net sales through access to medicine programs as well as investment in research targeting diseases that are prevalent in the developing world. They strive to eradicate in the midterm diseases such as malaria that can be prevented and treated to alleviate future suffering. In 2010, Novartis access-to-medicine programs reached 85 million patients in need, of whom 81 million were malaria patients.

Access Versus Monopoly

In India, Novartis suffered a setback owing to a Supreme Court judgment that rejected patent protection for Glivec, a cancer drug from Novartis. This judgment again highlighted the need to balance human interests vis-à-vis corporate profits, which are hidden in the guise of research and development, wherein drugs are modified in small proportions to allow continuous patenting and monopoly. The judgment allowed Indian companies making generic drugs to produce imitated versions of the drug Gleevec, which is spelled as Glivec in Europe and elsewhere. The drug provides treatment for leukemia and costs as much as $70,000 a year in developed countries, whereas in India, generic versions cost $2,500 a year. From the company’s perspective, it narrows down their profit margins, and as a result, they are less likely to invest in research in India.

Novo Nordisk (Denmark)

Novo Nordisk is a company that manufacturers and markets pharmaceuticals in the form of products and services. The company was created in 1989 by Nordisk Insulinlaboratorium and Novo Terapeutisk Laboratorium. Its primary products are equipment and medications for the care of diabetic persons. In addition to this, Novo Nordisk is involved with homeostasis management and hormone research. The company’s mission is to be the best supplier of pharmaceutical products in the world. This is to be achieved through supplying Novo Nordisk customers with high-quality products in regulatory compliance, with reliable delivery performance at a competitive cost, while remaining committed to operating in a clean, environmentally sound, and socially responsible way.

The company is currently researching pulmonary delivery systems for diabetic medications. It is also in the review of autoimmune and chronic inflammatory problems in the body with the intention of reviewing how antibodies may work.

Novo Nordisk’s headquarters are in Denmark. However, over time, the company has expanded to establish facilities and other offices in many places. The company has employed about 38,000 people globally and marketed its products in 180 countries. Novo Nordisk is the largest publicly traded company in the Nordic countries by market capitalization. It is part of the European Federation of Pharmaceutical Industries and Associations (EFPIA). In 2010, the company was ranked by Fortune Magazine 25th among the 100 best companies to work for. In January 2012, Novo Nordisk was named as the most sustainable company in the world by the business magazine Corporate Knights. In January 2014, the company was named on Fortune’s 100 Best Companies to Work For at position 72 within the U.S. state of New Jersey. Novo Nordisk’s B shares are listed on NASDAQ Copenhagen (Novo-B). Its American depositary receipts (ADRs) are listed on the New York Stock Exchange (NVO).

The company has a rich product line. It makes several drugs under various brand names. Even though the company’s main line is diabetes, it has diversified to other areas; therefore, it has drugs covering more than just diabetes. Some of the products from Novo Nordisk are NovoLog, Victoza, Novolin, NovoEight, Levemir, and NovoSeven. The company’s logo, which according to some has been the reason for penetration of markets like Egypt, is and has been since its inception, the Apis bull: one of the sacred animals in ancient Egypt.

The company is actively involved in publicly funded collaborative research projects with other industrial and academic partners. An example of this collaboration in the area of nonclinical safety assessment is the InnoMed PredTox. The company is expanding its activities in joint research projects within the framework of the Innovative Medicines Initiative of EFPIA and the European Commission.

Novo Nordisk is credited for founding the World Diabetes Foundation. The purpose of establishing the foundation was to save the lives of those affected by diabetes in developing countries and supported a United Nations (UN) resolution to fight diabetes, making diabetes the only other disease alongside human immunodeficiency virus (HIV) or acquired immune deficiency syndrome (AIDS) to have a commitment to combat at the UN level. The company was founded primarily to produce products targeting diabetes; therefore, products for the treatment of diabetes account for 85 percent of Novo Nordisk’s business. The company works with the various players in the health care system, doctors, nurses, and patients, for the purpose of developing products for self-managing diabetes conditions.

The company’s business model in the effort to deliver quality products and maintain the legacy established by the pioneers of the company is referred to as the triple bottom line. This model is founded on the belief that a healthy economy, environment, and society are fundamental to long-term business success. Through the model, the company is able to pursue business solutions that maximize
value to stakeholders as well as shareholders. In practice, the model requires people to review different studies: It has to be reviewed based on the responsibility points that come with the program at large. For solutions that meet the three considerations, the company is able to continuously optimize business performance and enhance contribution to the societies in which operations are available.

The company in 2001 conducted a study known as “Diabetes Attitudes, Wishes, and Needs” (DAWN). The study was a global survey on the psychosocial aspects of living with diabetes. The sample size was more than 5,000 persons with diabetes and about 4,000 caregivers. The purpose of the study was to identify barriers to optimal health and quality of life. In 2012, a similar study was done, and it involved more than 15,000 people living with, or caring for, those with diabetes. The second study was conducted in the United Kingdom (UK), and due to the findings of the study, a National Action Plan (NAP) was developed, with a multidisciplinary steering committee, to support the delivery of individualized, person-centered care in the UK. The purpose of the NAP is to provide a holistic approach to diabetes treatment for patients and their families.

Research in Novo Nordisk is a continuous activity. As a result, new and more-advanced products are produced every now and then. Currently, the company has quite a number of products awaiting approval. These include the following:

Tresiba is a type 1 and type 2 diabetes drug, a new-generation basal insulin with ultra-long duration of action of more than 42 hours administered through intravenous injection.

Liraglutide 3 Mg, commonly known as Victoza, is a one-per-day GLP-1 analogue. The drug serves as an adjuvant, intended for combination with lifestyle changes (including diet) to offer sustainable weight loss for people with severe obesity, including those at particular risk of developing diabetes.

Ryzodeg is a drug for persons with type 1 and type 2 diabetes. It is a soluble co-formulation of Tresiba and NovoRapid and is a rapid-acting meal-time insulin.

The board of directors of Novo Nordisk is made up of Goran Ando as the chair of the board as well as the chair of the nomination committee, Jeppe Christiansen as the vice chair, Bruno Angelici as a member, Liz Hewitt as a member, Liselotte Hyveled as a member and employee representative, Thomas Paul Koestler as a member, Anne Marie Kyraneland as a member and employee representative, Helge Lund as a member, Soren Thuesen Pedersen as a member and employee representative, Hannu Ryopponen as a member and chair of the audit committee, and Stig Strobaek as member and employee representative.

In March 2014, the company announced a partnership program to control the development of diabetes in many spaces around the world. The partnership is with the University College of London, the Steno Diabetes Center, and other local partners and health care professionals interested in diabetes.

Nuclear Industry

The nuclear industry is a global enterprise that involves a variety of participants, including companies, industry associations, individuals, and governmental and intergovernmental bodies. The use of nuclear materials has numerous ramifications for public health, including an association with the development of cancer. Nuclear radiation emits subatomic particles in the form of ionizing
radiation that can enter the body and damage DNA and initiate cancer due to cell proliferation.

A Brief History
Henri Becquerel, who was a French physicist and Nobel laureate, discovered radioactivity in 1896. It was quickly recognized that ionizing radiation could adversely affect human health. For example, persons who handled radioactive materials often suffered burns on their hands. Perhaps the most famous case of someone suffering from radiation exposure is Marie Curie, who identified the radioactive element radium and eventually died from leukemia, suspected to be associated with radiation exposure. Furthermore, Wilhelm Roentgen, who discovered X-rays, died from cancer.

Young women in the 1920s were employed to use radium paint to paint the dials of some instruments. Some later develop jaw, bone, and head cancers. The exposure occurred when the women wetted their paintbrushes with their tongues. In addition, miners in an area of Czechoslovakia who were exposed to a pitchblende ore used for isolating radium, polonium, and uranium began suffering from lung problems. Many were later identified as cases of lung cancer, associated with the high radon gas levels in the mine. Since that time, lung cancer has been associated with uranium mining.

Uranium Mining
The nuclear industry is composed of two main segments. The nuclear power industry includes reactor builders and operators. The other segment focuses on mines, nuclear fuel, storage, and waste. This industry segment includes activities such as preparing fuel for use in reactors; management, reprocessing, and disposal of final wastes; and fuel supply.

The nuclear industry works with a radioactive form of the element uranium. Uranium radiation exposure can lead to chemical toxicity, with high levels of exposure leading to kidney failure. Uranium’s radiological toxicity also can lead to an increased risk of developing cancers. It has been difficult to trace cancers definitively with nuclear radiation exposure because these cancers typically occur many years after initial exposure. However, scientists agree that, the higher the exposure levels to radiation, the greater the risk of developing cancer.

Toxicity due to radiation exposure can develop due to breathing air containing uranium dust and eating foods containing uranium. When radioactive rock is pulverized during the mining of uranium, it produces a dust and fine radioactive particles that can be dispersed via wind and water, thus contaminating the air, water, and soil. A potent lung carcinogen is radon gas, which is created by the leftovers, or tailings, from the ground-up rock and effluents (liquid waste) created in the radium mining process, which includes drilling and blasting that have the potential to contaminate aquifers.

The uranium mining process also includes the use of water to control dust and create slurries for extracting the uranium. Contaminants in the tailings can lead to radioactive material occurring in waterways due to leaking and leaching or other mistakes in the mining process. In addition, different organisms, such as bacteria, can lead potentially to radioactive material being transported to areas far from the contaminated sites. Sites containing uranium mining waste products remain radioactive for thousands of years.

Refining, Storage, Transportation, and Nuclear Reactors
Those who work in the segment of the industry dealing with uranium refining or storage typically are exposed to uranium radiation from decay products, although these are considered low-level exposures. However, low-level exposure over a long period of time still can cause health problems, including cancer. In addition, refining and enriching facilities are known to release radioactive particles that have the potential to contaminate nearby populations.

Transporting radioactive materials by rail or truck also poses a threat of exposure if accidents, such as spills, happen and contaminate the surrounding air, water, and soil. A major concern associated with the nuclear industry stems from the operation of nuclear reactors for energy purposes. Although all nuclear reactors release some radioactive substances into the atmosphere, only relatively few studies have looked at the impact on health, including cancer.

One health risk stems from the toxic, spent fuel that nuclear reactors produce. This fuel remains radioactive for thousands of years. Reactors that use heavy water, which contains larger amounts of the hydrogen isotope deuterium than is normally found in water, release radioactive material into the atmosphere, as does the water used to cool the reactors.
These reactors release a carcinogen known as tritium, a radioactive isotope of hydrogen.

A major health concern is how to dispose of the spent fuel created by nuclear reactors. One plan is to bury the waste deep inside the earth. Nevertheless, there is the potential for this type of storage to contaminate both the atmosphere and water.

**Studies**

Various studies have shown a connection between chronic, low-level radioactive emissions from nuclear reactors and cancer. One of the highest concerns revolves around childhood leukemia. Some studies have indicated that the low levels of radioactive material released cannot be connected to cases of childhood leukemia. British studies dating back to the late 1980s revealed a statistically significant elevated rate of leukemia in children who lived within a 10-mile radius of nuclear plants and were under 15 years of age.

Other studies conducted around 15 nuclear power plants in Germany from 1980 to 1990 failed to find such a relationship. However, the studies did show that, within approximately a three-mile radius of reactors, an increase in leukemia occurred in the childhood population. Yet another British study released in 2005 has suggested that childhood cancers may increase in children living near nuclear facilities.

Despite these findings, there are studies that show limited to no risk associated with nuclear radiation and cancer. The National Cancer Institute studied the problem in the 1980s and stated that there was no correlation between cancer death and nuclear power plants. This study was based on the review of more than 900,000 cancer deaths that occurred from 1950 to 1984. Skeptics point out that not everyone who gets cancer dies from it. They also stress that the data gathered has not considered the fact that people move, meaning they can develop cancer in one place due to radiation exposure but end up moving and dying somewhere else.

**Reactor Accidents**

The health care community recognizes that every stage of the nuclear fuel chain is associated with potential human health impacts. In addition, nuclear reactor accidents or meltdowns, a term used to describe what happens when the nuclear reactor’s core is damaged from overheating, can release large amounts of radioactivity into the air. One such accident occurred in the United States at the Three Mile Island nuclear reactor in Pennsylvania in 1979.

Fortunately, studies conducted by the University of Pittsburgh, Columbia University, and others of the Three Mile Island accident showed that only low levels of radiation were emitted. Researchers determined the accident had negligible effects on human health or the environment. However, a far more serious accident occurred in what was then the Soviet Union.

The Chernobyl accident in the Soviet Union in 1986 caused an explosion that sent radioactive gas and dust into the upper atmosphere, leading to dispersion in places as far away as Finland, Sweden, and other parts of Europe. Although the long-term health effects of the accident are still being determined, studies have already linked the accident to the deaths of nine children from thyroid cancer. In addition, researchers have estimated that nearly 4,000 deaths may occur in the future from cancer and leukemia due to the accident, after factoring in cancer survival rates.

Further studies have made dire predictions concerning the future rate of cancer cases and deaths in Europe due to the Chernobyl accident, which already has been connected to 1,000 cases of thyroid cancer alone. In addition, another 4,000 cases of various cancers have been associated with the accident. Overall, scientists believe that approximately 16,000 cases of thyroid cancer and an additional 25,000 cases of other cancers may occur by 2065. Another major nuclear reactor accident due to a tsunami occurred in Fukushima in Japan in 2011. It is still too early to determine the long-term health effects of this accident, with the greatest effects expected to be seen in those who worked at the plant.

**Protection and the Industry’s Future**

Researchers have noted that many of the studies concerned with the nuclear industry, radiation exposure, and its health effects have limitations. Furthermore, studies have produced conflicting results in terms of health effects, including cancer. The nuclear industry stresses that, by far, the amount of radiation produced in the environment by their industry is negligible.
Some industry experts have stated the chance of nuclear core damage at a reactor as being at 1 in 10,000. Nevertheless, a 2003 study conducted at the Massachusetts Institute of Technology (MIT) and titled the “Future of Nuclear Power” noted that the number of nuclear reactors could triple worldwide in the not too distant future. In addition to accidents, there are concerns over terrorist attacks on nuclear reactor sites, which could lead to releases of significant amounts of radiation.

At all stages of the nuclear industry, there are known by-products associated with toxicity and potentially the development of cancers. Because radioactive contamination lasts for thousands of years, any contamination of the environment is, as of this time, considered to be permanent and irreversible. In order to protect populations from cancer and other health effects or exposure to radiation, acceptable limits or exposure have been reduced by various governing bodies over the years.

People are protected from radiation due to the nuclear industry in various ways. Workers in the industry are limited in the amount of exposure time to radiation. In addition, scientists have noted that the intensity of radiation decreases as the distance from its source increases. Shielding via lead, concrete, or water also provides protection from high levels of radiation, which is why radioactive materials typically are stored or handled underwater and by remote-control devices in facilities constructed of concrete or lined with lead. Furthermore, nuclear reactors work within closed systems that feature various barriers to make sure radioactive materials are safely contained.

Concerns about oil supplies and the health effects of fossil fuels such as coal and oil have led to a renewed interest in nuclear power stations. Evolving technologies in the nuclear industry indicate that the industry can operate much safer than ever before. Nevertheless, a 2005 study under the auspices of the National Academy of Sciences (NAS) concluded that there is a carcinogenic effect due to exposure that increases proportionately with dose, especially in the area of leukemia mortality. The report also noted that regulatory controls in the United States may not be strong enough. In 2010, the Nuclear Regulatory Commission asked that the NAS conduct a modern study to determine future research strategies on the effects of radiation exposure from the nuclear industry. Study results will take years to formulate.

Obesity

The advent of technologies and the popularity of high-calorie foods in the 21st century have cultivated a sedentary lifestyle in which human beings engage in less physical activity and consume more calories than before. This has contributed to an unprecedented rise in the number of overweight and obese people in the world. Indeed, obesity has become one of the biggest health problems worldwide. According to the World Health Organization (WHO), obesity has doubled since 1980 throughout the world. In 2008, over 500 million adults suffered from obesity. In the United States, 35.9 percent of adults aged 20 and above are obese. High prevalence rates of obesity have also occurred in Europe. More than 20 percent of adults are obese in the European Union countries. For example, in the United Kingdom, over 25 percent of adults suffer from obesity, which are twice as many as in 1993. A projection suggests that four out of 10 adults in the United Kingdom will be obese by 2030 if existing trends persist. Obesity is not confined to Western countries, as the obesity rate in Asia is also creeping up at a dramatic rate. For example, China’s obesity rate is exploding at about 30 to 50 percent annually.

This phenomenon is not confined to adults. Obesity has more than doubled in children and quadrupled in adolescents over the last three decades. In 2012, over one-third of children and adolescents were overweight or obese. Obesity has become a global epidemic, which could lead to the problematic inflation of multiple health problems, such as diabetes, cardiovascular disease, and hypertension. Moreover, a growing body of evidence indicates an association between obesity and cancer risk of the breast, endometrium, kidney, esophagus, colon, and rectum.

To curb obesity, many antiobesity programs have been conducted by government sectors, civil society, and other stakeholders to encourage a healthy diet and physical exercise. Technology-based preventive strategies have also been implemented in recent years to combat obesity.

Definition and Measurements

Obesity is a condition in which a person has an excess of body fat that significantly increases their risk of ill health. The most common reference of obesity is the body mass index (BMI). BMI is a measure of weight adjusted for height. Specifically, BMI is calculated as weight in kilograms divided by the square of height in meters (kg/m²). According to WHO, a BMI that is between 18.5 and 25 indicates normal weight for an adult 20 years and older; a BMI that is between 25 and 29.9 indicates overweight; and a BMI of 30 or over indicates obesity. (There are international variations in some Asian countries in terms of the cutoff points for BMI.) Although BMI is considered an indicator of body...
Obesity technically measures excess weight rather than excess fat. For clinical purposes, diagnostic imaging such as dual-energy X-ray absorptiometry (DEXA) scanning, computerized tomography (CT), and magnetic resonance imaging (MRI) are usually used instead. DEXA refers to the use of two X-ray beams of different energy levels to develop estimates of bone mineral density, fat-free mass, and fat mass. Additionally, CT and MRI scans are two advanced imaging techniques that offer more precise measurements of body composition, including body fat, muscle, and bone mass. Although these scanning and imaging techniques are more accurate than BMI, they require expensive equipment and cannot be performed without the presence of professional medical personnel.

Causes and Consequences
Obesity can be caused by many different factors. More than 400 different genes play a crucial role in overweight or obesity. People are more likely to suffer from obesity if one or both of their parents are overweight or obese. Other than affecting people's appetite, satiety, metabolism, and body stress, genes could also affect the amount and location of fat stored in the body. Some studies have indicated that apart from genetics, parent-child resemblance in weight status might also be due to the fact that family members share similar food and physical activity habits.

Indeed, most cases of obesity result from unhealthy diet and inactivity. People who eat more high-calorie foods, such as sugary beverages, fried food, and processed meats, tend to have a greater chance of being overweight and obese. Meanwhile, doing little physical activity also contributes to overweight and obesity. Today, with the development of technologies, an increasing number of people are living a sedentary lifestyle. They spend a lot of time watching television or on their computers and smartphones instead of physically exercising. For example, people can easily engage in e-shopping on the Internet instead of walking to the nearest stores to purchase their goods.

The consequences of obesity include two main aspects—physical effects and psychological effects. Obesity contributes to deadly diseases, such as diabetes, cardiovascular disease, stroke, gallstones, and kidney stones. Although the relationship between obesity and cancer is not as clear as that for cardiovascular disease and diabetes, many studies have indicated that obesity is closely linked to several types of cancer. Additionally, obesity may also lead to psychological symptoms such as anxiety, depression, and isolation. Research has revealed that obese people are more likely to suffer from depression than those of healthy weight.

Obesity and Cancer Risk
Longitudinal observations of a large sample are required to examine the association between obesity and cancer. Over the past few decades, epidemiological studies have yielded evidence that increasingly supports the direct link between obesity and cancer. Excess body weight is now widely perceived as a major risk factor and is associated with increased incidence and risks of leukemia and cancers of the esophagus, endometrium, pancreas, thyroid, colon and rectum, kidney, gallbladder, and breast (for women who have gone through menopause). Studies have also pointed to the contribution of obesity to other types of cancer, including cancer of the liver, prostate, and ovaries.

A comprehensive review of findings regarding nutrition, physical activity, and obesity in relation to cancer conducted in 2007 found that a third of over 572,000 cancer deaths were related to obesity. Furthermore, 4 percent of nearly 34,000 new cases of cancer in men and 7 percent of over 50,500 new cases in women in the United States were attributed to obesity. Obesity is further expected to lead to around 500,000 new cases of cancer in the United States by 2030, which will increase the burden on the economy and health care system. Although the percentage of cancer cases that can be attributed to obesity is varied among the different cancer types, the percentage can reach as high as 40 percent for some, such as endometrial and esophageal cancer.

Various biological mechanisms have been proposed and investigated as mediators between obesity and cancer, such as obesity-related hormones, growth factors, and inflammatory processes. Different mechanisms promote obesity-related cancer, particularly at different sites. Excess body fat cultivates an environment that facilitates carcinogenesis. Adipose tissue, particularly abdominal or visceral fat, produces estrogen in excess amounts. High levels of estrogen are associated with some types of cancer such as breast, endometrial, and kidney.
Insulin resistance and adipose tissue dysfunction are mechanisms believed to explain the link between obesity and cancer. Adiposity results in excess release of nonesterified fatty acids, proinflammatory cytokines, and hormones, which triggers the development of insulin resistance. The pancreas compensates for this resistance by producing and secreting more insulin, releasing increased blood insulin levels, or hyperinsulinemia. An emergent body of evidence suggests that chronically high levels of insulin or insulin-like growth factors can promote cancerous tumor growth and cell proliferation in the colon, prostate, pancreas, and breast. Chronic low-grade inflammation has also increasingly been recognized for its modulating effect between obesity and cancer.

Several studies have shown that adiposity affects cancer treatment and therapy, resulting in adverse effects on prognosis. Obesity hinders diagnosis and treatment due to difficulties and uncertainties in surgery, imaging, and chemotherapy dosing, which may lead to poorer outcomes. Excess body mass has been shown to reduce the rate of survival after cancer diagnosis and to increase mortality related to cancer. Obese patients are more likely to suffer from more comorbid conditions and aggressive forms of cancer. Cancer survivors may also be at greater risk of cancer recurrence.

Following the establishment of the link between obesity and cancer, research generally suggests that losing weight will significantly decrease cancer risk. A longitudinal study in the United States that tracked more than 65,000 postmenopausal women found that women who adhered to healthy cancer-preventive lifestyle behaviors experienced lower total, breast, and colorectal cancer risk and cancer-specific mortality. Shedding extra body weight can help reduce inflammation, which may cause cancer.

**Obesity Preventive Strategies**

There are various strategies available to prevent obesity, ranging from personal lifestyle changes to larger societal and structural changes, such as (1) diet and nutrition, (2) physical activity, (3) sleep, and (4) mood control, as well as the role of (5) mass media, (6) technology, (7) parents and schools, and (8) governments.

**Diet and Nutrition**

A balanced and healthy diet is generally recommended as one way to combat the risks and effects of obesity. High-calorie diets are increasingly the norm in developed countries, and it is important for people to be mindful and adopt changes in their food and dietary intake in order to maintain a healthy weight. Healthy nutritional choices include the consumption of more vegetables and fruits, lean protein, nuts, and whole grains. It is also advisable for people to cut down on foods that are high in sugar, saturated fat, refined carbohydrates, and sodium, such as sugary drinks and processed foods. Another factor associated with obesity and cancer is alcohol consumption, which increases the risk of developing several types of cancers in the liver, colon, rectum, throat, and oral cavity. Limiting alcohol intake will help in cancer prevention.

**Physical Activity**

Besides maintaining a nutritious diet, physical activity also influences health. There is strong empirical support for the association between physical activity and a decrease in cancer risk in several sites including lung, breast, prostate, and colon. Regular exercise promotes the maintenance of the body from muscles to joints, as well as psychological well-being. Studies in general show that any uptake of physical activity, or increase in frequency, duration, or intensity, is beneficial for decreasing cancer incidence.

High-intensity physical exercise, such as jogging or running in particular, appears to be most effective in protecting people from the risks of cancer. In particular, high levels of physical activity may help reduce colorectal cancer risk by 30 to 40 percent, and endometrial cancer risk by 20 to 40 percent. Similarly, women who engage in regular, vigorous physical activity have a lower risk of developing breast cancer than women who lead a more sedentary lifestyle. A cohort study of more than 87,000 women showed that weight loss of 10 kilograms (about 22 pounds) after menopause reduced breast cancer risk by 57 percent.

Research indicates that physical activity helps in the maintenance of body mass, energy balance, and metabolism and the prevention of excess body fat. Physical activity also helps to regulate levels of hormones, insulin, and growth factors, which in turn reduce cancerous tumor growth and development. Physical activity may aid in cancer survival in terms of restoring and maintaining energy balance, as well as hormonal and insulin levels. Maintaining regular
exercise after cancer diagnosis has been found to lead to better cancer prognosis and outcomes by increasing survival and decreasing the chances of recurrence. There is a need for further research to determine the optimal levels of physical activity to protect against cancer risk and the extent of the positive impact of physical activity on people of varying body mass indexes.

**Sleep**

Getting adequate, undisrupted sleep is essential in helping the body protect itself from cancer. Increasing evidence suggests that sleep deprivation is linked to obesity. Reasons cited for the link include tiredness curtailing physical activity and overeating because of more waking hours and hormonal imbalance. People who sleep less are also believed to have stronger cravings for unhealthy fatty and sugary foods. Consequently, obesity develops when energy intake exceeds energy expenditure.

Evidence has shown that lack of sleep also affects glucose metabolism and appetite regulation. Sleep deprivation increases the release of the hormone ghrelin and decreases the secretion of the hormone leptin. Ghrelin and leptin are responsible for inducing hunger and signaling satiety, respectively. Thus, a lack of sleep can alter the hormones’ capacity to accurately signal the need for calories, which may then lead to excessive energy consumption and caloric intake.

Several epidemiological studies have shown evidence that support the association between sleep duration and body mass index. This puts people who habitually suffer from sleep deprivation or irregularity at a higher risk of weight gain and cancer. Hence, improving the duration and quality of sleep is vital in warding off cancer-related risk and mortality.

**Mood Control**

Psychological health is closely associated with both obesity and cancer. Studies suggest that psychological stress and obesity may have a reciprocal relationship. Research shows that stress is linked to eating patterns and behaviors, and overeating has been shown to be a coping reaction to stress. People who suffer from chronic stress in their lives are prone to stress-induced eating and often turn to comfort foods that are high in sugar and fat. This may then lead to weight gain and the development of obesity.

Conversely, an observational study conducted in Australia found that the body releases stress hormones such as cortisol after eating, and obese individuals secrete higher levels of cortisol in their bodies after a meal. High levels of cortisol may in turn increase appetite and preference for sugary and fatty foods. Evidence about the mechanism behind the increased release of cortisol in obese and overweight people remains inconclusive. Nonetheless, having excess body fat may lead to greater exposure to the stress hormone cortisol, which is linked to the development of chronic diseases. More research can be done to shed light on possible mechanisms such as hormones that may explain the link between stress and appetite regulation.

Psychological stress is also linked to cancer. While research does not generally support stress as a direct cause of cancer, it may affect the growth and spread of cancerous tumors. Stress may also indirectly influence and lead to poorer outcomes. People may feel a sense of fatality and choose not to pursue proper treatment or turn to risky behaviors such as drug use in response to the emotional and mental pressure. This then affects their chances of survival.

**Role of Mass Media**

The influence of mass media on obesity may be both positive and negative. Researchers caution about media use as a risk factor in the development of obesity from childhood. In particular, television and computer use is believed to encourage a more sedentary lifestyle and curb engagement in physical activity, thus decreasing energy expenditure. Simultaneously, television viewing and computer use may result in excess caloric intake due to snacking. A study conducted with over 2,400 pairs of parents and children found that children who have a television in their bedroom were 1.3 times more likely to be overweight than children who do not. Children who watch more television are exposed to advertisements and product placements for unhealthy food such as fast food, which may alter their food preferences and choices from youth. Unhealthy eating habits that last into adulthood increase the risk of lifetime obesity. Finally, high levels of media use can contribute to obesity by disrupting normal sleep patterns.
On the other hand, the mass media provides a platform for health intervention and communication efforts to encourage desirable behavioral change among people. Public engagement campaigns aiming to reduce obesity among the population, such as promoting physical activity or healthier diet choices, are typically disseminated through the mass media. These campaigns are often strategically designed to target specific groups of people at risk of obesity or developing diseases as a consequence of excess body weight, for example, through the marketing of social norms to motivate uptake of physical exercise. Studies evaluating the effectiveness of campaigns against obesity in Australia, the United Kingdom, and the Netherlands showed they were able to raise public awareness about obesity and its risks and encourage intentions to prevent weight gain. A pilot study in the United States tested a community-based and family-centered intervention aiming to reduce and prevent childhood obesity. Results showed positive improvements in the rate of obesity, uptake of physical activity, regular TV viewing, and dietary intake among children. Parents also felt more empowered in encouraging their children to eat more healthily and engage in physical activity.

Role of Technology
Technology—from television and video games to the Internet and smartphones—has made people, especially children and adolescents, more sedentary. People spend a lot of time on sedentary activities such as texting, using social media, and playing video games instead of physical activities. Thus, technology has been criticized as one of the key causes of obesity.

Technology can be a double-edged sword. Since people are increasingly immersed in the use of technology, high-tech solutions such as exergaming mobile apps and tracking devices have been developed to combat obesity. Exergaming
represents an alternative to traditional exercise, which provides an initial situationally interesting environment such that people must use their bodies instead of just their thumbs to play the video games. Today, there are many ways to participate in exergaming through systems such as the Xbox, Kinect, and Wii Fit. A meta-analysis has revealed that exergaming can reduce individuals' sedentary time and increase their physical activity levels, particularly for children and adolescents. Additionally, many big-name brands have launched a wide range of wireless tracking devices connected to mobile apps to track users' health, fitness, and physical activity data and to create customized plans for users in order to prevent or curb obesity. In other words, some evidence points to the usefulness of exergaming in encouraging and promoting physical activities.

Role of Parents and Schools
Since the foundation for lifelong health is laid in childhood, parents and schools are responsible for curbing the obesity epidemic. Family members usually share similar food and physical activity habits. In order to protect children from obesity, parents can foster children's healthy eating habits by offering healthy foods at home and limiting fried food and sugary drinks. Moreover, parents can limit children's time spent using the Internet or watching television and encourage them to engage in regular physical activities. Some studies have shown that parenting behaviors play an effective role in regulating children's food consumption and engagement in physical activities.

Outside of their homes, children spend most of their time in schools, which suggests that schools play a crucial role in childhood obesity. Schools can offer a variety of healthy foods in the cafeterias to improve children's nutrition. Furthermore, schools can hold regular sports events and offer interesting physical education courses to foster children's interest in sports and to increase their physical activity levels throughout the school day. Some evidence has revealed that school-based obesity prevention programs are effective in helping students achieve healthy weight.

Role of Governments/Policy Makers
According to WHO, governments and policy makers play a pivotal role in public health, including the prevention of obesity. Governments could provide an activity-friendly environment to encourage and promote individuals' daily physical activities, for instance, by constructing more recreation facilities such as parks, stadiums, swimming pools, and gyms, and lowering the cost of sports programs or equipment. Meanwhile, infrastructure such as footpaths and cycling routes could be built to increase individuals' opportunities to be active. To encourage healthy eating, governments could introduce more policies to limit or reduce fast-food consumption.

Strategies to combat obesity require changes in individual lifestyles as well as support from parents, schools, and governments. Furthermore, technology is both a contributing factor to obesity and a means to combat obesity. In the future, more technologies can be developed as approaches to combat obesity.

Occupational Therapy

Occupational therapists and occupational therapy assistants help people to perform their important everyday activities. Occupational therapy practitioners work in more than 70 countries around the world, and the U.S. Bureau of Labor Statistics
estimates there will be more than 145,000 occupational therapy practitioners in the United States by 2022. The largest number of occupational therapy practitioners work in the United States and are represented by the American Occupational Therapy Association (www.aota.org), which has over 50,000 members.

Occupations can be categorized as (1) activities of daily living (ADL) including grooming, toileting and hygiene, sexual activity, swallowing and feeding, bathing, and dressing; (2) instrumental activities of daily living (IADL) including care of others, shopping, meal preparation, driving and community mobility, and home and financial management; (3) rest and sleep; (4) education; (5) work, including volunteer activity; (6) play; (7) leisure; and (8) social participation. Occupational therapy practitioners work with persons across the life span to help them engage and participate in familiar roles such as student, worker, parent, family member, volunteer, hobbyist, and religious participant. Occupational therapy practitioners are experts at analyzing the relationship between the person, the occupation to be performed, and the factors that affect performance such as physical ability, cognitive ability, sensory and perceptual abilities, communication and interaction skills, psychosocial influences, and the environment.

Because persons of any age can have cancer, and because cancer and its treatments can negatively impact a person's ability to perform valued daily occupations, occupational therapy is highly relevant to the comprehensive treatment of persons with cancer. Occupational therapy practitioners work with persons at any point along the cancer care control continuum (e.g., prevention, detection, diagnosis, treatment, and survivorship). Common problems that are addressed by occupational therapy include (1) fatigue, (2) pain, (3) mild to severe cognitive impairment, (4) decreased strength, (5) decreased endurance, (6) visual deficits, (7) motor deficits (i.e., coordination, dexterity, praxis), and (8) decreased mobility.

Impact of Cancer on the Performance of Daily Occupations
Cancer and its treatments, which can include surgery, chemotherapy, and radiation, can negatively impact a person's ability to perform valued daily occupations. Occupational therapy practitioners work with persons at any point along the cancer care control continuum (e.g., prevention, detection, diagnosis, treatment, and survivorship). Common problems that are addressed by occupational therapy include (1) fatigue, (2) pain, (3) mild to severe cognitive impairment, (4) decreased strength, (5) decreased endurance, (6) visual deficits, (7) motor deficits (i.e., coordination, dexterity, praxis), and (8) decreased mobility.

Occupational Therapy Interventions for Persons With Cancer
Common occupational therapy interventions for a person with cancer include analyzing the demands of the occupations to be performed in order to identify gaps in the person's performance capability. These gaps can be closed through intervention at the person's home, in the hospital, in the workplace, and/or in the community. Specific interventions can be categorized by five approaches, which are to (1) create or promote through an intervention

Occupational Therapy Process
Occupational therapy services typically include the following:

- An individualized evaluation, during which the client/family and occupational therapist determine the person's goals through a client-centered approach. Occupational therapy services may include analysis of various environments including the home, school, or workplace.
- Customized interventions to improve the person's ability to perform daily activities and reach their goals. Interventions may include remediation of physical deficits or compensatory strategies to adapt to performance limitations such as the use of assistive/adaptive equipment or adapting the occupation to be performed or elements of the environment. While the person with cancer (i.e., patient) is the center of the evaluation, other persons such as family members, teachers, coworkers, or employers are included in the intervention.
- An outcomes evaluation to ensure that the goals are being met and/or to make changes to the intervention plan.
approach that does not assume any disability is present and can enrich the experiences of the person and the environments in which they perform, (2) establish the skills or abilities of a client that have been impaired or restore skills or abilities which have not yet been developed, (3) maintain performance capacities by providing supports to the client, (4) modify the occupations to be performed by changing task demands or providing supports to the client including techniques to compensate for deficits, and (5) prevent future problems with the performance of occupations by reducing or eliminating barriers and by changing the task or the environment or promoting change in the client.

In addition, occupational therapy practitioners often intervene through the provision of education and training to family members and other persons who provide social or functional support to the client. Occupational therapy practitioners also often assume an advocacy role for their clients or for organizations, communities, or populations at the community and societal levels. A focus on improving and maintaining quality of life is included at all levels.

Ohio State University Comprehensive Cancer Center

The Ohio State University Comprehensive Cancer Center—Arthur G. James Cancer Hospital and Solove Research Institute (OSUCCC–James), commonly known as the James Cancer Hospital, is a 306-bed cancer hospital and research institute located in Columbus, Ohio.

Founded in 1990, the facility is one of 41 centers in the United States to be recognized by the National Cancer Institute as a comprehensive cancer center. The new James Cancer Hospital opened in late 2014, leading to the closure of the original facility. The construction of the new center represents the largest expansion project in the history of Ohio State University.

History
Upon opening its doors in 1990, the James Cancer Hospital became the first freestanding cancer hospital in the Midwest.

The center is named in memory of two Ohioans who dedicated their lives to combatting cancer. The facility originally opened as the Arthur G. James Cancer Hospital in memory of the venerated physician and faculty member in Ohio State’s College of Medicine. James first met prominent Columbus-area real estate developer and philanthropist Richard J. Solove while treating Solove’s father’s thyroid cancer in the late 1950s. The two fostered a friendship and spearheaded an effort to construct the state’s first freestanding facility dedicated to cancer treatment and research. The facility’s research center was renamed the Solove Research Institute in 1999 after Solove bestowed a $20 million donation on Ohio State for cancer genetics research.

The New James
In 2009, the Ohio State University board of trustees approved a $1 billion expansion of the James Cancer Hospital and its medical center facilities, with the help of a $100 million grant from the U.S. Department of Health and Human Services’ Health Resources and Services Administration. The new James Cancer Hospital opened in December 2014 and is dedicated to fostering a new era of interaction...
and collaboration between researchers, doctors, and patients.

The new facility is the third-largest cancer hospital in the United States, with 21 floors, 1.1 million square feet, and 306 inpatient beds, including a 36-bed bone marrow transplant unit. Inpatient floors specialize in treating specific subtypes of cancer, and are staffed by subspecialist multidisciplinary teams of physicians, nurses, and pharmacists. Each room is equipped to provide patients with nearly all of their treatments, bringing an end to multisite and multifacility visits that are often required of cancer patients enduring the advanced stages of the disease. A cancer emergency department is scheduled to open in March 2015.

Inpatient floors will also contain translation research labs, where researchers will work to develop effective, targeted treatments. Past research at the center has ranged from work covering experimental cancer treatments to analysis of molecular carcinogenesis and viral oncology.

The Ohio State University Comprehensive Cancer Center is one of five centers in the United States with approval to offer both Phase I and Phase II clinical trials. The new hospital contains a cancer clinical trials unit dedicated to early-phase clinical trials.

In 2013, the hospital received one of the nation’s most prestigious nursing honors when it achieved Magnet designation as part of the American Nurses Credentialing Center’s Magnet Recognition Program. The center’s achievements, cancer awareness campaigns, fund-raising efforts, and medical staff are profiled in the organization’s quarterly magazine, Frontiers.

The center also includes five specialized medical facilities. Three of the facilities—the Stefanie Spielman Comprehensive Breast Center (SSCBC); JamesCare at Martha Morehouse Medical Plaza, which specializes in hematologic disorders; and JamesCare at University Hospital East, which works to provide home-based care for patients suffering from cancers and blood disorders ranging from colon cancer to melanoma—are located in Columbus. The Gynecologic Oncology at Mill Run facility is in Hilliard, Ohio, and the James Care at Stoneridge Medical Center is in Dublin, Ohio. In 2014, the SSCBC received the prestigious Breast Imaging Center of Excellence designation from the American College of Radiology.

The James Cancer Hospital also has ongoing affiliations with Ohio’s two major pediatric cancer centers, the Ohio State University/Cincinnati Children’s Cancer Consortium and the Nationwide Children’s Hospital in Columbus. The three facilities work together to share research and treatment methods for children.

**Pelotonia**

In 2003, Michael Caligiuri, the director of the OSU Comprehensive Cancer Center and a research physician, cofounded the Columbus-based nonprofit Pelotonia, an annual bike race whose proceeds go directly to research at the center. Caligiuri founded the annual race with friend and cancer survivor Tom Lennox. The two drew inspiration from their participation in a 2008 charity bike race for Boston’s Dana-Farber Cancer Institute. In the years since its founding, Pelotonia has become one of Ohio’s most popular charitable events, helping to raise over $40 million for the center’s research.

The Pelotonia organization’s efforts also include the Pelotonia Fellowship program, which grants $2 million annually to undergraduate, graduate, and postdoctoral students interested in dedicating their scholarship and careers to helping to cure cancer.

**ORIEN Network**

Funds from the hospital’s annual Pelotonia fund-raising drive were instrumental in the founding of its Oncology Research Information Exchange Network, or ORIEN. Established in May 2014 in conjunction with the Moffitt Cancer Center in Tampa, Florida, the network is the world’s largest cancer-research, patient-information, and tissue-sample database. The state-of-the-art system was designed to provide researchers and clinicians with a faster way to match eligible patients to clinical trials and to conduct larger and richer analysis of data for research.

OHSU Knight Cancer Institute

Seventy-seven percent of patients over age 55 years of age will be diagnosed with a type of cancer. Five to 10 percent of cancers are hereditary. A man’s chance of developing cancer is 50 percent and a woman’s chance is 34 percent. Because of the large role cancer plays in worldwide healthcare, the Oregon Health Science University (OHSU) Knight Cancer Institute (KCI) was developed. The Knight Center, founded in 1986, is an international leader in the research and treatment of cancer. This includes advances in melanoma, prostate, breast, and colon cancer, as well as leukemia, lymphoma, gastrointestinal, and stromal tumors. Additional specialty areas are breast, brain, colon, esophageal, gastrointestinal stromal tumor (GIST), head and neck, lung, lymphoma, melanoma, myeloma, myelodysplasia, ovarian, and sarcoma cancers.

Public support and philanthropy provide most of the finances for continued research and treatment of cancer. Nike donated $100 million in 2008, and then pledged to match dollar-for-dollar equal to $500 million, if the Knight Cancer Institute could raise $500 million in its two-year fund-raising campaign. With the original gift of $100 million, the Institute changed its name from the Oregon Cancer Institute to the Knight Cancer Institute. There are additional corporations who provide support to the Knight Cancer Institute. Gert Boyle, Chairman of the Board for Columbia Sportswear, gave $100 million. Other corporate collaborators are Intel Corporation and FEI Co. The money raised goes toward research; patient support services such as wellness programs and patient assistance funds; community outreach for early detection and healthy lifestyles; and education programs.

The mission of KCI is to end cancer and to decrease Oregon State’s cancer death rate to the lowest in the nation. Currently, Oregon has the highest rate of melanoma diagnoses in the nation. At KCI more than 400 clinical trials and more than 1,000 research studies are managed each year. The end results are new cures are discovered, better standards of care are developed, and new treatments and therapies for cancer are found.

The Institute accomplishes its mission by focusing on holistic individualized healing featuring a multidisciplinary team made up of medical, radiation, and surgical oncologists, nurses, pharmacists, physical therapists, social workers, nutritionists, and nurse navigators. Each cancer physician is fellowship-trained in a specialty. This highly skilled team of specialists produces a customized treatment plan, individualized for every patient.
The team meets on a weekly basis to discuss every patient under their care.

Based on Brian Druker’s 1993 discovery that cancer cells can be shut down at the molecular level by disabling the tumor’s ability to grow without harming the body’s healthy cells, each patient’s cancer is targeted based on DNA and the specific cancer. Even the radiation therapy is designed to target only tumor cells. As part of the holistic focus, alternative medicines are offered to heal mind and spirit, otherwise known as personalized cancer medicine.

The Knight Cancer Institute was the first in the region to provide access to the Calypso image guidance system and the stereotactic body radiation system. These treatment options reduce radiation toxicity and side effects. They have the region’s largest bone marrow transplant program offering both autologous and allogenic marrow transplants.

The National Cancer Institute (NCI) was formed by the Cancer Centers Program as part of the National Cancer Act of 1971. The goal of a NCI is to be known as a leader in scientific excellence and the provider of diversity in cancer research. They are to be the major source of new knowledge regarding cancer, its diagnosis, prevention, and treatment. This designation was given to the Institute in 1997. It remains the only NCI within the state of Oregon and the only one between Seattle, Washington, and Sacramento, California.

As a result of the research completed at KCL, standards in cancer care have changed. The Prostate Cancer Program joined the National Cancer Consortium to share the breakthroughs in detection, treatment, prevention, and standards of care for prostate cancer. KCL provided the evidence that established a colonoscopy as the international gold standard of care for the early detection of colorectal cancer.

In 2005, with the aid of the Lance Armstrong Foundation, the Knight Cancer Institute established the first Adolescent & Young Adult cancer program in the United States. The Adolescent & Young Adult cancer program is a rarity in the United States and abroad, offering comprehensive, personalized services for patients between the ages of 15 and 39 years of age. Persons in this age-group have different needs than other cancer patients. Cancer therapy affects education, career, fertility, and many other aspects. In 2011 in the United States, there were 69,212 diagnoses of cancer in this age-group, six times higher than those ages 0 to 14. Leukemia, lymphoma, testicular cancer (germ cell tumors), breast, melanoma, and thyroid tumors are the most common cancers seen in this age-group. Cancer in this age-group is the leading disease-related cause of mortality in the United States.

In an effort to provide better treatment to all of Oregon’s residents, KCL works with local healthcare facilities around the state by providing access to research results and treatment options within the local community. This allows the patients to remain near their homes during treatment.

With the increased demand for beds, the Institute expanded in 2009. It now boasts more cancer beds in one location than any other facility in Oregon. This expanded facility includes specialized areas for bone marrow transplants, hematologic malignancies, and many more. There is a new radiation treatment facility and with additional clinics and more laboratory space, for a total of more than 200,000 square feet of space solely dedicated to cancer research and treatment.

Continuing the societal focus on cancer, KCL is involved in the state’s legislature. In 2009 Senate Bill 316, requiring health insurance plans to provide coverage of routine qualifying clinical trials with copays and cost sharing requirements and limiting the liability of the insurers in the event of adverse effects from the clinical trials, passed.

Oncology Nursing Society

The Oncology Nursing Society (ONS) is a professional association of more than 35,000 members committed to promoting excellence in oncology nursing and to transforming cancer care. The group's mission is to promote excellence in oncology nursing and quality cancer care. The ONS national office is in Pittsburgh, Pennsylvania.

In 1973, a small group of oncology nurses attending the First National Cancer Nursing Conference in Chicago began discussing the need for an organization to support their profession. In 1974, communication regarding a formalized group continued at the American Cancer Society–National Cancer Institute National Conference on Advances in Cancer Management in New York. ONS was incorporated on July 17, 1975, with a charter membership of nearly 500 members.

Since then, ONS has provided a professional community for oncology nurses, developed evidence-based education programs and treatment information, and advocated for patient care, all in an effort to improve quality of life and outcomes for patients with cancer and their families. Together, ONS and the cancer community seek to reduce the risks, incidence, and burden of cancer by encouraging healthy lifestyles, promoting early detection, and improving the management of cancer symptoms and side effects throughout the disease trajectory.

Organization Activities
ONS has more than 230 local chapters throughout the United States and 27 special interest groups, communities of members who share ideas, information, and experiences with others in the same cancer care subspecialty. The society is involved in education and outreach around the world, both to nurses and to interdisciplinary audiences; priority topics for nursing education include chemotherapy and safe handling of cytotoxic drugs, clinical trials, pain control, palliative care, diseasespecific education, evidence-based practice, and leadership development.

ONS is active in health policy, working collaboratively with policy makers, cancer and nursing community advocates, and other stakeholders at the local, state, federal, and international levels to advance legislative and regulatory efforts and integrate the nursing perspective throughout the policy-making process. Society members are encouraged to join programs that connect them to decision makers who are educated on the importance of oncology nursing.

In addition to its annual meeting each spring, ONS offers numerous continuing nursing education programs both in the classroom and online to enable oncology nurses to stay current on the latest cancer treatments and symptom management techniques. ONS is accredited as a provider of continuing nursing education by the American Nurses Credentialing Center's Commission on Accreditation. In 2013, ONS offered 1,567 chemotherapy/biotherapy courses that provided education to 19,161 nurses. In 2014, the in-classroom chemotherapy course was replaced by an online course.

ONS collaborates with the American Society of Clinical Oncology to develop standards for the safe administration of chemotherapy; the original standards were published in 2009, with revisions published in 2011 and 2013. As of December 2012, the society's Putting Research Into Practice (PEP) resources have summarized more than 1,700 studies and provided evidence for 466 discrete interventions for the 20 PEP topics.

Publications
ONS publishes two scholarly scientific journals, Clinical Journal of Oncology Nursing and Oncology Nursing Forum, as well as a news magazine, ONS Connect, all of which are published in both print and online formats and included in indices and databases such as MEDLINE, Cumulative Index to Nursing and Allied Health Literature (CINAHL), and Google Scholar, among others. ONS members
receive all three publications as a membership benefit. The *Oncology Nursing Forum* consistently ranks among the top impact factors of journals in the nursing category as determined by Thomson Reuters. ONS also publishes books, monographs, and other publications for the cancer care community, with more than 70 books in print and between eight and 10 new titles every year. In addition, the society produces patient-oriented books under its Hygeia Media imprint. ONS and Hygeia books are available in print and e-book formats. ONS publications have received awards from the American Society of Healthcare Publication Editors, Association Media & Publishing, the American Journal of Nursing, and numerous other organizations.

The society has a Web site at www.ons.org and is active in social media via Facebook, Twitter, LinkedIn, YouTube, and Pinterest. The national office has a library that is a full member of the National Network of Libraries of Medicine, as well as an archive with project files, photographs, oral history recordings, and other materials of historical significance to ONS and oncology nursing.

**Affiliated Corporations**

ONS has three affiliated corporations. The Oncology Nursing Certification Corporation (ONCC) was incorporated in 1984 for the development, administration, and evaluation of a program for certification in oncology nursing, and has met all standards established by the Accreditation Board for Specialty Nursing Certification and the National Commission on Certifying Agencies. As of April 2014, ONCC offered six certification examinations—Oncology Certified Nurse, Certified Pediatric Hematology Oncology Nurse, Certified Breast Care Nurse, Advanced Oncology Certified Nurse Practitioner, Advanced Oncology Certified Clinical Nurse Specialist, and Blood and Marrow Transplant Certified Nurse.
The Oncology Nursing Society Foundation is a nonprofit, tax-exempt, charitable organization established in 1981 with a mission to support oncology nursing in order to improve the lives of people with or at risk for cancer. Contributions from individuals, ONS chapters, corporations, and foundations enable the ONS Foundation to meet its mission; since its inception, it has provided more than $23 million in funding support for oncology nursing awards, grants, scholarships, and educational initiatives.

ONS:Edge is the for-profit subsidiary of ONS, and is a specialized advisory firm providing marketing communications strategy and execution as well as services such as live events, Web presentations, and market research for pharmaceutical, medical device, and other companies. Its purpose is the transfer of cancer knowledge to oncology nurses in order to improve patient outcomes.

Ono Pharmaceutical (Japan)

Ono Pharmaceutical Co., Ltd. is one of the smaller Japanese pharmaceutical corporations, with 2,858 employees worldwide as of early 2014. In “Medical Care & the Pharmaceutical Industry,” an overview of pharmaceutical corporations’ 2012 sales figures compiled by the Japanese company Astellas Pharma, Ono Pharmaceutical ranked number 13 in Japan.

History and Corporate Philosophy
The precursor to Ono Pharmaceutical was founded by Ichibe Fushimiya in 1717 and sold traditional medicines in Osaka. Ono Pharmaceutical Co., Ltd. was formed in 1947, and the company’s shares were listed on the Osaka Securities Exchange and on the Tokyo Stock Exchange in 1962 and 1963, respectively. Ono completed the world’s first synthesis of prostaglandin (PG) in 1968. In an effort to internationalize, the company opened a London office in 1982, followed by a Seattle office in 1990 and a Seoul office (later Seoul Branch) in 1994. Ono’s offices in the United Kingdom (UK) and the United States were later replaced with Ono Pharma UK Ltd., established in the UK, and Ono Pharma USA, Inc. In 2013, Ono Pharma Korea Co., Ltd. was established in South Korea.

Ono has implemented an environmental self-regulating action plan, which consists of six elements. One element, relations with the communities in which the company is located, includes participating in cleanup activities and striving for the prevention of workplace accidents that involve employees’ injuries. A low-carbon economy plan aims for carbon dioxide emissions in 2020 to be 23 percent less than the company’s emissions in 2005. The company is also working to control chemical substances by reducing its discharge of chemical substances, and aims to reduce its waste disposal in 2015 by 40 percent of the volume disposed in 2010. Within the plan there are also measures to combat air and water pollution and measures for environmental accounting in accordance with the guidelines of the Ministry of the Environment.

Key Products
Based on sales figures for fiscal year (FY) 2012, the best-selling products were Glactiv for the treatment of type 2 diabetes (34.8 billion yen) and Opalmon for the treatment of peripheral circulatory disorder (33.9 billion yen). Other key products include Recalbon for osteoporosis (7.7 billion yen), Onon for bronchial asthma and allergic rhinitis (16.1 billion yen), Foipan for chronic pancreatitis and postoperative reflux esophagitis (8.8 billion yen), Kinedak for diabetic peripheral neuropathy (8.7 billion yen), Staybla for treatment of overactive bladders (6.4 billion yen), Rivastach for Alzheimer’s disease (3.9 billion yen), Onon for bronchial asthma and allergic rhinitis (7.3 billion yen), Elaspol for certain
kinds of acute lung injury (3.9 billion yen), and Onoact for the treatment of tachyarrhythmia during and postoperation (3.7 billion yen).

One key product is related to oncology—a treatment for chemotherapy-induced nausea and vomiting (7.9 billion yen in FY 2012) marketed as Emend in the form of capsules and as Proemend in the form of intravenous injection. The capsule version had been developed solely by Ono in Japan, was launched in December 2009, and has been marketed in Europe and in the United States by Merck & Co. The injection was launched in December 2011.

Ono Pharmaceutical has additional oncology-related candidates within its pipeline of global development projects. The candidate with the development code ONO-4538 (nivolumab) is undergoing Phase III clinical trials for indications such as melanoma, renal cell carcinoma, non–small cell lung cancer, and head and neck carcinoma. Nivolumab is a drug that can block a protein called programmed cell death 1 (PD-1), and is therefore also referred to as an anti-PD-1 immuno-oncology drug. In July 2014, nivolumab was approved for sale in Japan as a treatment for unresectable melanoma.

Ono Pharmaceutical entered into a collaboration with the U.S. company Medarex in 2005, enabling Ono to secure the Japanese rights to nivolumab. Medarex, which had started development of nivolumab for therapeutic use, was later acquired by Bristol-Myers Squibb (BMS). Ono and BMS have since collaborated on several of the trials being conducted by BMS, and the two firms are jointly developing the drug for treatment of renal cell carcinoma.

Research and Development
Research and development (R&D) activities at Ono Pharmaceutical have two distinct characteristics. First, the corporation is known for its active investment in R&D, with R&D expenditures between 30 and 32 percent of sales revenue from 2011 to 2013. This amount is much higher than that of most other Japanese pharmaceutical corporations, such as Astellas Pharma, Daiichi Sankyo, Eisai Co., Ltd., and Takeda Pharmaceutical, which all spent between approximately 18 and 23 percent for R&D during the same period. Second, Ono has organized a compound-oriented R&D process. A library of novel compounds is at the heart of the firm’s research into bioactive lipids and enzyme inhibitors. Ono continuously updates its compound-oriented process and library with technologies that aim to accurately and quickly pinpoint compounds that may be suitable for further development.

Ono applies the concept of open innovation, in the sense that its own original drug discovery methods may be combined with technologies acquired through alliances with Japanese or foreign companies, as well as through collaborations with academic and research institutions. Ono’s research staff is organized into project teams comprised of members from different departments. Drug discovery research is coordinated at the firm’s three Japanese laboratories—the Minase Research Institute, the Tsukuba Research Institute, and the Fukui Research Institute. The Minase Research Institute focuses on medicinal chemistry research and on the properties and efficacy of compounds and formulations. The Tsukuba Research Institute analyzes disease-causing substances and conducts exploratory research for new compounds that can control these substances, as well as focusing on genomics, metabolomics, and pharmacokinetics. Much of the Tsukuba facility’s research is in collaboration with academic and research institutions. The Fukui Research Institute concentrates on issues related to the safety of compounds as well as on mass production and cost reduction for the clinical and commercial supply of pharmaceutical substances.

Oral Cancer, Childhood

Childhood oral cancers are very rare and present normally as benign and sometimes as malignant forms. Although these age-specific cancers differ from many characteristics of adult oral cancers, they are similar in their pattern of onset. Both begin as precancerous regions and then advance to benign or malignant tumors, which are further identified as sarcoma or carcinoma. Sarcoma is a malignant tumor that arises from mesenchymal origin, while carcinoma is a malignant tumor that arises from epithelial origin. Childhood cancers also follow the same TNM staging system as in adult cancers, where T stands for the size of the tumor, N stands for regional lymph node involvement, and M stands for extent of metastasis.

Childhood oral cancers often have symptoms that are nonspecific and different in onset, making detection and diagnosis difficult. On the other hand, cancer types and risk factors for these cancers are very specific and often have additive effects. These conditions are difficult to diagnose because children are not always aware or expressive of changes in their oral cavity. This is especially worrisome considering the need to identify and prevent further tissue overgrowth as early as possible. With time, many complications may occur, especially during sensitive developmental growth periods consistent with the timing of childhood cancers.

Signs and Symptoms
Diagnosis is difficult because the symptoms that children experience are different from those relevant to adult-onset cancers. In this respect, childhood cancer patients may experience analgesia or chronic pain in the oral cavity, neck, or face, sometimes accompanied by ear pain and observable weight loss. These symptoms cause confounding symptoms including continuous sore throat and difficulty in actions that involve opening the mouth while chewing, speaking, and swallowing. At the later end of childhood cancers, adolescents who abuse alcohol and tobacco can acquire red and white patches of tissue and bleeding in the oral cavity. In some cases, these present as continuing lesions in the mouth, neck, or face that do not heal and bleed easily. Additionally, it can be difficult for children to communicate the cause of their discomfort, oftentimes delaying detection, diagnosis, and exacerbating symptoms.

Risk Factors
Cancer occurs most frequently as the result of interactions between a person’s genes and the environment. Among children, previous radiation therapy to treat childhood tumors may increase the risk for oral cavity cancer as well as many other secondary cancers. Additionally, genetic disorders such as Fanconi anemia can also predispose a child to develop oral cancer, as well as other risk factors that increase the rate of cancer occurrence. These additional diseases and conditions include dyskeratosis congenita, a mutation in connexin genes, chronic graft-versus-host disease, epidermolysis bullosa, xeroderma pigmentosum, and human papillomavirus infection. Recently, human papillomavirus has become increasingly common and is associated mainly with an increase in oral cancer incidence among teenage girls.

Cancerous Precursors
Dysplasia is a precancerous tissue that presents as white or gray patches called leukoplakia, or as red, flat, relatively raised areas called erythroplakia, and may lead to cancer. When both of these symptoms are present, the tissue is referred to as erythroplakia. Dysplasias are graded on their microscopic appearance as mild, moderate, and severe. Severe cases may become cancers, while mild conditions have a high chance of full recovery. It is very important to prevent the advancement of dysplasia to cancer, especially in adolescent teens since the most frequent causes of dysplasia include alcohol consumption and smoking, which are highly avoidable.

Benign Tumors
Benign tumors occur within skeletal and smooth muscles and are often surgically removed because
they are unlikely to recur. There are many different types of benign tumors that originate from cells of the mouth or throat. These tumors are not life-threatening and likely do not cause problems since they normally remain within their site of origin. Examples of the more common benign tumors include hemangiomas, hamartomas, and lymphangiomas.

Salivary Gland Tumors
Many salivary gland tumors arise in the parotid gland, with 15 percent of salivary gland tumors arising in the submandibular and other minor salivary glands. The majority of these cancers are benign and can include sialoblastomas, which are usually found within the first few months of birth. Malignant salivary gland tumors generally arise as a result of radiation therapy and chemotherapy, which might have been given to treat primary leukemia or solid tumors. The malignant salivary gland tumors include adenocarcinoma, undifferentiated carcinoma, acinic cell carcinoma, and mucopepidermoid carcinoma. As long as these tumors are treated with complete surgical removal in combination with radiation and chemotherapy, these patients’ prognosis is good.

Malignant Tumors
Malignant oral tumors in children, although rare, usually occur as lymphomas and sarcomas. Oral squamous cell carcinoma in children, unlike adults, is rare. However, if oral squamous cell carcinoma is found in the adolescent population, the affected should be screened for Fanconi anemia, which increases the risk of some cancers in this age-group.

Treatment
Cancer treatments are available in the form of surgical intervention, radiation therapy, chemotherapy, or a combination of these therapies. Treatment of these cancers depends on the specific site of incidence, as well as the advancement of the overgrowth defined by factors characteristic to the tissue’s staging classification including extent/depth of invasion, tumor size, and presence/absence of regional lymph node metastasis. Treatment interventions are different for benign and malignant tumors. Since benign tumors are not hazardous, they are normally removed through surgical procedures. On the other hand, malignant tumors are treated by an individualized, patient-centered approach including a combination of surgery, chemotherapy, and/or radiation therapy.

Complications
Childhood oral cancers normally overlap with developmental growth periods, which makes them especially sensitive to the adverse effects of radiation therapy. This combination results in developmental changes including microdontia (smaller than normal teeth), early loss of teeth, and dental root abnormalities and xerostomia (dry mouth), which directly results in an increased risk for dental caries. Further, surgical procedures may remove too much tissue or radiation therapy may lead to tissue necrosis, both of which ultimately decrease muscle function such as trismus (limited mouth opening) and complicate functions including eating, chewing, and swallowing.

After removal or treatment of cancerous tissue, cancer patients are at an increased risk of developing secondary cancers. More specifically, these patients are at an increased risk of secondary head and neck cancers including salivary gland tumors, thyroid cancers, and cancers of the bone. In children, this threat is especially increased because they will live longer than average cancer survivors and will, therefore, have an increased risk of developing these cancers. Especially in the oral cavity, where turnover rate is high, the risk of developing cancer is greater.

Further Readings
Oral Cavity Cancer, Lip and

The oral cavity, similar to most of the human body, is lined and defined by connective tissue and is highly susceptible to cancer. The oral cavity is a region encompassed by the lip anteriorly, below and posteriorly by the circumvallate papilla (taste buds) of the tongue, and above the junction of the hard and soft palate superiorly. The lateral borders of the oral cavity are the anterior tonsillar pillars and glossotonsillar folds, which is where the oral cavity meets the oropharynx. The oral cavity contains many sub-sites that differ in cancer prevalence including the lip, tongue, floor of the mouth, lower alveolar ridge and retromolar trigone, upper alveolar ridge and hard palate, and buccal mucosa.

Cancers begin as precancerous regions and then advance to benign and malignant tumors. When a tissue is identified as a malignant tumor, it is further subclassified by two main suffixes—sarcoma or carcinoma. Sarcoma is a malignant tumor that arises from malignancies of mesenchymal origin, while carcinoma is a malignant tumor that arises from malignancies of epithelial origin. Cancers are recognized on a basis of stage 0 through 4 classification, in which larger numbers indicate more advanced cancers.

Cancer treatments include surgical interventions, radiation therapy, chemotherapy, or a combination. Treatment of these cancers depends on the advancement of the cancerous tissue and is defined by characteristics including extent/depth of invasion, tumor size, and presence/absence of regional lymph node metastasis.

Cancer occurs most frequently as an interaction between a person’s genes and the environment. Additionally, risk factors may increase the rate of cancer occurrence. In an attempt to reduce risk factors and decrease the likelihood of disease assembly, cancer prevention focuses on adjusting patients’ environmental and lifestyle factors.

Cancerous Precursors
Dysplasia is a precancerous tissue that presents as white or gray patches called leukoplakia, or as red, flat, relatively raised areas called erythroplakia, and may lead to cancer. When both of these symptoms are present, the tissue is referred to as erythroleukopla. Dysplasias are graded on their microscopic appearance as mild, moderate, and severe. Severe cases may become cancers, while mild conditions have a high chance of full recovery. It is very important to prevent the advancement of dysplasia into cancer, especially since the most frequent causes of dysplasia, including alcohol consumption and smoking, are highly avoidable.

Benign Tumors
Benign tumors occur within skeletal and smooth muscles and are often surgically removed because they normally remain within their site of origin. There are many different types of benign tumors that originate from cells of the mouth or throat and are not life-threatening.

Cancer Prevalence
Within the oral cavity, cancer within various sub-sites occurs at different prevalence rates and manifests numerous disease advancements. Subsites that require focused attention include the floor of the mouth, oral tongue, buccal mucosa (cheeks), and lip. Cancer of the floor of the mouth has tendencies to be locally invasive. Advanced forms of this cancer invade the bone of the mandible and metastasize to the lymph nodes. Cancer of the oral tongue is the
most common subsite for cancer in the oral cavity and is associated with the worst prognosis compared to other subsites. On the other hand, cancer of the buccal mucosa has the worst survival rate and highest probability to recur in the same region. This cancer is often found in more advanced stages because it is misdiagnosed as an infection or trauma. Cancer of the lip is usually characterized as squamous or basal cell carcinoma and is often diagnosed at early stages because the cancer is freely visible.

Squamous cell carcinoma is the most common among cancers of the oral cavity. First, these cancers are classified as carcinoma in situ, which means it is only present in epithelial cells (the outermost layer of cells). These cells then migrate to deeper layers of the tissue and are considered invasive. Additionally, the location of infection is crucial. For example, squamous cell carcinoma originating in the upper lip has a worse prognosis than in the lower lip.

**Symptoms**
Cancer patients may experience analgesia or chronic pain in the oral cavity, neck, or face, sometimes accompanied by ear pain and observable weight loss. These symptoms cause confounding symptoms including continuous sore throat and difficulty in actions that involve opening the mouth while chewing, speaking, and swallowing. Adults who abuse alcohol and tobacco can also acquire red and white patches of tissue and bleeding in the oral cavity. In some cases, these present as continuing lesions in the mouth, neck, or face that do not heal and bleed easily.

**Treatment**
Treatment of oral cancers differs based on progression of the tumor and is mainly divided into early (stages I and II) and advanced (stages III and IV). Surgery is preferred over radiation therapy for early cancers because it preserves more functional tissue. Radiation therapy is suggested to patients who have advanced stages of cancer, where surgery would be too invasive and result in severe loss of function. Ultimately, treatments combining surgery with concurrent radiation therapy showed the best results for patients with advanced cancer.

There are some complications that arise from surgical intervention and radiation therapy. Surgical interventions affect speech and swallowing functionality; however, these deficits can be reduced by ideal reconstruction of tissues and avoided in early-stage cancers. Some complications can occur during surgery, including infection, aspiration, bleeding, fistula, and flap loss. On the other hand, radiation therapy results in complications associated with radiotherapy toxicities, such as secondary cancers, and dry mouth, which continues posttreatment.

**Risk Factors**
Risk factors include environmental influences, hygienic tendencies, consumption patterns, and predispositions of some infections and genetic factors. Exposure to influences, such as radiation, and materials commonly found in the workplace, such as asbestos and pesticides, increases the risk of cancer in the oral cavity. Furthermore, exposure to irradiation for tumor intervention has been associated with salivary gland tumors and squamous cell cancers.

Poor oral hygiene and periodontal disease have also been linked to oral cancers. Further, consumption of tobacco has been found to be a causative factor for oral cavity cancer. Even light alcohol consumption has been associated with an increased
risk of oral cancer, specifically oropharynx cancers. Additionally, consumption of preserved meats with high levels of added nitrates has shown increased risk of nasopharyngeal carcinoma. Viruses and genetic predispositions can also increase the risk of cancer occurrence. For example, human papillomavirus (HPV) and Epstein-Barr virus (EBV) have been associated with squamous cell carcinoma and nasopharyngeal cancers, respectively. Genetic factors also increase the risk of oral cancer, as seen between Fanconi anemia and squamous cell carcinoma. Prevention of cancer involves avoiding or decreasing exposure to these risk factors.

Organisation of European Cancer Institutes

The Organisation of European Cancer Institutes (OECI) had its origins in the desire and recognized need for collaboration and cooperation among the leading cancer research and treatment centers across Europe. The organization was initially modeled after the Association of American Cancer Institutes, founded in 1959, which proved to be an efficient mechanism for bringing together the most current knowledge and practices from cancer research and treatment centers across the United States. Other regional cancer organizations had also been formed in Latin America, Asia, and the Middle East; thus, a European organization was seen as part of a necessary trend toward making the fight against cancer an international one.

Over the course of the last half century, all of these regional cancer organizations have worked collaboratively in order to stimulate oncology research and improve the quality of treatment and care for cancer patients worldwide. The benefits of such collaborative efforts have been many, including more efficient and far-reaching research methods, multicenter cancer research studies and clinical trials, speedier development and approval of cancer medications, and overall improved diagnosis and treatment for cancer patients as well as lower mortality rates for various types of cancer.

Origins
Prior to the founding of the OECI, the many cancer institutes that existed in Europe were local organizations with their own histories and traditions, languages, and economic and political problems. This fragmentation caused many difficulties for researchers, physicians, and patients who sought...
the most up-to-date information about and treatments for cancer. The need for more cooperation in the fight against cancer was apparent to many in the field. A few international agencies dedicated to the fight against cancer did exist during the first half of the 20th century.

One of the most prominent was the Union for International Cancer Control (UICC), and it was under its auspices that the idea of the OECI was first conceived and implemented. In 1977, Pierre Denoix, then president of the UICC, called a meeting of leading European cancer institute directors to celebrate the anniversary of the Cancer Research Institute in Vienna. Denoix told his audience of more than 60 leading oncology experts from all over the world that he wanted the UICC’s Committee on International Collaborative Activities (CICA) to develop a plan to promote more communication and cooperation between the world’s cancer centers and institutes. His idea was enthusiastically supported by those attending, and the CICA members—six cancer institute directors from Eastern and Western Europe—began mapping out a framework for the OECI. The next year their plan was presented to members of the UICC’s Business Committee who were meeting at the 12th International Cancer Congress in Buenos Aires. In May 1979, a second meeting of the European Directors of Cancer Institutes was held in Dubrovnik, Yugoslavia, and the OECI was formally established.

The requirements for membership in the Organisation of European Cancer Institutes are fairly simple. A cancer institute wishing to become a member has to be located in Europe and has to follow a multidisciplinary approach to cancer. At the Dubrovnik meeting, an executive board for the OECI was formed and it set up two committees—a program committee and a membership committee—to develop a mission statement and guidelines for future activities. From the beginning, the OECI decided to link its activities to those of the UICC in the belief that both entities would benefit from increased collaboration between themselves and with other cancer organizations around the world. However, the OECI has developed its own unique collaborative programs and activities while maintaining ties with other regional cancer groups and with its sister organization, the Association of American Cancer Institutes.

Organization and Activities
The structure and organization of the OECI have undergone some changes since its founding in 1979. Originally composed of nine working groups and an executive board, the OECI was reorganized in 2005 when it was designated a European Economic Interest Grouping (EEIG). The EEIG designation provides a business and legal framework for the OECI and enables it to operate within a unified set of regulations without having to adapt its policies and procedures to the laws of individual European countries. The OECI remains a nonprofit, nongovernmental entity, but as an EEIG its operation has been streamlined, and coordination of its research and other projects has become more efficient and therefore more effective.

There are now six working groups within the OECI: accreditation and designation, biobanking and molecular pathobiology, communication and dissemination, cost benefit, palliative care, and Central and Eastern European countries. The last two are currently under development, but the others are fully operational. The accreditation group is responsible for developing assessment tools to evaluate European cancer centers that apply for designation as comprehensive cancer centers. As of 2012, 10 centers had gone through the accreditation process and five have been designated comprehensive cancer centers. The communication and dissemination working group oversees all forms of communication both within the OECI and between it and other cancer centers worldwide. In 2010, the OECI was officially designated a publishing entity and now produces books, pamphlets, and scholarly articles in its online journal eCancermedicalscience.

Perhaps the most important working group within the OECI is the biobanking and molecular pathobiology group. Under its guidance, a number of activities and platforms have been established to further cooperation and collaboration in cancer research throughout Europe and worldwide. For example, using EuroCanPlatform, developed with funding from the European Commission and various European ministries of health and research, the OECI has established TuBaFrost, a digital repository of tumor samples collected, catalogued, and made available to researchers through an open access database. START is another project sponsored and developed through the OECI. A state-of-the-art online database of information about
various topics relating to cancer, START has links to information on cancer for both professionals and the general public.

Oropharyngeal Cancer

The word oropharynx describes the middle part of the throat in the oral cavity that includes the base of the tongue, the soft palate, the tonsils, the side and back wall of the throat, and the epiglottis. Patients with oropharyngeal carcinoma, or cancer that starts in the oropharynx, may present with a persistent sore throat, sore tongue, earaches, pain with swallowing, changes in voice quality, hoarseness, and enlarged lymph nodes, although some patients do not have any signs or symptoms. Historically, oropharyngeal cancer was grouped together with other squamous cell carcinomas of the head and neck due to similar characteristics and risk factors including alcohol and tobacco use. Recently, with the discovery of human papillomavirus (HPV) involvement in oropharyngeal cancers, oropharyngeal carcinoma (OPC) has been divided into HPV-positive and HPV-negative subtypes. Although tobacco use is still the leading cause of oropharyngeal carcinoma in the world, HPV is believed to be the leading cause of OPC in many developed countries. HPV-negative OPC is mostly associated with older age and alcohol and tobacco use, and its incidence is declining in the United States as tobacco use becomes less prevalent. HPV-positive OPC (HPVOPC) is associated with a greater number of sexual partners and is becoming more prevalent in the United States. These subtypes differ in presentation, gene expression, prognosis, and management.

HPV Status and the Classification of Oropharyngeal Carcinoma

The presence of HPV infection is an important clinical feature of OPC, as it often drives the presentation, prognosis, and management of patients with oropharyngeal carcinoma. HPVOPC usually presents in younger patients of higher socioeconomic status, while HPV-negative OPC presents in older patients with a history of smoking and/or alcohol use. Worldwide, approximately 65 percent of oral cavity cancer and 66 percent of pharyngeal cancers can be attributed to tobacco smoking, although these rates are higher in developing countries and lower in developed countries. Recently, HPV-DNA was found in two out of three cases of OPC in the United States, implicating it as the leading cause of OPC in the United States as well as in other developed countries. HPVOPC has a significantly better prognosis, with the three-year survival rate for patients with HPVOPC being 82.4 percent, compared to only 57.1 percent for those with HPV-negative OPC.

The primary lesion in HPVOPC is usually smaller, located in the tonsils or at the base of the tongue, and has more advanced lymph node involvement. Histologically, it is composed of nonkeratinized, poorly differentiated cells. HPV-negative OPC can be found anywhere in the oral cavity, oropharynx, hypopharynx, or larynx and is composed mostly of keratinized epithelium. The human papillomavirus contains two oncogenes, E6 and E7, which inhibit
the tumor-suppressor genes p53 and Rb, respectively. The inhibition of Rb leads to increased p16 expression, a feature unique to HPVOPC. HPV-negative OPC, on the other hand, is associated with an increased epidermal growth factor receptor gene copy number.

The leading cause of mortality in survivors of head and neck squamous cell carcinoma (SCCHN) is the development of second primary malignancies (SPMs), which may develop synchronously or metachronously as the original lesion. The etiology of SPMs in SCCHN has experienced a significant change over the past 30 years. In the late 1970s and early 1980s, oropharyngeal cancer carried one of the highest risks of a synchronous SPM among SCCHNs. However, since the early 1990s, there has been a gradual but significant decrease in the risk of synchronous SPMs in OPC, while the risk has remained steady in other head and neck SCCHNs. This decreased risk coincides directly with the increased prevalence of HPVOPC, leading researchers to believe that HPV-positive OPC is much less likely to present with synchronous SPMs. This may directly contribute to the improved prognosis of HPVOPC compared to HPV-negative OPC.

Treatment of Oropharyngeal Carcinoma
Due to its nature and location, a physician must take into account many factors when considering the treatment for OPC; these include stage, grade, location, and HPV status of the carcinoma. In the past, low-stage OPC was generally treated by a combination of surgery and radiation therapy, but radiation therapy alone is now preferred due to the high number of complications affecting speech and swallowing. Radiation therapy alone in low-stage OPC has comparable locoregional control and survival rates as surgery and radiation with lower rates of serious complications. Among OPC subtypes, HPVOPC is more sensitive to radiation therapy and is linked to improved outcomes. The advance of robotic surgery in recent years has led to a renewed interest in surgical treatment of low-stage OPC. Early studies reveal promising findings regarding functional and quality-of-life outcomes, although further studies are needed to determine an advantage over radiation therapy alone.

In more advanced disease (lymph node involvement, large tumor size, or invasive disease), survival is improved with the use of a chemotherapy regimen in addition to radiation therapy. The chemotherapy drug cisplatin administered concurrently with radiation therapy is generally considered the standard of care. With the revelation of HPV involvement in OPC, and the improved prognosis of HPVOPC, there is interest in tailoring therapy to the HPV status of OPC. Due to the comorbidities associated with high-dose chemotherapy and radiation therapy, ongoing clinical trials are studying the deintensification of chemotherapy and intensity-modulated radiation in treatment of HPVOPC. Researchers are hoping to maintain the efficacy of treatments while reducing morbidity and improving long-term mortality.

A 2006 trial revealed a significant improvement in the treatment of SCCHN with the addition of cetuximab (an epidermal growth factor receptor inhibitor) to radiation therapy. Although the HPV status of patients in the trial is not available, patients who benefited most from concurrent cetuximab therapy were younger, had primary oropharyngeal involvement, smaller primary tumors, and more extensive lymph node involvement, factors all indicative of HPVOPC. Subsequent trials studying cetuximab therapy must include the HPV status of oropharyngeal carcinomas to confirm that the response to treatment is related to HPV infection.

As HPV-positive OPC has become more prevalent over the past three decades, the prognosis of HPV-negative OPC has gradually improved. However, this has obscured the lack of improvement in the treatment of advanced HPV-negative OPC. Locoregional failure is the most common cause of failure of combined chemo- and radiation therapy. Novel therapies specific to HPV-negative SCCHN are currently being studied. A trial studying the use of the chemotherapy drug nimorazole in addition to radiation therapy shows improved survival specific to patients with HPV-negative SCCHN.

Conclusion
Although oropharyngeal carcinoma in humans has been a known pathology since the introduction of tobacco to the Western world, the recent differentiation of HPV-positive and HPV-negative OPC provides an opportunity for potential breakthroughs in both mechanism of disease and treatment. Researchers and physicians together will continue
Ovarian Cancer, Childhood

Ovarian cancer is the seventh of the 18 most common cancers in women worldwide. The global five-year prevalence of ovarian cancer is 22.6 per 100,000 people. Ovarian cancer is normally misdiagnosed or diagnosed late because there are often no symptoms at its early stages of development. With appropriate treatment, ovarian cancer can be contained or survived without further incident, as research has shown that the five-year survival rate for ovarian cancer is 30 to 50 percent.

Unlike the majority of ovarian cancer in adult women, which usually emerges in the form of epithelial carcinomas that begin in the cells on the surface of the ovary, childhood ovarian cancer emerges as a malignant germ cell tumor (GCT), a neoplasm derived from primitive embryonic gonad germ cells that begins formation in the egg cells of the ovary. Although epithelial tumors compose approximately 90 percent of ovarian tumors in adults, these are rarely seen in children. Rather, GCTs are the most common ovarian tumors in children and young women, composing about 70 percent of all cases. Ovarian GCTs compose 15 to 20 percent of all ovarian neoplasms and are the second-largest group of ovarian neoplasms. Overall, less than 5 percent of ovarian cancers originate as germ cell formations. Incidence of GCTs decreases as the patient’s age increases.

In children, ovarian tumors (or pediatric ovarian tumors) usually occur at birth or in girls’ early adolescence. The cause of these tumors is unknown; however, having certain inherited and nonhereditary disorders can increase one’s risk of developing germ cell tumors. A common noninherited syndrome known to be related to ovarian cancer in children is Ollier disease, a disorder of the skeleton; other inherited syndromes known to be linked to ovarian cancer in children include pleuropulmonary blastoma (PPB) and multinodular goiter (MNG). Epithelial tumors in children have the same morbidity and mortality as in adults.

Epithelial tumors can be benign or malignant; the majority of ovarian tumors in children are benign because the malignancy level decreases as the ovary matures and grows. The most common malignant ovarian tumors in children are dysgerminomas, accounting for 24.5 percent of all cancerous childhood ovarian tumors.

Seven percent of dysgerminomas are found in children less than 10 years old, while 34 percent are discovered in children between 10 and 19 years old. Another type of GCT common in children is immature teratomas, which constitute 28 percent of GCTs and 19.7 percent of childhood ovarian cancers; there are also yolk sac tumors (composing 7.2 percent of ovarian cancers in children), primary choriocarcinomas (0.9 percent), mixed germ cell tumors (8.6 percent), sex-cord stromal cell tumors (17 percent), and surface epithelial-stromal tumors (7 percent).

Symptoms and Treatment

There is usually about a three- to four-month delay in the clinical onset of ovarian cancer in children and the diagnosis of the disease; this is a result of...
Ovarian Epithelial Cancer

the variety of symptoms that can be experienced. Observed symptoms vary depending on tumor type, rapidity of tumor growth, tumor location, or degree of malignancy, among others. However, pain or mass in the abdomen are the most common symptoms in children. Tests that can be conducted to diagnose and stage ovarian cancer include blood tests, physical examination, computed tomography (CT) scan, ultrasound, and biopsy, among others. Laparotomy is often conducted for both diagnosis and treatment.

Treatment options for ovarian cancer in children, which include surgery, radiation therapy, and combination chemotherapy, depend on where the tumor is located, type of tumor, and level of malignancy, among other factors. If the tumor has spread beyond the ovary, a total hysterectomy, bilateral salpingo-oophorectomy, appendectomy, and omentectomy need to be performed. However, if the tumor has not spread, unilateral salpingo-oophorectomy with a biopsy of the opposite ovary can be done. It is recommended that treatment options be individualized in order not to harm the reproductive potential of the child later in life.

It is difficult for researchers to obtain tissues for study purposes due to the uncommon nature of childhood ovarian cancer; thus, treatments have mostly been performed on mouse models. Further, a lack of funding for childhood ovarian cancer, and all childhood cancers, greatly limits research advancements. Nevertheless, recent improvements in research have led to a better understanding of the causes of ovarian cancer in children. One of the discoveries is that the presence of a genetic material from a Y chromosome is necessary for a germ cell to be cancerous; however, how this leads to ovarian GCT is still not known. Thus, more research and funding are essential.

Ovarian Epithelial Cancer

Ovarian epithelial cancer is a type of ovarian cancer that develops when cancerous cells form in the tissue covering the ovary. It accounts for about 75 percent of all ovarian tumors and about 90 percent of all ovarian malignancies. The global incidence of ovarian epithelial cancer varies greatly; Scandinavia, Israel, and North America have the highest incidence of the disease, while the lowest incidence rates are seen in developing countries and Japan. The five-year survival rate for the disease rose from 37 percent in the 1970s to 45 percent in the 1990s and early 2000s.

As is the case with ovarian cancer in general, the common risk factor for ovarian epithelial cancer is family history of ovarian or breast cancer;
family history accounts for about 5 to 10 percent of all cases of ovarian epithelial cancer. Specifically, women with at least one first-degree relative (mother, sister, or daughter) or at least one second-degree relative (grandmother or aunt) with ovarian cancer are at higher risks of ovarian epithelial cancer. Other risk factors include environmental and dietary factors including use of talcum powder that has asbestos, a high-fat diet, consumption of lactose, delayed childbearing, late menopause, and early menstruation, among others.

In the United States, since the 1970s talcum products for use in the home have been required by law to be asbestos-free; this requirement is based on the relationship between asbestos and ovarian cancer risks. Factors known to reduce a woman's ovulation cycle, including the use of oral contraceptives, breast-feeding, and multiple pregnancies, are also known to reduce the risk of ovarian epithelial cancer.

Women at high risk of developing ovarian epithelial cancer can undergo a procedure called prophylactic oophorectomy to have healthy ovaries removed so they do not become cancerous. Ovarian epithelial cancer is usually diagnosed in women of advanced age (median age is 63); between 3 and 17 percent of women 40 years old or younger are diagnosed with the disease.

Two main hypotheses have been advanced to explain occurrences of ovarian epithelial cancer. First is the incessant ovulation hypothesis, which holds that repetitive damage and repair of the ovarian surface as a result of continuous ovulation eventually leads to mutations in the epithelial cells. The other is the gonadotropin theory, which maintains that excessive stimulation of the gonadotropin strain the ovarian surface and leads to epithelial cell mutation.

Characteristics and Symptoms
Ovarian epithelial cancer can spread to other parts of the body through tissue, the lymph system, or the blood. Its histological classification (i.e., the type of tissue from which the cancer originates) includes serous cystomas, mucinous cystomas, endometrioid tumors, and clear cell tumors, among others. Each of these is further classified as benign, malignant (invasive), or borderline (low-malignant potential). The majority of ovarian epithelial cancers are benign (not cancerous); these include serous adenomas, mucinous adenomas, and Brenner tumors. The cancerous ones begin in the tissue that lines the ovaries, and about 70 percent of cancerous epithelial tumors are diagnosed late.

Ovarian epithelial cancer can be recurrent (meaning that it has come back) or persistent (meaning that it did not go away after treatment). Ovarian epithelial cancer does not show symptoms during the early stages. Common signs include pains or swelling in the abdomen; pain in the pelvis; and having gas, bloating, or constipation.

Detection and Treatment
To find out its level and specific location, ovarian epithelial cancer is normally staged through surgery. Blood tests to measure one's cancer antigen (CA 125) level are required as a follow-up test and to restage the cancer. A higher CA 125 level points to a higher likelihood of ovarian epithelial cancer; however, a negative CA 125 level does not indicate absence of the disease. Thus, CA 125 levels are used with histologic diagnosis to determine the presence of ovarian epithelial cancer.

The standard treatment for ovarian epithelial cancer includes surgery, radiation therapy, and chemotherapy; more treatment options are being tested through clinical trials. Treatment options may depend on the stage of the cancer and whether the cancer is recurrent or persistent. Research has shown that about 80 percent of ovarian epithelial cancer patients will relapse/recur after first-line platinum-based and taxane-based chemotherapy/treatment; thus, after completing treatment patients are closely monitored with follow-up CA 125 tests at intervals of one to three months.

When detected early, ovarian epithelial cancer survival has improved, given empirical optimization of chemotherapy combinations and surgery. Nevertheless, ovarian epithelial cancer is the fifth-leading cause of cancer-related deaths in the United States.

Ovarian Germ Cell Tumor

An ovarian germ cell tumor is a disease caused by tumors developing in the egg-producing cells. Ovarian germ cell tumors are rare and account for about 2 to 3 percent of all ovarian cancers; 3.7 per one million women are affected annually. Most germ cell tumors are benign (noncancerous), but some are malignant (cancerous); they can be recurrent (if the tumors return after initial treatment) or persistent (if the tumors did not go away after treatment). Cancerous germ cell ovarian tumors occur mostly in teenagers and young women in their 20s and often affect only one ovary.

Unlike the majority of ovarian cancer in adult women, which usually emerges in the form of epithelial carcinomas that begin in the cells on the surface of the ovary, childhood ovarian cancer emerges as a malignant germ cell tumor (GCT), a neoplasm derived from primitive embryonic gonad germ cells that begins formation in the egg cells of the ovary. Although epithelial tumors account for approximately 90 percent of ovarian tumors in adults, these are rarely seen in children. Rather, GCTs are the most common ovarian tumors in children and young women, composing about 70 percent of all cases. Ovarian GCTs compose 15 to 20 percent of all ovarian neoplasms and are the second-largest group of ovarian neoplasms. Overall, less than 5 percent of ovarian cancers originate as germ cell formations. Incidence of GCTs decreases as the patient’s age increases.

There are different types of ovarian germ cell tumors; each behaves differently and is treated differently. The World Health Organization (WHO) has classified ovarian germ cell tumors into dysgerminoma, endodermal sinus, teratoma, choriocarcinoma, embryonal carcinoma, polynembryoma, mixed GCT, and combo GCT/stromal. Of these, dysgerminoma is the most common, accounting for 40 to 50 percent of ovarian germ cell tumor cases; about 15 to 25 percent of dysgerminomas recur. Teratomas are classified as immature (malignant), mature (dermoid cyst), and specialized (struma ovarii and carcinoid tumors).

The mature teratoma is mostly benign and can contain noncancerous tissues including bone, hair, and teeth. Immature teratoma can contain tissues
Ovarian germ cell tumors are treated with surgery and chemotherapy; however, if the patient is young, fertility-sparing and fertility-preserving surgical procedures including unilateral salpingo-oophorectomy are performed. Following fertility-preserving surgery and adjuvant chemotherapy, girls and young women who have survived malignant ovarian germ cell tumors can experience normal menarche and menstruation.

Bilateral salpingo-oophorectomy and hysterectomy are performed if the patient has completed childbearing. Chemotherapy as a treatment option can lead to secondary malignancies (i.e., cancers caused by treatment with chemotherapy) such as acute myelogenous leukemia (AML).

There are no known causes of ovarian germ cell tumors; recent studies have indicated an inverse association between family history of ovarian cancer and ovarian germ cell tumors. Ovarian germ cell tumors are hard to diagnose, and thus are often diagnosed late because there are no symptoms in the early stages. The common symptoms are swelling and/or pain in the abdomen and vaginal bleeding after menopause.

Elevated cancer antigen (CA 125) levels can also indicate presence of ovarian germ cell tumors, but these can be nonspecific. A physical exam, pelvic exam, laparotomy, computerized tomography (CT) scan, and serum tumor marker are tests that can be used to diagnose ovarian germ cell tumors. Ovarian germ cell tumors secrete biologic markers such as β-HCG and a-fetoprotein (AFP); these can be used to monitor treatment results and recurrent incidences.

Ovarian cancer is the seventh of the 18 most common cancers in women worldwide. The global five-year prevalence of ovarian cancer is 22.6 per 100,000 people. Ovarian cancer is normally misdiagnosed or diagnosed late because there are often no symptoms at its early stages of development. With appropriate treatment, ovarian cancer can be contained or survived without further incident, as research has shown that the five-year survival rate for ovarian cancer is 30 to 50 percent. Chances of recovery and treatment options (prognosis) depend on the type of cancer, the size of the tumor, the stage of the cancer, and the person's general health status.

With improvement in research, about 90 percent of malignant germ cell tumors are now curable. However, if the disease recurs, this normally happens within one year after diagnosis. Recent developments in chemotherapy regimens, more precise staging of the disease, improved radiographic imaging, and improved supportive care, among others, have led to improved survival rates of ovarian germ cell tumors.

Ovarian Low Malignant Potential Tumor

Ovarian low malignant potential (LMP) tumor is a disease that occurs when tumors form in the tissue covering the lining of the ovary. These types of tumors usually remain in the ovary and do not become cancerous. Ovarian LMP tumors, also known as borderline tumors or atypical proliferative tumors, show features or characteristics that are between benign ovarian tumors and malignant ovarian cancers. The unique characteristic of borderline ovarian tumors is that they do not invade the ovarian stroma. Ovarian LMP tumors account for 10 to 20 percent of all ovarian epithelial cancers. The incidence rate is 1.5 to 2.5 per 100,000 people per year.

The risk factors of ovarian LMP tumors include delayed childbearing or not having children, infertility, and aging rapidly among others. Breast-feeding, use of oral contraceptives, and multiple pregnancies can decrease one's risk of developing ovarian LMP tumor. Research findings are inconclusive as to whether BRCA1 (breast cancer 1, early onset) and BRCA2 (breast cancer 2, early onset) mutations are related to ovarian LMP tumor risk. However, certain mutations in the TP53 (tumor protein p53), BRAF, and KRAS genes have been found to be associated in varying degrees with risk of ovarian LMP tumor. Ovarian LMP tumors are usually diagnosed in women in their reproductive years; about 27 percent of patients are less than 40 years old.

There may not be signs for ovarian LMP tumor; about 16 percent of patients do not observe any symptoms at the time of diagnosis. However, if there are symptoms, they are usually in the form of abdominal swelling or pains, pain in the pelvis, constipation, gas, or bloating. Ovarian LMP tumor is usually diagnosed at an early stage and because patients are usually young, treatment options should be mindful of preserving the fertility of patients. Tests performed to diagnose and stage ovarian LMP tumor include physical exam, pelvic exam, ultrasound, CT (computerized tomography) scan, CA 125 (cancer antigen 125) blood test, and biopsy, among others.

When seen under the microscope, the LMP tumors cannot be clearly identified as cancerous. A biopsy is usually performed to confirm that the tumor is low malignant. Ovarian LMP tumor is classified as Stage I, Stage II, Stage III, and Stage IV depending on how the mutated cell has spread in the ovary and to other parts of the body; it is important to know the stage of the disease in order to choose appropriate treatment options. The common types of ovarian LMP tumors are the serous and mucous subtypes; the serous type accounts for 43 to 53 percent of all LMP tumor cases, while the mucous type accounts for 42.5 to 52 percent. Serous ovarian LMP tumors affect both ovaries (bilateral) in one-third of the cases. Eighty-five percent of mucous ovarian LMP tumors are intestinal, while 15 percent are endocervical.

Surgical treatments for ovarian LMP tumor include unilateral or bilateral salpingo-oopherectomy and hysterectomy; the type of surgery performed depends on the stage of the tumor and whether the patient wants fertility to be conserved. Chemotherapy may be considered if the tumor was diagnosed at an advanced stage; however, some studies suggest that chemotherapy and radiotherapy are not effective for treating the disease. Also, there is evidence that hormone treatment can be used to treat ovarian LMP tumors. Research has shown that about 15 percent of ovarian LMP tumors may recur about 20 years or more after the initial diagnosis. Recurrence rates are higher if conservative surgical treatment was used; conservative surgery, which involves complete staging and preservation of the uterus and at least one ovary, is preferred for fertility-sparing and hormonal functional purposes. Radical surgery, on the other hand, has a lower recurrence rate. Thus, there is a need for patients to be aware of the advantages and
disadvantages of both the conservative and radical surgery treatment options. Recurrences can be treated if detected early.

The 10-year survival rate is about 95 percent; the survival rate can be even better depending on age at which patient was diagnosed, the stage, and the type of tumor.

It is recommended that the gynecologic oncologist collaborates with the reproductive endocrinologist to ensure preserving the fertility of the patient. Follow-up is recommended, especially, if the conservative method of treatment was used.

Pain and Pain Management

During the past decade, video games have provided new ways to effectively alleviate the pain experienced during cancer treatment. Several theories explain how involvement in entertainment media reduces the experiences of pain. While the brain is engaged in entertainment, it has less capacity to process pain. This article discusses the recent pain management research that demonstrates how video games are rapidly becoming an important factor in cancer treatment.

Growth of Video Games

Since the first video game appeared on an oscilloscope screen in 1958, video games have rapidly proliferated to become an important part of popular culture. T. Baranowski and colleagues define a video game as “any game played on a digital device and encompasses a wide range of games played at arcades, over the Internet on personal computers, or on dedicated game consoles (e.g., Nintendo GameCube, Sony PlayStation, or Microsoft Xbox) or handheld units (e.g., Nintendo Game Boy, Sony PSP).” Active video games like Nintendo Wii and Xbox Kinect have become extremely popular among children and adolescents. In 2012, for example, Nintendo Wii sold 99 million game consoles worldwide. In a study of children and adolescents, D. Roberts, U. Foehr, and V. Rideout found that in 2005, the 8- to 10-year-olds in their study spent an average of 65 minutes per day playing video games; and the 11- to 14-year-olds spent an average of 52 minutes per day playing video games. A. Lenhart and colleagues reported that 97 percent of American youth between 12 and 17 years of age reported playing video games. In a study of seventh- and eighth-graders’ media use, 94 percent indicated that they had played video games within the past six months, and half of them said they had played a video game within the previous day. C. K. Olson and colleagues’ 2007 study of children’s video game use several years ago indicated that 94 percent of seventh- and eighth-graders played video games within the previous six months, and at least half reported playing games the day before they completed the survey. These studies demonstrate that video games reach large and diverse audiences of young people who spend a considerable amount of time and attention playing them. The long-term and widespread exposure to video games makes them a powerful potential motivator of behavior change.

Theoretical Foundations for Video Game Effects

Given the wide popularity of video games among youth and their potential to affect health beliefs and practices, their growing use in the fields of health
and medicine is of no surprise and is one of the most exciting new uses of communication technology in the 21st century according to W. J. Brown. There are several important communication theories that explain how video games influence video game consumers. One group of theories falls under the general heading of audience involvement, broadly defined as the degree of psychological response by a person to a mediated message or persona. Involvement is a dynamic process in which a motivational state of arousal forms and fluctuates both during and after media consumption. P. Vorderer distinguished two levels of audience involvement: a low-level involvement characterized by media consumers who are distant and analytical, and a high-level involvement characterized by cognitively and emotionally engaged media consumers. Drawing on entertainment media theory, C. Klimmt, D. Hefner, and Vorderer’s 2009 research of video game experiences shows video game users experience high levels of involvement, which increases their media enjoyment.

One specific form of audience involvement in media narratives is called transportation. M. C. Green describes the process of transportation as becoming “cognitively and emotionally involved in the story.” Green and T. C. Brock used the phrase transportation into a narrative world to describe the power of narratives to totally immerse audiences into a story, such as when a reader is “lost in a book.” Although originally focused on written fiction, the study of transportation into narrative worlds has evolved beyond audience involvement with novels and now encompasses all forms of media, including video games, according to Brown. Transportation theory provides a powerful explanation for understanding the potential for video games to decrease pain experienced during medical treatments. Closely related to transportation theory is the attentional hypothesis, which explains how the brain functions when people focus their attention. The attentional hypothesis explains that virtual reality reduces pain by creating an entertainment experience that captivates the attention of patients receiving medical treatment, thus diminishing the brain functions that register pain, as reported by H. G. Hoffman and colleagues.

Another important theoretical framework for understanding the effects of entertainment media is A. Bandura’s 2004 social cognitive theory. Bandura explains how media consumers role model the characters they engage in narratives and other forms of entertainment programming. His research shows that when positive characters reap beneficial outcomes in a story and negative characters reap negative consequences, then audiences are motivated to adopt the positive beliefs and behavior of those who are rewarded. Thus personae (virtual characters) in video games can provide exemplary role models for patients receiving medical treatment. One of the important components of Bandura’s theory is self-efficacy, or the belief that a person has that he or she can enact a specific behavior that is being advocated. For example, a cancer patient receiving chemotherapy must believe that he or she can develop the skills and confidence needed to manage the treatments successfully in order to minimize the potential negative side effects of chemotherapy.

In summary, video games create a high level of audience involvement, provide media enjoyment, present potential positive role models for beneficial health beliefs and practices, and transport those who play them into narrative worlds that can divert attention away from the pain experienced during medical treatments.

Video Games for Pain Management

Several video games that are commercially available have been shown to have beneficial therapeutic effects for cancer patients dealing with the negative side effects of their treatment, including nausea, vomiting, anxiety, and pain from chemotherapy and radiation treatments. B. A. Primack and colleagues’ 2012 review of the academic literature indicates that active interventions based on video games improved 59 percent of the physical therapy outcomes, 50 percent of the physical activity outcomes, and 42 percent of pain distraction outcomes. Their own study of the daily use of Nintendo Wii games by children for at least 30 minutes and during hospitalization for an eight-week period to manage the pain of cancer treatments is now in progress, with expectations that Nintendo use will significantly improve the pain management of the treatments.

One of the first video games used by doctors to lessen pain is called Snow World, the first virtual world custom-designed for burn patients. When patients play this game, they can cognitively
transport themselves into an immersive virtual world that reduces their pain experience. Patients are distracted from focus on their painful burn wounds by wearing a virtual reality (VR) helmet, which enables them to see themselves floating through an icy 3-D canyon where they can shoot snowballs at snowmen, igloos, and penguins. D. A. Das and colleagues found that playing *Snow World* can reduce patients’ pain ratings during severe burn wound care by 30 to 50 percent.

As noted above, virtual reality games can reduce experiences of pain by creating an alternate entertainment experience that captivates the attention of patients receiving medical treatment. M. Griffiths reported one case study of an 8-year-old boy with neurodermatitis and scarring due to continual picking at his upper lip. Conventional treatments had failed to help him, but after he was given a handheld video game, within two weeks the affected area healed. Medical researchers at the University of Maryland tested a 3-D underwater virtual reality video game called *Free Dive* during medical procedures for children. Their research indicated that children engaged in *Free Dive* were able to better manage painful medical procedures.

T. Baranowski and colleagues reviewed 27 articles in 2008 that reported the effects of 25 different video games on health-related behavior changes. Many of the games they examined exhibited three characteristics that contributed to their effectiveness in promoting positive health behaviors. First, they merged the immersive, attention-maintaining properties of stories and fantasy. Second, they provided engaging properties that generated a high degree of interactivity. Finally, the behavior-change technology enabled its users to engage in role modeling, vicarious identifying experiences, and learning a story’s “moral,” among other change possibilities.

**Effects of Video Games on Cancer Treatment**

The positive effects of video games in helping medical patients to divert their attention away from the pain of medical procedures and treatments makes them an important source of pain management for cancer patients receiving radiation and chemotherapy. Controlled studies using both treatment and control groups with random assignment show that video games can provide cognitive distraction for children during chemotherapy for cancer and treatment for sickle-cell disease. These studies indicated that distracted patients had less nausea and lower systolic blood pressure than control groups (who were simply asked to rest) after treatment and needed fewer analgesics. D. J. Kolko and J. L. Rickard-Figueroa assessed the effects of video games on three young male cancer patients aged 11, 16, and 17. All three patients had been distressed before their chemotherapy treatments, but after playing video games, their anticipatory symptoms decreased, as did aversive chemotherapy side effects that they had previously experienced. In two studies of cancer patients ranging in age from 9 through 20, W. H. Redd and colleagues found in 1987 that patients who played a video game for 10 minutes during chemotherapy induction significantly experienced less nausea compared with control group patients. Children assigned to the video game group condition could choose from 25 different games on an Atari 800 XL computer system. Another study by J. Vasterling and colleagues in 1993 explored cognitive distraction through video games in comparison to standard relaxation techniques with a control group of young cancer patients. The patients who played video games experienced less nausea prior to chemotherapy and had lower blood pressure following chemotherapy compared with the patients who used the standard relaxation techniques. There were no differences in the effectiveness of the cancer treatments between the video game group and the control group. However, the administration of the standard relaxation techniques, requiring a trained therapist, was substantially more expensive than making video games available to patients.

In a 2008 study, P. M. Kato and colleagues investigated the effects of *Re-Mission*, a video game designed for adolescents and young adults with cancer. The objective of *Re-Mission* is to improve cancer treatment by helping young people manage pain during their treatments. The game features a nanobot named Roxxi that navigates through the bodies of cancer patients to destroy cancer cells and tumors with chemotherapy and radiation. Roxxi also fights against side effects of cancer treatment such as pain, nausea, infection, and constipation. Their study of 374 cancer patients aged 12 to 29 from 34 medical centers in the United States, Canada, and Australia indicated that those who played
Re-Mission over a three-month period maintained higher levels of chemotherapy in their blood and took their prophylactic antibiotic medication more frequently as prescribed than patients in the control group. In addition, patients who played Re-Mission showed greater increases in knowledge about cancer and increased self-efficacy to manage their cancer than patients in the control group. The research showed that a video game made specifically for young people with cancer can significantly increase important health behaviors that are related to survival outcomes.

Kato’s 2010 review of video game medical research shows that tailor-made games for specific medical treatments go beyond the strengths of commercial games in their ability to increase specific disease-related knowledge about self-care. He found that even though commercial video games have superior graphics and gameplay, medical patients give high ratings of acceptability to video games designed for patients fighting specific illnesses and find them engaging.

Conclusion
The academic literature indicates that video games can have powerful positive effects on health beliefs and practices. In particular, the high degree of psychological involvement created when people become immersed in video games and transported into narrative worlds has made video games an important means of pain management for cancer patients. In addition to reducing the pain experienced during chemotherapy and radiation, video games also can increase patients’ self-efficacy in successfully dealing with the potential negative effects of cancer treatment. Video games increasingly will serve an important role in successful cancer treatment in the future.

**Paint**

Paint is a liquid or liquefiable composition that dries into a solid film after being applied in thin layers, and is used to apply color, texture, or protective coating to objects. Paint is one of the oldest human technologies, dating back at least tens of thousands of years. The technology to make paints has changed over time, with different media used for the base (egg yolks, oils, and water are among the possibilities) and different methods used to obtain pigment.

Today, paint pigments are taken from both natural and synthesized sources. Many paints are toxic—lead-based paints were common in household use before their toxicity was well understood—and studies have found correlations between working in the painting trades or paint manufacturing industry and the development of cancers of the lung, bladder, liver, esophagus, larynx, and oral cavity.

The film-forming component of paint is called the binder or vehicle, and it provides the adhesive properties of paint, as well as contributing to the gloss, flexibility, and toughness of the dried product. Binders used today include oils, epoxy, melamine resins, polyesters, polyurethanes, vinyl-acrylics, acrylics, and alkyds. Casein, derived from milk, has been used in paint since ancient Egypt and remained the tempera paint binder of choice until the 1960s, though it is still used today. It has been found not only to be an allergen for a small percentage of the population but to promote carcinogenesis, according to one Chinese government study; however, the study focused on casein consumption through milk drinking, and it is not clear that even chronic exposure to casein in other contexts would have the same effect.

In addition to the pigment, which may be derived from calcium carbonate, mica, silica, talc, various clays, and even insect sources or from synthetic sources, paints contain fillers that thicken the film, such as talc, lime, or diatomaceous earth. Some
Paints may also include antifreeze additives or additives that affect the speed at which they dry or the effects of ultraviolet light or age.

Lead paints include lead chromate, or chrome yellow, and lead carbonate, or white lead. When added to paint, lead makes the resulting film more durable, resists moisture in order to avoid corrosion of metal surfaces, and speeds drying. It is also one of the most widely known environmental and health hazards and has been banned from household paints in the United States since 1978.

Lead paint continues to be used in some other countries, as well as on outdoor signs and other applications. Asbestos paint is less known, though the general public is aware of the dangers posed by asbestos in general. Asbestos exposure is linked to a large number of respiratory problems, including most seriously mesothelioma, lung cancer, and chronic obstructive pulmonary disorder (COPD). It was used in paints for a long time because of its fire resistance, which therefore was thought to add additional safety to whatever was being built and painted. It is not often found in this form in new paints but remains in use in old paints. The mechanism by which asbestos causes lung cancer seems to be mechanical: the very small fibers of asbestos irritate the lung tissue and may be small enough to actually cause gene damage mechanically. Many of the solvents used in paints are associated with a host of health hazards, in some cases applicable only in accidental ingestion or chronic exposure. Inhalation of large amounts of vapor from most solvents will lead to unconsciousness, for instance, which is sometimes exploited recreationally but which can lead to permanent blindness or even death. Methanol, or “wood alcohol,” is one of the most dangerous in this respect, and it is additionally dangerous because it burns with an invisible flame. Chronic exposure to solvents in the workplace, such as in the painting trades or the paint manufacturing industry, can lead to neurotoxic effects as well as to a host of cancers and hypotension. There is also a correlation between exposure to solvents and alcoholism.

Benzene, found in many professional paints and paint sprays, is strongly linked to aplastic anemia, bone marrow abnormalities, acute myeloid leukemia, myelodysplastic syndrome, acute lymphoblastic leukemia, and chronic myeloid leukemia. It can also lead to birth defects and damage to the liver, kidneys, lungs, heart, brain, and DNA strands. Asbestos is thought to cause as much as 80 percent of all mesothelioma cases.

Benzene is a volatile organic compound (VOC), and one of several that is often used in paint. Others include aliphatic hydrocarbons, ethyl acetate, glycol ethers, and acetone. In addition to several VOCs being carcinogens, they are believed to play a role in so-called sick building syndrome when they are used to paint and coat the interiors of buildings or are otherwise used in their construction and contents. They frequently cause allergic or immune system reactions in adults and children alike and they react with other airborne chemicals like nitrogen oxides to produce secondary aerosols that cause irritation; damage the liver, kidneys, and central nervous system; and can cause discomfort of the nose and throat, allergies, nausea, nosebleeds, fatigue, loss of coordination, and chronic headaches or dizziness. Historically, many traditional paints included a variety of heavy metals.

These are currently used less commonly, and when they are used, they are accompanied with health warnings. Cadmium, for instance, is associated with kidney damage resulting in excess protein in the urine, lung inflammation, osteomalacia, and lung cancer, as well as being used to make yellow paints. Arsenic, a well-known poison, can also cause hyperkeratosis, diabetes, and cancer. Chromium can cause lung cancer, acute renal failure, gastrointestinal hemorrhage, and lung cancer. Mercury is linked to diarrhea, fever, vomiting, and a variety of nerve disorders. Cobalt can induce cardiomyopathy, contact dermatitis, and intoxication. Nickel sulfide is a carcinogen, and some people are allergic to nickel in any form. Selenium, although an essential trace element in nutrition, is toxic in excess, leading to cirrhosis of the liver and death. Titanium dioxide, which is used in both paint and sunscreens, is a Group 2B carcinogen according to the International Agency for Research on Cancer, meaning “possibly carcinogenic to humans.” Titanium dioxide pigment is suspected to cause lung cancer and gene damage, although a link has not been found between carcinogenesis and occupational exposure.

Pakistan

The south Asian nation officially termed the Islamic Republic of Pakistan has historically been the location of numerous cultures, kingdoms, and peoples. In the decades before Pakistan declared its sovereignty in 1947, the nation was a part of India and thus, by extension, under British rule. After independence was declared in 1947, the people created a new constitution that instituted the Islamic Republic of Pakistan. The country is currently one of the top 10 most populated countries in the world, having over 180 million citizens. Pakistan is currently facing huge obstacles in its battle against cancer, and nowhere is this more apparent than in the nation’s struggle against breast cancer. Pakistan experiences some of the highest rates of breast cancer in the entire world, as it is estimated that over 10 percent of all Pakistani women will be diagnosed with the disease in their lifetime.

The problem is that there are extreme cultural obstacles impeding access to cancer care for Pakistani breast cancer patients; in the nation, which is very conservative culturally, even uttering the phrase breast cancer can be cause for public backlash as a result of its perceived sexual connotations. In light of the negative connotations surrounding breast cancer, many women in the country refuse to seek treatment for the disease, much less have themselves checked for a diagnosis. Because breast cancer is the leading cancer of women in the country, resulting in over 40,000 fatalities a year, much needs to be done to raise public awareness of the issue, though this will be difficult. A recent survey conducted at Pakistan’s Rawalpindi General Hospital revealed that nearly three-fourths of the women surveyed had no idea what breast cancer is, nor its health implications.

For Pakistan, there are many, more difficult issues related to cancer treatment in the country. For instance, Pakistan has no nationally representative cancer registry with which to track cancer trends in the country. Also, in general, Pakistan’s health care industry is internationally regarded as lackluster. The nation simply does not have the funding that is required to aggressively combat domestic incidences of cancer, which has led to the country’s not being able to afford advanced treatment facilities and the newest cancer drugs. Even the vast majority of the hospitals that Pakistan currently has are not outfitted with cancer screening or treatment equipment.

The lack of medical funding, specialist facilities, and cancer drugs has thus instigated the cancer crisis that the nation is currently facing. Due to cultural taboos and lackluster health care, a large portion of Pakistanis who are faced with a cancer diagnosis will first go visit their local tribal healers for treatment. Usually when Pakistani cancer patients are finally seen by medical experts, they have waited so long that their cancer has advanced to the point of it being virtually untreatable. Though Pakistan has no national cancer registry, inferences can be made from the Karachi regional registry with regard to incidences and trends in the country. Presently, data suggest that the most prevalent forms of cancer in Pakistan are breast cancer, laryngeal cancer, liver cancer, oral cancer, and ovarian cancer.

In light of the fact that over 40 percent of the male population of Pakistan smoke, lung cancer is the most common form of cancer in males in the country, followed by incidences of larynx cancer and oral cancer. For Pakistani women, breast cancer is by and large the most prevalent form of cancer incidence in females, followed by oral cancer and ovarian cancer. Regrettably, cancer is a taboo subject in Pakistan, and so it is not often talked about publicly in the country. The female Pakistani politician Fahmida Mirza has done her best to reverse this trend, however. After being
diagnosed with breast cancer in early 2012, Mirza continued to play an important and very public role in domestic and international politics. After aggressive bouts of chemotherapy, Mirza’s cancer went into remission, and she has since used her platform in the Pakistani government to help raise domestic awareness of and treatment options for the disease. She has recently been involved with legislative attempts to institute a national cancer registry in the country, as well as to mandate yearly breast cancer screenings for the entirety of the nation’s female population. With public figures like Mirza campaigning against breast cancer, there is hope that the cultural stigmas that have impeded treatment for Pakistani citizens may be reversed.

Pancreatic Cancer

Pancreatic cancer is a highly aggressive malignancy that currently ranks as one of the major causes of cancer-related death in various countries around the world. Several chemotherapeutic regimens have shown great potential as treatment options for advanced stages of pancreatic cancer based on the results of phase III clinical trials that show an increase in patient survival. The standard of treatment of patients with pancreatic cancer is gemcitabine, which has been used for at least 10 years, replacing 5-fluorouracil. The benefits observed with the administration of gemcitabine included less pain, lower level of functional impairment, and a smaller risk of weight loss.

After the introduction of gemcitabine as the standard of care for patients with pancreatic cancer, additional randomized phase III clinical studies were launched to determine the efficacy of gemcitabine-based combinations compared to the use of gemcitabine alone. However, these studies have also sparked some controversy regarding gemcitabine-based drug combinations. For example, a couple of phase III clinical trials initially showed encouraging results of increased patient survival. However, two other phase III clinical studies generated the opposite results, wherein the study participants failed to achieve a significant improvement in survival rate after receiving gemcitabine-based drug combinations compared to those using gemcitabine alone. In addition, a subsequent clinical study that pooled the data collected from two phase III clinical trials as well as a phase II randomized clinical study showed that the gemcitabine-capecitabine drug combination resulted in a small but statistically significant improvement in survival rate. Furthermore, two additional independent meta-analyses also showed a small yet significant increase in survival.
rate using a gemcitabine-based drug combination compared to gemcitabine alone.

Another drug that has been used in combination with gemcitabine is erlotinib, which has resulted in a 23 percent survival rate of patients with pancreatic cancer, compared to the 17 percent survival rate in patients who received gemcitabine alone. It appears that erlotinib is the only drug that could consistently generate improved outcomes in patients with pancreatic cancer. The rest of the drugs administered in combination with gemcitabine still require additional clinical trials to verify their actual effect on the survival rate of pancreatic cancer patients.

Recent studies such as ACCORD 11/0402 as well as that conducted by T. Conroy and colleagues have thus examined the efficacy of other gemcitabine-based drug combinations for the treatment of pancreatic cancer. The cocktail consisting of 5-fluorouracil, folinic acid, irinotecan, and oxiplatin, collectively called FOLFIRINOX, has been combined with gemcitabine for the treatment of metastatic pancreatic cancer. The initial study showed promising results of higher response rates and extended progression-free survival, as well as enhanced overall survival rates. However, these positive patient outcomes were also strongly associated with a higher incidence of toxicity effects such as diarrhea, neutropenia, and vomiting. In addition, the combinations of gemcitabine-capecitabine, gemcitabine-erlotinib, and FOLFIRINOX have not been assessed directly against each other in a single clinical study. It would also be helpful to identify the most cost-effective gemcitabine-based drug combination for the treatment of pancreatic cancer. This need to identify a cost-effective treatment regimen is mainly based on the limited budget provided by insurance programs, amid the rapid rise in the price of cancer drugs over a short period of time.

In a more recent study conducted by C. L. Attard and colleagues, the cost-effectiveness of FOLFIRINOX as a first-line drug for the treatment of pancreatic cancer was assessed and compared with gemcitabine alone. Similar to the findings of previous clinical trials, FOLFIRINOX was associated with a higher number of life-years, as well as quality-adjusted life years. In terms of sensitivity, FOLFIRINOX showed >80 percent sensitivity compared to using gemcitabine alone. Calculation of cost-effectiveness included the expenses incurred based on the dosage of FOLFIRINOX compared to that of gemcitabine, as well as the duration of treatment and the positive outcomes observed in the patients with pancreatic cancer. The patients included in the study thus showed a significantly longer life expectancy compared to that observed using the standard of care, gemcitabine. Although gemcitabine extends the life expectancy of a patient with metastatic pancreatic cancer by six months, those who received FOLFIRINOX as a first-line treatment showed an increase in life expectancy of 11.1 months. Furthermore, the cost of using either gemcitabine or FOLFIRINOX was essentially the same and, therefore, the newer drug formulation is considered the more cost-effective approach in treating patients with metastatic pancreatic cancer.

Despite these promising results, some discrepancy continues to influence and possibly delay the establishment of a new standard of care for metastatic pancreatic cancer. For example, to date, the universal definition of a cost-effective treatment regimen for pancreatic cancer is uncertain. Some analysts have previously suggested that an intervention that costs less than $20,000.quality-adjusted life year should be considered as cost-effective, whereas those costing more than $100,000.quality-adjusted life year should be considered not cost-effective. It is important to note that these thresholds for cost-effectiveness were established in the early 1990s and thus might not be totally representative of the current quality of health care that the patients received.
In addition, the cost of these drugs varies among countries and continents around the world. Interestingly, even the two countries in North America, namely, the United States and Canada, have significantly different costs for the same drugs for the treatment of metastatic pancreatic cancer.

The World Health Organization (WHO) has also attempted to assist in defining the term cost-effectiveness. This international organization thus recommended that the threshold of a cost-effective treatment regimen for pancreatic cancer should be based on the gross domestic product per capita of each nation. Thus, in Canada, for example, the threshold for cost-effectiveness of a treatment regimen for metastatic pancreatic cancer is approximately $151,000 per quality-adjusted life year. Using this approach, FOLFIRINOX continues to appear to be the more cost-effective treatment for pancreatic cancer. Subsequent clinical trials assessing the cost-effectiveness of gemcitabine and FOLFIRINOX continue to generate different results; however, it appears that these discrepancies were mainly due to the exclusion of cycles of administering FOLFIRINOX to a pancreatic cancer patient. The earlier ACCORD trial supports this reason, as the study participants received FOLFIRINOX ranging from one to 47 cycles. Further evaluation is thus warranted for this new treatment approach.

pancreatic cancer in childhood. 85 percent of pancreatic adenocarcinomas will have metastasized (spread to other organs) at the time of presentation. Acinar adenocarcinomas generally present after metastasis has occurred and have been described in children as young as 3 years. Some of these patients present with a constellation of findings, including polyarthralgia (joint aches), extrapancreatic fat necrosis, and eosinophilia (elevation in the blood of a type of white blood cell). These tumors frequently demonstrate allelic losses on chromosome 11p and alterations in the APC/β-catenin pathway. Treatment is direct excision and prognosis is more favorable than that for ductal adenocarcinoma.

Pancreatoblastoma is more common in boys than girls and presents often as an incidental abdominal mass. A number of patients will secrete anti-diuretic hormone from their tumor. Serum alphafetoprotein will be elevated and can be useful to follow the course of disease. Primary resection is the treatment and prognosis is good in these children.

Islet cell carcinomas arise from functional pancreatic lesions and are associated with hypoglycemia, or can be part of the Zollinger-Ellison syndrome (caused by a tumor that secretes the hormone gastrin). These cancers are usually associated with multiple endocrine neoplasia type I syndrome. There is also an association between von Hippel-Lindau (VHL) disease and islet cell carcinoma, which is caused by a germline mutation of the VHL gene on chromosome 3p25.

In multiple endocrine neoplasia type 1 (MEN1), nonfunctioning pancreatic neuroendocrine tumors (NF-PETs) are considered the most prevalent PETs and represent the main cause of death in MEN1 patients in their second decade of life. With the increased ability to molecularly detect patients who present with insulinasms as MEN1-related PETs, practice guidelines on MEN1 have been revised to start screening as early as age 10 for MEN1 carriers with suspected clinical disease. Congenital anomalies of the pancreas-associated enteric small bowel duplications have now been associated with chronic pancreatitis and pancreatic cancer in a few rare case reports. While duplications are benign in children, malignant degeneration has been described in adults, and a minority of these demonstrated adenocarcinomas of the pancreas in origin. In one report, the small bowel cancer demonstrated over-expression of the HER2/neu oncogene, a gene involved in apoptosis. This discovery has led to chemotherapy treatments with antibodies directed against the HER2 protein. A variety of nonepithelial tumors of the pancreas have been described, although rarely in children. Rhabdomyosarcomas and lymphomas and primitive neuroectodermal tumors can sometimes present as primary tumors of the pancreas. Secondary involvement of the pancreas by tumors can result from hematogenous spread in malignant melanoma, renal and lung tumors, and leukemia.

Pancreatic Cancer, Islet Cell

Pancreatic islet cell tumors are also known as islet cell tumors, islet of Langerhans tumors, neuroendocrine tumors, pancreatic neuroendocrine tumors (pNETs), neuroendocrine tumors (NETs), pancreatic endocrine cancer, islet cell carcinoma, and pancreatic endocrine tumors (PETs). They comprise fewer than 4 percent of all diagnosed pancreatic tumors, with gastrinomas and insulinomas more common than the other types. This article includes an introduction to pNETs, descriptions of the different types and symptoms, risk factors, exams and tests to diagnose pNETs, treatments, and prognosis.

Introduction
Islet cell tumors form from the islet cells of the pancreas, which include hormone-secreting cells. As a result, islet cell tumors usually produce excess hormones, and most of the initial symptoms are the result of the actions of these hormones. pNETs that produce excess hormones are called functional tumors. A smaller subset of islet cell tumors, referred to as nonfunctional tumors, have no significant symptoms due to hormones or peptides that the tumor makes. Instead, symptoms of nonfunctional tumors are mainly caused by growth and spreading of the tumor. In addition, some NETs are not cancerous, and these benign tumors might or might not cause symptoms.

Types and Symptoms of pNETs
There are several types of pNETs that result in different symptoms depending on the hormones they produce. They are described below. Glucagonomas produce glucagon, a hormone that signals the body to raise blood glucose levels. The most distinctive feature is necrolytic migratory erythema (NME), a red, blistery rash on the face, stomach, legs, groin, or buttocks. Other symptoms can include high blood sugar resulting in hunger, thirst, fatigue, weakness, headaches, dry skin and mouth, and frequent urination, diarrhea, weight loss, and malnutrition; blood clots in the lungs causing shortness of breath, coughing, and pain in the chest; blood clots in an arm or leg resulting in swelling, warmth, and redness of the limb; glossitis (swollen tongue); or angular cheilosis (sores at the corners of the mouth).

Gastrinomas (Zollinger-Ellison syndrome, ZES) produce gastrin, a hormone that signals the stomach to make acid. Symptoms include abdominal pain that may spread to the back, diarrhea, ulcers in the stomach and small intestine, vomiting blood, gastroesophageal reflux, and decreased appetite.

Insulinomas produce insulin, which lowers blood glucose levels. Symptoms include hypoglycemia that can result in fatigue, weakness, shaking, sweating, headache, hunger, double/blurry vision, rapid heartbeat, nervousness, anxiety, irritability, lightheadedness, and confusion. If blood glucose levels become too low, the patient can experience fainting, seizures, or even coma.

VIPomas (Verner-Morrison pancreatic cholera, WDHA) produce excessive vasoactive intestinal peptide (VIP). Symptoms include watery diarrhea, weight loss, dehydration, low blood potassium levels that can cause muscle weakness, aching, cramps, numbness and tingling, low acid levels in the stomach resulting in problems digesting food, frequent urination, rapid heartbeat, confusion, or abdominal pain or cramps.

Somatostatinomas produce excessive somatostatin, which regulates the production of several other hormones. Symptoms include steatorrhea, diarrhea, weight loss, gallstones, gallbladder problems causing abdominal pain, nausea, decreased appetite and jaundice, and high blood sugar resulting in headaches, frequent urination, dry skin and mouth, hunger, thirst, fatigue, and weakness.

Carcinoid tumors produce serotonin (5-HT) or 5-HTP, a precursor of serotonin. Because these molecules are broken down by the liver, carcinoid tumors generally do not cause symptoms until they metastasize. After spreading to the liver, the tumors can cause carcinoid syndrome with diarrhea, flushing, wheezing, and rapid heartbeat and can eventually cause damage to heart valves.

Other types of pNETs include PPomas, GRFomas, ACTHomas, and PTHrPomas. PPomas make pancreatic polypeptide and cause an enlarged liver, abdominal pain, and watery diarrhea. GRFomas secrete growth hormone releasing factor. ACTHomas secrete adrenocorticotropic hormone (ACTH). PTHrPomas secrete PTHrP and cause hypercalcemia.

While nonfunctional NETs do not secrete hormones that cause significant symptoms, as the tumors grow and invade the liver they can cause
diarrhea, indigestion, a lump in the abdomen, pain in the abdomen or back, and jaundice.

**Risk Factors**

Risk factors for pNETs include multiple endocrine neoplasia, type I (mutations in MEN1), neurofibromatosis type 1 (von Recklinghausen disease, VRH, mutations in NF1), von Hippel–Lindau disease (VHL), and tuberous sclerosis.

**Exams and Tests**

Exams and tests include general physical exams, exams of the abdomen, and tests to look for altered hormone levels or the metabolic results of increased hormone levels. An initial physical exam could identify jaundice, masses or fluid buildup in the abdomen, an enlarged gallbladder or liver, and swelling of lymph nodes. Examinations of the abdomen might include an abdominal computed tomography (CT) scan, abdominal ultrasound, intraoperative ultrasound, endoscopic ultrasound (EUS, endosonography), magnetic resonance imaging (MRI) of the abdomen, and endoscopic retrograde cholangiopancreatography (ERCP). Sometimes surgical examination of the pancreas through laparoscopy is used. An angiography might be used to look for extra or abnormal blood vessels feeding a tumor or for compression of blood vessels by a tumor. Somatostatin receptor scintigraphy (octreotide scan, OctreoScan, SRS) using radioactive octreotide, a hormone that attaches to tumors, might be used to look for somatostatinomas. Biopsies of pancreatic tumors can be performed through fine needle aspiration biopsy (FNA) through the skin, or a biopsy might be performed during an endoscopic ultrasound.

Blood tests include a fasting serum glucose level, fasting serum gastrin level, fasting serum somatostatin test, glucose tolerance test, blood glucagon level, blood insulin c-peptide, blood insulin level, chromogranin A test (CgA; if this is high but other hormones are normal, it could be a sign of nonfunctional NET), serum VIP, sodium and potassium in stool (for VIPoma), pancreatic polypeptide level, neuron-specific enolase (NSE), or substance P. In addition, levels of 5-hydroxyindoleacetic acid (5-HIAA, a product of serotonin degradation) may be measured in the urine. Additional tests include a test of basal acid output from stomach contents after fasting or a secretin stimulation test, which measures the acid level of the small intestine contents after secretin is injected.

**Treatment**

The treatment of pNETs varies depending on the type of tumor and whether it has spread to other tissues. In general, treatment might include surgery to remove the tumor. This could be enucleation to remove only the tumor, pancreateoduodenectomy (Whipple procedure), distal pancreatectomy, total gastrectomy, parietal cell vagotomy, or, if the cancer has spread to the liver, liver resection. Hepatic arterial occlusion or chemoembolization might also be used. Radiofrequency ablation or cryosurgical ablation are other options. For gastrinomas, the nerve that causes cells to make stomach acid might be cut to relieve some symptoms. If the cancer has spread, chemotherapy might be included. Supportive care used to treat symptoms includes pain control, treating stomach ulcers with proton pump inhibitors, histamine blockers, or somatostatin-like drugs, treating diarrhea with IV fluids and somatostatin-like drugs, treating low blood sugar with frequent meals or drug therapy to increase blood sugar levels, or treating high blood sugar with oral drugs or insulin injections. If excess production of hormones is causing symptoms, hormone therapy or other medications to counteract their effects are used. For example, in treating gastrinomas, drugs are used that decrease stomach acid levels, and in treating insulinomas, drugs are used to decrease insulin production.

**Prognosis**

pNETs are less common than pancreatic exocrine tumors and often have a better prognosis. The prognosis depends on the type of cancer, in which part of the pancreas it is located, whether it has spread to other tissues, the age and general health of the patient, and whether it is a new or recurring cancer. If it is found early enough, there is the possibility that the cancer can be cured if the tumor is removed before it can spread to other tissues. In general, potential complications of pNETs can result from increased expression of hormones, including diabetes, hormone crisis, severe low blood sugar, and severe ulcers in the stomach or small intestine. If the tumors spread to the liver, symptoms can include enlargement of the liver with pain and poor
Paper Industry

Paper is produced by pressing moist fibers together and drying them into flexible sheets. The process of making paper from cellulose pulp (derived from grass, wood, or rags) was developed in ancient China, and China continues to be the leading paper producer today. The United States, with its vast natural resources and rapid development of mills during the Industrial Revolution, is the second-biggest country in the pulp and paper industry. In addition to wood, paper is made from fiber crops like jute, flax, hemp, kenaf, bamboo, cereal straws, cotton, and corn stalks. Paper applications include paper currency, writing and printing paper, the various papers of the publishing industry (for books, magazines, and newspapers, each of which uses distinctly different papers), packaging materials from wrapping paper to corrugated boxes, blotting paper, emery paper, electrical insulation paper, litmus paper, paper chromatography, sand paper, cat litter, paper towels, toilet paper, and tissues. From the Industrial Revolution until World War II, the sulfite process was the dominant method for making wood pulp into paper. Instead of mechanically grinding wood into pulp, sulfur and oxygen are burned, creating sulfur dioxide, which is combined with water to create sulfurous acid. This "cooking liquor" extracts lignin from wood in order to leave behind cellulose-rich pulp. Though the sulfite process is no longer dominant, it continues to be used for fine paper, tissue, and other specialty papers, as well as to produce cellulose from wood pulp for non-paper purposes.

The kraft process, however, has overtaken the sulfite process in most papermaking. It uses a cooking liquor called "white liquor," a mixture of sodium hydroxide and sodium sulfide, to break the bonds connecting lignin to cellulose in order to separate the two. The resulting paper is stronger than that created by the sulfite process, and it can be used with a greater variety of woods. When pine is used, it also results in a by-product of raw turpentine.

Paper can also be made from waste paper, including "mill broke," which consists of the trimmings and scraps left over from the papermaking process; pre-consumer waste, which is finished paper that for one reason or another never made it to consumers; and postconsumer waste, which includes used paper, corrugated containers, magazines, and newspapers. Paper recycling today is a relatively simple process, using chemicals to remove the ink from the pulp in a process called de-inking, before bleaching and wetting the pulp as normal. De-inking is done through pH controllers, bleaches, soaps and fatty acids, and other chemicals. The by-product sludge—a combination of ink, plastic, and filler—is burned at some mills as a fuel source but can also be used as a fertilizer.

Both papermaking processes involve many other steps to process, treat, and bleach the pulp and paper. Chalk or china clay may be added to the pulp to improve writing- and printing-related characteristics. The pulp is fed through a paper machine to form a web, and water is removed through pressing and drying through both air and heat. Sizing cuts the paper to suit various applications, and paper is frequently calendared (polished) and coated to make it more appropriate for high-resolution uses.
like photography or high-quality printing. Rollers add textures or watermarks if desired. Many of these chemicals contribute to the pollution contributed by the paper industry.

Some of them can be dangerous to human health as well. Ethylenediaminetetraacetic acid (EDTA), which is used in the bleaching process, is weakly genotoxic, whether consumed orally, inhaled, or contacted on the skin. Though sulfur dioxide is normally not considered a carcinogen—a single study on mice has found it to be carcinogenic—studies show that it is linked to lung cancer in pulp and paper industry workers. A 2002 study of almost 58,000 workers found a positive increase in lung cancer, non-Hodgkin’s lymphoma, and leukemia among pulp and paper industry workers exposed to sulfur dioxide in the course of their jobs, compared to workers of similar age and nationality who were not exposed to sulfur dioxide in their workplaces.

The risk for non-Hodgkin’s lymphoma increased with the dose of sulfur dioxide; no such increase appeared evident with the other cancers. An earlier study of workers in sulfuric acid plants had similarly found increases in mortality due to sulfur dioxide exposure, specifically in increased bladder cancer risk and cardiovascular disease. Organochlorides are also used in paper processing. These hydrocarbons are organic compounds that include at least one covalently bonded chlorine atom. Many are highly toxic to people, animals, or the environment; for example, the pesticide DDT is one such organochloride and it was the focus of Rachel Carson’s book *Silent Spring* (1962), which began the environmental movement. The greenhouse gas carbon tetrachloride is another organochloride used in the paper industry, and exposure to its vapor alone can cause damage to the central nervous system, kidneys, and liver; chronic exposure is linked to liver, kidney, and other cancers. Other organochlorides have been linked to breast cancer risk in numerous studies.

The paper industry is also a significant polluter. Wastewater contains lignin, alcohol, chlorates, transition metal compounds, and enough nitrogen and organic matter to accelerate the eutrophication of freshwater lakes and rivers and change the ecological balance. When the waste sludge is burned, many of the chemicals contained are carcinogenic, and because de-inking involves its own chemical waste products, there is some debate about the level of environmental remediation represented by paper recycling. (Paper recycling also consumes a great deal of clean water.) The papermaking process produces a large amount of dioxins in the bleaching stage, though this problem has improved considerably since the 1980s. Dioxin production results from the use of chlorine, but by 2005, 75 percent of papermaking mills using the kraft process had converted to the elemental chlorine free process, with minimal dioxin production, while 5 percent were using the totally chlorine free technique, with almost no dioxin production. The sulfur dioxide produced in both the kraft process and the sulfite process is a major contributor to acid rain, and other sulfur compounds like hydrogen sulfide, methyl mercaptan, dimethyl disulfide, and dimethyl sulfide are also released by these processes.

Colonial Period and Early Independence
Cancer treatment among foreigners living in PNG in the 19th and 20th centuries relied upon Western medicine, namely surgical removal of tumors. Modern health services provided under Australian rule began to reach rural PNG after World War II; however, the people rarely had access to cancer diagnosis and treatment unless they were in walking distance of an urban hospital in Port Moresby, Lae, Goroka, or Rabaul. There was a significant lack of cancer incidence and treatment data.

Australia established the Territory Tumour Registry in 1958. Total registered cases from 1958 to 1970 were 3,926 (302 per year; 13.8/100,000). Analysis of registry data in 1962 and 1965 found significant incidence of oral and skin cancers in coastal lowland and island regions. Oral cancers of the cheek linings, lips, and tongue were linked to the cultural practice of chewing betelnut, which later spread in popularity among the Highland peoples. Skin cancers (primary non-melanomatous) arise from malignant changes to tropical ulcers and burns, usually occurring on the lower leg. Cancers of the stomach, liver, breasts, and cervix, leukemia and lymphosarcoma among children, and others were found. However, these data reflected cancer among only those persons who had access to an urban hospital (less than 10 percent of the people). Females often went untreated due to taboos about discussing gynecological functions and symptoms.
Papua New Guinea gained independence from Australia on September 16, 1975. Beginning in 1977, the South Pacific Commission’s Pacific Islands Cancer Registry began collecting annually standardized cancer data from Papua New Guinea as well as 21 other Pacific island countries and territories that agreed to participate. This agreement has permitted comparative analyses for better understanding of causes, treatment, and prevention among Pacific peoples. Cancer registration rates increased steadily in the following years.

Risk Factors
Risk factors for common cancers in PNG include the hepatitis B virus (liver); smoking tobacco (lung); betelnut chewing (oral); the sexually transmitted human papillomavirus (HPV) types 16 and 18, which may cause as many as 70 percent of all cervical cancers; and exposure to malaria and the Epstein-Barr virus (lymphoma). The majority of
males (56.9 percent) and a quarter of females (24.8 percent) smoke tobacco. Among males, high rates of oral and liver cancer are linked to smoking, chewing betelnut, and excessive drinking.

**Incidence and Mortality**
Cancer is the fourth most common disease in PNG, affecting up to 15,000 people annually, 75 percent of whom experience poor health outcomes due to lack of diagnosis and treatment. Total PNG cancer incidence and mortality according to the Pulitzer Center/PRI are 139/100,000 and 109.3/100,000, respectively. One-third of these are oral cancers (41.5), which account for 22.8/100,000 deaths annually. Cervical (23.2) and breast (18.9) cancers combined, which almost exclusively affect females, account for one-third (42.1) of all cancers in PNG, and result in 29.4/100,000 annual deaths. About two-thirds of breast cancer patients are premenopausal and experience metastasis before the cancer is identified. Prostate (11.7), liver (9.4), stomach (7.4), and lung (7.3) cancers cause 33.5/100,000 deaths combined. Current data on skin cancer incidence and mortality is lacking.

In contrast to Polynesian, Micronesian, other Melanesian, and aboriginal Pacific peoples, who have high rates of prostate, breast, and lung cancer, PNG and the Solomon Islands have higher rates of oral, liver, and cervical, as well as breast cancer. Fiji and Vanuatu (other Melanesian peoples) also have high rates of cervical cancer.

**Education and Prevention**
Four of the leading cancers in PNG are preventable, that is, oral, cervical, liver, and skin cancer. Efforts at education and prevention have had mixed results. For instance, the Tobacco Products (Health Control) Act of 1987 prohibited advertising of tobacco products and sale to persons under age 18, required labeling that stated the level of harmful substances contained in a product, and authorized the Health Ministry to implement regulations prohibiting tobacco use in public places such as public transportation. None of these provisions was effectively implemented or enforced. The same has been true regarding curbing the use of betelnut.

The HPV vaccination is available to children prior to sexual development in many developed countries. Only private hospitals in PNG, however, offer the set of three vaccinations, which cost about US$600. The hepatitis B vaccine became part of the national vaccination schedule in the 1990s and is expected to produce a measurable reduction in the incidence of liver cirrhosis and cancer in the future. Notably, greater awareness and treatment of tropical ulcers and burns appears to have resulted in skin cancer decline.

Cancer education and prevention services primarily operate from the capital, Port Moresby, including the PNG National Cancer Centre and the Port Moresby Cancer Relief Society. The National Cancer Centre manages the national cancer registry, but it is understaffed and under-supported.

**Treatment**
In 2013 only two hospitals (Port Moresby General Hospital and Angau Memorial Hospital in Lae) had specialized cancer services, including radiation treatment and chemotherapy. A new screening system, the Visual Inspection With Acetic Acid test, is being used at the Mt. Hagen and Goroka General Hospitals in the Highlands, specifically for the detection of HPV. It has reported the screening of over 2,000 women, and early detection in about 15 percent, some of whom are treated with cryotherapy.

Overall, diagnosis and treatment services in PNG are quite limited and usually are provided by a few physicians and surgeons with specific cancer management skills who work in the hospitals noted above. Histopathology services, which examine tissue samples for disease, lack specialized staff and support, creating significant delays in reporting cancer results. Training of oncologists is largely dependent on overseas medical schools and donor agencies.

Paraguay

Paraguay is a country in South America. It is bordered by Argentina, Brazil, and Bolivia in the central region of South America and therefore is often referred to as the Corazón de América—the “Heart of America.” The indigenous community in Paraguay are the Guaraní and they had been living in Paraguay for at least a millennium before the Spanish conquered the territory in the 16th century. Paraguay was a part of the Spanish empire but was not well populated. At its independence in 1811, the country was ruled by a dictator who tried to maintain restrictive and rough policies that were often hard to work with. The disastrous Paraguayan War (1864–1870) truncated the development that had been made since independence. During this war, the country lost 60 to 70 percent of its population to war and disease and about 140,000 square kilometers (54,054 square miles) of territory to Argentina and Brazil. Paraguay’s population as of 2009 was estimated to be around 6.5 million. The capital and largest city is Asunción, whose metropolitan area is home to nearly a third of Paraguay’s population. Paraguay has long been one of the region’s most isolated countries, although it has grown to have a 2013 gross domestic product of $45.9 billion.

Cancer in Paraguay is not considered a major health issue. In general, modern biomedical practices are combined with herbal and folk remedies not only for cancer but for the full range of health cases. Public health clinics and hospitals are inaccessible to many people, especially in rural areas, and the urban and rural working classes and the poor often depend on self-medication or private pharmacies for medical treatments. As a result of this, herbal remedies are used alongside various pharmaceuticals for medical treatments. Some herbal specialists exist, but most people are knowledgeable about the medicinal uses of common plants or resort to relatives or neighbors for advice on their use. However, because cancer is not yet known to be cured by herbal remedies, the majority of medicines used for the treatment of cancer in Paraguay are imported. Donations are also one of the ways these products are made available to cancer patients in Paraguay. On April 21, 2014, the National Cancer Coalition (NCC) announced the donation of $3 million worth of cancer medicines and essential pharmaceuticals to assist the needy in Paraguay.

The cancer scenario in the country got more attention when the immediate former president of the country, Fernando Lugo, was admitted to a hospital. Due to the limitations of the country’s hospitals to handle cancer patients, he was transferred to the Syrian-Lebanese Hospital in San Paolo, Brazil. Lugo, aged 59, was suffering from redness and swelling around the face and was diagnosed with non-Hodgkin’s lymphoma. Reports from the American Cancer Society state that non-Hodgkin’s lymphoma is common in Latin America, accounting for about 5 percent of all cancers. However, due to the changes in recording or even diagnosing these conditions, it is possible that these statistics are far lower than the actual situation.

The most prevalent cancer in Paraguay is breast cancer, with a rate of 18.96; second is lung cancer with a rate of 15.29, and third is prostate cancer with a rate of 11.54. These are followed by stomach cancer with a rate of 10.19, cervical cancer with a rate of 8.28, colon-rectum cancer with a rate of 8.10, leukemia with a rate of 5.12, pancreatic cancer with a rate of 4.41, lymphomas with a rate of 4.34, and, in tenth place, esophageal cancer with a rate of 4.06. Even though cervical cancer ranks fifth in Paraguay, it is among the highest rates in the world. A study was conducted by E. Kasamatsu and colleagues (2012) to see how human papillomavirus (HPV) spreads in women based on how serious cervical lesions are. The sample was composed of more than 200 women who did not have lesions, 164 with low-grade intraepithelial lesions, 74 with high-grade lesions, and 41 with cervical cancer. The procedure determined what forms of HPV may develop. The results showed 12 high-risk and 24 low-risk HPV types. HPV 16 was the most prevalent, followed by HPV 18 in cervical cancer (14.6 percent), HPV 31 in high-grade intraepithelial lesions (14.9 percent), HPVs 58/42 in low-grade intraepithelial lesions (9.1 percent each), and HPVs 31/58 (2.4 percent each) in women who did not have any of these lesions.
The risk for cancer in Paraguay is considered to include tobacco smoking, use of any tobacco product among youth, fruit and vegetable intake in adults, alcohol consumption, low physical activity in adults, obesity among adults, and HPV prevalence (women with normal cytology). One key risk factor specific to Paraguay, and Latin America by extension, is maté, an Ilex paraguariensis infusion. It is a key factor for the development of cell carcinoma. However, this remains a theory because no meta-analysis on the subject has been performed to date.

The only incidence of cancer screening that is well governed is cervical cancer. Physicians and oncologists are required to adhere to guidelines when screening patients for cervical cancer. The guidelines recommend tests to be performed per age-group per frequency; that is, Pap tests should be conducted for individuals between 25 years and 49 years of age every three years after several negative Pap tests. Support for screening and cervical cytology is generally available in the public and the private sectors while visual inspection with acetic acid is not open in the public and the private sectors.

Treatment for cancer—any type of cancer—can be done in a public health facility or in private health facilities. Radiotherapy is generally not available in public hospitals and only a few private hospitals offer the service. In the country, there are only seven radiation oncologists, four medical physicists, and three radiotherapy centers.

Paranasal Sinus and Nasal Cavity Cancer

Inverted papilloma (IP) is considered one of the most prevalent benign tumors that occur in the nasal cavity. It is responsible for at least 4 percent of all cases of sinonasal malignancies. Although IP has a relatively high incidence rate and is strongly associated with squamous cell carcinoma, its treatment has mainly involved the minimally invasive technique of endoscopic resection. Differentiating IP from the rest of the malignancies involving the nasal cavity is therefore essential in order to prevent the application of chemotherapy for those cases that do not require such treatment. Distinguishing this specific type of cancer can also identify which patients should receive radiotherapy. It is important to understand that both chemotherapy and radiotherapy can increase the incidence of morbidity among patients, particularly when they do not require these treatments. One challenge is that the clinical features of IP prevent minimal diagnostic importance. In addition, the accuracy of diagnosing IP using a biopsy derived from an endoscopy incision might not be high because it is generally difficult to determine whether the collected tissue is indeed the correct specimen that should be used for the analysis. Based on these experiences in the clinic, distinguishing IPs from other malignancies occurring within the nasal cavity has been a challenge in a majority of cases.

Two techniques that have been evaluated in terms of their capacity to resolve the issue of differentiating IPs from other malignant tumors are computed tomography (CT) and magnetic resonance...
Paranasal Sinus and Nasal Cavity Cancer

imaging (MRI). CT presents limited information on the characteristics of a soft tissue mass because these often generate low contrast during imaging. On the other hand, contrast-enhanced MRI has been extensively used because it facilitates characterization of an unknown mass. Previous reports have shown that a convoluted cerebriform pattern generated on T2-weighted images, or in other cases, T1-weighted images with contrast enhancement significantly enhances the sensitivity in IP diagnosis. Despite this improvement, the diagnostic specificity of contrast-enhanced MRI has been relatively poor due to the presence of a convoluted cerebriform configuration that is observed in a significant number of malignant tumors.

Based on these discrepancies in the sensitivity and specificity of imaging techniques, it is therefore essential that the extent of use and the limitations of each technique be identified. In a recent study led by Mohammed Gomaa, the level of input, which reflects the actual value of a specific imaging system, was compared between MRI and CT. This comparative assessment was conducted using various imaging modalities in cases of sino-nasal neoplasms. Their study involved a total of 30 patients, of whom 16 were males and 14 were females, who presented with a chief complaint of sinonasal tract symptoms. After completion of both clinical and local assessments, the study participants underwent the following procedures: conventional radiography, imaging (both CT and MRI), and histopathological examination. The results of the study showed that the nasal cavity was the site most commonly associated with sinonasal malignancies. The maxillary sinuses were the second most common sites of sinonasal malignancies. The site showing the lowest frequency of involvement with sinonasal malignancies was the frontal sinuses. The study identified 14 cases of benign sinonasal tumors. In addition, the most frequent benign lesion was determined to be juvenile nasopharyngeal angiofibroma, which was detected in six cases. IP was observed in three cases. The study also showed that although malignant sinonasal tumors were observed in 16 cases, five of these cases presented squamous cell carcinoma, and three showed undifferentiated carcinoma. The findings of the study also showed that MRI allows high-contrast evaluation of soft tissues of the sinonasal cavity, which is superior to that provided by CT for the pretreatment assessment of malignant tumors.

In another recent study, E. Allegra and colleagues utilized CT in combination with positron emission tomography (PET) in assessing IPs prior to treatment. The proponents of the study were aware that CT and MRI are commonly used for the assessment of sinonasal tumors; however, these imaging techniques are often limited in their capacity to differentiate between IPs and squamous cell carcinomas. Based on this difficulty, the investigators examined the usefulness of F-18 fluorodeoxyglucose (18FDG)-PET in imaging the head region of patients with sinonasal malignancies. A total of 12 patients who were suspected to have sinonasal IPs were included in the research study. Using 18FDG-PET, the standard uptake value of each patient was estimated. The results of the study showed that seven of the 12 patients showed a standard uptake value that ranged from 1 to 8.1. In addition, the histopathological diagnosis post-operatively confirmed an IP diagnosis in five of the seven patients, who then presented the maximum standard uptake value of at least 3. On the other hand, the other five cases that did not show signs of 18FDG uptake were diagnosed to be without IP.

The findings of the research study conducted by Allegra’s group are timely and of great interest because reports on the diagnostic role of newer imaging techniques such as 18FDG-PET/CT are limited. Those that are currently available in the literature are generally case reports that require additional studies to validate those findings. Nonetheless, these earlier reports show that the standard uptake value of benign IPs was generally lower than that observed in IPs co-occurring with squamous cell carcinoma. The study conducted by Allegra and colleagues therefore provided additional information on the extent of decrease in the standard uptake value in benign IPs. Lesions that show a negative or diffused pattern of 18FDG uptake, particularly with standard uptake values of <3, are therefore classified as IP-negative. Although this recent study still requires additional investigations to verify the results described in the report, it directly shows that the combination of PET with CT is a promising approach in diagnosing and staging IP. The combined technique also shows advantages that could not be provided by CT or MRI alone. In addition, the use of PET in combination with CT allows
the analysis of morphological as well as metabolic data over a single session. The standardization of the PET-CT technique in cases of sinonasal malignancies and the establishment of a range for standard uptake values for this specific malignancy are essential in determining the reliability of the technique for IP diagnosis.

Parathyroid Cancer

Parathyroid cancer is a rare malignancy, accounting for only 0.005 percent of all cancers. Due to its rarity, there are no consensus guidelines available. The disease frequently presents as primary hyperparathyroidism, is difficult to detect preoperatively, and is often fatal.

Epidemiology

Parathyroid carcinoma is an uncommon cause of primary hyperparathyroidism, accounting for only 1 to 5 percent of cases. Risk factors include prior history of thyroid cancer and CDC73 germline mutations that can present with the phenotypes of hyperparathyroidism–jaw tumor (HPT-JT) syndrome, CDC73-related parathyroid carcinoma, CDC73-related familial isolated hyperparathyroidism (FIHP), or, rarely, MEN1 syndrome. Its recurrence rate has been reported at from 49 to 82 percent, most commonly in the first two to five years after initial surgery, although as late as 21 years. Overall survival has been reported ranging from 78 to 85 percent at five years and 50 to 77 percent at 10 years, with a median survival of 14.3 years. Factors associated with worse outcome include male gender, advanced age, presence of distant metastases, and nonfunctioning tumors.

Presentation

Parathyroid cancer typically presents as primary hyperparathyroidism, apparent by the presence of hypercalcemia. Calcium levels are often higher and the patients more symptomatic in carcinoma compared to adenoma. Renal and skeletal symptomatology is present in 80 to 90 percent of patients with carcinoma and may manifest as polydipsia, myalgias, nephrolithiasis, bone pain, or pathological fracture. Occasionally a neck mass is present. Up to 10 percent of parathyroid carcinomas are nonfunctioning and thus will be asymptomatic until the tumor has reached an advanced stage, where local invasion causes pain, hoarseness, or difficulty swallowing. At presentation, up to 30 percent of cases will have regional lymph node involvement, and one-third will have distant metastases, most commonly in the lung, liver, or bone.

Diagnosis

It may be difficult to distinguish benign parathyroid disease from malignancy based on preoperative testing and imaging or even by routine pathologic examination of the excised tumor. Factors indicating high risk for malignancy include a palpable mass, local pain, recurrent laryngeal nerve palsy, higher PTH (3–15 times the upper normal limit) and calcium levels (>14 mg/dL), and more severe clinical symptoms, particularly renal, bone, and neurological symptoms, or a significant family history of hyperparathyroidism or its associated syndromes including MEN and HPT-JT. Preoperative ultrasound features indicating high risk for malignancy include size >3.0 cm, lobulated hypoechoic appearance, infiltration of surrounding structures, calcification, or suspicious vascularity. In patients with CDC73 mutation, a 3rd generation:2nd generation PTH assay ratio may be greater than 1.0. Mutations in CDC73 lead to its inactivation and higher levels of amino-PTH, which is measured by the 3rd generation but not 2nd generation PTH assays. Based
on these criteria, patients may be preoperatively categorized as high risk versus low risk. Preoperative workup may also include chest and abdominal computed tomography (CT) or bone scan if there is concern about metastatic disease. Intraoperatively, a high index of suspicion based upon gross findings of a firm, white mass or a parathyroid gland densely adherent to surrounding structures could direct the surgeon to perform a more extensive operation. Intraoperative frozen sections are rarely helpful.

Pathologic diagnosis of parathyroid cancer is difficult, as histologic features may not distinguish it from an adenoma or hyperplastic gland. Gross or microscopic invasion or lymphovascular invasion is helpful. Weak or complete loss of expression of parafibromin, the protein encoded by CDC73 is seen in the majority of HPT-JT-related tumors and sporadic parathyroid carcinomas. On genetic profiling of tumors, high risk features include differential expression of specific microRNAs or mutation in CDC73 or, rarely, MEN1. These mutations may also be present in benign parathyroid disease, but any lesion in the presence of these mutations should be treated with a high index of suspicion. However, this data is not typically available preoperatively, as it requires the tissue specimen for analysis.

Treatment
Surgery is the mainstay treatment for parathyroid cancer, with the intention being curative. Surgical approach varies from local excision, en bloc resection, or oncological resection including the lymphatic drainage. Positive margins predict recurrence. If a parathyroid cancer is suspected, this mandates a minimum of en bloc resection of all involved adjacent structures. There is debate on whether this should include ipsilateral thyroid lobectomy, which is practiced by many surgeons but has not been demonstrated to improve survival when there is no clear tumor involvement. Nonetheless, any adjacent structures that are involved (most commonly ipsilateral thyroid lobe, strap muscles, ipsilateral recurrent laryngeal nerve, esophagus, and trachea) should be resected if feasible. Prophylactic neck dissection is not recommended unless there is evident lymph node disease. A common scenario is to not identify malignancy until postoperative histopathology examination. In this case, there is still debate about whether reexploration for ipsilateral thyroid lobectomy and central cervical neck dissection is necessary.

Surgical treatment is the same for patients with known presence of genetic mutations. However, in these patients it is critical to explore all four glands to avoid missing additional cancers or benign parathyroid adenomas. In the setting of metastatic disease, resection of the metastasis is indicated. Although this may not be curative, resection can reduce hypercalcemia and potentially improve patient survival. For unresectable disease, hypercalcemia should be treated with cinacalcet, as the most common cause of death is severe hypercalcemia rather than tumor burden.

Adjuvant therapy with radiation is not routinely used. Data show mixed results on whether there may be benefit to prevent local recurrence in high-risk patients or those with positive surgical margins. Survival benefit has not been shown. Chemotherapy is not recommended, as there is limited data and no evidence of benefit.

Follow-Up
While there is no consensus staging by the American Joint Committee on Cancer, A. R. Shaha and colleagues and N. Talat and colleagues have both proposed potential tumor node metastasis staging systems. K. M. Schulte and Talat suggest staging can be divided into low risk and high risk categories based on recurrence and survival. Low risk is defined as invasion limited to the capsule and soft tissue. High risk is when there is vascular invasion, lymph node metastasis, or invasion of the trachea, esophagus, or major cervical vessels. Approximately 50 percent of cancers fall into each category. The high-risk group had disease-specific mortality of 50 percent at five years, whereas the low-risk group had no deaths.

Due to high rates of local recurrence, patients should be followed closely. In low-risk patients, calcium and PTH should be monitored every six months for the first five years and annually thereafter. High-risk patients should be followed more closely, with lab work every three months for the first 10 years. In the 1 percent of patients with non-secreting tumors, imaging follow-up should be obtained instead.

Conclusion
Parathyroid cancer is a rare cancer that presents insidiously with severe hypercalcemia and its
manifestations. En bloc surgical resection is the mainstay for treatment. It is necessary to consider malignancy in the preoperative setting, as failure to suspect malignancy is the main reason for failure to perform oncologic resection. Multiple recurrences are common and repeat surgical excision, although difficult, may be needed, including metastasectomies, as the primary cause of cancer death is not from disease burden but rather from hypercalcemia. With proper surgical technique and careful follow-up, survival can be a decade or longer for many patients.

Passive Smoking

Smoking of tobacco products has produced a global health epidemic. In 2009, the mortality count from tobacco usage was more than 5 million people, and it is projected to exceed 8 million by 2030. Tobacco smoke has become one of the major causes of cancer mortality, accounting for approximately 30 percent of all cancer deaths. There have been more than 600,000 deaths each year attributed to secondhand smoke, with approximately 3,400 lung cancer deaths occurring among nonsmokers.

Secondhand smoke has also been associated with cancer of the respiratory, digestive, and reproductive systems, as well as the kidney and bladder in adults and the risk of leukemia, lymphoma, and brain tumors in children. The U.S. Surgeon General reported that exposure to secondhand smoke can result in an increase of up to 20 to 30 percent more lung cancer cases, particularly among individuals who live with a partner who smokes. Based on the fact that secondhand smoke has also been identified
as a carcinogen, with an increasing incidence of cancer among nonsmokers, it is therefore important that this topic be thoroughly investigated. This article highlights and explains the relationship between secondhand smoke and cancer and identifies strategies for reduction of this health hazard.

Several terminologies can be used to describe secondhand smoke, including passive smoke, environmental smoke, or involuntary smoke. Secondhand smoke is a combination of the “sidestream” smoke that is given off by a lighted tobacco product and the “mainstream” smoke that is exhaled by the person who is smoking. It consists of a mixture of gases and fine particles that tend to persist in the atmosphere. It therefore puts unsuspecting nonsmokers at increased risk of inhaling the tiny particles, which tend to have higher concentrations of carcinogens. Individuals can become exposed to secondhand smoke in a wide range of settings, including places of business, residence, employment, and recreational facilities. This smoke contains approximately 250 substances that have been identified as harmful, and about 50 of these have been confirmed as carcinogens. Several factors influence the makeup of secondhand smoke; these include the type and amount of tobacco, the chemicals added to the tobacco, the method of smoking, and the material in which the tobacco is wrapped. Some of the harmful substances that have been identified in secondhand smoke are arsenic, benzene, beryllium, cadmium, chromium, ethylene oxide, and nickel.

**Measurement of Secondhand Smoke**

The level of secondhand smoke exposure can be determined by testing body fluids such as blood, urine, and saliva for cotinine. Cotinine is a substance that is produced from the breakdown of nicotine. The average levels of cotinine have fallen over the past 20 years, which could be attributed to changes in the law that have prohibited smoking in workplaces and public places. Higher levels of secondhand smoke have been associated with persons of certain professions and ethnic groups.
Reports have suggested that although there is a general decline in cotinine levels, non-Hispanic African Americans tended to have higher levels compared to non-Hispanic white Americans and Mexican Americans. Persons in certain occupational groupings such as construction workers, blue-collar workers, and service providers have also been identified as having higher levels of exposure to secondhand smoke. There is no safe level of exposure, and so agencies such as the National Institute for Occupational Safety and Health and the Occupational Safety and Health Administration (OSHA) have instituted policy changes in smoking regulations for buildings, workplaces, and public spaces.

Different Types of Cancer
Secondhand smoke has been associated with many different types of cancers. Cancer is an abnormal malignant condition that can occur within any tissue of the body. It is characterized by uncontrollable replication of cells, which may result in abnormal growths and damage to surrounding tissues. The damage or change in the DNA results in failure to replicate in a normal manner. One of the substances that have been incriminated in causing damage to the DNA with subsequent malignancy is secondhand smoke. Some of the cancers include those of the respiratory tract such as the lungs, naso-pharynx, and nasal sinuses and those of the reproductive organs of the breast, cervix, and ovary. There is also evidence to suggest secondhand smoke may be linked with cancers of the brain, bladder, rectum, and stomach. The California Environmental Protection Agency has identified a causal relationship between secondhand smoke and cancers in younger women. Traces of secondhand smoke have also been identified in breast tissue and breast milk. However, based on the fact that a causal relationship was not identified among active smokers, the link remains inconclusive. The Surgeon General therefore reported that there was not sufficient evidence to link secondhand smoke with breast cancer.

Smoking accounts for 87 percent of lung cancer deaths in men and 70 percent in women. The U.S. Environmental Protection Agency, the U.S. National Toxicology Program, and the International Agency for Research on Cancer have classified secondhand smoke as a carcinogen, directly causing lung cancer. Exposure to secondhand smoke can increase the risk of lung cancer by 20 to 30 percent. Between 2005 and 2009, secondhand smoke exposure has been estimated to cause more than 7,300 lung cancer deaths annually among adult nonsmokers in the United States. Children are at particular risk for exposure to secondhand smoke. It is believed that children who are exposed to secondhand smoke are at increased risk of developing a malignancy such as lymphoma, leukemia, or brain tumor. In 2009, the International Agency for Research on Cancer reported that children of parents who smoked before and during pregnancy were more likely to have a child with hepatoblastoma, which is a rare liver cancer that may have started development in utero.

Reducing Secondhand Smoke
Although secondhand smoke may not be the cause of a number of cancers, there is evidence to suggest that it significantly contributes to morbidity and mortality associated with cancer. Governments in several countries have imposed a ban on the advertising, promotion, and sponsorship of tobacco products. These bans have resulted in reduced usage of tobacco products with subsequent reduction in the exposure to secondhand smoke. Some governments have also imposed increased taxes on tobacco products. The imposed taxes have also resulted in a decrease in tobacco consumption, which further contributed to a reduction in secondhand smoke. The World Health Organization (WHO) in its commitment to reduce secondhand smoke has established the WHO Framework Convention on Tobacco Control. The application of this convention was introduced in 2008 as MPOWER. This program seeks to help countries control tobacco usage, promote health education and prevention policies, and provide support for the enforcement of legislation and policy regarding tobacco usage.

Secondhand smoke is of particular concern within work environments. The Occupational Safety and Health Administration has issued guidelines for establishing and regulating smoke-free workplace policies. Local, state, and federal authorities have also passed clean indoor air laws in order to protect people from secondhand smoke. It is also important that homes and motor vehicles be kept smoke free. Based on the fact that
it is difficult to control ventilation by air cleaning or by separating smokers from nonsmokers, a smoke-free environment is recommended. Federal law has banned smoking in certain public areas; these include public buildings, malls, parks, parking lots, schools, colleges, hospitals, playgrounds, airline flights, buses, and most trains. The Pro-Children Act of 1994 also prohibited smoking in facilities that routinely provide federally funded services to children. The goal of the Healthy People 2020 program was to reduce exposure to secondhand smoke by 10 percent. The program also included a nationwide health promotion and disease prevention agenda that addressed reducing illness, disability, and deaths related to tobacco use and secondhand smoke exposure. Mass media campaigns with anti-tobacco advertisements and graphic warnings have contributed to a reduction in the numbers of children who begin smoking and increased the number of smokers who quit. Studies conducted in countries such as Brazil, Canada, Singapore, and Thailand show that the warnings have increased people's awareness of the harms of tobacco use.

**Economic Costs**

There are tremendous direct and indirect costs associated with tobacco usage. The direct costs are based on the costs required to address the morbidity and mortality associated with cancer. The indirect costs are those associated with reduced productivity or lost wages due to illness and death. Ten percent of the economic costs related to tobacco use are attributable to secondhand smoke. This is of great significance based on the fact that more than 94 percent of individuals in society are unprotected from secondhand smoke. In order to reduce these economic costs, it is important to establish and maintain smoke-free environments within society.

**Conclusion**

Secondhand smoke has become one of the major factors associated with several cancers. It has also been associated with cancer of the respiratory, digestive, and reproductive systems as well as the kidney and bladder in adults and the risk of leukemia, lymphoma, and brain tumors in children. Secondhand smoke is particularly dangerous because it contains particles with higher concentrations of carcinogens that can be more easily inhaled into the lungs. Although some reports indicate a causal relationship between secondhand smoke and breast cancer in younger women, other reports have been inconclusive.

Local, state, and federal agencies have established policy guidelines and legislation to reduce exposure to secondhand smoke. Strategies for reduction of exposure to secondhand smoke include restricting smoking in public places, such as parking lots, and instituting laws against smoking in public buildings, including schools, and in other enclosed spaces such as airplanes, buses, and trains.

Based on the fact that there are high levels of cancer morbidity and mortality among nonsmokers with increasing direct and indirect economic costs, it is of great urgency and utmost importance that strategies be put in place to protect society and that research continue to be conducted so that the true relationship of secondhand smoke and cancer can be conclusively determined.

Penile Cancer

There are many different forms of penile cancer, with the severity depending on the extent to which the cancer has spread. Early detection offers many advantages, and there are many treatment options, including surgery, radiation therapy, biological therapy, and laser therapy. Penile cancer usually begins as a small lesion on the skin of the penis and tends to grow very slowly, spreading the cancer. Malignancies are usually found in the head of the penis (the glans), with the foreskin (or prepuce) the next most common site. Tumors in the shaft of the penis are uncommon. Penile cancer usually involves squamous cell carcinomas (cancer not involving melanomas). One common type of penile cancer is epidermoid carcinoma (where the cancer develops in the skin of the penis). Another is verrucous carcinoma (a low-grade malignancy that may spread into surrounding tissue). Approximately 5 percent of penile cancer is caused by melanomas from pigment-producing skin cells, basal cell penile cancer (that is, cancer not caused by melanomas), and sarcomas (cancers of the connective or supportive tissue such as muscles and blood vessels). Another rare form of cancer that develops in the sweat glands in the skin of the penis is called adenocarcinoma.

The severity of penile cancer depends on whether the cancer is detected at the earliest stage (known as carcinoma in situ) and whether the carcinoma is localized or has spread to other areas. Early treatment can cure penile cancer, but there are no universally recommended tests for early screening. Penile cancer may be emotionally devastating, embarrassing, and shameful for men, and this may lead them to delay seeking treatment. Such delays in seeking appropriate treatment may exacerbate the problem. An important thing to remember is that with early detection, there is often little or no damage to the penis. Delaying treatment can mean that some (or all) of the penis may need to be removed.

Typically, penile cancer is treated with surgery, such as local resection for superficial carcinomas (partial amputation of the affected part of the penis, possibly treated with a penile reconstruction). It is important for patients to be aware of the kind of penile cancer they have, whether it has metastasized, and the treatment options. The treatment team usually includes a urologist, a radiation oncologist, and a medical oncologist. Such doctors can answer questions about whether the patient will be able to have sex, have children, or whether the cancer will affect their ability to urinate. When surgery occurs, a small incision is usually made until the surgeon reaches normal skin tissue. Such surgery usually does not prevent patients from being able to have sexual intercourse. However, in some cases, surgical removal of the penis and perhaps a lymph node may be necessary. Chemotherapy, radiation therapy, biological therapy, and laser therapy are other possible treatment options.

Risk factors for penile cancer include human papillomavirus (HPV) infection, age, not being circumcised, having phimosis or built-up smegma, smoking, having a history of being treated for psoriasis with a combination of psoralens and ultraviolet lighting, and having AIDS. The most common types of HPV (HPV 6 and HPV 11) are associated with genital warts but have a low risk of being associated with cancer. However, some types of HPV are considered high risk (HPV 16, HPV 18, and HPV 31, as well as some others). Usually, infection with a high-risk HPV has no visible signs until precancerous changes or cancer develops. Penile cancer usually affects older men (those over 60), although a small proportion occurs in younger men as well. Malignancies of the penis are rare among circumcised men: those circumcised as babies almost never develop penile cancer. Smoking also increases the risk of HPV infection, which is another risk factor for developing penile cancer.

Men who have the skin disease psoriasis are often treated with combinatorial psoralen drugs and ultraviolet lighting; because this treatment also increases the risk of penile cancer, men are required to cover their genitals when they use such treatments. Having AIDS is another risk factor for developing penile cancer, most likely associated with compromised immune systems.

The risk of mortality associated with penile cancer varies greatly according to whether there is carcinoma in situ (the earliest stage of squamous cell cancer) and whether the carcinoma is localized to a specific area or not. For men with stage I and stage II penile cancer, the five-year survival rate from penile cancer is approximately 85 percent. When the cancer has spread to lymph nodes and nearby tissues, the five-year survival rate is approximately 60 percent. If the cancer has metastasized
to distant parts of the body, the five-year survival rate is 11 percent.

Penile cancer is generally uncommon in Western countries. The American Cancer Society estimates that approximately 1,640 new cases will be diagnosed in 2014, and roughly 320 men will die of it in 2014. However, penile cancer is much more common in less developed countries and accounts for approximately one-tenth of all cancers diagnosed in men in Asia, South America, and Africa. Because penile cancer is relatively rare, it has been difficult to enroll sufficient numbers of men in new treatment options to test their efficacy. However, some new treatment options are being explored. For instance, laser therapy is being used to treat some men with penile cancer. Additionally, some new drugs are being tested, and researchers are exploring the possibility of gene therapy to treat various forms of penile cancer. Vaccines that prevent the development of HPV may also reduce the number of men who develop penile cancer.

Perfume

The word perfume comes from the Latin per fumare, “to smoke through,” originally in reference to the perfuming of the air through the burning of incense and resins. The science of fragrance dates to the 2nd millennium B.C.E., and in the ancient world people used almonds, citrus fruit, flowers, plant resins, and spices to prepare incenses, distillations, infusions, and scented oils in order to add scent to rooms, themselves, and objects. Norms of perfume use have varied considerably from culture to culture and time to time; the modern perfume industry originates from the use of perfume and cologne to mask body odor in the early Enlightenment period, when people bathed rarely, and the industry remains centered in Italy and France today as it was then.

Although we commonly use “cologne” to mean fragrance for men, and “perfume” to mean fragrance for women, in the industry the terms refer to the concentration of aromatic compounds in a neutral medium of ethanol or water. Perfume is usually 20 percent or as high as 40 percent. Espirit de parfum is usually 15 percent aromatic compounds, while the more common eau de parfum is 10 to 15 percent. Eau de toilette or toilet water is 5 to 10 percent. Eau de cologne has a concentration of 3 to 8 percent and refers specifically to a fragrance from the chypre family, characterized by the combination of citrus, oak moss, patchouli, and musk. Classically, chypre also included civet—an extract from the African civet's musk gland—but this is less commonly used today, and synthetic civets are noticeably different. Men's colognes today are usually eau de parfum or eau de toilette, formulated from scents deemed appropriate for men or, increasingly, relying heavily on aldehydes and calone for “fresh” or “aquatic” scents.

Individual fragrances are described using three terms: (1) top notes or head notes, the scents that are noticed first and form the initial impression, though because they consist of light molecules, they also dissipate the fastest and will often not be noticed by anyone except the individual wearing the scent at the moment they first apply it; (2) middle notes or heart notes, which emerge after the top notes disappear; and (3) base notes, which last the longest but may take more than 30 minutes to become noticeable. Much of a fragrance's power comes from the interplay between the middle notes and the base notes. Perfume formulation is much like cooking, in that it is not sufficient to combine various scents that an individual likes and assume that they will bring out the best in each other. Perfumes are traditionally grouped into families, although there can be considerable variation within
these families, and some of the smaller perfume houses have built their reputations on unusual outliers. The modern list of perfume families includes floral perfumes, which rely heavily on flowers, alone or in combination; oriental perfumes, which build on animalic scents by combining them either with woody scents, camphor, resins, or lighter scents like vanilla; woody perfumes, characterized by scents like sandalwood, cedar, and agarwood; leather perfumes, which alludes to leather through scents like tobacco, wood, and wood tar; the aforementioned chypre, named for the 1917 fragrance by François Coty; fougere, combining oakmoss, coumarin, and lavender; green, a chypre variant that includes bright scents like cut grass, green leaves, and cucumber; aquatic, oceanic, or ozonic, pioneered by the 1988 introduction of Davidoff Cool Water and dependent on the 1966 discovery of calone; citrus; and gourmand, coming into focus in the 1990s with a focus on vanilla, coumarin, and food flavors.

Traditional perfumes include animal-derived ingredients, and the oriental and chypre families were traditionally dependent on them. This practice fell out of favor, and synthetics were developed in the 19th and 20th centuries to replace them, most of which are called synthetic musks or white musks. White musks are also cheaper than animal-derived ingredients, and part of a larger trend of developing synthetic replacements for expensive ingredients, providing the foundation for department store fragrance products as well as the ability to cheaply add fragrances to deodorant, shampoo and conditioner, soap, air fresheners, laundry and dish detergent, and other products. One such white musk is musk xylene, which was the most widely used white musk until the 1980s. Discontinued in Japan in 1982 and no longer produced in Europe (though it continues to be imported and is legal for use in cosmetics products and perfumes), musk xylene fell out of favor in part because of its unexpected explosive properties—it is classified as an explosive under the European Union (EU) Dangerous Substances Directive—and its possible environmental damage, upon discovery that musk xylene is not completely removed by sewage treatment processes and thus enters the water system. Musk xylene has some toxic properties, especially to the liver, but its carcinogenicity, though widely reported in lists of consumer product components to be avoided, is not clear.

The International Agency for Research on Cancer (IARC) lists it as class 3: “not classifiable as to their carcinogenicity to humans.” A study on mice found an increase in liver cancer after oral exposure, but the study’s applicability to human health has been criticized.

Policyclic and macrocyclic artificial musks have overtaken musk xylene’s popularity. Like musk xylene, they are inefficiently removed by wastewater treatment processes (which they enter through bath and shower water, for example, when used as perfumes or to scent soaps), but there is as yet no indication that they are carcinogenic.

Coumarin is a common perfume component, and it is also used in pipe tobacco and fabric conditioners. It can be derived from a number of sources, including tonka beans and cassia.
cinnamon, and adds a sweet smell similar to that of new-mown hay. The carcinogenicity of coumarin is not yet established but is suspected by some authorities, and it is toxic to the liver and kidneys in animal studies. Coumarin is also one of the primary culprits in the allergic or sensitive reaction some people have to perfumes or fragrances; in such people it can induce or aggravate asthma-like symptoms as well as migraines with or without headache.

The modern perfume family of aquatics/oceanics relies heavily on aldehydes, especially associated with sharp and ozonic smells or fresh scents like Davidoff Cool Water or Christian Dior's Dune. However, different aldehydes have different scents, and most modern perfumes, regardless of fragrance family, include aldehydes in their formulation. In women's perfumes, for example, aldehydes are associated less with the aquatic family and more with Chanel No. 5, in which aldehydes provide a rich warmth rather than a sharp freshness. Aldehydes are also used in many “fresh laundry” or “fresh cotton” smells, both in perfumes and in detergent and air fresheners.

Aldehydes are organic compounds, at least some of which are believed to be carcinogenic. Acetaldehyde, for instance, is known to damage DNA and interfere with muscle development, and is classified as a Group I human carcinogen by the IARC. It is one of the carcinogens found in tobacco smoke, as well as a result of off-gassing from many building materials, including linoleum, wood varnish, pine flooring, and many water-based paints.

Studies have also found links between working in the fragrance industry and the development of prostate cancer or male breast cancer.

Perlmutter Cancer Center

The Laura and Isaac Perlmutter Cancer Center is a big name in cancer care. The center, which was founded in 1975 as the New York University Cancer Institute (NYUCI), is a National Cancer Institute (NCI)—registered group. The center gets its name from the New York University Langone Medical Center of which it is part. In 1983, the center was branded the Kaplan Cancer Center. In 1991, the NYU Cancer Center in New York City and the Cancer Center at the Nelson Institute of Environmental Medicine merged. Since its establishment, the mission of the NYUCI has been and still is to learn about how cancer is formed and to use that knowledge to control the development of this disease.

NYUCI is a translational cancer center and takes a team approach to cancer. The institution has over 250 members who come together from a variety of disciplines to create collaborative research endeavors and clinical care teams. The team at the center, the researchers and scientists, share a goal of understanding how cancer develops at the molecular level and how that knowledge can be harnessed to reduce the risk of cancer and to treat the disease. To achieve this, the center seeks and creates new opportunities for collaboration between investigators within and outside the institution.

For example, researchers at the center collaborate with others in the New York University network of campuses (such as the Washington Square Campus in Lower Manhattan) as well as with researchers at other academic, research, and medical institutions, including Smilow Cancer Research Center, Tisch Hospital, Kimmel Stem Cell Center, Skirball Institute, Rusk Institute, the Hospital for Joint Diseases, and the Nelson Institute for Environmental Medicine. The Perlmutter
Cancer Center also works in affiliation with other institutions, including Woodhull Medical Center, Bellevue Hospital Center, and the U.S. Department of Veterans Affairs.

The team structure adopted by the institution is based on the knowledge that cancer is a complex problem requiring complex solutions. Moreover, the solutions are not to be limited to a single study area. Therefore, to develop appropriate solutions for cancer, various experts from a variety of disciplines are brought in to create collaborative research endeavors and clinical care teams. The center offers a full continuum of personalized care, from prevention through diagnosis, treatment, and posttreatment support. This personalized care offers the most up-to-date treatments for all cancers, and the institution is accelerating the pace of research and clinical care for all types of human cancer to develop better, more sophisticated, and appropriate care strategies. In 2014, the Perlmutter Cancer Center launched key studies in cancer health care disparities, molecular research, lung cancer, melanoma, and genetic or cellular signals within the body.

The Perlmutter Cancer Center is part of the NYU Langone Medical Center. The NYU Langone Medical Center is a world-renowned academic medical center located in Midtown Manhattan. Patients in the Perlmutter Cancer Center who are also being treated for other non-cancer medical needs, for example cardiovascular disease, have access to expert medical staff in place to provide that specialized health care too. This means an individual seeking treatment at Perlmutter will receive treatment that focuses not only on cancer but a holistic kind of treatment that focuses on the person as a whole. Patients can get all the care they need in one facility.

Perlmutter Cancer Center serves a diverse patient population. Persons seeking health care here come from all cultural backgrounds, from a variety of socioeconomic levels, and from many different countries. According to research and as has been practically established, cancer patterns and outcomes may vary according to such demographics; this means doctors and other health care professionals at the center learn a great deal about cancer by observing its presentation and behavior in different patient groups. This knowledge can lead to the development of better diagnostic and treatment services for all patients, regardless of their backgrounds. This is a benefit not only to the health professionals at the center but also to the patients, because such knowledge is used by the professionals to offer better and more suited care according to the patient’s specific history.

In early 2014, the institution changed its name to the Laura and Isaac Perlmutter Cancer Center. Laura Perlmutter is a member of the advisory board of the Perlmutter Cancer Center and Isaac Perlmutter is chief executive officer of Marvel Enterprises; both are trustees of the New York University Langone. The institution was formally renamed to Laura and Isaac Perlmutter Cancer Center to recognize the remarkable gift by Laura and Isaac Perlmutter.

Perlmutter Cancer Center scientific research programs focus on either fundamental questions about the biology of cancer or disease-specific research questions related to various types of cancer. Some of the current research programs are in growth control, cancer immunology, epidemiology and cancer control, environmental and molecular carcinogenesis, genitourinary cancer, breast cancer, stem cell biology, thoracic cancer, melanoma, hematologic malignancies, sarcoma, and gastrointestinal cancers. The results of each research program are translated into improved and comprehensive care for patients.

In addition to research and health care for cancer patients, the Perlmutter Cancer Center offers a variety of outreach and education programs for both patients and members of nearby communities. These outreach programs take the form of community seminars, cancer screenings, special programs for diverse populations, and a speakers’ bureau. Through these activities, the center is able to educate the people it serves by making cancer care and education available to all.

Peru

The Republic of Peru is a South American country with extreme geographical differences within its territory, ranging from the high Andes mountain peaks to the vast Amazon Rainforest Basin to the arid plains of the coastal regions. For much of its history, Peru was home to the ancient Inca Empire, which built the colossal religious buildings that still today dominate the well-known touristic landscape of the Sacred Valley of Machu Picchu.

In 1532 Francisco Pizarro’s Spanish conquistadors defeated Inca Emperor Atahualpa and started the colonization period, exploiting Peru’s vast natural resources (mostly gold and silver), enslaving the population, forcing the Catholic religion with the Inquisition violence, and importing African slaves to increase the labor force. Peru revolted against the Spanish crown in 1824, defeating it in the Battle of Ayacucho and declaring its independence under the presidency of Ramón Castilla. Through the 19th and 20th centuries, Peru waged numerous wars against its neighboring countries (Chile, Ecuador, Colombia), and together with the negative influence on its economy of the Great Depression first and a series of political struggles and military coups later, the country bled to bankruptcy several times. In particular, Peru’s economic and social stability suffered much through the 1980s and 1990s because of the influence of chronic inflation and the terrorist campaign carried out by the Shining Pact and Túpac Amaru Revolutionary Movement (MRTA) leftist insurgent troops against the Alberto Fujimori government. Internal conflict provoked at least 70,000 victims, many human rights violations such as mass murder, summary trials, and use of torture, and it is still going on today. Today Peru is a multiethnic country struggling to improve its economy: while still suffering widespread poverty and wealth distribution disparity, it saw an economic boom during the 2000s and today continues to grow rapidly.

Despite the existence of a public system of primary care managed by the Ministry of Health of Peru (MINSA) and the EsSALUD social security program, the Peruvian health care system still shows significant disparities in care between middle-income and poor citizens. In particular, most of the rural or Amerindian indigenous population still seek medical treatment from traditional healers and shamans (the so-called curanderos), who mix modern medicine with a more philosophical and often nonscientific approach. However, many of the plant-derived medicinal products and even some insects from the Coleoptera family used in ethno-traditional Peruvian medicine show promising activities as anticancer agents, although more studies and clinical trials are still required to properly assess their real benefits. A total of 17 plant species are used in the preparation of herbal remedies used in cancer treatment by local healers, mostly coming from the Asteraceae and Gentianaceae families. Among those, three plants in particular have shown noticeable antitumor activity: cat’s claw (Uncaria tomentosa), maca (Lepidium meyenii), and dragon’s blood (Croton lechleri).

The first modern cancer treatment facility, the Instituto Nacional de Enfermedades Neoplasicas (INEN), was founded in 1932 under its original name Instituto Nacional de Radioterapia (National Institute of Radiotherapy), but it was reorganized in 1952 by Eduardo Cáceres. Today the INEN is still one of the most advanced cancer facilities in the country. Since then, many efforts have been made by the Peruvian government in terms of cancer prevention, such as introducing the human papillomavirus (HPV) vaccine, joining the international organization Union for International Cancer Control (UICC), implementing communication strategies to increase public awareness about cancer, and financing projects for massive population screening and early cervical cancer detection using acetic acid (VIA). In 2004 the Multisectorial Coalition Against Cancer was formed to write and implement a National Cancer Control Plan, and in 2011 a cancer control plan called Esperanza was launched to
provide cancer care for the low-income Peruvian population.

In Peru cancer is the second-leading cause of death, following cardiovascular disease as in most developed countries. According to data provided by the Health Ministry, the annual mortality from cancer is 107 per 100,000 population, with an incidence of 157 people per 100,000 population, a 75.9 percent lethality, and 45,000 new cancer cases diagnosed each year. In Peru, three national population-based cancer registries are available: the first two, the Registro de Cáncer de Lima Metropolitana and Registry of Cancer of Trujillo City were founded in 1968 and 1984, respectively, and the third, the Arequipa Poblational Cancer Registry, was inaugurated in 2000. In 2006 the System of Epidemiological Cancer Surveillance was established in an effort to unify population registries. The most common cancer types in Peru are stomach cancer for both sexes, cervical and breast cancer for females, and prostate and colorectal cancer for males. Risk factors are those most commonly found in well-developed countries: obesity, bad dietary habits, sedentary lifestyle, alcohol consumption, and smoking. Also, recent studies reported that elevated levels of heavy metals such as lead, copper, and arsenic have been found in Peruvian drinking water. In particular, in many samples collected from water around the entire country, arsenic concentration was found to be up to four times higher than the World Health Organization (WHO) recommended limit of 10 μg/l, probably the result of industrial pollution from smelters, mines, and refineries discharging wastewater in the Rímac river basin. Exposure to moderate-to-high (more than 50 μg/l) levels of arsenic in drinking water is associated with an increased risk of lung, bladder, and skin cancer.

Pesticides

The U.S. Environmental Protection Agency (EPA) defines a pesticide as “any substance or a mixture of substances intended for preventing, destroying, repelling, or mitigating any pest.” Pests are living organisms that are prevalent in unwanted areas or that cause damage to crops, humans, animals, or buildings. Pesticides are most broadly classified according to their target organisms. For instance, herbicides are used for weeds; insecticides for insects, etc. Pesticides encompass a variety of chemical structures and can be grouped by their common elemental forms. Phenoxy herbicides, organochlorine insecticides, and organophosphate insecticides are examples of different chemical categories. This article provides an overview of
the history of pesticide development and its uses, sources and routes of human exposure, environmental and human health effects, and regulations and exposure prevention.

History of Pesticide Development and Uses
The first recorded purposeful use of pesticides occurred as early as 2500 B.C.E. when Sumerians rubbed odorous sulfur compounds on their bodies to repel insects and mites. Ancient civilizations in Egypt, China, Greece, and elsewhere similarly developed compounds based on mercury and arsenic to control pests on their bodies and in homes. Personal and home uses eventually extended to protect agricultural crops from damage. Roman scholar Marcus Terentius Varro discovered the first chemical herbicide in the 1st century B.C.E. when he observed that amurca (a substance naturally produced from crushed olives) was toxic to weeds, as well as to ants and moles. Sulfur, mercury, arsenic, and salt also continued to be used alone or as part of simple mixtures to control weeds and insects.

Although pesticides have been used for centuries, progress in pesticide development was minimal until recent times. The agricultural revolution in the 18th and 19th centuries in Europe sparked the need for greater crop protection. Increased scientific knowledge about insects, fungi, and plants led to the design of agents targeted to specific organisms, such as Paris green to control the potato beetle. International trade also promoted the discovery and use of the naturally occurring insecticide pyrethrum. The organochlorine insecticide DDT (dichlorodiphenyltrichloroethane) was developed by Swiss scientist Paul Müller in 1939 as the first synthetic organic chemical for selective control. It was used extensively during World War II to kill typhus-carrying lice and malaria-carrying mosquitoes, earning Müller a Nobel Prize in Medicine. Although DDT was eventually banned in the 1970s and 1980s due to its harmful effects on wildlife and human health, it is still used to treat bed nets in malaria-endemic regions. Pyrethroids are an alternative to DDT for this purpose.

Pesticides that were developed for the purposes of warfare in World War II were later redirected for use on farms. Parathion and the phenoxy herbicides 2,4-D (2,4-dichlorophenoxyacetic acid) and 2,4,5-T (2,4,5-trichlorophenoxyacetic acid) are examples of agents developed during this era. Since then, the agrochemical industry has developed synthetic pesticides that have been widely used, for example, to sanitize water supplies and to protect buildings from structural damage. Thousands of years after their first recorded uses, pesticides remain the frontline means of controlling disease, weeds, insects, and other organisms at home, work, and in the environment.

Sources and Routes of Human Exposure
Occupational exposure to pesticides may occur during pesticide manufacturing processes and from mixing, applying, and/or handling pesticides in agriculture and other industries. Around the world, the highest levels of pesticide exposure are found in farmworkers, pesticide applicators, and people who live near heavily treated agricultural land. Farmers and farmworkers directly handle about 70 to 80 percent of the pesticides that they use and are at the highest risk of exposure. Three-quarters of U.S. households use at least one pesticide product at home and approximately 80 percent of most Americans’ exposure occurs indoors.

Residential pesticide exposure can occur from treated kitchen and bathroom surfaces, insect and rodent baits and traps, lawn and garden treatments, and flea and tick products on pets. Respiratory exposure to pesticide vapors and very small particles pose the most serious risks, and pesticides can be rapidly and completely absorbed through the thin and permeable lung tissues. Since pesticides are ubiquitous in treated water and store-bought fruits and vegetables, contact can also occur through the mouth. Skin absorption is the most common route of exposure in typical work environments. Genital and head regions are the most vulnerable areas. Certain pesticides continue to be used for preventing and killing bodily pests, such as lindane, a topical insecticide for head and body lice. The duration, frequency, and intensity of exposure are important variables in determining total or cumulative lifetime exposure and bodily absorption. The selection of the method(s) to assess exposure to pesticides is often guided by feasibility and cost.

Pesticide
Pesticide exposure is associated with many known and suspected environmental and human health effects. One of the most prominent findings was documented in Silent Spring, a book by Rachel
Carson published in 1962 that described declines in bird populations believed to occur as a result of eggshell thinning from DDT exposure.

The book was met with some criticisms; however, it spurred discussions about national pesticide policy and led to a countrywide ban of DDT for agricultural uses, as well as a grassroots movement that eventually created the EPA. Recently, scientists have found potential linkages between honey bee colony collapse disorder and the spraying of certain pesticides on agricultural crops that may affect bees’ immune systems. Identifying other possible causes is currently an area of active investigation. Studies are also ongoing for assessing possible reproductive health effects of atrazine, a commonly used herbicide, on frog populations. The intensive, repeated use of pesticides over time has contributed to insecticide resistance. Nearly every insecticide is now associated with insects that are genetically no longer responsive to its intended purpose. This often leads to more frequent insecticide applications until another agent becomes available. The risks of evolving resistance and cross-resistance are related concerns.

Children exposed to high levels of pesticides over a short period of time can experience neurological effects, nausea, and weakness; in the long term, exposure may cause learning disabilities, asthma symptoms, and birth defects, among other potential effects. Children are more vulnerable than adults to the adverse health effects of pesticides due to their smaller size, greater hand-to-mouth and outdoor activities, higher respiration rate, and active cellular development. Unintentional and intentional pesticide poisonings occur among children and adults worldwide, and these acute exposures are associated with illnesses and death.

Some of the human health effects that have been investigated over several decades of population-based research are immune suppression, neurological effects, skin and eye irritation, hormone disruption, and cancer. In a case-control study of Canadian men, there was a 30 percent increased risk of non-Hodgkin’s lymphoma among those who used 2,4-D and an over twofold risk associated with the use of mecoprop. In this population there were also higher risks of multiple myeloma observed for 2,4-D, glyphosate, mecoprop, malathion, carbaryl, and chlordane based on days per year of use. The small number of cancer cases is a major limitation of these analyses; nevertheless, they do provide important leads for further research.

The International Agency for Research on Cancer (IARC) has assessed the carcinogenicity of certain pesticides. To date, the pesticides that IARC has evaluated have been mostly categorized as “possible human carcinogens” (Group 2B) based on limited human and animal evidence. These include 2,4-D, DDT, 2,4,5-T, lindane, chlordane, mecoprop, and dicamba. Many were evaluated in the 1980s and 1990s. Evidence published since then confirms these findings and has identified additional pesticides that could be associated with specific cancers.

**Regulations and Exposure Prevention**
Countries have developed legislation and regulations that govern pesticide import and export, uses, and handling. For instance, in Canada, the Pest Control Products Act and Regulations is a legal document intended to ensure the acceptability of the risks, merit, and value of pest control products. Related laws, such as the Fertilizers Act and the Fisheries Act, are also involved in Canadian pesticide regulation. In the United States, pesticides are regulated federally by the EPA and by state-level agriculture offices. Some countries have developed bilateral agreements for trading pesticides and pesticide-treated products. The European Union has several pieces of legislation that set data requirements for active substances, plant protection products, sustainable pesticide use, implementation rules, and approval of active substances.

The International Code of Conduct on Pesticide Management provides a global framework for pesticide management, particularly for countries that use highly hazardous pesticides banned in other regions for health reasons. The known and potential harms of pesticides can be best addressed by preventing exposure. Eliminating, substituting, or reducing pesticide use can make meaningful impacts on lowered risks for some adverse health outcomes. The use of pesticide alternatives can also mitigate environmental concerns, save money spent on pesticides, and meet growing demands for organic food. Alternatives include but are not limited to integrated pest management and organic farming. Environmental health research organizations, such as the Environmental Working Group, aim to inform consumers about potential ways to reduce exposure through initiatives like Dirty Dozen
Plus and Clean 15. As a last resort, the correct use of personal protective equipment can reduce pesticide absorption and is especially relevant for occupationally exposed populations.

**Conclusion**

Pesticides have been used for centuries and play an important role in protecting human health, food and water supplies, and infrastructure. The history of pesticide development demonstrates a marked transition from localized use of elemental compounds to global application of complex, mass-produced synthetic mixtures. Exposure is widespread in workplaces, homes, and the environment and may occur dermally, orally, and through inhalation. Increasing evidence about adverse environmental and health effects associated with pesticides has prompted regulatory agencies to critically evaluate their use and make recommendations to reduce exposure. The advantages and risks of pesticides need to be carefully weighed in current and future uses.

**Pfizer (United States)**

Pfizer Inc. is the world’s largest research-based pharmaceutical company, with five primary areas of focus, including oncology. Pfizer’s independent business unit, Pfizer Oncology, focuses on the discovery and development of innovative cancer treatments. Over the years, the company has developed and/or marketed drugs to treat breast cancer, prostate and other male cancers, and lung cancer. Pfizer’s drug lines include therapies for leukemia, lymphomas, and other hematologic cancers; colorectal and other gastrointestinal (GI) cancers; bladder, kidney, and other urologic cancers; respiratory and thoracic cancers; and pancreatic, thyroid, and other endocrine cancers.

German immigrants and cousins Charles Pfizer and Charles Erhart founded Pfizer in 1849 as Charles Pfizer & Company. Based in Brooklyn, New York, the company called itself a fine-chemicals business. The company’s offices, laboratory, factory, and warehouse facilities were housed in one building. Over the years, Pfizer developed into a large pharmaceutical company that focused primarily on developing drugs for chronic diseases, such as hypertension. These patients numbered in the millions and typically had to take drugs for the rest of their lives. Pfizer’s later growth was based on drugs such as Lipitor (atorvastatin) for cholesterol and Norvasc (amolodipine)
for blood pressure. In contrast, Pfizer and some other large pharmaceutical companies were less inclined to focus on cancer therapies. Since most cancer cases were terminal, some pharmaceutical companies saw little promise for profit in developing cancer drugs. In 2012, cancer drug sales accounted for only 5 percent of the Pfizer's revenues.

Pfizer, along with other large pharmaceutical companies, eventually turned more attention to developing cancer drugs. The company has experienced falling profits from some of its major drugs, such as Lipitor. The price of cancer drugs, however, began rising dramatically in the 21st century. As a result, developing cancer drugs has become economically attractive. In 2013, some cancer drug therapies cost $100,000 a year or more. Ongoing, extraordinary discoveries of how to target cancers via genome and other biological mechanisms have also spurred drug research.

Pfizer increased its commitment to developing new cancer drugs when it established its Oncology Research Unit. With their primary cancer research facilities based in San Francisco, California, Pfizer has committed 1,000 scientists to focus on cancer drug research. These researchers are developing compounds aimed at customizing treatment options for cancer patients and extending survival rates.

Pfizer researchers are studying potential cancer compounds for multiple tumor types. The company has four cancer biology areas: anti-angiogenesis, signal transduction, cell cycle, and metabolism. The research is often conducted collaboratively with other researchers outside Pfizer. These collaborators include academic researchers, cooperative research groups, and governments. Pfizer places a special focus on researching compounds in early clinical development that have shown promise following randomized controlled multicenter trials.

Pfizer is expanding several key cancer areas, including renal cell carcinoma, lung cancer, hematologic malignancies, and breast cancers. In terms of emerging areas of cancer biology, Pfizer researchers are conducting studies in areas such as epigenetics and antibody-drug conjugates. The latter is a class of biopharmaceuticals and targeted therapies that combine the specificity of an antibody to distinguish between healthy and diseased tissue. The therapies involve combining antibody-drug conjugates with the cell-killing power of chemotherapy.

In 2010, Pfizer began a small clinical trial at the Dana-Farber Cancer Institute to study crizotinib, a drug that targets a specific gene alteration that can cause certain types of cancer. Pfizer received approval from the U.S. Food and Drug Administration (FDA) in 2013 to market crizotinib under the trade name Xalkori. Initially, the drug was marketed for certain non–small cell lung cancer patients. Non–small cell lung cancer is the most common type of lung cancer. Pfizer is also developing a drug called palbociclib for breast cancer. The drug targets certain proteins in the body called CDKs. In February 2014, the company started a Phase 2 clinical study of palbociclib that showed promising results for certain advanced breast cancers. Pfizer also started petitioning the FDA in 2014 to allow it to market palbociclib. The company based its case on a 165-patient study showing that palbociclib, combined with another current treatment for breast cancer, stopped tumors from growing for a median of 20-plus months, twice as long as the other treatment alone. In addition, Pfizer is evaluating palbociclib in other tumor types, including melanoma, lung cancer, and head and neck cancer.

Pfizer's immune-oncology program includes studies on how to harness the immune system to treat disease, specifically by targeting a protein involved in immune cell proliferation and survival. One such research area focuses on a smoothened protein inhibitor (SMO) that has potential to treat a wide range of hematologic diseases. The SMO works by blocking cancer cell growth and survival. Pfizer has also developed the first canine cancer drug in the United States approved by the FDA. The oral therapy is called Palladia and is used to treat mass cell tumors in dogs. Approved for use in 2009, the drug showed in a clinical trial that approximately 60 percent of the dogs given Palladia had their tumors stop growing, shrink, or disappear. Pfizer also seeks to collaborate with other institutions and drug companies in its cancer research efforts. For example, in 2014, the company entered into an agreement with GlaxoSmithKline Inc. (GSK) to research the anticancer efficacy and safety of GSK's trametinib combined with Pfizer's palbociclib. The study features Phase 1 and 2 clinical studies of patients with advanced metastatic melanoma.

In 2014, Pfizer and Merck began collaborating in Phase 1 and 2 clinical studies to test the safety and efficacy of Merck's MKp3475 in combination with
Pfizer’s axtinib (Inlyta). The Merck drug is an investigational anti-PD-1 immunotherapy (PD-1 stands for programmed death receptor 1, an immune-cell pathway). The clinical trial enrolled patients with renal cell carcinoma.

Pfizer also offers patient and prescription assistance programs, including cancer patients. These special programs are designed to help patients with limited incomes and those without insurance to obtain the drugs they need. Among the services are insurance counseling, co-pay assistance, and providing some medicines at increased savings. Pfizer also offers help in finding other assistance programs, both government and private programs. In 2013, the company saw a 29 percent operational growth in oncology.

Pharmaceutical Industry

Because cancer refers more accurately to a type of disease than a single disease, it is not likely that there will ever be a single “cure for cancer.” Some cancers are caused primarily by genetic factors; others, primarily or exclusively by viruses. Environmental factors loom large. Some cancers are more likely to metastasize than others, or are more resistant to some kinds of treatment than others. The existence of a great variety of cancers has made the pharmaceutical industry's role important insofar as it develops pharmaceutical remedies for specific cancers or the side effects of cancer and cancer treatments. The oncological specialty dealing with drug therapies is medical oncology, which encompasses chemotherapy, hormonal therapy, and targeted therapy, but other specialties—notably gynecologic oncology and pediatric oncology—necessarily rely heavily on drugs as well, and even other modalities of treatment like radiation therapy and surgery still require considerable knowledge of drugs to deal with side effects and comorbid conditions. Frequently, cancer patients are treated by a multidisciplinary team for this reason.

Standard Modalities of Cancer Treatment
Chemotherapy is the most obvious area in which the pharmaceutical industry is involved. A chemotherapy regimen used to treat cancer usually consists of a number of drugs selected for the synergistic effects of their use in combination. Chemotherapy drugs come from a variety of types, including antifungals, antiprotozoals (drugs for infection by protozoans), antibiotics, antituberculars (antituberculosis drugs), antileprotics (antileprosy drugs), antihelmintics (vermicides designed to kill parasitic worms), antivirals, corticosteroids (hormones produced in the adrenal cortex, involved in inflammation and immune response), and cytostatics (cell growth inhibitors) as the most common categories. Alkylating antineoplastic agents are drugs that transfer alkyl groups to a molecule, which can cause DNA damage. This is useful in damaging cancer cells, but like many chemotherapy treatments, alkylating agents can themselves be carcinogenic to healthy tissue. Nitrogen mustard, related to the mustard gas used as a chemical weapon in World War I, was the first modern chemotherapy treatment for cancer after experiments with the gas were conducted during World War II. There are dozens of different standardized combinations, many of which are associated with specific cancers. For instance,
COPP—cyclophosphamide (a nitrogen mustard alkylating agent), Oncovin (the mitotic inhibitor vincristine), procarbazine (an antineoplastic alkylating agent), and prednisone (a corticosteroid)—is used to treat Hodgkin’s lymphoma, while VAD—vincristine, Adriamycin (an antibiotic), and dexamethasone (a corticosteroid)—treats multiple myeloma. Chemotherapy is often used in conjunction with other therapies, including surgery, radiation therapy, targeted therapies, photodynamic therapy, and hyperthermia therapy. Adjuvant chemotherapy follows local radiotherapy or surgery in order to reduce the risk of recurrence.

Most chemotherapy drugs are administered intravenously, though a small number are available only in oral doses. Special catheters and other systems have been developed for chemotherapy patients in order to avoid the need for repeated insertion while also offering low infection risk. In a small number of cases, non-melanoma skin cancer can be treated with topical chemotherapy. Chemotherapy usually is performed in several rounds or cycles, partly because only a fraction of the tumor cells are killed with each treatment and partly because of the often severe side effects experienced by the patient. Dosage is usually calculated based on body surface area (BSA), though recent work has suggested that factors like obesity, genetics, age, gender, disease state, and drug interactions have a significant impact on drug absorption, which may result in different therapeutic outcomes for BSA-identical chemotherapy patients.

The pharmaceutical industry also develops hormones for the treatment of cancer, in order to control gene expression in cancer cells. This is particularly true for treating breast, prostate, endometrium, and adrenal cortex cancers, and to treat side effects of cancer or chemotherapy such as anorexia. Tamoxifen is a hormone treatment used in breast cancer treatments.

Aromatase inhibitors are some of the best known hormone treatments. These drugs block the production of estrogen in postmenopausal women, arresting the growth of hormone-receptor breast cancer. Aminoglutethimide similarly treats adrenal gland cancers, and the side effects of adenocortical carcinoma. While many aromatase inhibitors can promote osteoporosis in women, exemestane is an aromatase inactivator that lacks that side effect. It is used to treat metastatic breast cancer that is resistant to tamoxifen.

Another hormone treatment used is gonadotropin-releasing hormones, which induce chemical castration by suppressing the production of estrogen and progesterone in women or testosterone in men. This can be an effective approach to treating prostate cancer, the growth and survival of which is assisted by exposure to testosterone. Prostate cancer is also treated with anti-androgens, which inhibit the androgen receptor in order to block the effects of testosterone on the tumor.

The term targeted therapy is used for pharmaceuticals that are formulated to be more selective than chemotherapy regimens, and may include both drugs and biologics. Most targeted therapies are either monoclonal antibodies, a biologic treatment that binds to a specific targeted substance associated with a particular cancer, or small molecules—organic compounds with a molecular weight below 900 daltons. Targeted therapies include imatinib mesylate, Gefitinib, Erlotinib, Sorafenib, Sutinib, Dasatinib, Lapatinib, and Nilotinib, all of which are small molecule tyrosine-kinase inhibitors; Torisel, Afinitor, Mekinist, and Tafinlar, all of which are
small molecule serine/threonine kinase inhibitors; and a host of monoclonal antibodies. Tamoxifen is perhaps the best known targeted therapy. Developed by AstraZeneca's predecessor Imperial Chemical Industries, it targets the estrogen receptors in breast tissue in order to treat hormone receptor positive breast cancer in premenopausal women and is one of the most important and commonly used anticancer drugs.

**Experimental Cancer Treatments**

There are always numerous cancer treatments in various stages of experimentation. The Pharmaceutical Research and Manufacturers of America lists 771 drugs in development for cancer, either in clinical trials or awaiting review by the U.S. Food and Drug Administration (FDA).

A small clinical trial of dichloroacetate as a treatment for brain cancer seems to have been successful in killing off tumor cells by reactivating suppressed mitochondria. It has the benefit of being an inexpensive pill, compared to the costs and rigors of chemotherapy. The antioxidant quercetin has shown promising results in treating oral cancers, leukemia, skin cancer, and prostate cancer.

The first human trials of BI811283, a small molecule kinase inhibitor, were conducted in 2010 as a treatment for acute myeloid leukemia and solid tumors. There is sometimes a fine line between experimental treatments that are not yet proven and alternative therapies that have been proven ineffective.

Another possible treatment is HAMLET (Human Alpha-lactalbumin Made LETHal to Tumor cells), a complex of alpha-lactalbumin and oleic acid that acts selectively to kill cancer cells without harming healthy cells. It is derived from human breast milk and has been used successfully as an antibiotic adjuvant to treat MRSA infections and benign skin tumors. It is being studied for use in the treatment of numerous cancers.

**Treating the Side Effects of Cancer and Cancer Treatments**

Almost every use of chemotherapy results in a weakening of the immune system, typically through the decrease of white blood cells. This can lead to an increased likelihood of infection while receiving treatment. More than three-quarters of such infections come not from external sources like contact with contagions in public places but from microorganisms residing in and on the patient’s own body that the immune system is ordinarily able to resist. There is actually a cascading effect here, often leading to a series of interrelated treatments and illnesses:

1. Chemotherapy treats the patient’s cancer but weakens the immune system.
2. The patient becomes ill due to resident microorganisms such as bacteria on the skin.
3. Both the symptoms and the cause of the secondary illness are treated with a course of antibiotics prescribed to deal with the bacterial infection(s).
4. Just as chemotherapy weakens healthy systems in its efforts to kill off cancer, antibiotics kill off good bacteria in the attempt to kill off the bad bacteria.
5. No longer held in check by the bacteria with which they compete, fungal life that resides on and in the patient’s body thrives, resulting in one or more fungal infections, such as a yeast infection, thrush, rashes, or dandruff.
6. Antifungal medications are prescribed, either internal or topical, which in some cases can result in bacteria thriving once more.

Chemotherapy alone taxes the patient’s system, but it is these secondary and tertiary illnesses, and the toll exacted by adding these medications to those taken as part of the chemotherapy regimen, that can further exacerbate the patient’s exhaustion, weakness, and accumulation of side effects. It is not inconceivable for the above cycle to play out just in time for the patient’s next round of chemotherapy to begin, starting the pattern over again.

As difficult as this can be to experience, it needs to be pointed out that the alternative is still worse, and that the availability of these medications to deal with each stage of the process is key to the survival rate of modern cancer patients.

One of the most common side effects of chemotherapy and radiation therapy is nausea, which is worst with certain chemotherapy drugs and regimes and which tends to be exacerbated if the patient is female, under 55, experiences anxiety or
depression, or has a history of motion sickness or pregnancy-associated nausea. Nausea can also be caused by the cancer itself, by physical side effects of the cancer like bowel obstruction, by ongoing constipation, by radiation therapy, and as a side effect of other maladies caused by cancer or cancer treatments, like dehydration, electrolyte imbalance, aspiration pneumonia, or anxiety. More than half of patients with advanced cancer experience nausea or vomiting, as do about two-thirds of patients undergoing radiation therapy.

Chemotherapy-induced nausea can be treated through a number of drugs, many of which were developed for the purpose. There are both prophylactic drugs to prevent the nausea and rescue treatment to deal with nausea once it has occurred: 5-HT3 inhibitors such as dolasetron, granisetron, and ondansetron, which act as receptor antagonists to a type of serotonin receptor in the vagus nerve, have been approved for treating chemotherapy-induced nausea as rescue treatments, usually administered in the first 24 hours, and are available orally and as injections and transdermal patches. Newer NK1 inhibitors, which work on a receptor found in the central and peripheral nervous systems, are sometimes administered with setrons and together can control nausea almost entirely, often with few other side effects.

Antipsychotics like olanzapine have also been tested for treating nausea and can achieve complete prevention on their own in some patients, or with setrons or dexamethasone (a corticosteroid) in others. (Despite the name, antipsychotics—sometimes called neuroleptics and referred to as tranquilizers in older texts—are increasingly used to manage nonpsychotic conditions.) Medical marijuana is also a common remedy, and synthetic THC (tetrahydrocannabinol) has been developed under the brand name Marinol. Some nausea can also be treated with antihistamines that block the H1 receptors in the vomiting center of the medulla, or with anticholinergic agents that relax smooth muscle, which also helps in managing bowel obstruction. Anticipatory nausea, which is likely a learned response, develops in about 20 percent of chemotherapy patients. The only drugs shown to be effective in counteracting it are benzodiazepines like clonazepam and lorazepam, which become less effective with frequent use.

Chemotherapy can also induce peripheral neuropathy, a progressive pain, numbness, tingling, and/or sensitivity to cold in the hands, feet, and esophagus. This happens to about one-third of chemotherapy patients, though it is more likely to be induced by some drugs than others. Neuropathy increases in severity and extent with each round of chemotherapy, leveling off when treatment is completed—though with cisplatin, oxaliplatin, and carboplatin, all of which are based on platinum, neuropathy continues to worsen until several months after treatment has ended. Some chemotherapy-induced peripheral neuropathy (CIPN) is permanent, and the numbness in particular is treatment resistant. In other cases, pain can be managed, and several types of treatments have been developed to inhibit the development of CIPN. Two antidepressants—velafaxine and duloxetine—have shown promise here, as has intravenous administration of calcium and magnesium. Valproate, an anticonvulsant that is effective in diabetic neuropathy, has worked prophylactically in tests on rats.

One of the most serious side effects of chemotherapy is myelosuppression, also called myelotoxicity or bone marrow suppression. This condition results from damage to normal cells—specifically leukocytes, erythrocytes, and thrombocytes—by the drugs used to kill or suppress the cancer cells, and for this reason the risk varies according to the kind of cancer and the chemotherapy regimen being applied. Bone marrow is where blood cells, including the white blood cells of the immune system, are produced, so causing a deficiency of marrow and thus of blood cells puts the immune system in serious jeopardy. Normally minor infections can become life threatening due to the body’s inability to fight them, and a reduction of red blood cells leads to anemia. In some cases this is treated by changing the chemotherapy regimen. In others it is treated through the aggressive use of intravenous antibiotics in order to quickly stop any and all infections.

Almost all high-dose chemotherapy patients experience mucositis, the inflammation and ulceration of mucous membranes in the digestive tract or the mouth, as do many low-dose chemotherapy patients and radiotherapy patients with head or neck cancers. Bone marrow transplants increase the odds of developing mucositis as well. Oral mucositis is treated with medicinal mouthwashes, often containing a viscous preparation of topical analgesic lidocaine for pain relief. Episil, marketed by Can- gene, is approved for pain management caused by
oral lesions, including oral mucositis, and the FDA has also approved MuGard, an oral protectant that has some success in preventing the development of oral mucositis. Untreated, oral lesions can become severely infected, postponing the next round of chemotherapy.

“Chemo fog” or post-chemotherapy cognitive impairment is suffered by about a quarter of chemotherapy patients and involves difficulties in thinking, reasoning, memory, attention, and/or motor control. This may last a few days or as long as 10 years after the final chemotherapy treatment. The mechanisms are not well known, and oncologists do not always adequately prepare patients for the possibility that life after cancer may not be a full return to normal. Most treatments are either off-label or in clinical trials. Clinical trials and experimental treatments include stimulants and antioxidants, while modafinil, which improves alertness and is approved for narcolepsy, is sometimes prescribed off-label.

**Major Pharmaceutical Companies**
The largest pharmaceutical companies in the oncology field, by 2013 sales, are Roche (with sales more than twice as high as Amgen's), Amgen, Novartis, Celgene, Johnson & Johnson, Lilly, AstraZeneca, Merck & Co., Bristol-Myers Squibb, Takeda, Pfizer, GlaxoSmithKline, Bayer, Astellas, Sanofi, Merck (Germany), Biogen Idec, Eisai, Kyowa Hakko Kirin, Otsuka, AbbVie, Teva, Ipsen, Gilead Sciences, and PDL BioPharma.

**Pheochromocytoma**
Pheochromocytomas are rare catecholamine-producing neuroendocrine tumors originating from the chromaffin cells of the adrenal medulla. In some cases, tumors arise from within the extra adrenal chromaffin tissue and are called paragangliomas (PGL). They are also commonly associated with several metabolic and physiologic disorders, including the risk for hypertensive shock due to catecholamine secretion, including adrenalin, noradrenalin, and dopamine. The leading symptoms of pheochromocytoma—headaches, palpitations, anxiety, and diaphoresis—are caused by sporadic release of catecholamines into circulation.

Paroxysmal and persistent hypertension is also a common symptom in patients, while blood pressure is found to be elevated in over 10 percent of patients. There is no gender bias, and clinical signs vary, making diagnosis particularly difficult. Individuals may present first symptoms at any age; moreover, the age of presentation has been shown to provide insight into the affecting mutation and tumor phenotype. We know that individuals with the heritable syndrome often present at earlier ages than those with sporadic disease. Additionally, epinephrine-secreting tumors are shown to present later in life. Pheochromocytomas are most likely to be sporadic and without signs or symptoms in elderly populations. Patients demonstrating adrenergic spells, episodic palpitations, diaphoresis, pallor, and tremors should be evaluated for pheochromocytoma. Additionally, resistant hypertension in patients under the age of 20, alongside abnormal blood pressure during surgery or anesthesia in the presence of adrenal masses, should raise red flags. Individuals likely have a family history of pheochromocytoma and additionally clinical features of catecholamine-secreting tumors.
Tumors commonly arise within the adrenal glands, abdomen, and pelvis. Mutations in the following genes have been linked to tumorigenesis: SDHA, SDHB, SDHC, SDHD, SDHAF2, TMEM127, MAX, EGLN1, HIF2A, and KIF1B. Germline mutations in at least one of these genes accounts for almost a third of all paragangliomas in most individuals. Somatic mutations in genes encoding RET, VHL, NF1, MAX, HIF2A, and H-RAS have also been detected. Chromaffin cells, the underlying catecholamine-secreting tumor cell types, originate from neural crest tissue during development. Failure to diagnose and treat pheochromocytoma can have devastating consequences, such as adrenergic crisis and death. Adrenergic crisis is triggered by release of catecholamines from pheochromocytoma tumors at excessive levels. The release of hormones also occurs in response to drugs, particularly dopamine receptor agonists, sympathetic nervous system agonists, anticholinergic drugs, and catecholamine-sensitizing anesthetics. Physical deformation of tumor mass due to physical repositioning, tensile pressure, and straining or direct manipulation during procedures may also promote adrenergic storm.

Patients who are pregnant and are experiencing uterine contractions and fetal movement and those in delivery may also induce adrenergic crisis. While 24-hour urine tests have been used to make diagnosis, more sensitive methods of measurements include plasma-fractionated metanephrines by HPLC. Diagnoses are confirmed by the presence of plasma normetanephrine and metanephrine above reference values. These often include fourfold elevations in patients. Pheochromocytoma occurring in individuals with MEN 2 has been shown to produce predominantly epinephrine and metanephrine, whereas those in VHL syndrome produce principally norepinephrine and normetanephrine. PNMT, the enzyme that converts norepinephrine to epinephrine, has been found to be over-expressed in MEN 2–associated tumors, while under-expressed in VHL-associated tumors.

Elevated tyrosine hydroxylase activity has been found in patients with pheochromocytoma compared with those occurring in patients with VHL, leading to higher levels of catecholamines and metabolites in patients with MEN 2. Surgical resection remains the primary treatment option for patients with pheochromocytoma, though it is not routinely recommended for the treatment of acute adrenergic crisis. Complications occur, particularly in the context of lacking preoperative evaluation and medical management. These complications include infection and adrenergic crisis. Critical evaluation is recommended in patients undergoing tumor resection to mitigate risk of complications. Appropriate medical management significantly reduces morbidity and mortality risk during surgery. Laparoscopic adrenalectomy (LA) is a well-approved operative technique. The indications for LA include primary hyperaldosteronism, pheochromocytomas, and glucocorticoid-secreting adrenal tumors. A standard treatment regime for patients prior to surgery includes α-adrenergic blockade, and, subsequently, additional β-adrenergic blockade, is required to treat any associated tachyarrhythmias. Arterial blood pressure, heart rate, and arrhythmias are also followed closely.

Philippines

Cancer is the third leading cause of death in the Philippines. Prominent cancer types are lung, breast, cervix, liver, colon and rectum, prostate, stomach, oral cavity, ovary, and leukemia. Medical personnel, facilities, and organizations are acutely aware of this fact and are attacking cancer on several fronts. This entry reviews the efforts toward cancer prevention in and comments on their effectiveness.
The Republic of the Philippines consists of 7,107 islands, a total area of 111,830 square miles, located on the Pacific Rim of southeast Asia. Two thousand of its islands are inhabited. There are no boundaries. It is bordered on the west by the South China Sea, on the east by the Philippine Sea, on the south by the Celebes Sea, and on the north by the Luzon Strait, which separates the country from its neighbor Taiwan. The closest nations to the south are Malaysia and Indonesia. Vietnam and China are the nearest neighbors on the mainland of Asia.

Thirty million employed persons work in agriculture, forestry, and fishing. The unemployment rate is over 9 percent. Fifty percent of the population live below the poverty line. The employed work seven days a week and may take additional jobs to make ends meet. Eight hundred thousand citizens work overseas in Saudi Arabia, Hong Kong, and Taiwan. Over Seas Workers (OSWs) have a governmental agency that looks after their interests. There are laws governing overseas workers but workers may be exploited and mistreated.

Prevention and Treatment of Cancer
The Philippine Society of Medical Oncology, Inc., is a scientific professional organization of oncologists committed to the ethical and holistic practice of medical oncology. According to their definition of “medical oncologist,” there is no separate certification for oncology. Most physicians are internal medicine specialists with extra training in the treatment of cancer. It appears patients are treated in a holistic manner with herbs and traditional remedies as well as advanced modalities. On the subject of preventing cancer by herbal supplements, authorities say that despite the lack of scientific evidence about their efficacy, high doses of vitamins and herbal remedies can be legally administered by medical practitioners. However, they are aware that the applicable standard of care is treatment by chemotherapy and radiotherapy. Before administering alternative remedies, the treating doctor must advise the patient of this. They admit that many of the supplements are without or with only limited scientific evidence as to effectiveness. Nevertheless, there are supplements that are supported by high-level scientific evidence. These supplements include fish oil, vitamin D, medicinal mushrooms, beta-glucans (immune boosters), bioavailable curcumin (powerful antioxidant), green tea polyphenols, pomegranate, acetogenin molecules (shrinks cancer cells), and bioavailable silymarin phytosome (milk thistle plant). Another organization actively engaged in cancer research and treatment is the Philippine Cancer Society (PCS). It is involved in activities dedicated to the prevention and control of cancer. Its advocacies and programs are in cancer registry, education and information for prevention and early detection, patient services, and hospice and palliative care. Registered since 1956, the PCS pioneered in such innovative programs as cancer registry, tobacco control, hospice care, and patient navigation.

The Philippine Department of Health (DOH) is active in fighting cancer. It offers Packages of Services, including free cervical cancer screening every year in 58 DOH hospitals to screen women 30 to 45 years of age, free adjuvant chemotherapy in four pilot hospitals for women diagnosed stage 1 to 3A breast cancer, and free chemotherapy for acute lymphatic leukemia for children with cancer. It also offers various free programs in promotion of a healthy lifestyle for cancer prevention.

Causes of Cancer Deaths in the Philippines
As stated above, cancer happens when normal cells have an abnormal change and grow and spread within the body. These abnormal cells then transform into tumors that can be benign (not cancerous) or malignant. Seventy-five percent of cancer patients in the Philippines are at least 50 years old. The rate decreases for children up to age 14 to 3.2 percent. Unfortunately, cancer still ranked third on the list of leading causes of death in the country in 2010. According to the World Health Organization (WHO), the number of cancer deaths worldwide will increase from 7.6 million to 17 million deaths by 2030. Thirty percent of cancers can be prevented by avoiding smoking, exercising regularly, and eating the right diet. Discussed below are the top causes of cancer deaths in the Philippines for 2010.

Breast cancer is the most common cancer, with 16 percent of 50,000 cases resulting in death. It is the most common cancer among Filipino women. As for prevention, physicians advise women to frequently do breast self-examinations so the disease can be more easily treated in its beginning stages. The Philippine Cancer Society has promised to provide more free mammography services, fine-needle aspiration biopsy, and education campaigns
to help more Filipinas in combating the disease. The Department of Health is leading the way in providing these free services. Lung cancer is the leading type of cancer in Filipino men. It formerly caused more deaths than breast cancer. Lately, more women are contracting lung cancer. Experts advise against cigarette smoking, as nine out of 10 smokers die from the disease. Nonsmokers are also vulnerable due to second- and thirdhand smoke.

Liver cancer appears to be more common in the Philippines than in the United States. Doctors postulate that the higher rate for liver cancer is due to the fact that chronic hepatitis B affects one-tenth of all Filipinos. Chronic hepatitis B causes cirrhosis of the liver, and cirrhosis is a leading cause of liver cancer.

Statistics indicate that 12 Filipinas die of cervical cancer each day. This type of cancer often strikes women between ages 30 and 55. Twenty-two in 100,000 women will get cervical cancer; only 44 percent will survive. Doctors urge women to begin screening for cervical cancer three years after their first sexual contact. There is a cervical cancer (human papillomavirus) vaccine available that should be taken by Filipinas aged 10 years and above.

The remainder of the top cancers common to the Philippines are colon cancer, thyroid cancer, rectal cancer, ovarian cancer, prostate cancer, and non-Hodgkin’s lymphoma. Philippine people are spread out over a large area. Yet there is no shortage of competent physicians and hospitals. It would appear that the people exercise unhealthy lifestyles that lead to disease, especially cancer. Preventive programs are urged by the cancer associations, societies, and the Health Department. Should the Philippine citizens take the advice of experts, cancer rates can come down. Philippine citizens are prone to taking supplements and herbs for treatment, which may work to a degree but not like the care recommended by competent physicians.

**Photodynamic Therapy**

Photodynamic therapy, or photochemotherapy, combines phototherapy with the use of nontoxic light-sensitive chemicals that, when exposed to light, become toxic to targeted cells such as tumor cells or microbes. Photodynamic therapy is best known as an acne treatment, but because of its minimal toxicity and invasiveness, it has also become a useful cancer treatment. Pioneered as a cancer treatment in the early 20th century (though some skin cancers were treated similarly by ancient physicians), photodynamic therapy was clinically tested in the 1970s and has gained ground since.

Phototherapy, or light therapy, is the use of daylight or specific wavelengths of light for therapeutic purposes, usually exposing the patient or parts of the patient to the light for a prescribed amount of time. This has long been useful in treating skin conditions like psoriasis, vitiligo, and eczema, and seasonal affective disorder and some sleep disorders are treatable with light therapy of the eyes. Low-level light exposure may even be a useful adjunctive treatment for wounds.

Phototherapy for skin conditions often involves ultraviolet light exposure. Psoriasis, for instance, is caused by localized inflammation because of immune system responses, which can be suppressed
by exposure to ultraviolet B (UVB) light, and UVB is also useful in repigmentation of patients with vitiligo. However, ultraviolet light is also a key cause of skin cancer because of the genetic damage it causes, and direct exposure—whether via tanning bed or light therapy—exposes the patient to much more ultraviolet light than exposure to sunlight. That said, light therapy typically involves a much shorter period of exposure than do tanning beds, and has a clear therapeutic benefit that may balance out that risk. (Phototherapy lamps for sleep disorders and seasonal affective disorders do not emit ultraviolet light, which is not necessary to their therapeutic mechanisms, and so sustained use does not pose the same risk.)

Photodynamic therapy (PDT) relies not just on light but also on light-sensitive chemicals. Photochemical processes are chemical reactions that involve the absorption of light by molecules or atoms. Familiar examples include the way vitamin D is formed by the skin's absorption of sunlight, or the way plants create nutrients through photosynthesis. Light provides the activation energy necessary for the chemical reactions. Photodynamic therapy uses photosensitizers—molecules that photochemically produce chemical changes—in combination with a light source and oxygen available in the tissues. The resulting chemical reactions produce reactive oxygen species—chemically reactive oxygen-containing molecules. Though reactive oxygen species may be responsible for significant health problems when they overpopulate and cause oxidative damage (believed, by proponents of the free radical theory of aging, to be the fundamental cause of the degenerative effects of age, which is the logic behind the promotion of antioxidants as “anti-aging” substances), they are constantly created and destroyed by normal processes of the body. A wide variety of photosensitizers can be used, including dyes, porphyrins, and chlorophylls. Important characteristics are chemical stability, low dark toxicity, and high absorption. For skin cancer and skin conditions, they are applied topically; in treatment of internal cancers, they are administered intravenously, while the light is delivered by endoscope and fiber-optic catheter. The combination of light exposure and a topical photosensitive ointment for the treatment of skin conditions and possibly skin cancer has been used since ancient times.

Reactive oxygen species are deeply involved with cancer in the body in several ways. At low levels,
and can suppress tumor growth as well as killing off other species, however, activate cell-cycle inhibitors cells once they develop. Higher levels of reactive oxygen species in order to kill cancer cells. Normal cells are generally better able to survive this stress than cancer cells do, but chemotherapy and radiation therapy still both have the same problem—they kill large amounts of normal cells as part of a necessary sacrifice in order to kill even larger amounts of cancer cells.

Oxidative stress results from the imbalance of reactive oxygen species and the body’s ability to detoxify reactive intermediates or repair the damage they cause. Reactive oxygen species can damage every part of the cell, including the DNA, contributing to cancer growth. Oxidative stress is also thought to be implicated in sickle-cell anemia, Alzheimer’s disease, Parkinson’s disease, atherosclerosis, heart failure, autism, vitiligo, myocardial infarction, and chronic fatigue syndrome. The reactive oxygen species created by photodynamic therapy include free radicals in Type I PDT, and singlet oxygen in type II PDT. Photofrin, the trade name of porfimer sodium, was the first photosensitizer approved for use in photodynamic therapy in the West. First approved in 1993 in Canada for bladder cancer, it was subsequently approved by the U.S. Food and Drug Administration (FDA) in 1995 for esophageal cancer and later was approved for early non–small cell lung cancer. Concurrently, photodynamic therapy was intensively developed in Russia, with a photosensitizer called Photogem approved for clinical trials in 1992. China and Japan have made advances in PDT as well, with Chinese oncologists having particularly successful results in developing techniques of using photodynamic therapy on difficult-to-reach tumors.

In most photodynamic therapy, if the photosensitizer is not applied topically, 24 to 72 hours are allowed to pass after it has been injected in order to give the agent time to be absorbed by both normal and cancer cells and to be flushed from normal cells; cancer cells retain it longer. Ideally, the tumor is exposed to light during the period in which the cancer cells still retain the photosensitizer but the normal cells do not. Once activated, the photosensitizer not only kills cancer cells directly but damages blood vessels in the tumor in order to block the flow of nutrients to surviving cells and encourages the immune system to attack remaining cells. PDT is usually an outpatient procedure (overnight hospitalization is not required) like chemotherapy or radiation therapy and is often combined with those adjuvant therapies.

Some studies suggest that light therapy may activate certain hormones associated with reproduction, including testosterone, estradiol, and luteinizing hormone. In some cases, phototherapies should be avoided or side effects prepared for: if the patient is bipolar or is otherwise predisposed toward manic episodes (which can be triggered by intensive light exposure) or photosensitive as the result of a medical condition or medication. Side effects otherwise are usually limited to headache, nausea, and jitteriness. The photosensitizing agent used may have additional side effects, most commonly accompanied by a recommendation to avoid unnecessary exposure to direct sunlight or bright indoor light for six to 10 weeks following treatment. One of the greatest advantages of photodynamic therapy is its lack of long-term side effects, compared to chemotherapy and radiation therapy. Further, it is less invasive than surgery and easier for older or weakened patients to undergo. Unlike radiation therapy, multiple applications to the same site do not have cumulative damaging effects or become less effective; they are also much less costly than other new cancer therapies, such as gene therapy or biologics.

If a topical photosensitizing agent is used in the photodynamic treatment of skin cancer, the crust and scale is first removed from the skin cancer. The agent is applied in the form of a cream that remains on the applied area for three to six hours in order to ensure that the skin has time to absorb it. This makes the skin very sensitive to light; patients often report feeling a stinging or burning sensation (relieved by over-the-counter painkillers or even cool air from a fan) when light is shone on the skin. This is not serious. The area will form a scab after treatment and remain scabbed for at least a week,
Photodynamic Therapy usually three weeks. Thicker skin lesions require multiple treatments, usually spaced a month apart.

Because of the way the light is administered, photodynamic therapy is not useful for large tumors or those that lie far from the surface of the tissue or lining of the organ or cavity where the light can reach. More than one centimeter of tissue will block the light. This is one reason why the first photodynamic therapy approved by the FDA was for esophageal cancer, which is easily accessible to the implements used to expose the tumor to light. With topical applications, such as in treating skin cancer, this is not a concern. Similarly, PDT is not useful for metastasized cancer.

There are several journals devoted to photodynamic therapy, including Photodiagnosis and Photodynamic Therapy, published by the International Photodynamic Association.

Variants of Photodynamic Therapy

PUVA therapy is Psoralen UVA therapy, and uses the photosensitizing drug psoralen in conjunction with ultraviolet A (UVA) light exposure. The use of psoralen allows a lower dose of UVA to be administered. PUVA is useful in treating skin conditions like eczema and psoriasis, but is also a helpful therapy for cutaneous T-cell lymphoma. Further, PUVA therapy may be administered to patients suffering from graft-versus-host disease, such as following a bone marrow transplant. Long-term PUVA therapy is associated with higher risks of skin cancer and squamous cell skin cancer.

Photoimmunotherapy was developed at the National Cancer Institute and combines photodynamic therapy with biologic therapy in the form of a monoclonal antibody (mab). The mab targets human epidermal growth factor receptors associated with breast, pancreatic, and other cancers, while a photosensitizer is activated by near-infrared light. The combination of the two was able to destroy 80 percent of tumor cells in test mice. It has not yet (in 2014) been approved for clinical trials on humans.

Photopheresis (sometimes called extracorporeal photopheresis) is a form of photodynamic therapy incorporating apheresis, the technique of separating out a particular component from blood (the patient's or a donor's) before returning the blood to circulation. In photopheresis, buffy coat (part of a blood sample containing most of the white blood cells and platelets) is separated from the blood, treated with 8-methoxypsoralen, and exposed to UVA light before being returned to the patient. The UVA activates the photosensitive 8-methoxypsoralen, which induces cytotoxic effects on T-cell formation. This process was first described in 1987 and has been approved to treat cutaneous T-cell lymphoma. Side effects include hypotension. Photopheresis is in trials as a treatment for allograft rejection and graft-versus-host disease, which could help cancer patients receiving bone marrow transplants. It is related to the practice of blood irradiation therapy, which exposes blood to light radiation via an intravenous catheter or the blood vessels of the nose, a practice more common in Russia and China.

Photothermal therapy uses electromagnetic radiation—typically infrared light—to excite the photosensitizer to the point that it releases heat in order to kill targeted cells. It does not require the oxygen that standard photodynamic therapy requires. It can be used for various diseases, including cancer, and usually makes use of recent discoveries in nanoscience, particularly nanoparticles. Particles at the nanoscale have special properties, including preferentially accumulating in tumor tissue. For instance, gold nanoparticles can be delivered to the tumor and then heated with infrared light. The gold absorbs most of the light energy and releases it as heat, which destroys tumor cells. Gold has been explored in the form of nanorods and hollow nanospheres, which are absorbed more easily in the SPR region than are solid gold nanoparticles. Graphene nanoparticles in photothermal therapy have been tested on mice. Photothermal therapy is a type of hyperthermia therapy, which uses intense heat to denature cellular proteins and kill cancer cells through various means. Other types of hyperthermia use microwave heating, ultrasound, or induction heating.

Magnetic hyperthermia uses nanoparticles similarly to photothermal therapy, specifically magnetic nanoparticles. When magnetic nanoparticles are exposed to an alternating magnetic field, they produce heat, which in turn kills tumor cells. Clinical trials have been performed in Germany, treating prostate cancer with magnetic hyperthermia followed by radiotherapy.

Ineffective Therapies

In addition to the clinically proven and well-supported uses of phototherapy and photodynamic
therapy discussed above, there are some alternative light therapies for cancer that lack evidential support. One of these is called chromotherapy, color therapy, or colorology, and it purports to use different colors to balance energy levels in a person’s body in order to treat various conditions. Chromotherapy was popularized in the 1930s by Dinshah Ghadiali, who claimed different colored lights had different therapeutic benefits corresponding to different chemicals and organs.

The Dinshah Health Society founded by his son continues to promote chromotherapy, but there are many supporters of the basic concept whose approach is different from and not derived from Ghadiali’s. Often the color used to treat a given cancer is determined not by the fact that cancer is the disease being treated but by the part of the body in which it is found, each area of the body being assigned a different color. One form of color therapy is colorpuncture, which combines color therapy concepts with those of acupuncture in order to apply pressure to “acupoints” with colored quartz and which is predicated on the idea—developed by Peter Mandel in the 1980s—that illness results from poor choices by the individual.

A more recent form of cancer therapy pseudoscience is the use of a light box, emitting either much brighter light than a traditional lamp or lower-intensity light of a specific wavelength, in order to strike the retina and stimulate serotonin production and inhibit melatonin production. This is a reasonably effective treatment for seasonal affective disorder, though not all light boxes marketed for such purpose use the optimal wavelength or intensity. It has absolutely no demonstrated effect on cancer, however, any more than quartz crystal pendants or magnetic bracelets do. Light boxes may seem superficially similar to photodynamic therapy, which lends credence to the claims of their effectiveness, but the differences are important.

Physical Therapy

Physical therapy is a vital health care profession that assesses and treats individuals with medical or health-related conditions affecting their ability to move, function, and participate in daily activities. Physical therapists, also known as physiotherapists, are engaged in the restoration of movement and promotion of overall health and fitness, quality of life, and improved physical function. It is a dynamic and growing profession with 277,700 physical therapists and 100,700 physical therapist assistants expected by 2022. Physical therapists (PTs) and physical therapist assistants (PTAs) work with individuals who may be in all stages of life—from newborns to the elderly—in a variety of settings, including in oncology with cancer patients. With the
American Cancer Society reporting that nearly 14.5 million Americans are living with or have a history of cancer, and an aging population with increased cancer risk, the need for specific rehabilitation measures for cancer patients will continue to grow.

Cancer is a disease process that may involve body structures such as nerves, bones, blood, and muscles that may alter individuals’ ability to move. Cancer treatment can include surgery, chemotherapy, and radiation, each of which may have significant side effects. These include decreased joint and limb range of motion, diminished muscle strength, difficulty with balance and movement, pain, fatigue, poor endurance, and cognitive changes. Such effects in turn can limit activities such as walking, driving, working, and participating in recreational and social events.

Cancer patients can work to overcome the side effects of cancer treatment with physical therapy. Physical therapy in oncology rehabilitation focuses on helping persons with cancer optimize their physical, social, vocational, and recreational abilities within the limits of their disease. Cancer rehabilitation also aims to improve the quality of life for patients’ families and caregivers. It is a dynamic process, relevant at any stage of the disease process, including any of the five paradigms of health, namely, prevention, restoration of previous function, supportive and palliative care, and survivorship.

Physical therapists’ role in cancer prevention involves screening for risk factors, education, and lifestyle modification. A physical therapist may investigate factors that increase a person’s risk of cancer, such as smoking, use of tobacco and alcohol, unprotected sun exposure, and family history. A major risk factor for cancer on which physical therapists can have a large impact is in the area of obesity, weight management, and physical activity. Having an increased amount of body fat is a known risk factor for several types of cancer, including breast, colon, endometrial, kidney, and pancreas, among others. It is also recognized that physical activity is associated with a reduced risk of cancer. A physical therapist’s knowledge in this area of energy balance is vital to teaching individuals to reduce their overall risk of cancer. Because cancer and its treatment can affect body structures and function, PTs and PTAs work to restore patients to pre-illness levels of function without disability. Patients are examined to determine problems, and interventions are designed to resolve and limit impairments.

Examination may involve a review of the patient’s medical history, a body systems exam, and specific tests and measures. PTs determine impairments in the body systems that may limit an individual’s mobility and ability to participate in activity.

After a PT performs an examination and writes patient-centered treatment goals, either a PT or a PTA may treat patients according to a plan of care. Treatments may include exercise, balance work, gait training, manual therapy, work retraining, or any other specialized technique within their scope of practice. One of these specialized techniques may be manual lymphatic drainage used to treat lymphedema. Lymphedema is a complication of cancer and cancer treatment wherein the body’s lymphatic system is unable to transport lymph fluid from an area of the body. If untreated, the affected body part will swell, often very large, feel heavy, become fibrotic, and can interfere with daily activities such as getting dressed and walking. A physical therapist specially trained and certified in care of lymphedema patients is a very important member of the patient’s cancer treatment team. Physical therapists use special massage techniques, wrapping, and specialized garments, as well as education and exercise, to treat and manage lymphedema.

The supportive and palliative care of patients involves teaching patients to limit functional loss, reduce complications, and help caregivers to participate in managing patients’ symptoms and providing comfort. Survivorship includes patient care from the time of diagnosis throughout life. Because many patients experience long-term side effects, special considerations, programs, and follow-up are required. Exercise and physical activity is an integral part of survivorship care for cancer patients. Physical therapists’ knowledge in the area of exercise, pathology, and body systems place them in a position to provide a broad spectrum of care to cancer patients and survivors.

PTs and PTAs must have a degree from an accredited physical therapy program before taking a state licensure examination required for them to practice. After obtaining a bachelor’s degree, a typical physical therapy program takes three years, culminating in a doctor of physical therapy degree (DPT). Physical therapist assistant programs are two years in length, with several prerequisite courses, leading to an associate’s degree. Both degrees consist of didactic and clinical education. Class content includes but
is not limited to anatomy, physiology, biomechanics, kinesiology, neuroscience, pathology, pharmacology, ethics, management, and clinical reasoning. Therapists are required to renew their licenses every two years, including continuing education.

Pineoblastoma and Supratentorial Primitive Neuroectodermal, Childhood

Pineoblastomas and childhood supratentorial primitive neuroectodermal tumors (CSPNTs) are extremely rare and highly malignant soft tissue tumors affecting children. Pineoblastomas are malignant brain tumors arising in the pineal gland in the brain. The pineal gland, which is a tiny endocrine gland in the middle of the two brain hemispheres, produces the hormone melatonin, responsible for the sleep-wake patterns and circadian rhythms. Pineoblastoma accounts for about 0.05 to 2 percent of all brain tumors in children under 5 years old. CSPNTs are some of the most aggressive brain tumors in children, originating in the cerebrum, which is the largest part of the brain controlling processes such as thinking, learning, problem solving, speech, emotions, voluntary movements, reading, and writing. Less common origins of CSPNTs are the diencephalon and basal ganglia. CSPNTs are congenital tumors, and are also referred to as cerebral neuroblastomas or cerebral medulloblastomas. They were first described in 1973, and account for 3 to 7 percent of pediatric brain tumors, with around 65 percent of cases reported in children less than 5 years old. The current classification segregates them from medulloblastomas because the molecular origin and progression of pineoblastomas and CSPNTs is believed to be considerably different from that of medulloblastomas.

The duration of symptoms is short, and common symptoms include nausea, vomiting, headaches, ataxia with nausea, seizures, and personality changes. Increase in head size and lethargy may be observed in children less than 1 year of age. Seizures, along with signs of intracranial hypertension from hydrocephalus (collection of cerebrospinal fluid in the brain) and neurologic deficit are common symptoms associated with pineoblastomas and CSPNTs. Hydrocephalus can be life threatening, and requires immediate medical attention to release the pressure to the brain by removing the excess cerebrospinal fluid. Children diagnosed with pineoblastoma may also have changes in vision because the tumor may be located in proximity to a region in the brain that regulates movements. Pineoblastomas are currently classified by the World Health Organization as grade IV tumors. Because they are poorly differentiated, they are often studied along with other undifferentiated embryonic neuroectodermal tumors.

CSPNTs can be further classified according to the cellular subtype making up the tumor. Because CSPNTs are tumors of embryonic origin, they are generally phenotypically poorly differentiated, or

may exhibit differential degree of differentiation of neuronal, astrocytic, and ependymal cell types. Tumors with neuronal cell type differentiation are called central nervous system neuroblastomas. Tumors with features of embryonic neural tube formation are named medulloepitheliomas, and those with ependymoblastic rosettes are termed ependymoblastomas. Some CSPNT patients show cytogenic alterations, including deletions or translocations of chromosome 10q22-26 and translocations involving chromosome 6q. Although significant advances have been made in the diagnosis and management of CSPNTs, the prognosis remains poor.

Pineoblastomas are diagnosed after biopsies following computer tomography (CT) imaging or magnetic resonance imaging (MRI) that indicate the presence of a lesion. Treatment in children under 3 years old is restricted to chemotherapy to delay the development of tumors, whereas children over 3 years old may be subjected to radiation therapy, depending on the degree of advancement of the tumors. Because pineoblastomas and CSPNTs are extremely rare forms of tumors, the treatment options are normally based on therapies appropriate for metastatic high-risk medulloblastomas. Such treatment modality includes high-dose chemotherapy and radiation to the head and spine regions. Significantly inferior outcomes have been reported both prospectively and retrospectively with these treatment regimens in comparison to more localized treatment modalities. Several retrospective and prospective studies have consistently reported worse outcomes, even for localized CSPNTs treated with treatment modalities opted for high-risk medulloblastomas.

Survival rates for patients with pineoblastoma and other CSPNTs widely vary, depending on the type of treatment, whether the disease has metastasized at the time of diagnosis, and the age of the patient. Current standard treatment modality for pineoblastoma includes a gross total resection of the tumor, which is subsequently followed by radiation and chemotherapy. Complete recovery can be achieved if the tumor is completely resected. In
most cases, however, recurrent tumors are seen because of incomplete removal of pineoblastomas. Chemotherapy is an attractive modality to minimize the necessity for radiation therapy for treatment of children, and may be combined with autologous stem cell transplantation. Traditionally, pineoblastomas have a higher rate of unfavorable outcomes in comparison to CSPNTs.

Pinkel, Donald

Donald Pinkel is one of the pioneers of pediatric oncology, particularly recognized as the clinician who developed a “Total Therapy” for children with acute lymphoblastic leukemia. This combination chemotherapy plus radiation for the first time in the late 1960s achieved a “cure” or long-term remission in 50 percent of patients. Pinkel was also the first director of the cancer program at St. Jude Children’s Research Hospital in Memphis, Tennessee. Perhaps Pinkel’s greatest contribution to the field of pediatric cancer was his commitment to the idea that cancer could be cured. In the days of Pinkel’s training, cancer in children was almost certainly fatal, particularly leukemia. Pinkel has recounted in interviews how fatalism prevailed among doctors and hospital staff about dying leukemia patients and how they were reluctant to “torture” them by giving them drugs that would cause terrible side effects. Other than blood transfusion, there was not even supportive therapy, and children usually could not live long enough to benefit from the few drugs that could produce short remissions in the 1950s. As a medical student and resident, Pinkel made it his personal mission to know these patients and dedicate his career to their care and hopefully cure.

Pinkel was born in Buffalo, New York, in 1926. Even as a child, he was fascinated with science. His decision to study medicine came from his deep empathy for people. His older sister was a nurse and often discussed science problems with him at home after work.

As a medical student, Pinkel decided to enter residency in pediatrics and work with children with cancers. In 1951 he graduated from the University of Buffalo School of Medicine. He initiated a clinical cancer program in 1953 at Buffalo Children’s Hospital. His study of childhood cancer was interrupted by Army service. While working as chief of pediatrics at an Army hospital in Massachusetts, he contracted polio during an epidemic. During his rehabilitation in Boston, he worked with Sidney Farber, who developed the first effective drug against childhood acute lymphoblastic leukemia.

Pinkel returned to Buffalo in 1956 to develop and direct a pediatric research and treatment service at Roswell Park Cancer Institute. There he joined James Holland and Emil Frei and Emil J. Freireich of the National Cancer Institute. Their goal was to develop systematic comparative evaluations of chemotherapy of acute leukemia in children and adults. Although prolonged survival of children with acute lymphoblastic leukemia (ALL) was achieved by sequential or combination therapy with the five anti-leukemia drugs that became available between Farber’s 1948 discovery and 1961, the disease remained fatal. In addition, a new problem had emerged. Most of the children eventually succumbed to leukemia in the central nervous system because anti-leukemia drugs could not pass from the blood into the cerebrospinal fluid in effective doses.

After pioneering the program at Roswell, Pinkel moved to the newly established St. Jude Children’s Research Hospital, becoming its first director. There he served also as chief executive officer (CEO) from 1962 to 1973. His work focused on
childhood ALL. He and his colleagues identified four major obstacles to its cure: drug resistance, drug toxicity, meningeal relapse, and, most important, pessimism. They instituted a treatment program aimed at permanent cure of ALL. Called “Total Therapy,” it was based on all the available relevant research and experience at the time. There were four phases: remission induction, remission consolidation or intensification, specific preemptive meningeal treatment, and continuation chemotherapy for three years. Both radiotherapy and intra-thecal drug therapy were used for meningeal treatment. Eventually, a 50 percent cure rate was achieved in the 1967 to 1968 study V. This was the first significant cure rate for generalized cancer and for primarily drug treatment of cancer. This four-phase treatment plan is still used, with numerous modifications. Better use of chemotherapy drugs has generally replaced the need for prophylactic central nervous system therapy.

Pinkel and his colleagues also pioneered the multidisciplinary approach to children with solid tumors, the use of adjuvant chemotherapy to prevent metastases and of neoadjuvant chemotherapy prior to surgery or radiation.

Donald Pinkel has received many awards for his work and contributions in pediatric cancer, particularly that in the “cure” of childhood leukemia. His national and international awards include the Lasker Award for Medical Research, the Kettering Prize for Cancer Research, the Polin Prize for Pediatric Research, and the Zimmerman Prize for Cancer Research. From the American Cancer Society he received the Annual Award in Clinical Research, and from the Leukemia-Lymphoma Society of America he received the Return of the Child Award.

Pituitary Tumor

Pituitary tumors account for an estimated 9 to 15 percent of all intracranial growths and the overall majority of pituitary disorders. Recent estimates indicate that pituitary adenomas are common in the general population, occurring in from 14.4 percent to 22.5 percent of people (with an overall estimate of 16.7 percent). Pituitary carcinomas are much more rare, however, representing less than 0.2 percent of pituitary tumors.

Pituitary tumors are normally discovered as a result of pituitary hormone production symptoms, presentation of visual or neurological conditions stemming from mass effect, or incidentally in the course of using radiographic imaging to investigate unrelated questions. Once discovered, they are distinguished by size, functional status, and immunohistochemical characteristics. Treatment options vary according to the size and functional status of the tumor and include neurosurgical, pharmaceutical, and radiological options.

The Pituitary Gland

The pituitary gland is a small endocrine gland attached to and controlled by the hypothalamus. It is located below the hypothalamus, inside the sella turcica, a bony, saddle-shaped cavity. The posterior section of the gland is normally considered an extension of the hypothalamus, and it is where vasopressin (i.e., antidiuretic hormone) and oxytocin are stored. The anterior section of the gland is composed of glandular tissue and is responsible for the synthesis of six hormones: growth hormone (GH; somatotropin), thyroid-stimulating hormone (TSH; thyrotropin), adrenocorticotropic hormone (ACTH; corticotropin), luteinizing hormone and follicle-stimulating hormone (LH and FSH; gonadotropins), and prolactin. Most pituitary tumors begin in the anterior section of the pituitary gland and can emerge out of the sella.
turbica, exerting pressure on nearby tissue and possibly causing mass effects as they grow.

**Types of Pituitary Tumors**

Pituitary adenomas are classified according to size, functional status, and immunochemical characteristics. Adenomas smaller than 10 mm are referred to as microadenomas; those larger than 10 mm are called macroadenomas. Tumors larger than 4 centimeters (cm) are described as giant pituitary macroadenomas. Both micro- and macroadenomas can be functional, meaning they secrete hormones. Whereas functioning pituitary adenomas are hormonally active, nonfunctioning pituitary adenomas are those that do not secrete a detectible or clinically significant level of hormones.

Nonfunctioning pituitary adenomas account for approximately 28 to 37 percent of all pituitary growths. Functioning pituitary tumors are classified according to the hormone they secrete. Corticotrophs secrete ACTH and are clinically indicative of Cushing’s disease. Gonadotrophs secrete LH or FSH, lactotrophs secrete prolactin, somatotrophs secrete growth hormone and are associated with acromegaly, and thyrotrophs secrete TSH and relate to hyperthyroidism. Alternative diagnoses to pituitary tumors include pituitary hyperplasia, sarcoidosis, pituitary abscess, Rathke’s cleft cyst, germ cell tumors, and metastatic carcinoma, among others.

**Sources of Pituitary Tumors**

Most pituitary tumors emerge outside a family history of them, although about 5 percent occur in the context of a family history of multiple endocrine neoplasia type 1 (MEN-1). Nonetheless, pituitary tumors are believed to occur as a result of either inherited or acquired genetic mutations. Generally speaking, increased expression of tumor suppression genes and/or increased activation of oncogenes appear to be the primary routes by which pituitary tumors begin and/or grow.

The specific genes involved in the initiation and development of pituitary tumors depend on the type of tumor, but they are generally monoclonal, meaning that they initiate and progress from genetic changes in only one cell. Very little research has investigated the role of possible environmental or micro-environmental contributions to those mutations in humans.

**Presentation and Diagnosis**

The main clinical features of pituitary tumors are hormonal and neurologic, although approximately 10 to 20 percent of them are discovered incidentally, due to increased capability and use of neuroimaging to investigate other, unrelated questions. Nonfunctioning, intrasellar microadenomas that do not extend from the sella turcica are the most common incidentalomas, as they are normally asymptomatic.

When either functioning or nonfunctioning adenomas become parasellar, they can exert pressure on nearby tissue, leading to neurological mass effects stemming from pressure on cranial nerves III (oculomotor nerve), IV (trochlear nerve), and VI (abducens nerve). Effects on cranial nerve V (trigeminal nerve) have also been observed but are more rarely encountered than effects on nerves III, IV, and VI. Mass effects on these nerves can occur individually or in combination, and with varying degrees of severity depending on the tumor’s size, location, and growth rate. Mass effects on the oculomotor nerve are the most common, resulting in visual field changes that associate and progress as the tumor enlarges up and out of the sella turcica. Mass effects on the other cranial nerves result from lateral extension of the tumor outside the sella, into the cavernous sinus. Headaches are also a common complaint, although it is not believed that they associate with tumor size.

Functioning pituitary tumors normally present as a function of the hypersecretion of a specific hormone and the patient’s sex. Female menopausal state is an additional factor influencing the presentation. Hyperprolactinemia, stemming from prolactitrophs (prolactinomas), can relate to decreased libido, infertility, and milk production in both men and women. Corticotrophs (secreting ACTH and clinically identified as Cushing’s disease) associate with suppressed mood, skin changes, and weight gain. Gonadotrophs are associated with hypopituitarism, hypogonadism, and/or neurological mass effects. Somatrophs are typically recognized as a result of increased growth in hands and feet and change in facial features, particularly an enlarged mandible. Thyrotrophs are associated with symptoms of hyperthyroidism.

**Treatment Options**

Surgery is the main treatment for clinically significant pituitary adenomas, with the exception of
prolactinomas, which can be effectively treated pharmacologically with a dopamine agonist, such as a low dose of cabergoline or bromocriptine. In some other cases, functioning adenomas secreting ACTH are also potentially treatable with pharmaceuticals that reduce ACTH secretion, but the acceptability and effectiveness of such treatments for functioning adenomas other than prolactinomas is complicated and somewhat tentative at this time.

Unless the tumor is particularly large or accompanied with additional complicating morbidities, pituitary tumors can be effectively removed via transphenoidal surgery. In most cases, the tumor can be accessed transnasally, using endoscopic or microscopic procedures. The transphenoidal (transnasal) procedure is minimally invasive, has a quick recovery rate, and has very low complication and intraoperative mortality rates when conducted by a skilled surgeon. Patients with functioning adenomas may benefit from both surgical and pharmaceutical treatments, in addition to or apart from radiotherapy. Radiotherapy is often applied when surgery is not possible, when a tumor has recurred or was only partially removed, or when medications have effectively failed. Advances in Gamma Knife and Cyber Knife technologies are becoming the typical means by which radiotherapy is applied and have increased the possible effectiveness of this treatment.

Nonfunctioning microadenomas are often not immediately treated, especially when they are not causing any neurological symptoms. Rather, the recommendation is to follow the progression of the tumor growth and function through serial, annual, or bi-annual neuroimaging and through periodic endocrinological testing.

Plasma Cell Neoplasm/Multiple Myeloma

Molecular investigations have confirmed that multiple myeloma is a highly heterogeneous disease that consists of subtypes, each characterized by specific clinicopathological symptoms and treatment outcomes. Based on this genetic heterogeneity, it is therefore difficult to develop a universal treatment scheme for multiple myeloma because patients generally harbor different features. The best treatment approach would then be personalized therapy using targeted strategies. The RAG (red, amber, green) model is technically a simplified representation of the genetic data commonly generated from sequencing tests and, instead, presents an aggregate risk score. The RAG model was designed to integrate gross and molecular genetic modifications that occur in the DNA of a multiple myeloma patient. Gross genetic modifications include trisomies, deletions, and translocations, whereas molecular changes encompass missense substitutions.

Whole genome or exome sequencing analysis of a multiple myeloma patient’s DNA sample can generate an extensive amount of genetic information on this particular patient. More importantly, these DNA sequencing techniques can also yield mutational information that can be strongly associated with the disease. Unfortunately, the clinical significance of these genetic mutations is apparently lagging behind the improvements in the DNA sequencing technology. To circumvent this obstacle, a genetic information–based risk stratification scheme for multiple myeloma, known as the RAG model, has been proposed. The RAG model is technically a simplified representation of the genetic data that are commonly generated from sequencing and, instead, presents an aggregate risk score. The RAG model was designed to integrate gross and molecular genetic modifications that occur in the genome of a multiple myeloma patient. Gross genetic modifications include trisomies, deletions, and translocations, whereas molecular changes encompass missense substitutions. The RAG model utilizes a scoring system that ranges from 1.0 to 3.0, which in turn can be included in the diagnostic, treatment, and prognostic algorithms of the multiple myeloma patient.

Molecular studies have shown that multiple myeloma can present various genetically different
subtypes; therefore, a universal treatment scheme will be ineffective for this disease. The genetic heterogeneity of multiple myeloma is largely due to the capacity of plasma cells to undergo clonal proliferation, resulting in a variety of clinical subtypes. The most effective option for the treatment of this disease would therefore be based on the specific genetic subtype of each multiple myeloma patient. In order to achieve this personalized treatment approach, a combination of conventional and molecular cytogenetic analyses is necessary. Conventional cytogenetic analysis would include karyotyping of G-banded chromosomes, whereas molecular chromosomal analysis entails the use of fluorescent in situ hybridization (FISH) using DNA probes. In addition to these cytogenetic assays, it is also essential that DNA sequencing analysis be performed as a standard test for multiple myeloma. The integration of the data generated from these three genetic assays facilitates the development of an algorithm for the treatment of the multiple myeloma patient. The risk stratification system of RAG was designed to simplify the genetic data gathered from various genetic analyses, thus allowing the clinician to infer the disease risk of a patient.

The development of the RAG model was also based on the delay in the establishment of the clinical significance of most of the results of whole genome or exome sequencing. It should be understood that although the results of these high-throughput DNA sequencing assays are rapidly generated using computerized systems, the direct implications of the results to the clinical setting have not been fully established. Most of the reports published to date are disease associations, or a relationship of observing a specific genetic feature in a particular disease or disease subtype. However, the functional consequences of these genetic features have not been validated in terms of whether these indeed are the causative factors for a specific disease. The association of a genetic feature or mutation with a specific disease is therefore not very informative for the clinician because it does not indicate that it directly causes a specific disease. Nonetheless, genetic information generated by these tests continues to accumulate at a rapid pace, and its clinical power will eventually be realized over time.

The RAG model was developed based on the concept of risk stratification, wherein multiple myeloma patients could be grouped into specific clusters that would totally, partially, or minimally benefit from a specific treatment regimen. This model also includes information on whether a specific patient, based on the genetic features that were detected during analysis, would elicit toxic responses to a particular medication for the treatment of multiple myeloma. The specific drug response of a patient is mainly due to biomarkers present in his or her cells, which are often the molecular targets of cancer drugs. Without this information, it is possible that a multiple myeloma patient would not respond to a specific treatment regimen because the target molecule of the administered drug is absent or of a different form.

The first staging system employed for multiple myeloma was presented in 1975 and used standard laboratory values coupled with imaging data. This initial system was therefore based on the stage of the disease; however, the genetic heterogeneity of multiple myeloma was not well characterized at that time. This discrepancy often led to variable responses to treatment, wherein some patients responded to the administered medications but others did not. Subsequently, additional prognostic factors such as serum β2-microglobulin (Sβ2 M) and albumin were used. These factors provided more information on the condition of the patient, including the disease stage and renal function; these were then applied to the development of the international staging system (ISS) for multiple myeloma. Although the ISS system is readily accessible and simple to use for prognostication, there was yet more detailed information that needed to be integrated into the system, such as the genetic information of the patient. Molecular genetic studies since then have shown that high-risk patients for multiple myeloma could be identified using DNA sequence signatures and mutations. Coupling the ISS system with genetic data thus further strengthens the results generated by whole genome association studies.

By 2009, a consensus FISH algorithm was presented by the International Myeloma Working Group that could be used for prognostication of multiple myeloma patients. This algorithm indicated that a FISH panel that would screen for the chromosomal rearrangements t(4;14), t(14;16), and del(17p) significantly helps in the diagnosis of myeloma. These chromosomal aberrations have been documented to be indicative of patient survival
and risk. A second FISH panel screening for +1q as well as t(14;20), on the other hand, further helps in risk stratification. Because multiple myeloma is commonly associated with gross chromosomal rearrangements such as trisomies and translocation, these FISH panels, together with conventional karyotyping, can supplement the information generated by clinical tests.

Plastics Industry

Occupational exposure to chemicals in the plastics industry may contribute to an increase in breast cancer and reproductive problems, because the chemical substances in the industry either function as mammary carcinogens or disturb the function of the endocrine system or both. Most plastic products release estrogenic chemical substances. The plastics work environment contains endocrine-disrupting chemicals like phthalates, brominated flame retardants, and bisphenol A (BPA). Compounding the problem, a mixture of a large variety of the chemicals plus their combustion by-products exposes plastics workers to much higher levels of toxins, and the combined effect may be greater than the sum of the individual chemicals. Lung cancer also appears in association with the plastics industry, which might be related to the combinations of the chemicals.

A system of chaotic growth in the cells of the human body describes cancer. Both changes inside the body (i.e., genetic changes) and factors in the external environment (i.e., tobacco, asbestos) alone or together participate in the development of cancer. Exposure to cancer-linked particles over time weakens the body’s protective ability and the carcinogen overcomes the checks and balances in the body leading to cancer.

The Process of Making Plastic Products
Plastic products go through numerous steps in various occupational settings, and workers become exposed to cancer-producing chemicals at several stages of processing. In the first stage, monomers such as vinyl chloride, styrene, bisphenol A, acrylonitrile, butadiene, ethylene, and urethane come from processing crude oil and/or natural gas from a process the petrochemical industry dubs cracking. In the next stage, the ensuing monomers go to resin producers to undergo the procedure of polymerization. Polymerization encompasses a chemical reaction whereby molecules of a monomer such as vinyl chloride become interconnected to form large molecules with a molecular weight larger than the original monomer. Resin producers transform monomers into polymer products such as polyvinyl chloride, polystyrene, nylon, acrylonitrile-butadiene-styrene (ABS), and polyurethane. Resins travel to plastics merchandise manufacturers in the configuration of powders, liquids, or pellets. In the third and final stage, polymers move to downstream industries to create paints, adhesives, and plastics merchandise such as pipes, packaging, automotive components, toys, textiles, siding, medical devices, and tools.

Polymers consist of two primary categories of thermoplastic and thermoset. Thermoplastic polymers use heat and pressure to repetitively soften and reshape the items such as polyvinyl chloride (PVC), polyethylene, polystyrene, and acrylics. The other category, thermoset substances, go through a chemical process resulting in a permanent material that cannot be made pliable or restructured. Examples of thermoset products include polyurethane, phenolics, ureas, and epoxies. Resins take shape into diverse plastic products using one of these two categories of manner of development.

Worker Exposure to Chemicals
Every step in the plastic-making process exposes workers to different contaminants that are
discharged from mixing and processing of the plastic substances. The workers come into contact with gases, vapors, dust, and by-products. Unfortunately, thorough descriptions about worker exposures remained limited until recent qualitative studies conducted from 2008 to 2010. Example of comments gathered by R. DeMatteo and colleagues (2014) included statements like “lot of smells, a lot of fumes,” but no ventilation existed in workplace settings to dissipate the chemicals released into the air. The workers describe the effects: “You smell fumes, you taste [it] in your mouth, and then you get—it’s like a light-headedness, dizziness” and “We have skin and breathing problems.” Government agencies tested the air, but the contaminants failed to exceed the regulated levels. Even when inspectors found problems in plants, companies never followed up on clearing the violations.

Environmental studies measuring acrylonitrile, styrene, phthalates, and BPA found chemical body burdens in plastics workers significantly higher than those in the general population; even so, air sampling detected only levels far below exposure standards.

**Plastics Industry Toxins**

Massive amounts of toxic chemicals are used in plastics production. DeMatteo (2012) describes contaminants left by residual monomers, polymers, and additives to include plasticizers, stabilizers, pigments/colorants, flame retardants, activators, lubricants, and fillers. Many of these materials are known mutagens and known to cause cancers in humans, whereas others are suspected of producing cancer, and still others are identified as endocrine-disrupting chemicals. D. Lithner and colleagues (2011) found workers exposed to residual monomers that included vinyl chloride, styrene, acrylonitrile, BPA, formaldehyde, butadiene, ethylene, and urethane. Of these monomers, the ones with the highest hazard level consisted of polyvinyl chloride, styrene-acrylonitrile, and acrylonitrile-butadiene-styrene.

The carcinogen vinyl chloride causes angiosarcoma, testicular cancer, and male breast cancer,
whereas formaldehyde showed links to female breast cancer. Acrylonitrile demonstrated an association with genital abnormalities from mothers exposed during pregnancy, whereas research showed styrene as an endocrine disruptor.

Neeti and colleagues (2011) describe the phthalate chemicals in the form of polyethylene terephthalate (PET) that encompasses the material used to make the clear plastic containers for water bottles, soda beverages, sport drinks, and condiments (e.g., salad dressing, vinegar, catsup). Manufacturers of PET assert that the phthalate used in this product is chemically dissimilar from other plastics that cause endocrine disruption and cancer, but the research suggests the concentration of phthalate in these clear plastic containers varies depending on the contents of the bottle. Phthalates leach into lower pH products like soda or vinegar over bottled water. Elevated temperatures cause leaching of phthalates and antimony from PET (e.g., water bottle sitting in a hot car or at a picnic in the hot sun). The findings of studies even suggest that salad dressing stored in a warm warehouse for a month can potentially reach toxic levels.

Disposal of plastics by incineration results in the release of carbon dioxide, a greenhouse gas, and the carcinogenic substances polycyclic aromatic hydrocarbons (PAHs) and dioxins. North and Halden (2013) describe the negative environmental and health effects of the released carcinogens. Plastics revolutionized medicine with the switch from glass, metal, and wood, but the negative effects of plastic only arose in the last 20 years. In 2012, the Food and Drug Administration (FDA) amended its regulations to no longer use BPA-based polycarbonate resins in baby bottles and sippy cups. The FDA took this action based on a petition from the American Chemistry Council’s data. North and Halden (2013) report on the use of di-(2-ethylhexyl) phthalate (DEHP), another plasticizer used in PVC. This substance can leach out readily from any item made with it. Studies in animals show harmful health effects to the female and male reproductive systems and insulin resistance.

### Human Illness

A 1998 study by S. A. Petralia and colleagues initially identified breast cancer in women exposed to organic solvents and benzene in the plastics and rubber industry. The women demonstrated a nearly doubling rate (odds ratio [OR] = 1.8) of breast cancer. Occupational exposures to synthetic textile fibers, acrylic fibers, and nylon fibers prior to age 36 show an excess risk of breast cancer. Labreche and colleagues found in 2010 OR of 7.69 in these end products of the plastics industry. So, these women have nearly eight times the risk of developing breast cancer. This study supports the theory that younger women face higher vulnerability before breast tissue reaches full differentiation.

Research by D. G. Kern and colleagues found in 2011 exposure of workers to plastics carcinogens in the nylon flock industry caused lung cancers. The study showed a threefold increase in lung cancer risk.

Also in 2011, J. T. Brophy and colleagues found women in the automotive plastics industry developed breast cancer prior to menopause at a doubling rate (OR = 2.68) over the females in the control group. Food canning workers exposed to BPA in the plastic lining of cans also showed a doubling rate (OR = 2.35) of breast cancer.

A 2011 New Zealand study looked at occupations with high risk of lung cancer. M. Corbin and colleagues found multiple occupations with high rates of lung cancer after controlling for age, gender, socioeconomic status, and smoking. The occupations of a priori interest included rubber and plastics products machine operators (OR = 4.27); electric and electronic equipment assemblers (OR = 3.61); petroleum, coal, chemical, and associated product manufacturing (OR = 1.80); and loggers (OR = 4.67). Occupations not identified ahead of time but showing increased risk for lung cancer consisted of nursing professionals (OR = 5.45), enrolled nurses (OR = 7.95), car retailing (OR = 3.08), and road freight transport (OR = 3.02).

S. Villeneuve and colleagues conducted a 2011 population-based case-control study of 1,230 breast cancer cases and 1,315 healthy controls. The researchers found elevated rates of breast cancer in the occupational groups of textile workers, rubber and plastics product makers, nurses, and tailors/dressmakers. These workers face exposures in the workplace related to solvents, endocrine disrupting chemicals, nonmetallic mineral products, and night-shift work. Researchers found that agricultural workers displayed a significant decrease in breast cancer.
Pleuropulmonary Blastoma

Conclusion

The plastics industry exposures really came to light in the last two decades. Therefore, research only recently identified chemicals in this industry that cause major cancers of breast and lung. Further research is needed to ascertain the molecular details of the process in order to apply preventive measures.

Pleuropulmonary Blastoma

Pleuropulmonary blastoma (PPB) is a rare and highly malignant cancer originating in the lung or pleural cavity, accounting for less than 1 percent of all primary lung tumors in children. PPB was first described in 1988, and is known to occur most often in infants and young children. PPB begins in the lung tissue or the tissue lining the lung cavity (pleural tissue). PPB arises during fetal and/or infant lung development. PPBs are composed of both immature epithelial cells and mesenchymal cells, and the early stages have a cellular presentation resembling fetal lung tissue.

PPB is classified into four different types. Type I PPB is composed of cysts with early evidence that it is cancerous. Type I PPB is difficult to diagnose early, and is known to occur in infants. Type I PPB has a better chance of being treated successfully than Types II and III PPB. Type Ir (regressive) PPB has diagnostic features similar to Type I PPB and is devoid of cancerous cells. Type II PPB is a combination of cystic and solid neoplasm, with a high risk of cerebral metastasis. Type II PPB may exhibit signs of hemorrhage or necrosis, whereas Type III PPB is a completely solid neoplasm, with cerebral metastasis occurring in more than 50 percent of the patients. Types II and III PPB are known to occur in children aged 3 to 4 years. PPB may also spread to the bones, lymph nodes, liver, pancreas, kidneys, and adrenal glands. These are cancerous tumors, and the treatment modality includes intensive chemotherapy.

Common symptoms associated with PPB include sudden and stressful breathing resulting from the air escaping from lung cysts into the chest cavity. This phenomenon is known as pneumothorax. A careful diagnosis is necessary because pneumothorax
can result from a number of other causes. Symptoms associated with PPB are similar to the symptoms of pneumonia, and include cough and pain in the chest, accompanied with fever. An initial chest X-ray may often be interpreted as pneumonia.

The exact cause of PPB is presently unknown, and it is known to randomly develop. There may or may not be a genetic risk attached to the development of PPB. The presence of cysts in the lung and a family history of PPB increase the risk of development of PPB. It has been shown that around 40 percent of children with PPB have a family history of lung or kidney cysts, Wilms tumor, thyroid lumps, and rare ovarian tumors, among other types of tumors. Gains of chromosome 8 is one of the consistent chromosomal aberrations associated with PPB. Additionally, trisomy 2 (presence of an extra copy of chromosome 2), unbalanced translocation between chromosomes 1 and the X chromosome, and mutations in the tumor suppressor gene p53 mutations have also been reported. More recently, a mutation in a gene called DICER1 has been found in families with PPB. Mutation of that gene, resulting in DICER1 syndrome, is found in 50 to 70 percent of patients with PPB. The DICER1 gene encodes instructions encoding a protein involved in the production of microRNA (miRNA), which blocks the production of proteins by attaching to their respective RNA templates.

Pleuropulmonary tumors are generally located around the lungs. Later stages of tumor may move, however. Radiological evaluation of the tumor to assess the spread to the circulatory system plays an important role in decisions regarding treatment modality adopted against the tumor. Surgery and removal of the tumor and surrounding tissue is a primary treatment modality for PPB. If, however, the tumor is too large to be surgically resected, chemotherapy may be performed to decrease the tumor size before resection. Type I PPB may be completely cured by surgical resection alone. Chemotherapy is particularly beneficial for patients with Type I PPB, and is almost always recommended for Types II and III PPB. The side effects of chemotherapy are dose dependent, and also depend on the individual. The side effects are temporary, and may include fatigue, increased risk of infection, nausea, vomiting, and hair loss.

Radiation therapy is only recommended if the cancerous cells are not completely removed after surgery and chemotherapy. Radiation therapy can have severe side effects by interfering with normal bone growth, as well as the development of secondary cancers. Historically, pleuropulmonary blastoma has a poor prognosis, especially for Grade II and Grade III tumors. Total surgical resection of the tumor is associated with a better prognosis. Cystic Type I and Ir PPB has a better prognosis when compared to Type II PPB, and Type II has a better outcome than Type III PPB. The five-year survival rates of around 30 percent are reported for patients with Stage I disease, and recurrences are reported in 30 to 40 percent of cases. Metastasis to surrounding tissues is also commonly reported.

Poland

The history of cancer as an important problem in Poland goes back at least 400 years. The first hospital for cancer patients was established in Warsaw in 1591–1592. This was the first hospital treating
cancer patients in Europe and possibly in the world. Another milestone is the Radium Institute of Warsaw, inspired by Marie Skłodowska Curie and the result of a nationwide effort, opened on May 29, 1932. Curie personally brought the first gram of radium to the institute, purchased by Polish organizations in the United States and Canada. The Communist government from the late 1940s to 1989 oversaw further industrialization in Poland but did not invest sufficiently in public health. As a result, the incidence of cancer in the population increased. In 2011, the institute, presently known as the Marie Skłodowska Curie Memorial Cancer Centre and Institute of Oncology, served 28,000 patients in inpatient clinics; 26,000 patients in the One Day Chemotherapy Section; and more than 340,000 outpatients. The center is presently the nation’s most significant research, oncology data collection, prevention, and treatment facility.

Cancer, after cardiovascular disorders, is the second-highest cause of mortality in Poland. Every fourth death in Poland is caused by cancer. Although the incidence of cancer (about 20,000) in Poland has increased in recent decades, this increase must be considered alongside several other trends in public health. First, the increase in mortality among cancer patients is related mostly to the aging of the population. Mortality of men under 64 years of age decreased. The significant increase in mortality is only for older men. The effectiveness of cancer treatment actually improved significantly from 30 percent to 42 percent. At the beginning of the 2010s there are about 150,000 new incidences of cancer per year and about 100,000 deaths due to cancer. Each year about 360,000 people live diagnosed with cancer. It is estimated that in 2025 the new incidences of cancer in Poland will reach 180,000 annually. There are differences in cancer prevalence between genders. In 2012, the incidence of cancer for men was highest when detected in lungs (20 percent), prostate (15 percent), and colorectal (13 percent). For women the highest occurrence was breast cancer (23 percent), colorectal cancer (10 percent), and lung cancer (9 percent).

These four types of cancers are very common, accounting for half of all cancer problems in Europe. Lung cancer was the most common cause of death for men (31 percent) and women (15 percent) in Poland. For years, the role of environmental pollution and bad nutrition in the development of cancer were known. During the period of Communist rule from the late 1940s to 1989, ideological attitudes made it difficult to address questions of public health, especially those affected by nutrition and pollution. However, this situation changed after 1990. Poland now has a well-organized system of cancer-related reporting, data collection, research, and health care. As a member of the European Union (EU) and the World Health Organization (WHO), the Polish national program against cancer must respond to the requirements of those two international organizations. The guidance for national policies is delineated by the WHO formalized strategy “Health for All in the 21st Century” and the European Cancer Code. To improve the overall health of society the following action is advised and encouraged: decrease tobacco smoking, improve nutrition by increasing vegetable and fruit consumption and obesity control, increase exercise, limit alcohol consumption, and avoid sun exposure.

In 1990, the National Health Program was formulated to decrease mortality rates of the most critical health threats. Because the outcomes of this program were insufficient, the Polish government created in 2005 the National Program Against Cancer Diseases (NPACD), using significant financial and administrative resources. Several institutions coordinate efforts in responding to the threat of cancer. The Ministry of Health is responsible for policies and the coordination of programs. The National Health Fund finances programs and cooperates with health care providers. The Polish Union of Oncology cooperates with institutions outside the health sector such as public media and nongovernmental organizations. The National Cancer Registry (Institute of Oncology) collects national data. All these organizations support the main goals of the NPACD: prevention, improvement in early diagnosis and treatment, application of research findings, and monitoring programs' applications and effectiveness.

Polish media today offer more information to increase public awareness and knowledge concerning prevention and screening of cancer. Education about the critical role of tobacco smoking and diet in the development of cancer has led to a decrease in smoking among men and improvement in healthy choices in food consumption. There is ongoing education concerning breast and cervical screening that can significantly affect mortality among women. There are already measurable effects of these efforts.
Research performed in Poland has shown that the changes in diet have had a significant impact on the incidence of gastric cancer despite other negative health factors. Poland has a high prevalence of *Helicobacter pylori* infection, affecting up to 73 percent of the population. This infection is connected with the development of many gastric cancers. From 1950 to 1989 the national diet was based on the growing consumption of animal products and sugar. There was no import of fruits and vegetables that could be eaten throughout the year. This trend in consumption changed in 1990 and people began to eat relatively more fruits and vegetables. In 2006 morbidity related to gastric cancer was twofold lower than in 1960. That is a significant difference in spite of the high level of *H. pylori* infection.

Similarly there is an increase in the effectiveness of treatment for other kinds of cancer. There are, however, regional variations. The best results are achieved in the Mazowsze region (46 percent of patients survive) and the worst in the Lublin region (36 percent). The rate for survival after five years improved: 37 percent for men and 53 percent for women. To improve treatment effectiveness, there is a growing effort to apply molecular diagnostics to use a targeted, specific treatment for different types of cancer. Too often new treatment methods are used without regard to the type of cancer that needs to be treated.

The new national plan calls for each patient to have an individualized treatment plan created by a group of medical specialists. Patients will have their own oncological treatment cards that will have all relevant medical information that can be used by any health care provider. The main focus of the new government health program is to improve early detection and begin treatment as early as possible. It is recognized that when a cancer patient has identified symptoms, it may already be too late for successful treatment. To improve detection, the following action is advised: doctors will have incentives for establishing early diagnosis, there will be no financial limits for cancer treatment, and more medical personnel will have the necessary resources for cancer diagnosis. With a long history of national struggles with cancer, Poland is now able to use its best resources to decrease the rate of incidence and mortality due to cancer.

Further Readings

Polishes
Nail coloring practices date back to ancient Egypt and China. The materials used for nail polish came from natural substances (e.g., egg whites, flowers, henna, and wax). The history of artificial nails began about 600 B.C.E. in China with nails constructed from gold, silver, and precious stones. More recently, the Charles Revson Company (today known as Revlon) put together the first contemporary nail polishes in 1920 and the nail industry emerged onto the commercial market after 1932, motivated by enamel paint on cars.

Overview
Nail polish provides a means to beautification, a process to strengthen weak nails, and a means to cover surface irregularities or discolorations. The formulation of nail polish consists of the following:

- Film-forming elements (nitrocellulose used most routinely)
- Resins (e.g., tosylamide-formaldehyde) for adherence
- Plasticizers (e.g., dibutyl phthalate) for flexibility
- Solvents (butyl stearate and acetate compounds) for maintaining the polish in a fluid state and to assist in fast drying upon application
- Thixotropic agents (e.g., bentonite) to keep the ingredients in the polish uniformly suspended
- Variety of mineral pigments (calcium carbonate, zinc oxide, titanium dioxide,
Iron oxides) and synthetic pigments (D and C red 6/7/19, FDC yellow)
• Natural agents (guanine, bismuth, oxychloride, and micatitanium) to add color and shine to the nail polish

As noted above, nail polish represents one of the product categories that use the chemicals formaldehyde, toluene, and dibutyl phthalate (DBP). These specific chemicals show direct links to cancer. Other groups using formaldehyde, such as medical examiners and embalmers, show an elevated risk of leukemia and brain cancer compared to the overall population. Research indicates that these chemicals (called endocrine disruptors) probably disrupt the natural balance of hormones in the human body to produce cancer. Consequently, many smaller nail polish manufacturers eliminated these chemicals from their product line in 2005. The information below explains why other companies continue to use these three chemicals.

**Food and Drug Administration Regulation**
Nail polish falls under regulation by the U.S. Food and Drug Administration (FDA). As part of the FDAs’ wide-ranging authority, it can confiscate any cosmetic product found to be poisonous, harmful, lethal, adulterated, misbranded, or otherwise posing a health risk. The FDA as well as the Consumer Product Safety Commission and the Federal Trade Commission have responsibility for regulating cosmetics, including packaging, labeling, and advertising. The FDA expects the manufacturers of nail cosmetic products to list the ingredients on the package and to alert consumers to potential hazards if the product is used improperly. Since Congress decided in the early 1900s that risks caused by cosmetics remain low, the FDA does not require premarketing approval of cosmetics. The resources and tax dollars are diverted to the more harmful products of medicine and devices instead. Likewise, most other countries around the world also do not require premarketing approval of cosmetics.

**Risk Assessment**
Risk assessment refers to the ability to ascertain the health risks associated with a chemical. Many chemicals may produce an adverse impact at a high measurement dose so scientists set exposure limits for consumers and industry workers. The scientists look for the lowest level that produces an adverse health effect; then these professionals take into account how people become exposed and how frequently and to what degree. Based on this information, the scientists set the exposure limit at a level that will not harm people.

**Cosmetic Ingredient Review Expert Panel**
An independent group of leading scientists and medical doctors from colleges and universities comprise the U.S. Cosmetic Ingredient Review (CIR) Expert Panel. This group evaluates the safety of cosmetic components and carries out measurements of risk. Since the CIR was formed in 1976, it has reviewed thousands of cosmetic products. The Food and Drug Administration and the Consumer Federation of America take part in the panel's determinations of risk assessment.

The CIR has analyzed all the major elements in nail polish and proclaimed them safe. The organization states that keratin, a solid and primarily impermeable substance, forms the foundation of fingernails and toenails. Once the nail polish dries, the elements in the polish remain in the solidified film coating and fail to be taken up by the body or liberated to the environment.

**Occupational Safety and Health Administration**
The Occupational Safety and Health Administration (OSHA) requires companies that produce nail polish to provide material data safety sheets to employees and to nail salons. Plants that produce nail polish must give employees working in the manufacturing process adequate training and personal protective equipment for handling toxic chemicals.

**OPI Products**
The biggest producer of nail polish and nail treatment products in the world is OPI Products, Inc. Headquartered in California, the company delivers products to more than 70 countries, predominantly to nail salons, specialty spa salons, and beauty supply stores. Despite being a frontrunner in nail care, the company lingers behind in removing hazardous elements from its products. Industrial chemicals associated with cancer and reproductive impairment include formaldehyde, dibutyl phthalate,
Polishes

and toluene. OPI eliminates these chemicals from products in Europe but continues to sell the products containing the contentious components in the United States.

**Formaldehyde**

Formaldehyde or methylene glycol works as a nail hardener for nail polish. The FDA allows formaldehyde provided its weight does not exceed 0.2 percent of the total weight of the product. By avoiding the vapors, a person reduces the chance of inhaling it and exposing him- or herself to allergies or cancer risk. The International Agency for Research on Cancer (IARC) categorizes formaldehyde as a known human carcinogen. Formaldehyde, a strong-smelling chemical, appears in many building materials, in household products, and in nail polishes. It acts as an industrial fungicide, germicide, and disinfectant. Therefore, formaldehyde represents a good preservative in medical laboratories and in mortuaries. Other industries continue to use formaldehyde to manufacture furniture, wallpaper, carpets, and ceiling tile, despite its carcinogenic effects.

**Phthalate**

Phthalate exists as a variety of chemicals used primarily at concentrations below 10 percent in nail polishes. As plasticizers, the phthalate lessens cracking by making the nail less brittle, helps prevent chipping, and adds a moisturizing sheen to the nail.

In 2004 H. J. Koo and colleagues analyzed the amount of dibutyl phthalate (DBP) in nail polish and found that 19 of the 21 nail polishes tested positive for dibutyl phthalate. The median level of exposure to phthalates came to 22.917 g/kg bw/d, which represents a level far lower than the amount set by the International Programme on Chemical Safety of 66 g/kg bw/d. DBP continues to be used in food packaging, medical devices, blood bags, breast pumps, and toys.

In 2005 G. Latini reviewed the current monitoring techniques used to determine the exposure to phthalate in humans. A review of the toxicology of phthalates indicated that a limited number of studies exist on the sources and conduits of human exposure to phthalates. Since few studies report levels of phthalates, regular biological monitoring of phthalates in body fluids and tissues is needed to assist physicians in completing health risk evaluation for exposure in the general population and in directing government regulations to set the upper limit of acceptable levels in the environment, cosmetic products, and medications.

In 2009 J. L. Lyche and colleagues described the widespread use of phthalates in consumer products like nail polish and the constant contact of these chemicals with humans. Animal studies in rodents demonstrated an endocrine-disrupting effect that leads to developmental and reproductive toxicity. Furthermore, the research on exposure data shows inconsistent results suggesting that secondary metabolites may be more accurate indicators of internal contact with phthalates. The review by Lyche and colleagues shows insufficient human toxicity data to appraise developmental and reproductive effects in humans. The fact that phthalates occur in mixtures with other compounds represents a secondary problem to study. Therefore, future research must be initiated to address these issues.

**Toluene**

The National Highway Traffic Safety Administration reports that toluene acts as a solvent in various products like nail polish, nail hardeners, and nail polish removers. The toluene in the polish provides a smooth finish on the nail along with uniform color. The CIR Expert Panel rated toluene as safe for cosmetic use in 2005 if used in concentrations below 50 percent. It is best not to breathe in the fumes. Toluene can be found in ink, paint, glue, and detergents.

Exposure to toluene can occur by inhalation of vapor or by skin contact. Exposure to toluene in high doses produces neurological effects of drowsiness, confusion, fatigue, memory loss, delusions, and hallucinations; physiological symptoms of irritation to the nose, throat, and eyes, headache, nystagmus, slurred speech, impaired color vision, vigilance, nausea, vomiting, respiratory depressions, convulsions, severe organ damage, coma, and death can occur.

**Gel Manicures**

Gel nail polishes used in manicures provide a manicure enduring two weeks or longer without cutting the nail. Compared to standard nail polishes, gel polishes consist of much stronger content. A. F. Chen and colleagues (2012) describe the use of the ultraviolet lamps employed to seal the polish and
also the use of acetone to remove gel manicures. This small study reported problems with nail thinning, fragility, flaking, and breaking as the negative issues related to the gel polish. The researchers could not ascertain whether the nail problems related to the polish or to the use of the acetone to remove the gel manicures.

**Conclusion**

Modern nail polish arose in the early 1900s and continues to be part of the beauty routine to this day. The CIR Expert Panel started reviewing cosmetics in 1976 and ascertained the main cancer concerns with formaldehyde, dibutyl phthalate, and toluene. The FDA, the Consumer Product Safety Commission, and the Federal Trade Commission participate in the regulation of nail polish. These organizations concur with the CIR. The few studies to date show individuals have contact with very low concentrations of the three chemical substances. Because of the lack of studies, scientists raise the concern that little research supports these claims and therefore ongoing monitoring of the levels of these chemicals in humans is needed.

**Further Readings**

**Pollution, Air**

Air pollution is one of the most serious challenges the world faces. Air pollution refers to contamination of the outdoor or indoor environment by any chemical, physical, or biological agent. Air pollution therefore can be classified as outdoor and indoor pollution. The air quality around and within buildings and structures is known as indoor air quality. Some of the common indoor air pollutants include radon, molds, carbon monoxide, carbon dioxide, asbestos fibers, and the burning of biomass. An air pollutant is a substance in the air that can have adverse effects on humans and the ecosystem. This article explains air pollution—its types, causes, and health impacts, and especially its linkages to cancer.

**Sources of Air Pollution**

The sources of air pollution can be natural or man-made. The air pollutants can be solid particles, liquid droplets, or gases. Air pollutants are usually classified as suspended particulate matter (PM; e.g., dusts, fumes, mists, and smokes) or gaseous pollutants. Particulate matter is particles in the air that are a mixture of solids and liquid droplets of varying size. Some particles are visible; others are invisible. Very small particles with a diameter of less than 2.5 micrometers are called fine particles, and these are suspended in air. They are produced mainly by burning of fuels and wood. The suspended particulate matter includes diesel exhaust particles; coal fly ash; wood smoke; mineral dusts, such as coal, asbestos, limestone, and cement; metal dusts and fumes; acid mists (e.g., sulfuric acid); and pesticide mists. Dust particles with size from 2.5 to 10 micrometers in diameter are called coarse particles.

Natural processes that can release substantial amounts of pollutants into the air include volcanic eruptions, biological decay, and forest fires. Carbon dioxide, sulfur dioxide, and nitrogen oxide are the main pollutants released by these processes into the atmosphere.
Human or anthropogenic sources of air pollution include the combustion of fossil fuels such as petroleum or coal by motor vehicles and railways, industry, and thermal power stations; the release of chemical by-products from industrial and agricultural processes; and the incineration of waste. Human causes of air pollution also include vehicles, domestic heating and cooking, and aircraft pollution. Motor vehicles emit nitrous and nitric oxides, carbon monoxide, organic compounds, and lead. Toxic fumes come from factories, machines, and automobiles. The combustion of wood or agricultural waste is another major source of air pollutants. Globally, about 3 billion people cook and heat their homes using open fires and burning biomass (wood, animal dung, and crop waste) and coal.

Gaseous air pollutants include sulfur compounds such as sulfur dioxide, carbon monoxide, nitrogen compounds such as nitrous and nitric oxide and ammonia, organic compounds such as hydrocarbons, and halogen derivatives. Carbon dioxide is one of the major air pollutants, and it is mainly emitted from thermal power plants, vehicles, and burning of fossil fuels. Another major air pollutant is methane, which comes from raising livestock, decomposition of wastes, and chlorofluorocarbons (CFCs).

Dangerous indoor pollutants that can usually be found in the home include cleaning solvent, pollen, pet dander, glue from composite wood furniture, mold, bacteria, fungi, viruses, cosmetics, and plastics. Studies have shown that pets with fur or feathers (e.g., cats, dogs, birds) can be contributors to indoor air pollution. Air pollutants can also be classified as primary or secondary. Primary pollutants are usually produced from a process, such as ash from a volcanic eruption or carbon monoxide gas from motor vehicle exhaust. Secondary pollutants are not emitted directly; rather, they are formed in the air when primary pollutants react or interact.

**Impact of Air Pollution on Health**

Air pollution has serious effects on human health. It is one of the biggest global killers. Pollution saturates the air with toxic particles and other irritants, which creates poor air quality. Air pollution has both long-term and short-term health effects. Short-term health effects include eye, nose, and throat irritation; headache; and allergic reactions. Some long-term health effects include damage to the brain, kidney, and liver; heart and respiratory diseases; and cancer. Air pollution can cause diseases such as asthma, bronchitis, pneumonia, emphysema, chronic obstructive pulmonary disease (COPD), and cardiovascular diseases. Particulate matter may cause chest pain, palpitations, and fatigue. High levels of toxicity in the pollutants can impair the body’s defense mechanism, rendering it incapable of fighting off infection.

Indoor air pollution is often much worse than outdoor air pollution. About 4.3 million people die every year from exposure to household air pollution. Nearly half of them die prematurely from illness attributable to household solid fuel use. More than 1 million people die every year from chronic obstructive respiratory disease (COPD) that develops due to exposure to indoor air pollution. Exposure is particularly high among women and young children who spend most of their time indoors. The U.S. Environmental Protection Agency (EPA) has revealed that indoor air is one of the top five public health threats in the United States. This is alarming when one considers that most people spend 90 percent of their time indoors and approximately 65 percent of their time at home.
Fine and coarse particles in the air are more health hazardous, causing serious health problems. In poorly ventilated dwellings, indoor smoke can be 100 times higher than acceptable levels for small particles. Nearly half of deaths among children under 5 years of age from acute lower respiratory infections (ALRI) are due to particulate matter inhaled from indoor air pollution from household solid fuels.

**Air Pollution and Cancer**

Studies have shown there is a link between air pollution and increased incidence of cancer. Lung, skin, breast, nasopharyngeal, and laryngeal cancers are caused by air pollution. The International Agency for Research on Cancer (IARC) has classified outdoor air pollution as a cancer-causing agent (carcinogen). The main carcinogenic pollutants include diesel engine exhaust, solvents, metals, and dust. Another major component of outdoor air pollution is particulate matter—as a carcinogen on its own that increases the risk of lung cancer. Studies show people who live in places with high levels of air pollutants have a 20 percent higher risk of death from lung cancer than people who live in less polluted areas. Exposure to PM 2.5 and sulfur dioxides is associated with an increased risk of mortality from lung cancer. Studies show people who lived in areas with high nitrogen oxide concentrations have an increased risk of lung cancer. The EPA in its report estimated the concentrations of air pollutants across the United States of America. The report covered over 181 air pollutants, 80 of which are thought to contribute to cancer formation in humans. For example, benzene is a toxin released from car exhaust that may lead to cancer. According to the EPA report, about 30 percent of the cancers caused by air pollution are due to car exhaust and another 25 percent are due to local industrial activity.

Several types of air pollutants may increase the risk of cancer. Apart from lung cancer, air pollution also increases the risk of breast and bladder cancer. Air pollution is also linked to other forms of cancer, including cervical and brain cancer.

Approximately 17 percent of annual premature lung cancer deaths in adults are attributable to exposure to carcinogens from household air pollution caused by cooking with solid fuels like wood, charcoal, or coal. Women exposed to indoor smoke thus have double the risk of lung cancer compared to those not exposed.

Chlorofluorocarbons (CFCs) released from air conditioners, refrigerators, and aerosol sprays rise to the stratosphere, damage the ozone layer, and create ozone holes. As a result, harmful ultraviolet rays reach the earth’s surface and cause skin cancer.

**Conclusion**

Air pollution is preventable. Indoor air quality can be improved by proper ventilation, filtration, and control of sources of pollutants. There is a need to install a high-quality air filter or air purifier system to trap the allergens and pollutants indoors. Toxic household cleaning supplies, paint, chemicals, lawn and garden supplies, and other products with noxious fumes are to be used at home with utmost care.

Pollution, Water

Water pollution is one of the greatest threats to humankind. Water pollution refers to contamination of water bodies (e.g., rivers, streams, lakes, oceans, and groundwater) by pollutants. Pollutants are the particles, chemicals, or substances that make freshwater contaminated. Water pollution occurs when pollutants are discharged into water bodies without adequate treatment. Water pollution is a reflection of poor quality of environment. This entry explains water pollution—its types, sources, and health impacts, and especially its links to cancer.

Sources of Water Pollution

The sources of water pollution can be natural or man-made. With increasing world population and growing demand for water, sources of water are stressed and contaminated. Pollutants are very often added to water bodies by anthropogenic activities. Water pollution can be of two broad types: surface water pollution and groundwater pollution. Sources of surface water pollution are generally grouped into two broad categories based on their origin: point and non-point sources. Point source usually refers to pollutants that enter a waterway from a single and identifiable source, such as a ditch or a pipe. These sources of water pollution include discharges from an industry, a city storm drain, or a sewage treatment plant. On the other hand, non-point source refers to contamination that does not originate from a single source but often is the cumulative effect of contaminants accumulated from a large area.

An example is nitrogen compounds leaching into water sources from fertilized agricultural lands. Surface water pollution generally occurs by the discharge of wastewater from commercial and industrial sources, discharges from untreated municipal and domestic sewage, and contaminants flowing into water bodies from urban and agricultural runoff. Water bodies are often contaminated by seepage, leaks, spills, and accidents. Water pollution can be broadly classified as chemical, metallic, or biological pollution, based on its composition. Water gets polluted with toxic chemicals such as pesticides, herbicides, and vehicle fluids. Industrial chemical wastes, especially plastics, are major pollutants that often do not break down easily and remain a long time in the water bodies. It is estimated that about 14 billion pounds of garbage, mostly plastic, are dumped into the ocean every year.

Additives to water are another form of pollutant. All additives together, known as flocculants, are sources of water pollution. Chlorine and fluoride are the most common additives in drinking water. Chlorine is recognized as the most cost-effective method of purification of water supplies. However, chlorination is extremely volatile and combines with organic, carbon-based pollutants to form dangerous chemicals called tri-halo-methanes (THMs). Radioactive wastes are also added to water bodies as a result of inadequate disposal mechanisms.

Hydrocarbons also cause water pollution. These are the main ingredients of the chemical industry and are added to water bodies as industrial waste. They enter water supplies through agricultural runoff, sewage, and chemical dumps. Metals such as arsenic, aluminum, cadmium, lead, and mercury are the main water-polluting substances that originate from industries, electrical generation, mining, and vehicles. Arsenic contamination results from leaching from waste dumps, mines, or pesticides. Industrial pollution is one of the major sources of arsenic. Nitrates are another water pollutant commonly associated with the increased use of commercial fertilizers, animal waste, and human waste.

Biological pollution includes pathogens such as bacteria, viruses, protozoa, and worms that enter sewage systems and untreated waste. Parasites such as, for example, cryptosporidium are a form of biological water pollutant. Water bodies are polluted by natural phenomena as well. Events such as volcanic eruptions, algal blooms, storms, and earthquakes cause changes in water quality. Pollution of freshwater can also be caused by eutrophication, which is a process of excessive growth of nutrients in water bodies that promotes excessive plant or algal growth. The enrichment is often increased by human activities such as agriculture. It occurs mainly due to presence of nitrates and phosphates added by fertilizers through agricultural runoff and by untreated sewage effluents through urban runoff. The excessive plant growths cause low oxygen levels in freshwater and make it difficult for species to live; many aquatic organisms, especially fish, die when the dissolved oxygen level falls below 5 ppm (parts per million).

Groundwater is the source of drinking water for the vast majority of the global population.
Groundwater water pollution occurs when water below the earth’s surface becomes contaminated by seepage and by the presence of arsenic. Landfills are a major source of groundwater contamination. Buried chemical waste can seep into the groundwater. Groundwater pollution is much more difficult to abate than surface pollution because groundwater can move long distances through unseen aquifers.

Impact of Water Pollution on Health
Water pollution affects drinking water, rivers, lakes, oceans, and groundwater. It has adverse effects on human health. Water pollution is, in fact, one of the biggest global killers of human beings and animals. Over 1 billion people worldwide lack access to safe drinking water. Nearly 14,000 people die each day due to drinking dirty water. In addition, over 1 million seabirds and 100,000 sea mammals are killed by water pollution every year.

Arsenic is one of the water pollutants most hazardous to health. Arsenic in drinking water harms the central and peripheral nervous systems as well as the heart and blood vessels, and causes serious skin problems. Another contaminant is Escherichia coli (E. coli), which is a common, nonpathogenic bacterium. Its presence in water is an indication of fecal contamination. E. coli infection from water can cause dysentery. Contaminated water mainly causes diseases such as cholera, typhoid, diarrhea, and hookworm. Gasoline is one of the elements causing water contamination and is hazardous to health. It is estimated that one gallon of gasoline can contaminate 5 million gallons of drinking water. Water-soluble radioactive compounds cause cancer, birth defects, and genetic damage. Parasite pollutants can cause acute and chronic cases of diarrhea, cramps, fever, and vomiting.

Water Pollution and Cancer
Contaminants found in polluted water are known to have an effect on the DNA of reproducing cells. Water pollution adds toxins to the human body that may overwhelm the immune system. The drinking water contaminants that have carcinogenic risks include chlorination, arsenic, asbestos, fluoride, hazardous wastes, pesticides, tetrachloroethane, and nitrates. Trihalomethanes (THMs) in water have mutagenic and carcinogenic effects. These toxins are cause for concern as they are causing cancer. THMs increase incidence of rectal, bladder, and pancreatic cancer. Studies suggest fluoridated water presents an increased risk of bone cancer. Arsenic in drinking water causes bladder, lung, and skin cancer, and may cause kidney and liver cancer as well. Studies show that exposure to arsenic in groundwater causes cancer, and indicate that 1 in 10 people who drink water containing 500 μg of arsenic per liter may die from cancers. Fertilizers, insecticides, and herbicides also contain carcinogens that can filter down into water supplies, causing cancer. Atrazine, an herbicide used on crops, contaminates drinking water and is suspected of causing breast cancer. Studies have found a connection between polluted drinking water and ovarian cancer. Nitrates are contaminants that enter the water through the soil and are a suspected carcinogen. Studies also show that talc, a chemical often used in baby powder, feminine products, and cosmetics, has carcinogenic effects. Talcum powder has been suspected to increase the risk of ovarian cancer by 50 percent.

Conclusion
Minimizing the amount of contamination in drinking water is a topmost priority. People need to be aware of the quality of the water they drink and how to protect themselves. Various methods have been used to improve water quality. For instance, Floating Litter Traps and Boom Systems have been designed to collect floating litter, vegetation, and other debris in waterways. One of the main keys to preventing cancer is to limit the amount of harmful toxins that enter into the body. Drinking pure water helps the immune system to flush out the toxins and mutated cancer cells. Reverse osmosis filtering is one of the few effective ways to remove potential cancer-causing chemicals from water. A good water filtration system for clean water can prevent illnesses and diseases. A quality water purification system can remove up to 99 percent of harmful contaminants that cause illness and cancer.

Portugal

The Portuguese Republic is a coastal nation of the European continent bordering with Spain. During the Middle Ages, Portugal was a Moorish Muslim caliphate, until their defeat during the Reconquista. With the Renaissance, Portugal became one of the most prosperous colonial empires of the age, with dominions spanning the world, from Africa to North America and South America, giving birth to some of the most audacious explorers of all time, men like Vasco de Gama and Ferdinand Magellan. Today, Portuguese is still the sixth most spoken native language in the world, and Portuguese culture has influenced many populations, especially in South America. In 1910, the Republican Revolution deposed King Manuel II, founding a short-lived republic that was later overthrown by a right-wing dictatorship that eventually allowed António de Oliveira Salazar to establish his power in 1933.

During the second half of the 20th century, Portugal lost much, if not all, of its colonial and transcontinental power, as many overseas provinces declared their independence one after the other. In 1974 a bloodless leftist military coup called the Carnation Revolution restored democracy, and during the 1980s, Portugal followed a modernization process by rewriting its constitution and joining the European Union (EU). Today Portugal is an advanced developed country with a very broad-minded, peaceful, and globalized culture, although its economy has suffered since the beginning of the 21st century.

The Portuguese National Health Service (NHS) is a decentralized system funded through general taxation to provide every citizen with free universal health care. In addition to this, a series of special social health insurance schemes for certain professions (health subsystems) and voluntary private health insurance act to provide additional services. To improve population awareness and knowledge of cancer, many sensitization campaigns and projects are promoted every year by national and international associations and organizations, such as the European Colorectal Cancer Awareness Month sponsored by EuropaColon, or the annual breast cancer charity fund-raising sponsored by the Liga Portuguesa Contra o Cancro (NRS). Following World Health Organization (WHO) global guidelines on cervical cancer prevention in women, in 2007 Portugal launched a human papillomavirus (HPV) vaccination program by including it in the National Immunization Program (NIP), and in 2010 it was the only European country together with the United Kingdom to reach a coverage rate of more than 80 percent of total population.

Although a national cancer registry system comprising three regional registries (northern, southern, and central regions) was established in 1960, it is only since 1988 that cancer registration has been mandatory in Portugal. Cancer is the second leading cause of death in Portugal, following cardiovascular disease. The cancer forms that showed the highest incidence in men were prostate cancer (95.1), colorectal cancer (61.4), and lung cancer (49.1); for women, the cancers with the highest incidence were breast cancer (85.6), colorectal cancer (33.8), and cervical cancer (18). Cancers showing the highest estimated mortality in 2012 for both sexes in Portugal were lung cancer (22.8), colorectal cancer (21.4), and prostate cancer (19). Common risk factors for cancer in Portugal are those often seen in developed countries, such as sedentary lifestyle, obesity and bad dietary habits, tobacco smoking, alcohol consumption, and environmental pollution in highly urbanized settings. Specific genetic alterations in the human epidermal growth factor Receptor 2 (HER2) in local Portuguese populations seem to double the risk of breast cancer in women who
Poverty is defined as not having adequate resources (wealth) to purchase basic human necessities such as food, shelter, and clothing. But it is much more
than simply not having enough money. People who live in poverty often do not have access to societal services such as education and health care. Poverty is measured differently around the world. In the current economic climate, many individuals live at or just above the official “poverty level” and even people with middle-class incomes are struggling to meet basic needs. Such individuals may be only a paycheck away from poverty, and the loss of employment can quickly affect their quality of life. In such circumstances, people must decide which of their essential needs are primary, as all are not affordable.

Others, living above the poverty level, are also affected by living in stricken neighborhoods. Such communities are defined as having more than 20 percent of households living below the poverty level. In such cases, many of the environmental effects of poverty may affect all who live in these neighborhoods: unsafe housing, a high density of fast-food establishments and bars, and the lack of grocery stores with healthy (and fresh) food options.

Poverty affects health in numerous ways. Affected individuals may engage in unhealthy habits, reside in environments that pose health risks, lack access to recommended and preventive health care screenings, be unable to identify potential illness signals, and are deprived of affordable and accessible health care. And while poverty does not cause cancer, it is linked in myriad ways to behaviors, environmental factors, and social structures that may increase a person's cancer risks or the options available to them for prevention, detection, and/or treatment.

Poverty as a Risk Factor for Cancer
In 1991, Samuel Broder, then director of the U.S. National Cancer Institute (NCI), declared “poverty is a carcinogen.” It is not the poverty itself that causes cancer but rather the environment or behaviors engaged in by individuals living in poverty that increase their chances of developing cancers. The World Health Organization (WHO) suggests maintaining a healthful diet, avoiding tobacco, leading an active lifestyle, and limiting alcohol intake can prevent a significant percentage of cancers. Individuals living in poverty are less likely to engage in these preventive behaviors.

In 2011, the American Cancer Society (ACS) highlighted the role of poverty in cancer. Using education as an indicator of socioeconomic class, researchers found people with lower levels of education are more likely to have higher rates of cancer. The greatest difference was found in lung cancer, which had a morbidity rate four to five times higher in people with less education compared to the most educated. The ACS (2011) found persons with a lower socioeconomic status are more likely to engage in behaviors that increase cancer risks, such as tobacco use, physical inactivity, and poor diet. Tobacco and alcohol companies create products specifically marketed to poverty populations, often targeting the youngest consumers.

Youth, who may see limited opportunities, are often attracted to the use of these products and also illicit drugs as ways of coping or improving their social status. Older individuals, who may be unemployed or work at low-paying and/or low-status jobs, use substances as a way of dealing with stress. In addition, many with mental health issues who cannot afford care or medication or may be culturally discouraged from addressing or telling of their symptoms may be using alcohol, tobacco, and other substances to self-medicate. Access to health insurance and care is limited among the poor. While many may qualify for governmental assistance, the care may be hard to access, require long waiting periods, and be demeaning or substandard. Those without health insurance are less likely to utilize health care and are more likely to present for treatment when their illness is advanced and their prognosis poor.

While there may be differing cancer rates among various racial and ethnic groups, this is likely to be associated with cultural, behavioral, and economic dynamics rather than membership in a racial or ethnic group. Race/ethnicity is less of a factor than poverty when looking at cancer prevalence. The ACS (2011) indicates that “among African Americans, eliminating socioeconomic disparities has the potential to avert twice as many cancer deaths as eliminating racial disparities.”

Alcohol Use
Alcohol consumption increases the risk of cancer of the mouth, throat, esophagus, liver, and colon in men. In women, it also increases the incidence of breast cancer. Consuming more alcohol regularly over time increases one's risk of developing an alcohol-associated cancer. Based on NCI data from 2009, an estimated 3.5 percent of all cancer deaths in the United States were alcohol related.
For a variety of social reasons, people living in poorer neighborhoods are more likely to use alcohol, an established risk factor for cancer. Unemployed individuals are similarly inclined, but it is unknown which is the precipitating factor: using alcohol to deal with the stress of unemployment or alcohol use as a factor in unemployment. Unemployed individuals are also at risk of living in poverty. Stress, a factor in both unemployment and poverty, is also associated with increased alcohol use.

E. M. Berke and colleagues (2010) looked at the geographic density of retail alcohol locations within U.S. census tracts. Poorer neighborhoods were more likely to have more alcohol retailers. Alcohol access within poor communities may create social influences in which drinking behavior is observed and seen as a normal aspect of everyday life. Easy access and familiarity may increase alcohol use and, ultimately, cancer risks.

**Tobacco Use**

Tobacco continues to be the single greatest cause of preventable cancer mortality worldwide. The use of tobacco products increases risks for a variety of cancers (lung, stomach, neck, throat, and bladder). People who live in poverty are more likely to engage in cigarette smoking despite the cost and health promotion campaigns. According to the Centers for Disease Control and Prevention (CDC), in 2014, 18.1 percent of all U.S. adults regularly smoked cigarettes. Many more individuals who live in poverty are regular smokers (27.9 percent) and are at increased risk for cancer. In addition, the combination of tobacco and alcohol use among those living in poverty multiplies cancer risk.

**Diet and Exercise**

The ACS (2011) suggested approximately one-third of cancer deaths are preventable and related to obesity, physical inactivity, and poor nutrition. These factors are much more prevalent among poverty populations and are interrelated. Obesity is associated with increased risks of cancers of the esophagus, breast (postmenopausal), endometrium (the lining of the uterus), colon and rectum, kidney, pancreas, thyroid, and gallbladder.

Children living in poverty are more likely to be obese than children in higher socioeconomic classes. In addition, such children are at higher risk for obesity in adolescence. Numerous studies have documented the relationship between poverty and obesity. Multiple factors associated with poverty, such as the cost of fresh fruits and vegetables, access to grocery stores carrying healthy foods, and the prevalence of fast-food retailers, create a matrix of social and behavioral factors increasing opportunities for inadequate diets among the poor. “Value sizing” of convenience foods offers high caloric meals at lower prices attractive to individuals with fewer economic resources. The poor may be unaware of other dietary recommendations for the reduction of cancer risk, such as avoiding red and processed meats and grilled, broiled, and fried meats, which are major components of fast-food diets. Maintaining a healthy diet requires knowledge, effort, access, and economic resources. Diet is related to the use of alcohol and tobacco, and all three, together, increase the potential for cancer and other health complications among the poor.

**Health Care and Access Disparities**

Health disparities, according to the CDC, “are differences in the incidence, prevalence, mortality, and survival of a disease and the related adverse health conditions that exist among specific population groups.” According to the ACS, poverty is the overriding factor in creating obstacles to prevention, early detection, and treatment of cancer. In practice, the elimination of disparities should result in a reduction in cancer incidences and deaths and an increase in cancer survival among socioeconomically disadvantaged people to levels comparable to those in the general population. Individuals living in poverty are more likely to be unable to access health care or prescriptions due to the cost of such services. In 2012, among all American adults, 9.6 percent delayed or did not receive medical care because of cost, and 6.8 percent were unable to fill prescriptions. Those living below the poverty level were more likely to delay or not receive medical treatment (22.4 percent) or were unable to fill prescriptions (19.4 percent). The lack of access to health care has serious consequences for cancer detection, prevention, and treatment. Higher screening rates for three types of cancer (breast, cervical, and colorectal) are positively associated with education and the availability and use of health care. Those who are most poor often do not participate in early cancer screenings and present for treatment when they are much sicker and have less successful treatment outcomes.
Conclusion
For a variety of social, behavioral, and environmental reasons, people living in poverty are at greater risk for cancer and other serious medical problems. The Affordable Care Act expands access to many individuals living near or at the poverty level and offers opportunities for prevention, education, screening, and care. Public health efforts need to increase education to reduce risks, while creating opportunities for early detection and access to health care.

Prostate Cancer

Prostate cancer is the most common non-melanoma malignancy among men in the United States and is the second most common cause of cancer-related death among men. In 2013, 238,590 new cases and 29,720 deaths related to prostate cancer were estimated. Currently, one in six men will develop prostate cancer during their lifetime, which is higher than the ratio observed for breast cancer in women. Between 1969 and 1990, the incidence of prostate cancer increased steadily in the United States at an average annual rate of approximately 3 percent. The incidence rate was increased to 12.7 percent in 1990–1993, and decreased to 8.4 percent in 1993–1996. The highest incidence rate was observed in 1993, at 140.4 cases per 100,000 men.
Annual age-adjusted mortality rates from prostate cancer in the United States for white males were increased 0.7 percent from 1969 to 1987, 3 percent from 1987 to 1991, then decreased 1.2 percent from 1991 to 1994, and 4.5 percent from 1994 to 1999.

Changes of incidence rates in the 1990s reflect the increase in early detection of prostate cancer due to the introduction of the prostate-specific antigen (PSA) blood test. PSA is a glycoprotein generated exclusively by prostate tissue and present at low levels in blood from healthy men. The PSA's tissue specificity enables detection at an early stage of prostate cancer by a simple blood test. However, other abnormal conditions, such as benign prostatic hyperplasia (BPH) or prostatitis may also increase the PSA level. Therefore, this notoriously low specificity of the PSA test for prostate cancer has been a main subject of debate, although early screening and detection has been used historically as a strategy for prostate cancer prevention.

A meta-analysis of the five independent randomized studies suggested no difference in prostate cancer–specific mortality between groups with and without the PSA screening. Two large trials, the European Randomized Study of Screening for Prostate Cancer (ERSPC) and the U.S. Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial provided inconsistent results. The European study showed a 20 percent relative reduction in the risk of death from prostate cancer (RR 0.84, 95 percent CI 0.73–0.95) by PSA screening, but not the American study (RR 1.15, 95 percent CI 0.86–1.54). Therefore, these results suggested a high risk of overdiagnosis and/or overtreatment of prostate cancer due to false-positive results from PSA-based screening. Overdiagnosis and overtreatment often cause infection, pain, erectile dysfunction, incontinence, and low quality of life. Currently, there is no convincing data in support of or against PSA screening for prostate cancer in healthy men.

The burden of prostate cancer in society is substantial and has increased since the PSA testing was introduced. In the United States, the total estimated expenditure on prostate cancer was approximately $10 billion in 2006. The mean annual costs per patient were $10,612 in the initial phase after diagnosis, $2,134 for continuing care, and $33,691 in the last year of life. Although prostate cancer–specific mortality has decreased, costs are likely to rise due to increased diagnosis at an earlier stage and increased survival. The economic burden of prostate cancer will continue to rise because of the aging of the current U.S. population.

**Risk Factors**

Unlike lung and cervical cancers, there is no established cause for prostate cancer. However, several risk factors have been established by numerous epidemiological studies.

**Age.** Age is a major risk factor for prostate cancer. The probability of developing prostate cancer sharply increases in the sixth decade of life (7 percent) and further increases after age 70 (15 percent). This contrasts significantly with the probability of 0.01 percent among men less than 40 years old and 2.7 percent among men 40 to 59 years old. The aging of the current population means that the disease will become an even greater public health problem in the future.

**Family History.** Men with a family history of prostate cancer have two to three times higher risk and typically are diagnosed earlier than men without a family history of the disease. Further, men with more than one affected relative have a 35 to 45 percent risk of developing prostate cancer. Family history may also be associated with a risk for aggressive prostate cancer. Prostate cancer patients with family history may have a worse outcome at five years after treatments by radiotherapy or radical prostatectomy compared with patients without family history (RR, 1.8; 95 percent CI, 1.3–2.4).

**Genetic Factors.** Genetic factors are responsible in 5 to 10 percent of prostate cancer cases. Numerous studies have examined potential genetic factors associated with prostate cancer risk. However, most studies reported inconsistent results. Recent genome-wide association (GWA) studies identified several genetic loci, including 8q24 and 17q12. A more recent large consortium study identified 77 genetic biomarkers of associated risk for prostate cancer using blood DNA samples from 25,074 prostate cancer cases and 24,272 controls. Several studies reported that mutations at BRAC and CHEK2 also increased risk for prostate cancer.

**Race/Ethnicity.** Significant variations in prostate cancer incidence and mortality are observed at the
international level. These striking variations may be in part due to genetic factors that vary in different populations of the world. The highest risk of prostate cancer is found in the United States, especially in African American men, while the lowest risk is found in Asian countries. Migration studies reported that the incidence rate for prostate cancer leaned toward those of the host country. For example, Asian men living in the United States have a lower risk of prostate cancer than Americans, but a higher risk than Asian men living in Asia. The results of these studies indicated that environmental factors may play a role in risk changes in the host country.

Conclusion
The burden of prostate cancer in the United States is significant and will increase due to the aging population. SEER data indicate that prostate cancer will be diagnosed in one out of six men and be fatal in one out of 36. A diagnosis of prostate cancer carries a significant burden, and a reduction in the risk of prostate cancer could be very valuable to society. However, value of screening for prostate cancer is debatable. A clear understanding of risk factors, including the endogenous (family history, hormones, race, and aging) and exogenous (diet, occupation, and environmental agents) and their interplay, will help to design strategies to prevent carcinogenesis and the progression of prostate cancer. In most cancer cases, early detection usually leads to better outcomes. However, prostate cancer may not be in this category. The direction of future studies may be toward identification of biomarkers for aggressive type, progression, and response to treatments.

Proton Therapy
Proton therapy is a type of external beam radiation therapy that uses a proton beam to destroy cancer cells by irradiation. The physics of penetration of energetic protons through the tissue allows more precise delivery of the radiation dosage to the treatment area than with other types of external beam radiotherapy. Proton beam is characterized by higher relative biological effectiveness (RBE) when compared with conventional megavoltage (MV) photon radiation therapy. Recent progress in the proton beam technology makes this radiation therapy modality more affordable. A number of new proton therapy centers will open in the near future in the United States and around the world.

History of Proton Therapy
The use of the energetic protons in cancer therapy was proposed by Robert Wilson in 1946. The first clinical use of proton beam was in 1954 at the Lawrence Berkeley Laboratory (LBL) in California. European proton treatment history started in 1957 with the program in Uppsala, Sweden. In the 1960s, 1970s, and 1980s, proton programs were opened in Russia (St. Petersburg and Moscow), Japan (Chiba and Tsukuba), Switzerland (Villigen), and England (Clatterbridge). The first hospital-based proton center was established at the Loma Linda University Medical Center (LLUMC), California, in 1990. Today there are 43 operating proton centers worldwide; of this number, 14 are in the United States.
Particle Therapy Co-Operative Group statistics state that 93,452 patients were treated with protons worldwide (March 2013; http://www.ptcog.ch). Within the next five years, 10 to 20 new centers with proton beam will be opened in the United States and 10 to 15 will be opened around the world.

**Physics of Proton Therapy**

The potential of the proton beam for cancer treatment is defined by the physics of the proton interaction with the tissue. The tissue consists of relatively low atomic number chemical elements. The proton beam has weak scattering in the tissue. The ionization density of protons is very high at the end of their range. These factors lead to forming the Bragg peak at the end of the proton beam that entered the tissue. The protons stop close to one another and deposit a large amount of their energy within a 1 centimeter (cm) area. The dose at the shallow depths is lower than for the MV photons. The combination of the proton beams of different energies creates spread-out Bragg peak (SOBP) to cover the tumor. Protons deliver the dose only to the depths of the Bragg peak. These properties of the protons reduce the undesired dose delivered to healthy tissue in cancer treatment with proton beam therapy. The mechanisms of proton interaction with the tissue depend on the energy of the protons. The primary mechanisms are the ionization energy loss and multiple scattering. Energetic protons will produce secondary neutrons in the tissue and a small amount of induced radioactivity in nuclear reactions. The fraction energy loss in nuclear interactions is considerably less than for ionization energy loss by protons.

The cross sections of the nuclear interactions are nonlinear with energy, and this channel of energy deposition plays a different role along the proton penetration to the depth of its stop. The proton beam energies used in clinical applications are from 60 to 230 MeV (million electron volts) that cover all possible proton ranges to deliver the dose to the tumor. The proton therapy operates with the term of the proton range. The proton beam range is defined from proton fluence measurements as the depth of material at which half the protons that undergo only interactions have stopped. The value of the range well corresponds to the 80 percent of the dose at the distal edge of the Bragg peak. Therefore the range can be determined from the dose measurements.

**Technology**

The proton therapy facility consists of the major components, which are the source of the proton beam, systems, the beam transport system, treatment rooms, and treatment head. The source of the proton beam is the accelerator producing the protons between 60 and 250 MeV. Statistical analysis of the typical treatment depths for MV shows that 200 MeV proton facilities could cover 95 percent of the possible depths of the treatment, while 230 MeV will cover entirely all 100 percent. The operating facilities use cyclotrons or synchrotrons or SynchroCyclotrons. New solutions for the proton facilities are under testing currently. There are the linear accelerators of the protons, laser-plasma accelerators on the base of high-intensity lasers and dielectric wall accelerators. The typical beam today has from a 6 millimeter (mm) to 1 cm size with about 2 percent peak energy variation.

Until recently, the proton beam facility utilized a passive scattering technique. A proton beam passes through a set of scattering foils and propellers or ridge filters to create a SOBP. Although this technology is still in use, the main focus of the design for
facilities today is to use active electromagnetically scanning proton beams. The scanning beam facility utilizes the range modulator approach wherein thin plates made of the low atomic number materials are used to reduce proton range or accelerator capability of proton beam energy variation. Another possibility is an energy variable source of protons. There are two main approaches in scanning technology: one is uniform scanning and the second is spot scanning. The dose field shaping is performed with patient-specific devices called apertures, and depth pattern is achieved with compensators. Typically, the aperture material is brass. There is a discussion in the literature about the usage of the multi-leaf collimator (MLC) to replace the aperture. The MLC could advance the facility and increase the patient throughput.

However, the solution to use the same MLC technology as for MV photon therapy where tungsten is the material of choice will create unnecessary secondary neutrons. The alternative solution to select a material of low atomic numbers for the proton beam MLC has been proposed. The narrow, pencil beam could be deflected in the magnetic field. The active scanning technology has the possibility to reduce the secondary neutrons. Moreover, the narrow proton beams, once achieved, will have potential for the intensity modulated proton therapy. The tumor could be irradiated point by point. However, the physical limit imposed on the spot size that could be achieved in the tissue is approximately 5 percent of the initial proton range. There is also an undesired effect on the increase of the entrance to Bragg peak dose ratio for narrow beams. These factors implement the necessity of modifications for treatment planning and treatment strategies.

Two treatment room types are utilized now; one is a fixed beam room with a possible robotic arm treatment table and the other one is a gantry room. Although the dosimetrical properties of proton beams offer an ability to confine dose to those regions targeted, these properties can magnify the effects of any errors that may occur in the process of delivery. There are ongoing research and development studies to advance the control over the planned delivery of the proton beam. The primary focus is to develop the method of the dose and proton range verification. Three primary methods are considered: the positron-emitting tomography post treatment, prompt gamma method, and ultrasound tomography utilizing the thermo-acoustic effect from a proton beam. Another focus is image-guided proton therapy, control of the delivery depending on organ motion, beam gaiting, and intensity modulated proton therapy.

**Radiobiology of Proton Beam Therapy**

Protons have different relative biologic effectiveness (RBE) from photons due to higher ionization density. The established correction factor for dose modification is 1.1 relative to 60Co gamma radiation. Multiple studies have shown that the RBE increases close to the end of the range of the protons. Recent data has shown that RBE will be higher than 1.1 at the distal edge of Bragg peak. The SOBP has higher RBE close to the distal edge where the bio-effective dose increases.

**Treatment Planning**

Proton dose calculations for treatment planning are performed with a treatment planning system (TPS) based on computed tomography (CT) data acquired from the CT scanner. The CT scanner and the CT image interpretation are specifically customized for proton therapy. The CT numbers calibration is associated with the relative linear stopping power function of protons. The CT images acquisition, treatment planning, and treatment of the patient are performed with site-specific immobilization devices. There are specific procedures of the commissioning and quality assurance (QA) of the treatment planning and CT scanner for radiation treatment using a proton beam that includes validation of TPS calculations with the phantom measurements.

The treatment planning is typically performed with the dose computational algorithms based on a pencil beam approach. Analytical algorithms are based on measured dose distributions and include all contributions to dose deposition. The important method of dose calculation is the Monte Carlo technique of the particle transport simulation. There are remarkable differences between pencil beam algorithms and Monte Carlo simulation. The progress in computer technologies makes possible implementation of fast Monte Carlo–based algorithms for proton beam therapy planning or plan verification. Future progress in this direction will improve the accuracy of the planning, especially for intensity modulated proton therapy.
There were a set of studies on comparative treatment planning to investigate the dosimetric properties of the proton beams for various treatment sites. It has been shown that protons in comparison to photons produce dose distributions with better conformation of around-the-target volume, more homogeneous dose distribution in the target, and lower integral dose in healthy tissues. There are a few groups who are developing a bio-effective approach for treatment planning utilizing the increasing of the RBE at the distal edge of the Bragg peak. This research may create a new treatment approach and technique.

Dosimetry and Quality Assurance
The Report 78 of the International Commission on Radiation Units and Measurements (ICRU) and the protocol for dose calibration contained in Technical Report Series No. 398 published by the International Atomic Energy Agency (IAEA) are currently the guidelines for the dosimetry of the proton beams. The basic dosimetry standards require annual verification of the dose and credentialing by the Radiological Physics Center (RPC). The quality assurance (QA) procedures are developed to assure safe operation of the proton therapy system. The proton therapy machines are significantly different from the photon machines. This makes some QA procedures definite for the proton facilities and includes machine-specific procedures for mechanical components, beam calibration, TPS, and patient-specific components, such as patient-specific devices.

Clinical Experience and Perspectives
The main advantages of proton therapy are the physical properties of the proton beam, which enables the delivery of a high dose to the target volume while reducing the dose to the surrounding normal tissues, as well as ensuring higher conformity of the dose shaping around the tumor. Hence, proton therapy has established itself as ablative therapy and organ preservation therapy. In recent years the major cohort of the patients treated with the protons were prostate cancer patients, who accounted for up to 80 percent of treatments at some facilities.

Over the last five to seven years, the fraction of prostate patients has decreased to 20 to 30 percent due to an increase of patients with other treatment sides. The dosimetrical properties of the proton beams delivering a lethal radiation dose to the tumor tissue while sparing surrounding normal tissue make this modality attractive for a pediatric patient cohort. The limited accessibility of proton therapy is reflected in the number of treated patients (less than 100,000). New emerging centers will allow establishing more baseline data for clinical outcome of proton therapy.

During the last decade, a number of clinical evidences were established. In particular, proton therapy for uveal melanoma has shown over 90 percent for local controls over the five-year period of time. The reports from various groups indicate they were able to achieve local control between 70 percent and 100 percent for chordoma, and 89.8 and 100 percent for chondrosarcoma. In comparison, the conventional photon methods give the local control rates between 17 percent and 50 percent for chordoma of the skull base.

There are also data on improvement in local control for head and neck tumors, non–small cell lung cancer (NSCLC), esophageal carcinoma, hepatocellular carcinoma (HCC), pancreatic carcinoma, extracranial sarcoma/chordoma and chondrosarcoma, and prostate cancer.

The studies have shown the advantage of the higher RBE from protons in the case of radioreistant tumors. The dosimetrical properties of the dose deposition allow confining the dose within the target area and minimize the dose to healthy tissue in the case of HCC. One of the prospective future directions is a combination of systemic therapy and radiation. Though the potential of the combination of chemo- and radiotherapy, chemo-radiation, approach is not fully evaluated for photons yet, nevertheless it is a therapeutic gold standard in many diseases. The chemo-radiation approach has shown a higher local control rate and reduced distant failure for photons. There are few groups in proton therapy working toward establishing combined chemo-proton radiation therapy. There is ongoing discussion in the radiation oncology community on proton therapy perspectives and its advantage over photon therapy. There is also a discussion on necessity to establish clinical trials to compare the proton and photon treatments.

Side Effects
Proton therapy, like photon radiation therapy, may cause side effects. The accumulated experience
Proton Therapy

shows the side effects from proton therapy are milder, compared with photon therapy. The advantage of the dosimetrical properties of the proton beam in sparing tumor and normal tissue allows organ preservation from radiation damage. There is ongoing research to reduce the side effects from proton therapy, in particular, acute skin reaction.

Secondary neutrons are considered one of the possible risk factors of secondary malignancies, presenting possible long-term effects. This is an important aspect for deliberation for the pediatric cohort of patients whose life expectancy may exceed the latent period of secondary malignance. However, the yield of the nuclear reactions and neutron production is relatively small.

The main sources of the undesired secondary neutrons are the elements of the treatment machine. Published studies on the level of secondary neutron production show that the 16 and above MV linac machines could produce more neutrons than those in today’s proton treatment machines and modern approaches in proton treatment. The implementation of uniform scanning and spot-scanning pencil proton beams will reduce the secondary neutron contamination even further.

**Economic Considerations**

The major limiting factor for wide usage of proton therapy is the start-up cost of the proton facility. The typical price of the two-treatment-room facility is about $100 million. The capital cost of the facility includes real estate, a cyclotron/synchrotron and beam line, a number of treatment gantries, shielding, manpower, power supply, and patient specific devices (compensators and apertures). The estimate of the cost of a proton treatment facility totals about double the cost of a photon treatment facility, considering the initial investment and the operating costs. The capital costs will be distributed among a larger number of patients with the increase of patient throughput. That will reduce the cost per patient once the facility is operating at full capacity.

There are strong efforts in research and development in the field of medical physics, accelerator physics, and engineering, which form the basis of modern, cost-efficient proton facilities. Currently, vendors are proposing a single-room solution for a reduced price. The operational cost of the facility could be reduced with implementation of the pencil beam spot-scanning and multi-leaf collimator from optimized material for neutron contamination reduction. An analysis of the treatment facilities, patient statistics, and treatment planning statistics has shown that combination of fixed beam treatment rooms with gantry rooms in one facility can reduce the capital cost of the facility. The progress in acceleration technology over the last decade creates the basis for new, less expensive solutions for proton beam therapy. In particular, the linear accelerators of protons with the modular design or laser-plasma accelerators can reduce start-up costs of the proton facility. The cost of proton treatment trends toward reduction as the technology is further developed.

**Patient Education**

Accidents in the nuclear industry formed some pre-judgment against radiation applications among the general public. There is an important need to provide patient education on the benefits of radiation therapy and especially on proton therapy. The independent nonprofit National Association for Proton Therapy (NAPT; http://www.proton-therapy.org) was founded in 1990 for public education on proton therapy. NAPT provides information on the therapeutic benefits of proton therapy for cancer treatment in the United States and abroad. Thirteen operating centers are among the supporting members and nine centers are under development. Practically each established proton therapy center provides patient education resources on proton therapy as well.

**Future Development**

Today, research and development in beam delivery technology is focused toward more compact, more efficient, and less expensive accelerators. In the next few years new types of accelerators will become the source of the proton beam at treatment facilities. There is ongoing development of new treatment strategies such as spot-scanning techniques and intensity modulated proton therapy (IMPT) as well as more accurate TPS algorithms like Monte Carlo simulation.

More clinical trials and protocols are under development to expand proton therapy to different treatment sites and to increase efficacy of the therapy. The efforts to improve inter- and intrafractional motion management, beam delivery control
techniques, and image-guided proton beam therapy will improve the treatment outcome. It has been shown also that proton beam could be used for imaging purposes, and it has potential for proton-based CT. Bio-effective treatment planning may reduce the dose to achieve the same treatment effect. This could lead to reduction of side effects.

Conclusion
Proton therapy, invented four decades ago, is still a rapidly developing radiation therapy modality. The proton beam deposits most of its dose in the tumor volume, improving the tumor and sparing the surrounding normal tissues in comparison to conventional photon modalities. Proton therapy offers benefits of its physical and radiobiological properties (increased RBE) to improve the local control and reduce side effects of the treatment. Thousands of patients have been treated effectively with proton therapy for localized tumors. There is evidence in the clinical literature of the success of proton therapy for many types of cancer. Several clinical trials are under development for evaluation of proton beam therapy for new application sites. New technologies in accelerators and treatment delivery techniques make the future very promising for proton beam therapy.

Psychosocial Care/Support
Cancer has a profound impact on a person's emotional, psychological, and social well-being, and psychosocial care and support are central to health outcomes. Rates of clinically diagnosed anxiety and depression among those with cancer have been reported to be at least 30 percent, with caregivers and family members also experiencing distress, anxiety, and depression at similar levels. It is estimated that up to 70 percent of people across the cancer trajectory will experience some level of emotional and social distress.

A cancer diagnosis may bring feelings of denial, grief, and shock for those diagnosed, their families, and the wider community. These feelings quickly intensify when the practical realities of diagnosis disrupt all aspects of daily life. Social and professional roles and family functioning become compromised as people struggle with treatment side effects and the implications of illness in their everyday lives.

For a parent diagnosed with cancer, there are concerns about children's well-being and the practical realities of maintaining a functioning family home in the face of a life-threatening illness. For a single person, fear of being alone and concerns about how they can cope without daily support are paramount. For a child diagnosed with cancer, the impact on parents, siblings, friends, teachers, and the broader community are far reaching.

Parents of children with cancer have been identified as having a particularly high risk of developing symptoms consistent with a diagnosis of post-traumatic stress disorder. For older people, a cancer diagnosis is an additional burden in the presence of other co-morbidities.

As people move beyond initial diagnosis, the impact of cancer treatment and associated adverse effects, or the reality of progressive illness, and facing one's mortality, intensify feelings of anger, grief, helplessness, hopelessness, loss of control, and dependency.

The impact of cancer on the ability of people to maintain social functioning has been well documented. For young children, treatment, treatment side effects, and periods of hospitalization interfere with normative developmental stages. Physical changes resulting from the disease and treatment
adversely impact children’s social functioning, and reentering school can be particularly stressful. Adolescents often experience schooling interruptions, where diagnosis and treatment constrain future aspirations and limit normal adolescent experiences and the development of social skills and relationships. For adults, occupation and employment can be affected, with a loss of income and economic security. Career disruption or unplanned early retirement add to feelings of loss of purpose and worthlessness. Relationships become strained as the practicalities of ongoing support and caregiver roles are realized. Issues with body image, changes in sexual function, low self-esteem, and mood disturbances create challenges for the person with cancer and those with whom they interact.

The pervasive psychosocial impact of cancer on patients and their families extends to the survivor phase, as concerns about recurrence cause long-term stress. The financial burden of cancer can have long-lasting consequences; studies have demonstrated that savings can be exhausted through loss of income and the costs associated with treatment. In the United States, it has been estimated that approximately 5 percent of those who declare bankruptcy cite cancer as the underlying reason. The psychosocial burden of cancer traverses age, diagnosis, culture, socioeconomic status, and gender, but geography also creates adverse psychosocial outcomes. For rural people with cancer, the risk of serious psychological distress is higher than for their urban counterparts, as they are challenged by geographic isolation and lack of access to services. Additionally, delays in diagnosis can result in advanced disease and poorer survival rates.

Globally, there is recognition of the need for effective psychosocial care and support for people with cancer, caregivers, and families, but also there is acknowledgment that psychosocial needs are frequently not identified and often are unmet. People across the cancer trajectory indicate that they lack information to guide complex decision making and how to access the practical supports available to them. While there are a myriad of reports, studies, and trials that identify the importance of support from health professionals and the efficacy of psychological interventions and treatments, there is a growing body of evidence that indicates the people who would most benefit from support and interventions do not receive them.

The Provision of Care to Support Good Psychosocial Outcomes

Emotional and practical support provided by family and friends of people with cancer is considerable, and the patience, adaptability, and flexibility required can result in emotional exhaustion and substantial levels of stress. Rates of depression and anxiety among caregivers and family members highlight the need for psychosocial support to be targeted at all affected by cancer, not only those with a diagnosis. While family and friends informally provide the majority of psychosocial care and support, the role of health professionals in addressing emotional, familial, social, financial, and informational needs is also well documented. Psychosocial care by skilled health professionals is viewed as central to well-being across the cancer trajectory, with effective care linked to improved functional adjustment and quality of life. There is a demonstrable reduction in anxiety, depression, and cancer-related issues such as pain, fatigue, nausea and vomiting, and physical impairment.

Clear, honest communication by health professionals, opportunities to ask questions, information and choice surrounding treatment options, preparation for procedures and treatments, and emotional support and continuity of care by health professionals have all been identified as important for improved psychosocial outcomes. Optimally, psychosocial care provided by health professionals should occur from diagnosis, through the treatment trajectory and into the survivor period, or from curative to palliation, death, and bereavement. Active listening and empathy of health professionals, using a person-centered communication style, and skills in delivering information in ways that can be understood and retained have been consistently demonstrated to improve psychosocial outcomes for people with cancer, their caregivers, and friends and families.

Consistent with policy across most countries, there is increasing emphasis on involving the patient in all aspects of decision making. Shared decision-making models emphasize partnerships between clinicians, the person diagnosed with cancer, and his or her family and have been shown to consistently result in high levels of service user satisfaction. Strong partnerships between the health professional team and families are particularly important if the cancer patient moves to noncurative stages, where information and support can prepare people
to cope with anticipatory loss, grief, and bereavement. Reduced rates of depression and anxiety among people with cancer and their families have been reported, with targeted psycho-educational and psychosocial interventions deemed successful. Specific psychological therapies, such as cognitive behavioral therapy, have been shown to improve emotional adjustment and social functioning, and reductions in cancer-related symptoms and adverse effects have been reported. Other interventions such as support groups and drop-in centers (including Web-based), psycho-educational information, community-based programs, retreats and camps, and activities such as dragon boat race teams and expressive writing groups have all been documented as successful in improving psychosocial outcomes.

**Barriers to Effective Psychosocial Care**

Treatment side effects, fatigue, pain, emotional exhaustion, stress, anxiety, and depression all impact a person’s receptivity to psychosocial care. Lack of education and information influence a person’s ability to make decisions and fully understand treatment and treatment options; but even when good information is provided, timing is crucial. Information needs and receptivity to this information change over time.

Studies have shown that even when people are provided with good, clear information and develop knowledge to support their psychosocial well-being, lack of service availability, transportation, and financial difficulties can further impede their receptivity to access the support they need. Large surveys have indicated that lack of transportation can be a particular barrier to accessing psychosocial care. Lack of social support from family, friends, and the broader community significantly compounds psychosocial issues for people with cancer. Throughout the cancer trajectory there will be periods when caregivers, friends, and families become exhausted and face their own psychosocial issues, which in turn impact their capacity to continue to support their loved ones. For those people with cancer who enter the survivor period, there can be significant psychosocial challenges when their support network expects them to return to “normal” and reenter their life, grateful for surviving the cancer experience. Although supportive care by health professionals has been identified as central to the psychosocial well-being of people with cancer and their families, there is a wealth of research that identifies a lack of professional confidence and specialized knowledge of how to best address psychosocial needs. Inadequate education and training and lack of knowledge about services, techniques, and strategies for improving psychosocial care have been identified as professional shortcomings.

Lack of access to health professionals with the expertise to deliver effective psychosocial care has been identified as a major barrier to improving outcomes. In rural areas, lack of access to specialist staff and lack of confidence among health professionals, who are expected to be multiskilled generalists, have been consistently shown to impact the psychosocial outcomes for those with cancer and their families. Additionally, the impact of lack of confidence and skill among health professionals has been shown to impact their own well-being and create professional stress when they feel that the care they are delivering is inadequate. Despite the development of clinical practice guidelines to support psychosocial care of people with cancer and their families, there is evidence that these guidelines are often not implemented. Consistently, cancer patients and their families report that health professionals fail to assess, understand, and respond to their psychosocial needs, and that clinicians often lack awareness of existing services and resources. Overall, many health professionals fail to acknowledge psychosocial needs, care, and support as a central part of their role and integral to overall quality cancer care.

“Emotional Toil: Providing Psychosocial Care to
Purdue University Center for Cancer Research

The Purdue University Center for Cancer Research is a National Cancer Institute–Designated Cancer Center that specializes in translating lab findings as quickly as possible into new therapies. The center facilitates an understanding of the cancer cell, develops technology, creates diagnostic tools, and synthesizes chemical components utilizing the university’s core strengths in engineering, nutrition, pharmacy, veterinary medicine, chemistry, structural biology, and the biological sciences.

In 1975, a committee funded by a two-year grant from the National Cancer Institute (NCI) was established to plan the center. A year later the Purdue Cancer Center was created. Three years later, in 1978, the center was awarded an NCI Cancer Center Support Grant (which has been renewed ever since). In 1989, the center developed a scientific partnership with the Walther Cancer Institute. A partnership with the Indiana University (IU) Simon Cancer Center was established in 2004. The center officially became the Purdue University Center for Cancer Research in 2009. Membership in the Purdue University Center for Cancer Research is considered by the director and executive committee.

The committee consists of two associate directors, a deputy director, four scientific program leaders, four program co-leaders, and a managing director. Membership includes e-news and announcements regarding funding opportunities, sponsored retreats, symposia, and member discounts. Once approved, membership is granted for three years. Every three years, depending upon the recommendation of program leaders, members update their curriculum vitae and provide statements outlining their contributions to the center.

Several state and local organizations have supported the center for many decades. Since 1981, the Carroll County Cancer Association has funded a Summer Undergraduate Research Program. Beginning in 1948, the Indiana Elks Charities, Inc., has funded the Innovative Grants. These grants support faculty research.

The Lafayette Lions Club has honored a faculty member with a research award every year since 1978. The West Lafayette Sagamore Lions Club contributed $250,000 to establish an endowment fund to support an annual symposium on cancer research. Participants have included Purdue University, Indiana University, and the University of Notre Dame as well as other cancer organizations.

A Cancer Benefit Concert that is also sponsored by the Purdue Musical Organizations was established in 2005.

Since 2008, an annual 5K challenge has existed. The Jordan-Rieger Event supports pancreatic cancer research at the center.

The Purdue Center for Cancer Research has also established several endowments to expand funding resources. The Carl J. and Irene E. Dexter Fund was created in 1981 to support equipment and materials. The Bernice L. Anderson Cancer Research Fund established in 1989 supports general cancer research. The Melba M. Schumacher Cancer Research Fund created in 1993 also supports general cancer research. The Joyce Fox Jordan Fund created in 2001 supports cancer research at the center. The Jim and Diann Robbers Cancer Research Grant for New Investigators established in 2003 supports new researchers selected by the executive committee. The James R. Lowe Lung Cancer Research Fund created in 2004 supports lung cancer research. The Eva Bergstrom Cancer Research Fund created in 2005 supports postdoctoral research, with recipients and award amount determined by the executive committee. The Vision of Hope for Research in Women’s Cancer was established in 2006 to support research of women’s cancers. The Glenn A. and Marian J. Karch Cancer Research Fund was created in 2010 to support cancer research. The Indiana Extension Homemakers Association Cancer Research Fund,
also created in 2010, supports cancer research. The Darrel B. Sims Matching Fund doubles every donation, but the center must raise a total of $100,000 to be awarded funds in the amount of $200,000.

The Purdue University Center for Cancer Research has also identified six important areas of funding needs. The Scientific Research Fund assists with new imaging techniques, early detection tests, and new treatments. The Strategic Asset Enhancement Fund supports the development of innovative ideas that may not be typically funded or explored. The Women’s Cancer Fund sustains research in breast, ovarian, and cervical cancers. The Jordan-Rieger Fund for Pancreatic Cancer supports pancreatic cancer research specifically. The Prostate Cancer Research Fund supports research regarding prostate cancer specifically. The James R. Lowe Lung Cancer Research Fund supports research specific to lung cancer.

There are 18 departments, six colleges, and more than 90 scientists who gather at Purdue University to research, share ideas and insights, and promote cancer research. Faculty and researchers focus on one of the four research programs at the center. The Cell Identity and Signaling Program studies the key molecules and processes that distinguish normal cells from cancer cells. Program members rely on biochemistry, molecular biology, genetics, and developmental biology in their expertise. The Chemical and Structural Biology Program uses a wide variety of chemical, biochemical, and structural approaches to investigate the unique biological targets for chemotherapy and to develop new chemical treatment methods. This program develops an understanding of cancer molecules and their interactions, mutations, and modifications. In this manner, new inhibitors can be developed. The Drug Delivery and Molecular Sensing Program develops new initiatives, including nanotechnology and cancer imaging. This program researches cancer cell growth, cancer cell differentiation, cancer drug design, cancer drug discovery, chemical biology of cancer, and structural biology of cancer. Finally, the Medicinal Program focuses on the development of cancer chemotherapeutic agents. Research in this program includes chemical, biochemical, cellular, and animal methods to discover and design chemotherapy drugs.

The Purdue University Center for Cancer Research currently organizes cancer forums in breast cancer research and prostate cancer. Three clinicians (oncologist, radiologist, and pathologist) and a nationally renowned physician scientist will present information about building partnerships among scientists, engineers, and clinicians. The first breast cancer forum is scheduled in November of 2014. The first prostate cancer forum is currently being developed and is scheduled to take place in March 2015. Both events will be free to faculty and research scientists at Purdue University. The center also offers seminars and an annual scientific retreat.

Radiation

Radiation is energy released as either particles or electromagnetic waves. The average United States citizen receives a total dose of about 360 millirems of radiation per year through a combination of man-made and natural sources. There are five types of radiation that pose a serious risk to human health, which are alpha and beta particles, gamma and X-rays, and neutrons. Ionizing radiation makes these types of radiation a significant risk to human health because the energy transferred is high enough to disrupt chemical bonds (radical formation or ionization), including living tissue. In contrast, nonionization radiation, such as radio waves, microwaves, and cellular devices do not have enough energy to disrupt the chemical bonds, but can cause other biological effects on humans. Ionized radiation also provides benefits to humans in regard to the application of medicine, especially in the treatment of cancer.

The main sources of man-made radiation in humans are three medical procedures, which are diagnostic examination (predominately X-ray images), malignant disease treatment (radiation oncology), and nuclear medicine (radiopharmaceuticals for diagnosis and treatment of diseases). Man-made radiation accounts for about 18 percent of the annual radiation dose, of which 11 percent comes from medical X-rays, four percent from nuclear medicine, three percent from consumer products, and less than one percent from various radiation sources that include occupational (0.3 percent), fallout (< 0.3 percent), nuclear fuel cycle (0.1 percent), and miscellaneous (0.1 percent). Commonly utilized radioactive isotopes by the medical community include cesium-137, colbalt-60, iodine-131, iridium-192, strontium-89, and technetium-99m.

Natural background radiation has three main sources (cosmic, terrestrial, and internal) accounting for 82 percent of the natural sources of radiation, specifically, radon (55 percent), internal (11 percent), terrestrial (8 percent), and cosmic (8 percent). The Earth is constantly receiving a steady trickle of mostly beta and gamma radiation from space (cosmic source—the Sun and stars). Significant terrestrial sources of radiation are from uranium and thorium and their decay products (e.g., radium-226, -228, -224 [and radium's decay product is radon]) which are found everywhere on Earth and thus are in the water, soil, and vegetation. Humans have a number of naturally occurring radionuclides within our bodies from birth, such as potassium-40, uranium-238, thorium-232, and their decay products, as well as carbon-14, rubidium-87, and lead-210.

Radioactivity

Radioactivity is the spontaneous decay of the nuclei of particular radioactive atoms (radioisotopes) with the emission of ionizing radiation. Nuclei exhibiting
Radiation

Radioactivity are unstable and in a continual process of gradual breakdown (i.e., disintegration), which is referred to as radioactive decay. The effect of radioactivity is to produce a more stable state. The decay is typically of three main types, alpha and beta particles and gamma radiation, accompanied by the emission of ionizing radiation in the form of high-energy particles or rays. The rate of breakdown or decay is calculated by the half-life, or the time it takes for a given number of atoms to decay by half, which can range from milliseconds for short-lived isotopes to billions of years. The amount of radioactivity exhibited is measured by the number of disintegrations per second (dps); 1 becquerel (Bq) = 1 dps, and 1 curie (Ci) = $3.7 \times 10^{10}$ dps = $3.7 \times 10^{10}$ Bq.

**Alpha and Beta Particles, Gamma and X-rays, and Neutrons**

Alpha particles are positively charged, high-energy particles emitted from the nuclei of a radioactive atom. They are the largest in mass and the slowest traveling at less than one-10th the speed of light. Alpha particles are produced following the decay of radioisotopes of heavy nuclei such as americium, actinium, radium, radon, thorium, plutonium, and uranium. The process of alpha decay transforms one element into a different element that has a lighter nucleus than the original radioisotope by emitting an alpha particle, which consists of two protons and two neutrons. The total energy (including the masses of the new element and the alpha particle) is the same as before, but some of the nuclear binding energy is converted into kinetic energy of the alpha particle. Naturally occurring alpha particles are generally not harmful to humans, unless they enter the body via a cut or are inhaled or ingested where they are potentially dangerous to human health. Alpha particles from cosmic rays are the exception, which can emit very high amounts of energy.

Beta particles are electrons emitted from the spontaneous decay of unstable nuclei when one of its neutrons turns into a proton and emits an electron and an electron antineutrino. Tritium, carbon-14, cobalt-60, cesium-137, iodine-129 and -131, phosphorus-32, and strontium-90 all decay by beta emission. Beta particles travel at a high velocity, which can be as fast as 98 percent of the speed of light and are fast enough to travel a few feet before losing most of their initial energy. Beta particles are electrons and thus have only have about 1/2,000 the mass of a proton or neutron, and their emission does not affect the mass number, and no new element is created. Since beta particles travel farther than alpha particles they are capable of penetrating living tissue more easily and causing health damage, especially phosphorus-32. Exposure to a beta particles source, if intense, is capable of causing redening of the skin (called "beta burn") and/or eye damage. As alpha and beta particles penetrate matter they bump electrons out of atoms or molecules, thus ionizing them.

X-rays, like gamma radiation, are composed of high energy electromagnetic rays (photons) and are identical in physical characteristics and biological effect. They do not have an electric charge or mass. The difference between the two is their origin. Specifically, X-rays originate outside of the nucleus (commonly a shell of electrons bending around the nucleus), while gamma rays originate from within the nucleus during fluorescence and radioactive decay. As the X-rays’ electromagnetic rays collide with atoms, the energy of the electromagnetic ray is absorbed by the atom, typically resulting in a higher orbital level. If the electromagnetic ray is very energetic, it can bump an electron out of the atom, causing the atom to ionize. More dense materials, like bones, absorb the electromagnetic rays more readily than smaller atoms found in soft tissue material (skin, organs, muscles) resulting in dark shadows being visible on photographic film (an X-ray image). An X-ray machine utilizes this difference in absorption resulting in images of human structure through the skin. Medical diagnostic procedures, such as dental, chest, or mammography are where people are exposed. Gamma rays are produced following spontaneous decay of radioactive material, such as cobalt-60 and cesium-137. They are similar to ordinary visible light but differ in their wavelength. Gamma rays have a wavelength that is far shorter than visible light and thus higher in energy, greater than 100 keV. Gamma decay generally occurs simultaneously with an alpha or beta decay and does not affect the atomic number or the mass number of a nucleus, and no new element is created.

Neutrons are electronically neutral (uncharged) and heavy particles that interact with atomic nuclei and are more deep penetrating than alpha or beta radiation (sometimes more than gamma radiation). They have both particle-like and wave-like
properties. Today, neutrons primarily come from nuclear power plants and cosmic rays. There is also limited use of neutrons in radiotherapy, industrial radiography, and explosives. Neutrons do not damage living tissue cells by ionizing them directly, but instead disperse atoms as a result of colliding with protons (hydrogen nucleus, principally). The colliding with other atoms scatters the atoms resulting in the scattered atoms emitting alpha, beta, gamma, or X-rays that in turn produce ionization (called indirectly ionizing radiation). Neutrons being heavy and uncharged only lose energy from interactions with nuclei, which results in a sudden large loss of energy from a single event that is not uniform. Therefore, neutrons are more carcinogenic than electromagnetic waves (gamma and X-rays) because they release more of their energy in clusters of ionizing events and thus cause a variety of DNA damage with lower reparability than gamma and X-rays. When comparing the same absorbed dose, neutrons are more efficient at causing gene mutations, chromosomal aberrations, and decreasing cell survivability than gamma and X-rays. Thus, the calculation of the effective dose of neutrons is weighted more heavily than X-rays or gamma rays.

Alpha, beta, gamma, and X-ray radiation each produce differing amounts of ionization radiation called low linear energy transfer (low LET) radiation. Ionizing radiation is used in radiation therapy. Its principal effect is its capacity to shrink tumors, damage or stop cancer cells from replicating, or sever their DNA strands. The damaged cancer cells are broken down by the body and expelled naturally. The damage to cancer cells from photon beams (electron and proton radiation) is by activating radicals from the atomic interactions. Alpha particles produce the most ionization because they are heavy, slow moving, and carry two positive charges. Gamma and X-rays produce the least because they are photons that carry no charge, while beta particles have an ionizing potential in between alpha and gamma rays. The ionizing potential of alpha and beta particles and gamma radiation causes damage on contact or proximity with living cells and can
result in radiation sickness. In contrast, neutrons are high linear-energy-transfer (high LET) radiation. The damage from neutrons is essentially from nuclear interactions. Low LET tumor cell damage is not complete and the cells can repair and thus continue to grow, while high LET radiation-damaged tumor cells’ ability to repair is significantly limited. Fast neutrons are able to treat large cancerous tumors regardless of their stage and do not require oxygen to destroy cancer cells like low LET radiation.

**Radiation Therapy**

Approximately half of cancer patients experience some form of radiation therapy. The type of radiation therapy is dependent on the cancer, its size, location, proximity to normal tissue, and the general health and social dimensions (age, gender, etc.) of the patient. Radiation therapy damages not only cancer cells but also normal cells. There are several processes for radiation therapy, such as outside the body (e.g., external-beam radiation therapy), placing a radioactive material inside the body near the cancer cells or tumor (internal radiation therapy, also called brachytherapy), or by mouth or injecting radioactive materials into the bloodstream (systemic radiation therapy) for targeting and destroying cancer cells.

External-beam radiation therapy commonly uses photon beams (either X-rays or gamma rays) targeted at a specific part of the body with a cancer tumor or cancerous cells. Gamma rays have a higher amount of energy than X-rays. The amount of energy used is based on the cancer tumor or cancerous cells targeted. The photon beam is commonly delivered by various machines, such as a linear accelerator (LINAC), Intensity-Modulated Radiation Therapy (IMRT), 3-dimensional conformal radiation therapy (3D-CRT), etc.

Internal radiation therapy involves radioactive materials placed inside or on the body to shrink a tumor or destroy the cancer cells. The delivery device emits radiation causing the tumor or cancer cells to shrink or be destroyed. One type of internal radiation therapy is called “brachytherapy” where a radiation source is sealed inside tiny pellets (called “seeds”), capsules, or ribbons and placed in the body by needles, catheters, or another delivery device. The seeds can be temporary or permanent and deliver a continuous low-dose (several days) or high-dose (conducted one session at a time via a device/machine that places the radioactive source(s) in or near a tumor and is removed after the session) of radiation. The advantage of brachytherapy is that it can be targeted to a smaller part of the body with a high dose of radiation than external-beam radiation therapy resulting in less normal tissue damage. The delivery device can be left in the patient for few weeks or even months where the radioactive isotopes decay and the seeds are rendered harmless. The seeds can be left in the body or removed. Brachytherapy can be used as a stand-alone treatment or in conjunction with external beam radiation, chemotherapy, surgery, or as an increased dose of radiation. Internal radiation therapy can be in liquid form (e.g., taken orally, IV drip, or pill) resulting in the liquid radiation traveling throughout the body killing the cancer cells.

Systemic radiation therapy is when the patient takes a radioactive substance orally or receives it by injection. Common examples are radioactive iodine or a laboratory made protein that binds to substances in the body including cancer cells (called monoclonal antibodies). The monoclonal antibodies are critical in enabling the radioactive substance to target the specific area and/or cells in the body. These antibodies are coupled with the radioactive substance which travels around the human body locating and killing tumor or cancer cells. Radiation therapy is also used to relieve pain (palliative) from the cancer treatment, such as in cases of metastasized cancer, cancer of the esophagus that prevents food or water intake, or when tumors are pressing against the spine or growing in the bone. Systemic radiation therapy can be used to reduce pain for patients with bone metastases. Some radioactive drugs to treat pain are strontium-89 chloride, radium-223, and samarium-153-lexidronam.

The side effects of radiation therapy range from acute to secondary malignancies many years later. The side effects are based on the type of cancer, the length and type of the treatment (type of radiation used, dosage, concurrent with other chemical therapy), and the damage to normal tissue or organs. Common acute side effects of radiation therapy include nausea and vomiting, damage to the epithelial surfaces, sores of the mouth, throat, and stomach, hydropsy, intestinal discomfort, infertility, and fatigue. Long-term side effects (occurring months to years after treatment) are primarily localized to
the area treated, such as damage to the blood vessels and the cells of the connective tissue. Other side effect conditions include hair loss (epilation), dry mouth (xerostomia), dry eyes (xerophthalmia), reduced elasticity of irradiated location (fibrosis), fluid retention and tissue swelling (lymphedema), heart disease, cognitive decline, and rectal problems (proctitis).

Radiation, Gamma

Gamma radiation is probably the most well-known type of radiation thanks to Dr. Bruce Banner. Anyone familiar with the Marvel Comics character knows that gamma radiation was responsible for the mutagenic damage that turned the mild-mannered Dr. Banner into the Incredible Hulk. It is not as unusual as one might think that a comic book character is making an appearance in a cancer encyclopedia. In 1962, when the Incredible Hulk made his comic book debut, it was just over 15 years since the first atomic test bomb was detonated in the deserts of New Mexico, followed by the dropping of atomic bombs over Hiroshima and Nagasaki. A generation had grown up with increasing concerns about the long-term effects of radiation. While the real-world concern was directed at the possibility of nuclear war, and the more immediate possibility of cancer from radiation exposure, speculative fiction dramatized these concerns in the form of Godzilla and other irradiated, havoc-wrecking monsters in Japanese film. At the same time, Marvel comics capitalized on the science by creating a line of superheroes—Spider-Man, the Fantastic Four, the Incredible Hulk—all mutants who received their powers (and status as outcasts) in the aftermath of radiation exposure. Further expanding on the fears of the long-term effects of radiation exposure, Marvel’s X-Men were the result of increases in ambient levels of radiation which caused mutagenic changes at the germ line level, causing the creation of “gene X,” the mutant gene.

Gamma radiation is a type of ionizing radiation, with a very high frequency. These rays are named for their principal source of production, the decay of atomic nuclei from a high-energy state to low-energy gamma decay, and are the product of the alpha and beta rays of radioactive decay. Gamma decay is often a result of nuclear reactions like nuclear fission or fusion, though gamma rays can occasionally be produced in other lesser-known ways.

Gamma rays were first named in 1903, by analogy to alpha and beta rays, which had been discovered and named in the preceding decade. Unlike alpha and beta rays, gamma rays are not easily deflected by magnetic fields. Their wavelengths overlap with those of X-rays, and so they are distinguished by their origins, with gamma rays emitted by the nucleus, while X-rays are emitted by electrons.

While alpha and beta rays can be blocked by very thin materials, gamma rays can be blocked only by significant amounts of mass, preferably including materials of high density and high atomic number. This is one of the reasons Cold War fallout shelters were lead-lined and/or used exceptionally thick walls, for instance, and benefited from being built fully or partially underground. Shielding in nuclear power plants and fuel rod storage facilities is of course even more extensive and massive.

Alpha and beta rays produce only surface damage to living organisms, because they don’t penetrate further than the skin. Gamma rays can produce the same damage that alpha and beta rays do—radiation burns and other skin damage—but also result in radiation sickness, DNA damage and cell death, and very often cancer. Survivors of Hiroshima and Nagasaki, for instance, were a third more likely to die of cancer, while among nuclear
workers with chronic low-dose exposure, the risk of leukemia increases from between 2 percent to 10 percent, depending on the exposure level.

Gamma rays occur naturally in radioisotopes like the americium-241 used in household smoke detectors and the gadolinium-153 used in X-ray machines, as well as from interactions between the atmosphere and cosmic rays (the source of the Fantastic Four’s powers, incidentally). More rarely they occur from gamma-ray flashes or lightning strikes. Terrestrial gamma-ray flashes are produced in the atmosphere and have been recorded by the Compton Gamma Ray Observatory as well as terrestrial observatories. Most or all are caused by the electric fields of intense thunderstorms. A 2013 study found that passengers of commercial aircraft are occasionally exposed to gamma radiation as a result of these storms, in doses about the same or less than that of a full-body CT scan.

Gamma radiation is responsible for the “zone of alienation” surrounding Chernobyl, in the aftermath of the 1986 catastrophic nuclear accident that released nuclear particles into much of the Soviet Union and Europe. Though only 31 deaths were confirmed during the accident, the number of cancer deaths, birth defects, and other long-term effects is considerably higher; however, due to the handling of information by the Soviets and later the Russian government, the statistics are ultimately unknowable. (Chernobyl was evacuated before non-Soviet authorities were even notified of the event; the outside world discovered it only because radiation was detected in Sweden, prompting an inspection of the Forosmark Nuclear Power Plant and subsequent discovery that the source of the radiation came from much farther afield.) Four hundred times more radioactive material was released during the meltdown than in the bombing of Hiroshima. The handling of the disaster played a significant role—not understood until much later, due to the cloak of obfuscation over the matter at the time—in the dissolution of the Soviet Union, and created friction with Ukraine (which reported thousands more deaths than the Soviets would acknowledge), and remains pertinent today almost 30 years later.

Bodies of water surrounding Chernobyl, which was located on the Pripyat River that feeds into the Dnieper reservoir system, one of the largest surface water systems in Europe (and experiencing spring flooding at the time of the accident), were almost certainly contaminated, though the guidelines for acceptable levels of radioiodine were temporarily raised in order to permit the government to report the drinking water as safe, and authorities claimed that radioactive material had sunk to the bottom of aquatic systems in a form that would not dissolve for centuries. Contamination of fish became a concern throughout Europe in the short term and for years to come in Russia, Ukraine, Belarus, and Scandinavia. Groundwater, though, was not badly impacted, by comparison.

A large area of pine forest was renamed the Red Forest after it turned from green to reddish-brown in rapid death, and horses and cattle that were not evacuated died with massive thyroid damage. Wild boar in Germany in 2010, 24 years later, were found to be contaminated with radiation that could only be attributed to Chernobyl (through the boars’ consumption of radioactive mushrooms, in large part, or of animals that had eaten those mushrooms), leading to a ban on wild game meat. Norway has had similar trouble in the livestock industry, with plants used for grazing found to be contaminated with Chernobyl radiation. In the United Kingdom, restrictions on sheep farming were not lifted until 2012.

The primary long-term health impact of Chernobyl appears to be thyroid cancer, which was rampant in children in the aftermath, with at least 6,000 cases of thyroid cancer in children and adolescents attributed to Chernobyl radiation. Against expectations, there does not seem to be an increase in leukemia or solid cancers like lung cancer, according to the International Atomic Energy Agency, the Chernobyl Forum, the United Nations Scientific Committee of the Effects of Atomic Radiation (UNSCEAR), and the World Health Organization (WHO) Radiation Program. The International Physicians for the Prevention of Nuclear War has argued that the thyroid cancer figure is at least 10,000, with 50,000 more expected as a result of ongoing radiation exposure. Outside the highly contaminated zone, there are an estimated 5,000 cancer deaths and an unknown number of additional cancer cases that are attributable to Chernobyl gamma rays.

Radiotrophic fungus, appearing similar to black mold, has been discovered growing inside and near the Chernobyl Power Plant, having evolved the ability to convert gamma radiation into chemical energy. They thrive on radiation the way other
plants thrive on sunlight, and demonstrate once again the unbelievable versatility of life.

Radiation, Ionizing

Ionizing radiation is any radiation that carries enough energy to ionize electrons by freeing them from atoms. It consists of ions, atoms, subatomic particles, and electromagnetic waves. Ionizing radiation includes the upper part of the ultraviolet spectrum, gamma rays, and X-rays. Radio waves, microwaves, infrared light, and visible light are nonionizing. Ionizing radiation occurs naturally through cosmic rays, radioactive decay, lightning, plasma discharge, the high temperatures of the solar corona, and phenomena like supernovae, and it is generated through a variety of means, including X-ray tubes, particle accelerators, nuclear power, and the detonation of atomic bombs.

Ionizing radiation is both important to the medical field and a source of serious health hazards. Different types of ionizing radiation vary considerably. Alpha, beta, and gamma rays all result from radioactive decay, for instance. While all three can be damaging, alpha and beta particles are stopped by fairly thin materials and don't penetrate further than the skin, and so they cause radiation burns — this damage can result in skin cancer as well. Gamma radiation, on the other hand — named because it is produced later than alpha and beta — not only penetrates the body, but can do so after passing through shielding that is 12 inches thick (depending on its intensity). The gamma radiation released as a result of the 1986 Chernobyl Power Plant meltdown has resulted in at least 10 thousand — and very possibly tens of thousands of — cases of thyroid cancer, and continues almost 30 years later to be a severe health hazard.

Ionizing radiation's most common and most serious health impact is in inducing cancer that develops years or even decades after exposure. Scientists understand how ionizing radiation causes cancer, but there is much less consensus about the frequency with which it happens. As a result, there is considerable disagreement about the risks of exposure, and about projections of future cancer rates related to Chernobyl and, more recently, the 2011 Fukushima nuclear disaster in Japan. Ionizing radiation can similarly cause cognitive decline and heart disease, again developing long after exposure.

The culprit in Chernobyl-related thyroid cancer, and in similar problems in the aftermath of the significantly smaller Fukushima disaster, is iodine-131, or radioactive iodine. A radioactive isotope of iodine, it's a major uranium, plutonium fission product, and causes mutation and death in penetrated organic cells. However, it's also used for medicinal purposes, to treat hyperthyroidism, Graves' disease, and some cancers, including thyroid cancer, neuroblastoma, and pheochromocytoma. The related isotope iodine-125 lacks beta radiation, emitting only low-energy but deep-penetrating gamma rays, and so is used in diagnostic testing as well as brachytherapy.

Brachytherapy is also called sealed source or internal radiotherapy, and is an important form of radiation therapy in the treatment of cancers. In brachytherapy, instead of being exposed to a beam of radiation originating outside the body, the patient is treated via a radiation source that is placed inside the body. Radioisotopes like iodine-125 and other sources of ionizing radiation (cesium-137, cobalt-60, iridium-192, palladium-103, and ruthenium-106 are all common) are enclosed inside a capsule or wire to prevent them from moving inside the body or being dissolved by body fluids. This allows for highly targeted radiation exposure in order to kill
off tumor cells, and for a faster course of treatment than external beam radiotherapy. The strength of brachytherapy is the ability to use a high dose of radiation on a very small area, ideally minimizing the destruction of healthy tissue associated with both radiation therapy and chemotherapy. Minimizing that destruction cuts down on side effects, and also reduces the extent to which the treatment interferes with and limits the body’s natural ability to heal and cure itself. Patients who have difficulty taking time off from work for treatment, or who live far from their treatment center, especially benefit from the convenience of brachytherapy. The treatment is also useful in cases where surgery isn’t technically feasible or doesn’t offer the best chance of a cure, though there are also cases combining brachytherapy with surgery.

Brachytherapy is most commonly used in treating breast, skin, cervical, and prostate cancer, but can treat tumors in many parts of the body. Contact brachytherapy puts the radiation source next to the targeted tissue, such as inside a body cavity like the cervix, on the surface of the skin to treat a skin cancer, or in the empty space of the trachea or esophagus. Interstitial brachytherapy, in contrast, is placed directly inside the targeted tissue, as with breast cancer.

Doses vary and are generally discussed in terms of four types: low-dose rate (LDR) brachytherapy, which is common for oral cancers, sarcomas, and prostate cancer; medium-dose rate (MDR), which is less common; high-dose rate (HDR), which is used for many interstitial applications of brachytherapy, especially in treating breast and prostate cancer; and pulsed-dose rate (PDR), which uses short pulses once an hour, to treat head and neck or gynecological cancers. Temporary brachytherapy applies the radiation source for anywhere between a few minutes (in the case of high-dose rate brachytherapy) to a 24-hour period for pulsed-dose rate, while permanent brachytherapy implants small radioactive pellets the size of rice grains, which are allowed to gradually but permanently decay inside the tumor tissue. This is the common form of brachytherapy used for treating prostate cancer.

For cervical cancer, LDR, PDR, or HDR brachytherapy are all possibilities, depending on the individual case. In prostate cancer, permanent brachytherapy is typically used for patients who have not metastasized and have a good prognosis.
erectile dysfunction in prostate cancer patients, ongoing digestive or urinary issues for prostate or cervical cancer patients, and fat necrosis (resulting in swollen tender breasts beginning some months after treatment) in breast cancer patients.

Radiation Therapy

Cancer refers to the group of diseases that occur when cells from organs or tissues grow out of control. This growth can materialize as a mass or tumor, which can dislocate healthy cells. A tumor can spread to nearby tissues or organs as tiny cells detach and journey throughout the body, through the blood or lymph system, and begin growing in new locations. Radiation therapy uses targeted energy (e.g., X-rays, radioactive substances) to destroy cancer cells, shrink tumors, and/or alleviate certain cancer-related symptoms.

The medical field has utilized radiation therapy as a treatment for cancer for over a century, with its initial origins traced to the discovery of X-rays in 1895 by Wilhelm Röntgen. Emil Grubbe is recognized as the first American physician to use X-rays to treat cancer, beginning in 1896. The arena of radiation therapy began to grow in the early 1900s mostly due to the revolutionary work of the scientist Marie Curie, who discovered the radioactive elements polonium and radium in 1898. This discovery ushered in a new era of medical research and the development of new treatments. Radium was utilized in various forms until the mid-1900s, when cobalt therapy and cesium units came into use. Radium became medical linear accelerators, which have been utilized as radiation sources since the late 1940s.

In 1971, when Godfrey Hounsfield invented computed tomography (CT), three-dimensional planning became a possibility and created a shift from two-dimensional to three-dimensional radiation delivery. CT-based planning allows physicians to make a more precise determination regarding the dosage distribution, using axial tomographic images of the patient’s anatomy. Megavoltage linear accelerators, useful for their penetrating energies and lack of physical radiation source have essentially replaced Orthovoltage and cobalt.

Historically, the three leading classifications of radiation therapy are external beam radiation therapy (EBRT or XRT) or teletherapy, brachytherapy or sealed source radiation therapy, and systemic radioisotope therapy or unsealed source radiotherapy. These are distinguished by the position of the radiation source; external is external the body, brachytherapy utilizes sealed radioactive sources placed accurately in the treatment area, and systemic radioisotopes are given by infusion or oral ingestion. Brachytherapy can use temporary or permanent placement of radioactive sources. The temporary sources are usually placed by a technique called afterloading. In afterloading a hollow tube or applicator is placed surgically in the organ to be treated, and the sources are loaded into the applicator after the applicator is implanted. This minimizes radiation exposure to health care personnel who are administering the radiation therapy. Particle therapy is a special case of external beam
Radiation therapy where the particles are protons or heftier ions. Intraoperative radiation therapy or IORT is a special type of radiation therapy that is delivered immediately after surgical removal of the cancer. This method has been employed in breast cancer (TARGeted Introperative radiation therapy or TARGIT), brain tumors, and rectal cancers.

The introduction of new imaging technologies, including magnetic resonance imaging (MRI) in the 1970s and positron emission tomography (PET) in the 1980s, has led to the creation of more targeted treatment practices. Three-dimensional conformal radiation therapy has given way to intensity-modulated radiation therapy (IMRT) and image-guided radiation therapy (IGRT) tomotherapy which permit radiation oncologists to zoom in on tumors. The result is improved therapy outcomes, more organ preservation, and fewer side effects.

**Radiation Therapy Explanation**

Radiation therapy, also known as radiotherapy, or radiation oncology (frequently abbreviated RT, RTx, or XRT), is the medical utilization of ionizing radiation, commonly as part of cancer treatment, to manage or kill malevolent cells. Radiation therapy could be restorative in numerous forms of cancer if it is localized in a single area of the body. It could also be utilized as a portion of adjuvant therapy, to prevent tumor recurrence after surgery or to remove a primary malevolent tumor, such as in the early stages of breast cancer. Radiation therapy is cooperative with chemotherapy, and has been utilized before, during, and after chemotherapy in sensitive cancers. Radiation therapy utilizes targeted energy to abolish cancer cells, minimize tumors, and/or relieve specific cancer-related indications. In other words, this type of therapy could be utilized as a primary remedy to abolish cancer cells; in amalgamation with other treatments to impede the growth of cancer cells; before another treatment to minimize a tumor; after another treatment to impede the growth of any remaining cancer cells; and to relieve indications of progressive cancer.

Radiation therapy is commonly applied to the cancerous tumor because of its ability to control cell growth. Ionizing radiation works by damaging the DNA of cancerous tissue leading to cellular demise. To spare normal and healthy tissues such as skin or organs, which radiation must pass through to treat the tumor, shaped radiation beams are aimed from numerous angles of exposure to intersect at the tumor, providing an increased absorbed dosage at the site. The radiation fields could also include the draining lymph nodes if they clinically or radiologically involve with a tumor, or if there is a cause of subclinical malevolent spread assumptions. It is mandatory to include a margin of normal tissue around the tumor to allow for uncertainties in daily set-up and internal tumor motion. These uncertainties can be actualized by internal movement (for example, respiration, and bladder filling) and development of external skin blemishes relative to the tumor position. Radiation therapy has numerous applications in non-malevolent conditions, such as the remedy of trigeminal neuralgia, acoustic neuromas, severe thyroid eye disease, pterygium, pigmented villonodular synovitis, prevention of keloid scar growth, vascular restenosis, and heterotopic ossification. Utilization of radiation therapy in non-malevolent conditions is limited partly by worries about the occurrence of radiation-induced cancers.

Radiation oncology is the medical specialty concerned with prescribing radiation, and is distinct from radiology, the use of radiation in medical imaging and diagnosis. Radiation could be recommended by a radiation oncologist for curative or for adjuvant therapy. It could also be utilized as palliative treatment (where cure is not possible and the aim is for local disease control or symptomatic relief) or as a therapeutic remedy (where the therapy has survival benefit and it can be curative).

**Radiation Therapy Methods**

*External beam radiation therapy* is directed from a machine external the body onto cancerous cells within the body. Examples of this type of radiation therapy are 3D conformal radiation therapy, IMRT, IGRT, TomoTherapy, and stereotactic radiosurgery. External beam radiotherapy or teletherapy is the most common form of radiotherapy. The patient sits or lies on a couch and an external source of radiation is pointed at the affected part of the body. In contrast to internal radiotherapy (brachytherapy), in which the radiation source is inside the body, external beam radiotherapy directs the radiation at the tumor from outside the body. Kilovoltage X-rays are utilized for treating skin cancer and superficial structures; while megavoltage X-rays are utilized to treat deep-seated tumors (e.g., bladder, bowel, prostate, lung, or brain). Despite the fact that
X-ray and electron beams are by far the most widely utilized sources for external beam radiotherapy, a small number of centers operate experimental and pilot programs employing heavier particle beams, particularly proton sources.

Conventional external beam radiation therapy (2DXRT) is delivered via two-dimensional beams using linear accelerator machines. 2DXRT mainly consists of a single beam of radiation delivered to the patient from numerous directions: often front or back, and both sides. Conventional refers to the way the remedy is planned or simulated on a specially calibrated diagnostic X-ray machine known as a simulator because it re-creates the linear accelerator actions (or sometimes by eye), and to the usually well-established arrangements of the radiation beams to achieve a desired plan. The aim of simulation is to accurately target or localize the volume that is to be treated. This technique is well established and is generally quick and reliable. The apprehension is that some high-dosage remedies could be limited by the radiation toxicity capacity of healthy tissues, which lie close to the target tumor volume. An example of this problem is seen in radiation of the prostate gland, where the sensitivity of the adjacent rectum limited the dosage, which could be safely prescribed using 2DXRT planning to such an extent that tumor control could not be easily achievable.

Prior to the invention of CT, physicians and physicists had limited knowledge about the true radiation dosage delivered to both cancerous and healthy tissue. As a result, 3-dimensional conformal radiation therapy is becoming the standard remedy for a number of tumor sites. Worth mentioning, a new technique to reduce rectal radiation damage in prostate cancer patients involves the employment of an absorbable spacer placed between the prostate and rectum. It has been shown via MRI that a hydrogel spacer can push the rectum away from the prostate in the course of radiotherapy. Note that such spacers are commercially obtainable in some areas, and are a part of clinical trials in others. As a result of provisionally modifying the anatomy, these products have the capacity to allow for improved cancer targeting while minimizing risk to bordering healthy tissues. For all intents and purposes, prostate rectum spacers should be compatible with all prostate cancer radiotherapy treatments including 3D conformal, IMRT, stereotactic radiation, and brachytherapy.

Internal radiation therapy (brachytherapy) is a radioactive material placed directly into or near a tumor via a catheter or other carrier, such as a high-dosage rate brachytherapy. Brachytherapy is delivered by placing radiation sources inside or next to the area requiring remedy. Brachytherapy is commonly utilized as an effective remedy for cervical, prostate, breast, and skin cancer and can be utilized to treat tumors in many other body locations. As with stereotactic radiation, brachytherapy remedies are often known by their brand names. For example, brand names for breast cancer brachytherapy remedies include SAVI, MammoSite, and Contura. Brand names for prostate cancer include Proxcelan, TheraSeed, and I-Seed. In brachytherapy, radiation sources are precisely placed directly at the site of the cancerous tumor, which means that the irradiation affects are much localized. These characteristics of brachytherapy provide advantages over external beam radiation therapy: the tumor can be treated with very high dosages of localized radiation, at the same time reducing the probability of unnecessary damage to surrounding healthy tissues. A treatment of brachytherapy can frequently be completed in less time than other radiation therapy practices. This can help reduce the chance of surviving cancer cells dividing and growing in the intervals between each radiation therapy dosage. As one example of the localized disposition of breast brachytherapy, the SAVI device delivers the radiation dosage through multiple catheters, each of which can be individually regulated. This approach decreases the exposure of healthy tissue and resulting side effects, compared to both external beam radiation therapy and older methods of breast brachytherapy.

Systemic radiation therapy is a radioactive substance that is swallowed or injected and journeys through the blood to locate and abolish cancerous cells. An example of this type of radiation therapy is radioactive iodine therapy. Systemic radioisotope therapy is a form of targeted therapy; targeting can be due to the chemical properties of the isotope such as radioiodine. This process is specifically absorbed by the thyroid gland much better than by other bodily organs. Targeting can also be accomplished by attaching the radioisotope to another
molecule or antibody to guide it to the target tissue. The radioisotopes are delivered through infusion (into the bloodstream) or ingestion. Examples are the infusion of metaiodobenzylguanidine (MIBG) to treat neuroblastoma, of oral iodine-131 to treat thyroid cancer or thyrotoxicosis, and of hormone-bound lutetium-177 and yttrium-90 to treat neuroendocrine tumors, and peptide receptor radionuclide therapy. Another example is the injection of yttrium-90 radioactive glass or resin microspheres into the hepatic artery to radioembolize liver tumors or liver metastases. These microspheres are utilized for the remedy approach known as selective internal radiation therapy. The microspheres are approximately 30 μm in diameter (about one-third of a human hair) and are delivered directly into the artery supplying blood to the tumors. These remedies begin by guiding a catheter up through the femoral artery in the leg, navigating to the desired target site, and administering remedy. The blood feeding the tumor will carry the microspheres directly to the tumor enabling a more selective approach than traditional systemic chemotherapy. There are currently two different kinds of microspheres: SIR-Spheres and TheraSphere. A major use of systemic radioisotope therapy is in the remedy of bone metastasis from cancer. The radioisotopes move carefully to areas of damaged bone, and spare normal undamaged bone. Isotopes commonly utilized in the remedy of bone metastasis are strontium-89 and samarium (153Sm) lexidronam.

**Radiation Therapy Side Effects**

There are actually two kinds of side effects from radiation therapy; they are early and late. Early side effects, such as nausea or fatigue, are usually momentary. They cultivate during or right after radiation therapy treatments and last for numerous weeks after remedy ends, but then improve. Late side effects, such as lung or heart problems, could take years to develop and are often permanent when they do. The most common early side effects from radiation therapy are fatigue and skin problems. Other early side effects such as hair loss and nausea are typically specific to the site being treated.

Radiation therapy itself does not impose pain on the patient. Many low-dosage palliative remedies (i.e., radiation therapy to bony metastases) cause minimal or no side effects, although temporary pain outbreak can be experienced in the days following treatment due to edema compressing nerves in the treated area. Higher dosages can cause varying side effects during remedy, which are acute, in the months or years following remedy long-term side effects, or after remedy, cumulative side effects. The nature, severity, and longevity of side effects depends on the organs that receive the radiation, the treatment itself (type of radiation, dosage, fractionation, concurrent chemotherapy), and the patient. Most side effects are predictable and expected.

Side effects from radiation are usually limited to the area of the patient’s body that is under treatment. Modern radiation therapy aims to reduce side effects to a minimum and to help the patient understand and deal with those inevitable side effects. The main side effects reported are fatigue.
and skin irritation, like a mild to moderate sunburn. The fatigue often sets in during the middle of a course of radiation remedy and can last for weeks after radiation ends. The irritated skin will heal, but may not be as elastic as it was before.

**Early Side Effects.** This is not a general side effect of radiation therapy, and mechanistically is associated only with remedy of the stomach or abdomen that commonly react a few hours after remedy or with radiation therapy to specific nausea producing structures in the head during remedy of certain head and neck tumors, most commonly the vestibules of the inner ears. As with any distressing remedy, some patients vomit immediately during radiotherapy, or even in anticipation of it, but this is considered a psychological response.

Epithelial surfaces could sustain damage from radiation therapy. Depending on the area being treated, this could include the skin, oral mucosa, pharynx, bowel mucosa, and ureter. The rates of onset of damage and recuperation from it depend upon the turnover rate of epithelial cells. Typically, the skin starts to become pink and sore numerous weeks into remedy. The reaction could become more severe during the remedy and for up to about one week following the end of radiation therapy, and the skin could break down. Although this moist desquamation is uncomfortable, recuperation is usually quick. Skin reactions tend to be worse in areas where there are natural folds in the skin, such as underneath the female breast, behind the ear, and in the groin.

**Late Side Effects.** These occur months to years after remedy and are generally limited to the area that has been treated. They are often due to damage of blood vessels and connective tissue cells. Many late effects are reduced by fractionating remedy into smaller parts. Fibrosis is experienced; tissues, which have been irradiated, tend to become less elastic over time due to a diffuse scarring process. Epilation (hair loss) could occur on any hair bearing skin with particular dosages. It only occurs within the radiation field(s). Hair loss could be permanent with a single dosage of a precise amount, but if the dosage is fractionated permanent hair loss could not occur until dosage exceeds that specified amount. Dry mouth (xerostomia) and dry eyes (xerophthalmia) can become irritating long-term problems and severely reduce the patient’s quality of life. In the same way, sweat glands in treated skin for example of the armpit tend to impede working, and the naturally moist vaginal mucosa is often dry following pelvic irradiation. Lymphedema, a condition of localized fluid retention and tissue swelling, can result from damage to the lymphatic system sustained during radiation therapy. It is the most commonly reported complication in breast radiation therapy patients who receive adjuvant axillary radiotherapy following surgery to clear the axillary lymph nodes.

Radiation is a potential cause of cancer, and secondary malignancies are seen in a very small minority of patients—usually less than 1/1,000. It usually occurs 20 to 30 years following remedy, although some haematological malignancies could develop within 5 to 10 years. In the vast majority of cases, the empirical risk is greatly outweighed by the reduction in empirical risk conferred by treating the primary cancer. The cancer occurs within the treated area of the patient. Radiation has possibly excess imperial of demise from heart disease seen after some past breast cancer RT regimens. In cases of radiation applied to the head radiation therapy could cause cognitive decline. Cognitive decline was especially apparent in young children, between the ages of 5 and 11. Studies found, for example, that the IQ of 5-year-old children declined each year after remedy by numerous IQ points. Radiation proctitis can involve long-term effects on the rectum including bleeding, diarrhea, and urgency and is associated with radiation therapy to pelvic organs. Pelvic radiation therapy can also cause radiation cystitis when the bladder is affected.

**Cumulative Side Effects.** Cumulative effects from this process of radiation therapy should not be confused with long-term effects—when short-term effects have disappeared and long-term effects are subclinical, re-irradiation can still be problematic. During the first two weeks after fertilization, radiation therapy is lethal but not teratogenic. High dosages of radiation during pregnancy induce anomalies, impaired growth, and intellectual disability, and there could be an increased empirical risk of childhood leukemia and other tumors in the offspring. In males previously having undergone radiotherapy, there appears to be no increase in genetic defects or congenital malformations in
their children conceived after therapy. However, the use of assisted reproductive technologies and micromanipulation techniques might increase this risk.

Different people have different side effects with radiation. You could have little or only mild side effects from your remedy; someone else could have many or very severe side effects. Unfortunately, it is impossible to predict who will have what side effects. In addition, the specific side effects you could have depend on the type of radiation being utilized, the dosage of radiation, the area of the body that is being targeted, and the state of your health.

Conclusion
Cancer cells duplicate quicker than normal cells in the human body; radiation therapy focuses on these rapidly dividing cells. Radiation therapy involves the use of high dosages of radiation to kill cancer cells. New developments have made radiation therapy safer and more effective than ever. External radiation remedies are scheduled four or five days a week for numerous weeks. You must complete all sessions to achieve the best result. Internal radiation therapy is now being utilized for more types of cancer. Patients who experience side effects should contact their medical practitioner or nurse right away. Patients of radiation therapy are recommended to take good care of themselves by resting and eating properly. Skin in the treated area could become sensitive and easily irritated.

Approximately 60 percent of all cancer patients will require radiation therapy as part of their care. Radiation therapy can be utilized to help cure cancer or to relieve indications alone or in combination with other therapies, such as surgery or chemotherapy. Overall, patients who need radiation will have treatments four or five days a week. This regimen can last for five to seven weeks. Generally, cancer patients receive radiation therapy for one to five minutes per remedy.

Further Readings

Raloxifene

Raloxifene was approved in 1997 for preventing bone loss in women after menopause. Subsequently, it was approved in 2007 for breast cancer prevention. On September 13, 2007, the U.S. Food and Drug Administration (FDA) approved raloxifene hydrochloride tablets (under the brand name Evista) to prevent and treat osteoporosis (bone thinning) in women past menopause. In bone cells, raloxifene acts like estrogen to prevent osteoporosis in women who have gone through menopause. It also helps to lower the fat in the blood, known as low-density lipids or “bad” cholesterol. Raloxifene can reduce breast cancer peril in these women, although it cannot entirely prevent it; it is not a cancer medication and is not considered a remedy for breast cancer.

Raloxifene is also utilized to reduce the peril of spinal fractures related to osteoporosis. In the course of studies, scientists noticed that among postmenopausal women who took the drug there was a lower rate of invasive breast cancer. After additional studies, the FDA approved the consumption of raloxifene for prevention of breast cancer. Raloxifene is a selective estrogen receptor modulator (SERM). SERMs have anti-estrogen influences on some tissues and estrogen-like influences on other tissues. To be clear, they are utilized to reduce the peril of invasive breast cancer in postmenopausal women that are at a high peril of developing breast cancer. However, women who have already
had breast cancer should not consume it nor should it be utilized in the treatment of breast cancer.

**Raloxifene Administration**

Raloxifene improves osteoporosis by decreasing bone breakdown and thinning. It works to help prevent invasive breast cancer by blocking estrogen in breast and uterine tissue. One out of every four cancer diagnoses in women each year is invasive breast cancer which can be deadly if not detected and treated early. Noninvasive breast cancer remains in the milk ducts or lobules (lobes of the breast) and does not spread to the surrounding tissue. Invasive breast cancer, however, spans outward from the milk ducts and lobules into the surrounding breast tissue, and ultimately, travels to other areas of the body.

Raloxifene is comparable to the drug tamoxifen, which also blocks estrogen in breast tissue. Since raloxifene does not act extensively like estrogen in the uterus, it has a significantly lower peril of causing cancer of the uterus than tamoxifen. It may also cause fewer blood clots. Studies found raloxifene to be just as effective as tamoxifen in reducing breast cancer risk (by up to 40 percent), however with fewer side effects.

**Raloxifene Studies**

Research studies of raloxifene include the Multiple Outcomes of Raloxifene Evaluation (MORE) trial, the Raloxifene Consumption for the Heart (RUTH) trial, and the Continuing Outcomes Relevant to Raloxifene (CORE) trial. All of the before listed studies compared raloxifene to placebo, also known as a sugar pill, in women past menopause. Taken together, these three studies revealed a qualified peril of invasive breast cancer in excess of half (59 percent). The studies revealed about a 70 percent qualified reduction in the peril of ER-positive breast cancer. These studies were not designed to find differences in death rates between the groups taking the SERMs and the placebos, and no differences were observed. So far, women who took SERMs had no survival advantage (did not live longer), although more follow-up is needed. There were other studies, such as the Study of Tamoxifen and Raloxifene (STAR) and the Selective Estrogen Response Modifier (SERM) studies.

*The Study of Tamoxifen and Raloxifene (STAR).* The largest study to look at the effect of raloxifene on breast cancer peril was the STAR trial. This study compared the influences of tamoxifen and raloxifene on breast cancer peril in more than 19,000 women past menopause who had an increased peril of breast cancer. Half were assigned to take tamoxifen and half were assigned to take raloxifene each day for five years. Both drugs reduced the peril of breast cancer, although tamoxifen seemed to reduce the peril more.

*Selective Estrogen Response Modifier (SERM) Studies.* A 2013 analysis put together the data from well-controlled studies, which (combining all of the studies cited above with a couple of contemporary ones) was an accumulation in excess of 80,000 women. The researchers concluded that SERM drugs lowered breast cancer peril by 38 percent over a period of 10 years—the five years of taking the drug plus the next five years. Based on the rate of breast cancer in the studies in the analysis, this would translate to about one case of invasive breast cancer being prevented for every 53 women taking a SERM drug. If you include non-invasive breast cancers such as ductal carcinoma in situ (DCIS), only about 42 women must take SERMs for five years to prevent one case of breast cancer with respect to a 10-year peril of breast cancer of around 6 percent. By definition, DCIS is a noninvasive form of breast cancer because the cancer cells are confined to the milk ducts of the breast. DCIS does not cause any symptoms. Rarely, a woman may feel a lump in the breast or have nipple discharge. However, most cases of DCIS are detected with a mammogram.

For a group of women with higher peril, the number that would need to be treated would be much lower. You would need to treat many more women to prevent one case of breast cancer if the group started out with a lower peril. Understand that some of the SERMs utilized in this large analysis are only available in Europe, but most of the women took tamoxifen and raloxifene. Studies continue to show that SERMs do not reduce the peril of endocrine receptor (ER) negative breast cancers. These cancers are more common in younger women and those with BRCA1 mutations. Although these drugs have not specifically been studied in women with BRCA mutations, it is not clear how helpful they are in those women.

*BCPT Trial.* In this trial, tamoxifen did not seem to help women with BRCA1 genetic mutations, but
it did seem to help those with BRCA2 mutations. BRCA1 and BRCA2 are human genes that produce tumor suppressor proteins. These proteins help repair damaged DNA and, therefore, play a role in ensuring the stability of the cell’s genetic material. When either of these genes is mutated, or altered, such that its protein products are not made or do not function correctly, DNA damage may not be repaired properly. As a result, cells are more likely to develop additional genetic alterations that can lead to cancer.

**RUTH, MORE, and CORE Trials.** Protection and efficiency for reduction in the peril of invasive breast cancer in postmenopausal women with osteoporosis were demonstrated in three clinical trials (RUTH, MORE, and CORE).

**The MORE (Multiple Outcomes of Raloxifene Evaluation) Trial.** This trial was a randomized, placebo-controlled, double-blind, multinational osteoporosis treatment study in 5,133 postmenopausal women. The effect of raloxifene hydrochloride on the incidence of breast cancer was assessed as a secondary safety endpoint. After a median of four years on treatment, raloxifene hydrochloride reduced the incidence of invasive breast cancer by 71 percent compared with placebo. There were 11 invasive breast cancers in 2,557 women on the raloxifene hydrochloride arm compared to 38 in 2,576 women on the placebo arm.

**The CORE (Continuing Outcomes Relevant to Raloxifene) Trial.** This trial was a follow-up study conducted in a subset of 4,011 postmenopausal women originally enrolled in the MORE trial. After a median of three additional years on treatment, raloxifene hydrochloride reduced the incidence of invasive breast cancer by 56 percent compared with placebo. There were 19 invasive breast cancers in 2,716 women on the raloxifene hydrochloride arm compared to 20 in 1,274 women on the placebo arm.

**The RUTH (Raloxifene Consumption for the Heart) Trial.** This trial was a randomized, placebo-controlled, double-blind, multinational study in 10,101 postmenopausal women at increased peril of coronary events. After a median of five years on treatment, raloxifene hydrochloride reduced the incidence of invasive breast cancer by 44 percent compared with placebo. There were 40 invasive breast cancers in 5,044 women on the raloxifene hydrochloride arm compared to 70 in 5,057 women on the placebo arm.

In the MORE, CORE, and RUTH trials, the reduction in incidence of breast cancer was primarily due to a reduction in the incidence of ER-positive invasive breast cancers. There was no reduction in ER-negative invasive breast cancers, and there was no difference in incidence of noninvasive breast cancers between the raloxifene hydrochloride and placebo groups. Most invasive breast cancers were stage I or II. The number of women required to be treated for one year to prevent an invasive breast cancer in one woman ranged from 323 to 862 in the three trials.

**Risks of Raloxifene**

Raloxifene is the second drug to be approved by the FDA to prevent invasive forms of breast cancer. The first drug, tamoxifen, has been on the market for several decades. Raloxifene works by blocking estrogen in the breast tissue of women at high peril. The medication helps prevent the spread of tumors that require estrogen to grow. Raloxifene is not effective, however, in women who currently have invasive breast cancer or who have had invasive breast cancer. It will not prevent cancer in these women, nor will it treat cancer once it appears. Although raloxifene can reduce the likelihood of invasive breast cancer, it is important to be aware of its serious side effects.

Those serious side effects include but are not limited to increased chance of blood clots in the lungs and legs; and increased chance of stroke in women with coronary artery disease. Other milder side effects include those of leg cramps; joint pain; swelling of the extremities; flu-like symptoms; sweating and hot flashes; trouble sleeping; and vaginal dryness and discomfort. Experts caution that some women who take raloxifene will still get invasive breast cancer. Therefore, women need to consider the pros and cons of taking a medication with very serious side effects.

As discussed previously, protection and effectiveness for decrease in the peril of invasive breast cancer in postmenopausal women at high peril of breast cancer were evaluated in the STAR (Study of Tamoxifen and Raloxifene) trial. The influences of raloxifene hydrochloride 60 mg/day versus
The results from a non-inferiority analysis are consistent with raloxifene hydrochloride potentially losing up to 35 percent of the tamoxifen effect on reduction of invasive breast cancer. Fewer noninvasive breast cancers occurred in the tamoxifen group compared to the raloxifene hydrochloride group. Raloxifene hydrochloride had a lower incidence of deep vein thrombosis, pulmonary embolism, cataract surgery, and hysterectomy than tamoxifen and there was a trend for a lower incidence of endometrial cancer.

Raloxifene hydrochloride is associated with an increased peril of deep vein thrombosis, pulmonary embolism, and retinal vein thrombosis. An increased peril of death due to stroke was observed in a trial in postmenopausal women with documented coronary heart disease or at increased peril for major coronary events. If you have heart problems or are at peril for a serious heart problem, it is recommended that a consultation occur with a physician to be sure that the benefits of using raloxifene outweigh the perils. Raloxifene may increase the peril of serious blood clots. It is recommended that individuals who have a history of serious blood clots (e.g., in the lung, leg, or eye) do not take raloxifene. Other adverse reactions (greater than two percent and more common than with placebo) include hot flashes, leg cramps, peripheral edema, flu syndrome, arthralgia, and sweating. Each individual postmenopausal woman’s peril/benefit ratio must be carefully considered.

**Indications of Raloxifene**

Hormones are chemical substances that are produced by glands in the body, which enter the bloodstream and cause influences in other tissues. For example, the hormone testosterone is made in the testicles and is responsible for male characteristics such as deepening of the voice and increased body hair. The use of hormone therapy to treat cancer is based on the observation that receptors for specific hormones that are needed for cell growth are on the surface of some tumor cells. Hormone therapy can work by stopping the production of a certain hormone, blocking hormone receptors, or substituting chemically similar agents for the active hormone, which cannot be utilized by the tumor cell. Their function and/or the type of hormone that is affected categorize the different types of hormone therapies.

Raloxifene is indicated for the reduction in peril of invasive breast cancer in postmenopausal women at high peril of invasive breast cancer. The effect in the reduction in the incidence of breast cancer was shown in a study of postmenopausal women at high peril for breast cancer with a five-year planned duration with a median follow-up of 4.3. Twenty-seven percent of the participants received drug for five years. The long-term influences and the recommended length of treatment are not known. High peril of breast cancer is defined as at least one breast biopsy showing lobular carcinoma in situ (LCIS) or atypical hyperplasia,
one or more first-degree relatives with breast cancer, or a five-year predicted peril of breast cancer ≥1.66 percent (based on the modified Gail model). Among the factors included in the modified Gail model are the following: current age, number of first-degree qualifies with breast cancer, number of breast biopsies, age at menarche, null parity, or age of first live birth. Currently, no single clinical finding or test result can quantify peril of breast cancer with certainty. After an assessment of the peril of developing breast cancer, the decision regarding therapy with raloxifene should be based upon an individual assessment of the benefits and perils. Raloxifene does not eliminate the peril of breast cancer.

Patients should have breast exams and mammograms before starting raloxifene and should continue regular breast exams and mammograms in keeping with good medical practice after beginning treatment with raloxifene. Imperative limitations of consumption for breast cancer peril reduction do exist. There are no data available regarding the effect of raloxifene on invasive breast cancer incidence in women with inherited mutations (BRCA1, BRCA2), which allows for specific recommendations on the effectiveness of raloxifene. Raloxifene is not indicated for the treatment of invasive breast cancer or reduction of the peril of recurrence. Raloxifene is not indicated for the reduction in the peril of noninvasive breast cancer.

**Raloxifene Administration**
The recommended dosage is one 60 mg raloxifene hydrochloride tablet daily, which may be administered any time of day without regard to meals with a full glass of water once a day. There is no intravenous (IV) preparation available. If a dose is missed, it is recommended not to take a double dose the next day. In addition to raloxifene, a health care provider may recommend that the patient take a calcium supplement with vitamin D (absorbs calcium better). The amount of raloxifene that is prescribed depends on many factors, including your general health or other health problems, and the type of cancer or condition being treated. A physician will determine the dose and length of time to take raloxifene. Before starting raloxifene treatment, it is recommended to alert the prescribing physician about any other medications (including prescription, over-the-counter, vitamins, herbal remedies, etc.). Recommendations suggest not to take aspirin, or products containing aspirin, unless your physician specifically permits this, since this medicine may increase your peril for developing blood clots.

Raloxifene may cause fetal harm when given to a pregnant woman. Raloxifene must not be given to a pregnant woman or a woman who intends to become pregnant. If a woman becomes pregnant while taking raloxifene, the medication must be discontinued without delay and the woman given appropriate counseling. Furthermore, it is recommended for both men and women, not to conceive a child (get pregnant) and to utilize contraception while taking raloxifene; nor should a mother breastfeed while on the drug. A physician should approve when it is safe to become pregnant or conceive a child after therapy.

Raloxifene self-care tips include but are not limited to wearing light clothing, staying in a cool environment, and putting cool cloths on your head to reduce symptoms if hot flashes are experienced. In addition, a physician should be contacted if the hot flashes worsen, or become intolerable. For flu-like symptoms, keep warm with blankets and drink plenty of liquids. There are medications that can help reduce the discomfort initiated by chills. Acetaminophen or ibuprophen may help relieve discomfort from fever, headache, and/or generalized aches and pains. However, be sure to talk with a physician before taking it.

Raloxifene causes little nausea. Nevertheless, if nausea is experienced, take antinausea medications as prescribed by your physician, and eat small frequent meals. Sucking on lozenges and chewing gum may also help. Exercise is recommended as often as possible. Light walking four or five times per week, for 20 to 30 minutes at a time will increase your energy level, decrease your chance of developing blood clots, and help strengthen your bones. Other self-care tips involve avoiding sun exposure by wearing SPF 15 (or higher) sunblock and protective clothing. In general, drinking alcoholic beverages should be kept to a minimum or avoided completely; as well as getting plenty of rest and maintaining good nutrition. Any symptoms or side effects experienced while taking raloxifene should be discussed with a health care provider, as he or she can prescribe medications and/or offer other suggestions that are effective in managing such problems.
Monitoring and testing occurs while taking raloxifene. A health care provider will want to do blood tests to see how well the patient is responding to raloxifene; as such, all appointments for tests and office visits should be carried out. Women will need a gynecologic examination before therapy, and in the course of therapy, at regular intervals; the appropriate schedule should be discussed with your health care provider. In addition, bone mineral density (BMD) should be done periodically to determine how strong your bones are; a patient may need this at least every two years or sooner if your health care provider suggests. Your physician may also monitor other types of blood work, to see if the medication is affecting other parts of your body.

Rectal Cancer

The international impact of rectal cancer has not been established due to the scarcity in the number of studies that investigate the epidemiology of this disease. Rectal cancer is considered as a malignancy that is strongly influenced by ethnicity, as well as geographic distribution. Based on the limiting features of this malignancy, the details of its etiology have remained uncertain.

The incidence of rectal cancer globally is generally very low, though in some parts of the world, the rates are relatively high. For example, in certain populations in southern China, north Africa, southeast Asia, and the Arctic region, rectal cancer is recognized as the most common type of malignancy. The unique distribution of rectal cancer in specific geographical areas indicates that its occurrence may be influenced by environmental and genetic factors.

To determine the impact of environmental and genetic factors on the incidence of rectal cancer, it is essential to initially establish the global incidence rate of this malignancy. However, previous reports have shown varying rates of rectal cancer due to the lack of integration in conducting epidemiological studies. Additionally, mortality data has not been established, as most of the areas afflicted by rectal cancer do not have a health registry to record deaths from the disease. The best source for statistics on rectal cancer both globally and on a country-by-country basis is the International Agency for Research on Cancer (IARC).

The IARC was established by the World Health Organization (WHO) to collect information on various cancers worldwide. The Section of Cancer Information maintains a large database that holds specific information on various cancers, such as incidence and mortality rates. The IARC lists international and national cancer registries. Unfortunately, the information on rates of specific cancers is limited to certain countries, and is therefore not a comprehensive record of less-common malignancies, including rectal cancer. In order to gather more comprehensive statistics on rectal cancer, scientists have begun integrating the data from various countries and reviewing the information for accuracy. The information collected in this database could be a starting point for further research on rectal cancer.
One of the major contributions of the IARC is GLOBOCAN, a database on the incidence of cancer in five continents. The data collected by GLOBOCAN is compiled into a report that represents information collected from 300 registries in a total of 61 countries around the world. Analysis of this data can then be used to identify countries showing the highest mortality rates for a specific cancer, as well as to determine the global trends in diagnosis. Epidemiologists utilize data from GLOBOCAN in order to develop preventive programs against specific cancers.

According to the GLOBOCAN data on rectal cancer, there are significant variations in the diagnosis of this specific disease around the world. Furthermore, the incidence of rectal cancer between males and females varied per country. For example, the incidence of rectal cancer in Central America was estimated as 0.2 per 100,000 person-years, whereas in southeast Asia the estimate was 6.5 per 100,000 person-years. The incidence rates for rectal cancer were lowest in Central America, South America, and western Europe. The highest incidence rates of rectal cancer were among males from southeast Asian countries such as Malaysia, Indonesia, Singapore, Cambodia, Brunei, and Myanmar.

The incidence rates of rectal cancer in females also varied per country. For example, among women in Central America the rate was 0.1, whereas in southeast Asia it was 2.8, reflecting at least a twofold increase. As with males, the highest incidences of rectal cancer among females were observed in the registries of southeast Asian countries, specifically Singapore, Myanmar, Indonesia, Bhutan, and Thailand.

Overall, statistics indicate that rectal cancer occurs at a higher rate among males than females, reaching a 200 percent increase. On the other hand, the low incidence rates of rectal cancer in both males and females in China were uniquely low, possibly reflecting a dilution in this specific population. However, in order to fully establish and validate this claim, additional investigations are warranted.

Another approach in studying the epidemiology of rectal cancer is through mortality rates. By comparing mortality rates between those of the World Health Organization and those collected by GLOBOCAN, it is possible to generate a more accurate estimate of this parameter within a five-year period. The mortality rates of rectal cancer varied across the globe, ranging from 0.1 among males in Central America to 4.2 among males in southeast Asia. Most of the registries showing the highest mortality rates involved males from counties in Asia, South Africa, and Micronesia. On the other hand, the lowest mortality rates were observed in countries of western and northern Europe, South Africa, Central America, and Melanesia. The mortality rates of rectal cancer in females ranged from 0.1 to 1.8 in Central America and southeast Asia, respectively. The highest mortality rates in females were observed in countries from Asia, South Africa, and Micronesia. However, in order to fully assess the severity of this particular malignancy on a global scale, additional studies covering more countries should be conducted.

Religion

Religion, as a form of social structure, can serve the function of influencing attitudes toward health and illness among individuals. Religion not only affects the mind; religious beliefs and practices can affect the physical state and health in general. Hence, the role of religion in cancer control and prevention cannot be underrated. Religion often involves faithful devotion to a deity, ritual beliefs and observances, and a set of normative values and behaviors.

While there are mixed opinions on the relationship between religion and health, most
Religion generally show a positive relationship. Specific religious practices found to be beneficial to health include prayer, regular church attendance (community), and faith-driven beliefs and practices. However, religion alone is not the defining factor regarding overall attitudes toward disease and illness. Individuals are also influenced by other social structures such as ethnicity, race, marital status, education, and income.

Association with religious groups can provide not only spiritual support, but emotional and economic support for individuals with cancer as well. In addition, religion can act as a coping mechanism for those afflicted with disease. Church-based support is considered a source of material and psychological sustenance.

The role of religion in reducing cancer mortality has been documented. Studies found reduced risk of cancer among members of religious groups characterized by doctrinal orthodoxy and behavioral conformity. Frequency of church attendance and general commitment are important predictors of cancer mortality among those with some religious affiliation.

It is believed that religious beliefs affect attitudes and behaviors on two levels. Health attitudes are shaped by doctrine or teaching, while health behaviors are indicators of the strength of devotion. Doctrine may prescribe behavioral expectations that impose certain lifestyles that prohibit known health risks (for example, banning alcohol or tobacco use).

Evidence shows lower rates of cancer among some religious groups due in part to their dietary and hygiene practices. It is generally observed that behaviors influenced by doctrines are found more often among adherents of conservative rather than liberal religious groups.

Ellen Idler in her research has identified four areas where religion (whether practiced publicly or privately) can have positive effects on health.

- **Health Behaviors**: Religious belief helps reduce health-destructive behaviors.
- **Social Cohesiveness**: Participation in religion can create a social network for coping and support.
- **Cognitive Coherence**: Faith can lead to a belief system that helps one make sense of life.
- **Theodicy**: Religious belief modifies perceptions of distress associated with physical suffering, often giving hope to the individual.

Émile Durkheim examined religion as having a beneficial effect on human social life and individual well-being because it regulates behavior and integrates individuals into caring social circles. It provides stability and support. Religious belief systems may include prohibitions against certain high-risk behaviors such as smoking, excessive alcohol use, or sexual experimentation, lowering the incidence among religious group members of illness and disease.

During times of critical illness, such as cancer, people turn to religion for support. Religious groups can offer physical and spiritual assistance to the sick through prayers, visits, and meals, among other things. These help to reduce distress and restore hope. Prayers are seen as a cognitive and emotional resource immediately accessible to the sick and disabled.

Religion’s role in prevention includes greater access to services and health information, and motivation to maintain a healthy lifestyle. Studies have demonstrated that women who attended church regularly were more likely to be screened for cervical cancer than women who never attended church services. However, there is no clear research on the role of religious beliefs and denominations and the use of preventive health care services.

The positive influence of religion can be felt across age, gender and ethnic group. However, certain psychological factors have been found to mediate the relationship between health and religion. These include perception of personal control over events in one’s life, cognitive processes, acceptance of other people or God, attribution of purpose and meaning to negative life events, and perceiving negative events in life as having an external cause and positive events as having an internal cause.

Individuals with fundamental religious beliefs are typically more optimistic, hopeful, and socially involved than those with liberal beliefs. Belief in the superiority of spiritual or religious intervention by a deity through prayers or other means may help explain why some people delay medical treatment. For example, it may explain why some women delay seeing a doctor regarding noticeable breast lumps,
thereby contributing to advanced stage breast cancer at diagnosis. In some studies religion and spirituality were positively related to health care, leading one to seek medical help for minor illness; but religion became a barrier to seeking help for more serious conditions such as cancer.

To understand the complex relationship between religion and health, it helps to examine the functions that religion serves for the faithful. Jean Byrne identified at least 10 needs that religion fulfills, and that interact with health decisions, including providing a source of social support and strength in critical times.

Church attendance has been correlated with better health outcomes. Data suggest that weekly religious attendance is associated with longer life, lower physical disability, faster recovery from depression, and greater life satisfaction. Naguib Samir and colleagues noted that religious support or church attendance is linked to lower cancer pain, lower risk of cancer, lower instances of colorectal cancer, and decreased incidence of cervical cancer.

During times of great difficulties, such as being diagnosed with cancer, religious belief may help provide a greater sense of purpose, since death is seen not as an end to life but rather a time in which one will be judged for their actions and given either eternal life or eternal condemnation.

Religion can be seen as one important factor in understanding complex social phenomena. Since religion has demonstrated an impact on the reduction of unhealthy behaviors such as alcohol abuse, smoking, drug abuse, and an unhealthy diet, it is possible to view religion as a tool in cancer control. Additionally, the social network that is part of organized religious practice could be used as a way to reach out to those living with cancer and to encourage compliance with cancer management recommendations.

Religion: Jewish Women and Cancer Risk

In the United States, ethnic Jewish women demonstrate a greater risk of early-onset breast cancer than the general population. In 1990, genetic mutations to the tumor-suppressing genes BRCA1 and BRCA2 were discovered in a group of Ashkenazi Jewish families of eastern European descent. Harmful mutations in these genes can increase the risk of cancer incidence in both women and men. These genetic mutations can be passed from parents to children by both mothers and fathers, and about 2.5 percent of the ethnic Ashkenazi Jewish population carries the mutations. Norwegian, Dutch, and Icelandic peoples have also been found to have higher incidence of harmful mutations to these genes. People with a family history of cancer can be tested for mutations in the BRCA1 and BRCA2 genes.

The BRCA1 and BRCA2 genes produce proteins that help to repair damaged DNA. Mutations in these genes cause higher incidence of breast and ovarian cancers when compared with cancer rates in the general population. Studies show that women with mutations to the BRCA1 gene (chromosome 17q21-q24) have a 60 percent chance of developing breast cancer and women with mutations to the BRCA2 gene (chromosome 13q12-q13) have a 45 percent chance of developing breast cancer. In contrast, women in the general population have a 12 percent chance of developing breast cancer. Women with a mutated BRCA1 gene have a 40
percent chance of developing ovarian cancer and women with a mutation to the BRCA2 gene have a 17 percent chance of developing ovarian cancer. Men with the mutated BRCA2 gene have a 6 percent chance of developing breast cancer, representing a 100 percent higher chance than the general male population. BRCA2 mutations can also indicate a higher risk of colon cancer, prostate cancer, stomach cancer, pancreatic cancer, and cancer of the gallbladder.

The increased prevalence of mutations causing breast and ovarian cancer among American Ashkenazi Jewish families may have been caused by the migrations that resulted from World War II (1939–45) and the German Nazi Holocaust. Prior to World War II, approximately 9 million Ashkenazi Jews were living in eastern Europe. The Nazi genocide reduced this population by two-thirds, consequently reducing the overall genetic diversity of Ashkenazi Jews. Many of the surviving Ashkenazi Jews migrated to the United States during this period, becoming the “founders” of a new population of ethnic American Ashkenazi Jews. In population genetics, this is known as a founder effect: due to random chance selection, a smaller population is produced when it separates from a larger population. The result is a loss of genetic variations among the new, smaller population and specific genetic characteristics which are passed on to subsequent generations.

Genetic tests are available to screen for mutations of the BRCA1 and BRCA2 genes. A positive test result does not guarantee that the patient will develop cancer, but rather that he or she has an increased genetic predisposition for certain cancers. Some women with BRCA1 or BRCA2 mutations may choose to begin screening for breast cancers at an earlier age than the general population. Some experts recommend that women who test positive for these mutations begin annual breast examinations or mammograms at age 25 to 35. By screening at a younger age, breast cancers may be caught at an earlier stage and more successfully treated. However, women with the BRCA1 or BRCA2 mutations may be more susceptible to developing cancer due to radiation exposure during routine screenings from mammogram and X-ray machines.

The U.S. Food and Drug Administration has approved the drugs tamoxifen and raloxifene to reduce the risk of breast cancer in women. However, the efficacy of chemoprevention (the use of drugs to reduce the risk or delay the recurrence of cancers) in patients with BRCA1 and BRCA2 mutations remains unclear. Women with these mutations may lower their risk of developing ovarian cancer by taking oral contraceptives (birth control pills).

The significant genetic risk of cancers among families of Ashkenazi Jewish descent have prompted many otherwise healthy women to receive prophylactic surgeries to remove breasts and ovaries. Jewish women whose relatives have had cancer are more likely to view prophylactic surgeries as acceptable medical procedures. These surgeries are controversial because they cannot reduce all cancer risks in the patients who receive them and can cause side effects such as early menopause. Patients who undergo prophylactic surgeries can still develop breast or ovarian cancers, although their risk of mortality from these cancers is greatly reduced.

Within Israeli and American ethnic Jewish populations, Orthodox and Ultraorthodox (Haredi) Jewish women were found to have the highest risk of breast cancer incidence. In addition to the prevalence of BRCA1 and BRCA2 genetic mutations, other health factors might contribute to the higher incidence of breast cancer among Haredi women. Within this subset of the larger Ashkenazi Jewish population, Orthodox and Ultraorthodox women tend to have access to fewer health education resources, undergo cancer screening at lower rates, and are more likely to face other contributing health factors such as poor diet or obesity.

Haredi Jewish populations live in insular communities, maintain a strict religious way of life, and reject secular society. Haredi women express the belief that a religious lifestyle provides protection from harmful medical conditions and reduces the need for visits to physicians.

They often consult rabbis when making decisions about health care and health screenings in order to ensure compliance with religious practices. Some Haredi consider healthcare providers to be the means by which God heals people on Earth, rather than seeing them as trained medical experts or scientists. Among Haredim, illness is commonly seen as God’s indictment of the
community and an opportunity for atonement. For this reason, Haredi Jews often consider it their duty to pray for the health of ill community members and view individual instances of illness as the responsibility of the whole community.

Some preventative treatments for breast cancer and all available preventative treatments for ovarian cancer can result in reduced fertility in female patients. For religiously observant Jewish women, the canonical texts of Judaism (the Torah, Midrash, Mishnah, and Talmud) can provide ethical and moral guidance regarding fertility treatments. Jewish scholars have interpreted procreation as a duty based on the Book of Genesis. This duty is understood to fall primarily on men, making female infertility less of a religious transgression. However, following the deaths of 6 million Jews in the Holocaust, the religiously defined duty to procreate has taken on a new and historically related significance. While infertile Jewish women may not feel the pressure to procreate from religious doctrines, they may feel this pressure from family and community members.

Halacha (Jewish laws derived from religious texts) are rarely cited as objections to fertility treatments. In addition to the duty to procreate, Halacha also outlines a duty to heal which ethically aligns the religious doctrine with the goals of oncofertility (interdisciplinary research into the reproductive futures of cancer survivors).

Religion: Meditation and Risk

Meditation is an individual practice of mental training for the purpose of inducing a particular mode of consciousness. There are a wide variety of meditative practices requiring different levels of focus and concentration. While meditation is often discussed in the context of religious practice, meditation has evolved beyond its religious roots. In the West in particular, it is common to find many people practicing different forms of meditation outside of any formal religion, similar to the way practitioners of yoga often separate it from a larger spiritual belief.

In the West, “meditation” commonly refers to “meditation practices from the East,” which became of interest to Western intellectuals and New Age practitioners in the 19th century as new patterns of immigration, trade, and translation brought Eastern and Western ideas together. In 1893, the year of the
famed Chicago World’s Fair, or World’s Columbian Exposition, held to celebrate the 400th anniversary of Columbus’s arrival in the New World, the first Parliament of Religions was held concurrent with the fair. It was the first formal meeting of representatives of both Eastern and Western religions, including an Anglo-American convert to Islam, the first Zen Master to teach in the United States, the wandering Hindu monk Vivekananda, the Theravada Buddhist preacher Anagarika Dharmapala, and many others. This marked the start of Western interest in Zen practices, and in various meditative practices from the East, including India.

That said, meditation has a long history in the West under other names. Mysticism has generally not been embraced by the mainstream in either Christianity or Judaism, though in the late 19th century a wave of charismatic and born-again Christian movements began which embraced such mystical practices as snake handling, speaking in tongues, ecstatic dancing, and faith healing. Individual mystics like Saint John of the Cross have been revered, and their practices often included states of intense prayer that are identical to meditation practices in all but name. For that matter, the Catholic recitation of the Rosary, in which formulaic prayers are recited repeatedly, is essentially a meditative practice. And in both the Catholic and Orthodox churches, there is a 2,000-year history of religious figures engaged in deep contemplation that is likewise indistinguishable from a state of meditation.

Meditative practices originating in the West are typically devotional or scriptural, explicitly religious in nature, while meditation in the East, and Eastern meditative practices adopted by Westerners, are more likely to be pragmatic in nature. This is a generalization pertaining to overall trends, rather than the goals of any one individual. Another key difference is that Eastern religion has a long history of focus on proper posture, which can often become highly technical. Western traditions not only lack this, but Westerners are often cavalier about matters of posture in their adoption of Eastern practices.

Scientific research on meditation dates to the 1930s, and increased dramatically with the growth of neuroscience in the 1970s. Cross-cultural studies of meditation have often attempted to categorize different types of meditative practice, rarely with much satisfactory success. Even defining what exactly counts as meditation, in a way that excludes practices that are clearly non-meditative, is a challenge not yet met.

Among Eastern practices, Buddhist meditation is the most familiar, though it is misleading to speak of “Buddhist meditation” as though it is a single tradition or school of thought. Still, there are certain important commonalities, including a focus on breathing (which is also true of Hindu meditative practices) and the value assigned to tranquility and insight (vipassana, in Pali). Tranquility or serenity is the state or practice of calmness, which steadies and concentrates the mind during meditation and prevents it from turning into an opportunity to let one’s thoughts wander—or to fall asleep. By developing tranquility through practice, the meditator is able to avoid “hindrances”—distractions that prevent meditation—and in so doing, develops insight. (Actually, the Buddha’s disciple Ananda said that serenity and insight are developed in three ways: serenity is developed and leads to insight, insight is developed and leads to serenity, or serenity and insight are developed together.)

Buddhist meditation is often called mindfulness, which is similar to the Western psychological idea of mindfulness. In fact, Buddhism and psychotherapy share a lot of common ground, and are similar in their goals, in that they seek to understand the mind and the individual, and aim to free the individual from being overburdened by the world.

In the modern world, it is meditation’s putative “healing” power that is so often extolled. This can be a difficult topic to talk about without wandering into the New Age aisle and so-called alternative medicine. Meditation does not have the ability to cure cancer. Deep meditation, putting the individual into a mystical state, does have the ability to expel the awareness of pain, discomfort, and suffering from the individual’s mind—both the East and the West have a long tradition of mystics and martyrs who are transported into such states of mind and thus escape experiencing the unpleasantness of their violent ends. (This is not quite the same as the legendary yogi’s ability to walk on hot coals or pass nails through his palms, which involves a degree of body control that goes beyond the scope and intent of meditation, but the practices did develop side by side.)

But perhaps more important than limiting the suffering experienced by those few cancer patients
who have the time, attention span, and discipline to practice meditation at the level of an exalted master or who are natural-born mystics, meditation when properly performed has the scientifically proven ability to reduce stress. Heart rate, blood pressure, and breathing all slow during proper meditation, and the effects last longer than the meditative session itself. Experienced meditators have less need for sleep with no ill effects—though to be fair, a rephrasing of this might be simply that sitting very still in meditation for an extended period of time confers enough of the benefits of restfulness that the meditator is less tired at the end of the day—and experience less work stress. As a result, mindfulness-based programs have been put together in the medical community for dealing with the stress of illness and to reduce pain, though one of the benefits of meditation as a practice is to hopefully reduce the incidence of cancer.

Although studies attempting to establish links between stress and cancer incidence have had limited success due to the difficulties of design and implementation, there is general agreement in the oncology community that stress is a contributing factor to the development and metastasis of cancer, perhaps some cancers more than others.
example, suggest that the most frequently cited causes for developing cancer are God’s will, karma, and fate. In Buddhist and Hindu philosophy, karma is the belief that the deeds of one’s past lives are reflected in one’s current life. Therefore, suffering in the present life—such as being diagnosed with cancer—is attributed to misdeeds of a previous life. Similar beliefs about cancer diagnoses are also cited by Muslim patients who report that cancer is Allah’s punishment for one’s sins; embracing the disease is seen as a form of penance. Studies indicate that people who believe in karma, God’s will, or that human destiny is preordained are less likely to participate in cancer screening and are more likely to use complementary alternative medicine (e.g., Ayurveda, acupuncture, religious healing practices).

Cancer fatalism, by virtue of emphasizing an external locus of control (i.e., “God will cure me of cancer.”), engenders passive acceptance of the illness. On the other hand, the concept of Divine Providence focuses on internal locus of control (i.e., “I can cure myself of cancer.”) and free will. In Christian and Jewish philosophy, God is seen as benevolent, giving man an opportunity to correct wrongs and shape his or her destiny. As a consequence, the influence of religion on health beliefs and behavior may vary among religious groups.

In a study examining health beliefs and attitude toward breast cancer screening, it was found that Christian women reported more positive attitudes toward screening and were more likely to participate in breast cancer screening than Druze and Muslim women. Religious beliefs can sometimes override cultural norms. For example, Vietnamese women living in the United States were less likely to undergo cervical cancer screening if they were Buddhists as compared to being Christians.

Reflecting the important role that religion plays in health behavior, research also highlights variances in treatment choices and medical decisions based on religious backgrounds. In a study of patients with lung cancer, religious faith was found to be the second most important influence on treatment decisions after the oncologists’ recommendations. In a review of literature, it was found that a range of spiritual and religious factors influenced African American patients’ treatment preferences in cancer. Spiritual beliefs impacted healing, and patients were likely to feel that God is responsible for one’s health and that physicians carry out God’s will. Religious and spiritual beliefs are observed to influence attitudes toward other outcomes of cancer treatment such as pain management, handling side effects, and even end-of-life decisions.

Therefore, when public health and physician recommendations do not take religious beliefs into account it can result in nonparticipation or nonadherence. For instance, in a qualitative study, Muslim women reported that although they were aware of the benefits of breast cancer screening, they did not attend screening programs because they were designed in a way that was not in line with their Islamic beliefs and customs. Research recommends a culturally sensitive public health approach in order to gain maximum participation in cancer prevention programs.

In many countries where the religious and cultural beliefs about female modesty determine cervical cancer screening practices, the visual inspection with acetic acid (VIA) method is often used. This test involves swabbing the cervix with an acetic acid solution (usually vinegar), waiting for a minute, and then visually examining the cervix for any changes in color. White areas are suspected to be precancerous and treatment is recommended. The VIA is a simple, accurate, and inexpensive test that can be administered by trained health care staff such as midwives and nurses, thereby overcoming religious barriers for attending cervical cancer screening. Extensive research in developing countries has shown a positive response to the VIA method.

Recognizing the significant and influential role of religion on health, recent research emphasizes the inclusion of religious institutions as a channel for health promotion and risk prevention. Church-based health promotion (CBHP) interventions have gained increasing interest owing to the proven significant impact they have on a range of health behaviors. CBHPs have been effective in raising awareness about cancer prevention through screening (mainly colorectal, breast, prostate, and cervical cancers) and the benefits of physical activity and proper nutrition. Studies that used mosques as a site for health awareness programs reported similar positive findings, highlighting the importance of using religious institutions to target groups that are difficult to access.
The influence of religion on other cancer-related aspects such as mortality and adherence are inconclusive. In a review of studies it was found that the evidence was inadequate to support the link between religion and cancer mortality. Findings about adherence to cancer treatment, on the other hand, are conflicted with some studies reporting no negative impact of religion on compliance and a few studies evidencing a link between culture (not religion, specifically) and compliance.

**Religious Coping**

Numerous studies have examined coping in respect to religion when faced with a cancer diagnosis, treatment, and at end of life. Religious coping comprises three key processes: emotional (e.g., expression of fears), cognitive (e.g., finding a causal link to God), and behavioral (e.g., going to a religious shrine). Patients have reported reverting to their religious beliefs when diagnosed with cancer.

In a study of Hindu patients in India, it was observed that they discussed their faith in God, accepting God’s will, and praying. Taiwanese women diagnosed with breast cancer viewed their illness as an existential quest where they could find meaning in their experiences of illness and suffering. African American patients who were successfully treated for cancer reported that believing that healing was God’s work, praying, and letting God take over were their primary forms of coping. These patients believed that being diagnosed with cancer helped them attain increased spiritual awareness. Further, religious coping strategies were related to treatment preferences and end-of-life decisions.

Positive religious coping is observed to lower psychological distress, improve illness adjustment and quality of life, and encourage treatment choices that will extend life. Negative coping strategies, although less common, result from fatalistic attitudes toward the diagnosis, prognosis, and treatment of cancer. Some research indicates negative coping can result in increased levels of distress, poor illness adjustment, poor quality of life, and refusal to undergo treatment.

Religion has a significant influence on health beliefs and behaviors. Consequently, public health systems and physicians are beginning to take more culturally aware approaches to patient care. Adopting a method that is sensitive to religious backgrounds can increase participation in cancer screening programs, early detection, proper utilization of health resources, and treatment adherence.

**Further Readings**

**Religion: Use of Interventions**

Religion and spirituality play an important role at various times during the cancer trajectory, such as when a patient is faced with the diagnosis of cancer, when they receive treatment, when cancer is in remission or cured, and at the end of life. While the primary goal of a doctor–patient consultation is to discuss a diagnosis and subsequent treatment modalities, patients may also have questions that are more existential in nature (e.g., Why me?...
What have I done to deserve this?). Research suggests that there are many benefits for using religion and spirituality (R/S) as a coping mechanism when diagnosed with cancer, especially in terms of acceptance, problem solving, and emotional regulation. In spite of the numerous benefits of R/S coping, it appears that R/S concerns and needs of patients are rarely met. Indeed, interventions that were focused on R/S needs of patients were reported to be preferred, helpful, and effective. This entry will describe key religion- and spirituality-centered interventions in cancer care and the outcomes and challenges of these interventions.

**Religion- and Spirituality-Centered Interventions in Cancer Care**

Effective R/S interventions are built on psychotherapy models such as those used by psychologists, counselors, or psychiatrists. These R/S psychotherapy interventions can be delivered to individuals, in a group, for a short term or long term. There is a growing interest in alternate models such as logotherapy (therapy developed by neurologist Viktor Frankl that attempts to help patients find meaning in their lives beyond their medical diagnoses) and dignity therapy (individualized, short-term therapy designed specifically for the terminally ill and their families).

A classic study by Brenda Cole and Kenneth Pargament used a psychotherapy and spirituality intervention for cancer patients. The intervention focused on helping patients adjust to their diagnoses, aiding in developing spiritual coping, and settling any spiritual conflicts. The framework of this intervention included four main existential issues individuals encounter when faced with a health crisis: finding one's locus of control, retaining a sense of identity, maintaining relationships, and finding existential meaning. Using a randomized control study design, the authors reported that after the intervention was completed and at two-month follow-up the patients in the intervention group had stable levels of pain and depression, whereas the group that received no intervention had higher levels of pain and depression.

Group psychotherapy is another form of intervention that includes a peer support framework wherein patients can share and get support for their cancer-related issues. William Breitbart developed Meaning-Centered Group Psychotherapy (MCGP), a spiritual intervention that was modeled after logotherapy. MCGP was used for advanced cancer patients with the goal of helping them develop and maintain a sense of meaning, peace, and purpose in their lives. This group therapy was delivered over an eight-week period and included a combination of a didactic approach, discussions, and experiential learning that was meaning-centered. Randomized controlled trials that used MCGP reported that the group therapy format was especially beneficial to cancer patients who were approaching end-of-life as it reduced their feelings of loneliness and anxiety. Further, these studies found MCGP to be effective for cancer patients at various stages of their disease, namely during treatment, advance stage, palliative stage, and during survivorship.

Dignity therapy is a novel, patient-centered intervention used for end-of-life patients that focuses on enhancing meaning, purpose, and a sense of worth. In this intervention, patients are encouraged to create a "generativity document" that is left for the patients' loved ones. Dignity therapy is believed to help patients establish their sense of worth through appraising their life with a therapist. Studies show that dignity therapy significantly decreases patients' levels of physical and mental suffering.

Recently there is a growing interest in including health care professionals such as nurses and doctors in delivering R/S interventions. Kristeller and colleagues conducted the Oncologist Assisted Spiritual Intervention Study (OASIS) in which oncologists were trained to deliver a semistructured and brief spiritual intervention to their patients during their consultations. The intervention is tailored to individual patient needs and involves inquiring after the patient's spiritual concerns, how they are adjusting to their illness, how they are finding peace and meaning, what resources they have available, and offering appropriate help. Patients who received the intervention reported decreased levels of depressive symptoms, improved health-related quality of life (HRQoL), and increased satisfaction with their care as compared to the control group that did not receive the intervention. Further, 85 percent of the oncologists rated the intervention as "quite" or "very" comfortable in delivering the intervention. Although the findings of OASIS need to be replicated in order to establish success of the intervention, these findings indicate that
OASIS may help in patients’ adjustment to cancer, especially in terms of their HRQoL, depression, and care from their oncologist.

This brings up the question of which health care professional should deliver R/S care and interventions to patients. Tom Gordon and David Mitchell suggested a multilevel framework for assessing and providing spiritual care for patients that is being implemented in Scotland. First, all staff who have regular, casual interactions with patients and their caregivers are expected to identify patients who have R/S needs and pass them on to the care team. The more senior the staff member, the greater the expectation that he or she will be better able to assess patients’ R/S needs. A recent study that examined the effectiveness of a short-term training intervention for health care staff in providing patients with existential support reported that the participants who received the intervention felt more confidence during patient communication. Hence, with appropriate training and referral, it is possible to improve health care staff’s sensitivity and skills in identifying and addressing patient R/S needs and concerns.

**Outcomes and Challenges of Religion- and Spirituality-Centered Interventions**

Religion- and spirituality-centered interventions are evidenced to have positive effects on patients in terms of their well-being and quality of life. The benefits of using R/S interventions for patients include increased levels of hope, optimism, resilience, self-esteem, and emotional bonding with others. Consequently, these feelings are believed to increase patients’ desire to survive the cancer which, in turn, results in patients being more actively engaged and compliant toward their treatment. The main emphasis of R/S interventions is on religious coping skills which, as research suggests, help reduce levels of stress that can arise from the lack of control and a sense of helplessness in the face of cancer. The central feature of religious coping strategies is to achieve a balance between those aspects of cancer that one can control and those that one cannot control (in other words, allowing God to take care of those that are out of one’s control). Therefore, through focusing on building religious coping skills of patients, R/S interventions help distressed patients attain a sense of inner peace by striking a balance between encouraging patients to be actively involved in their care and accepting the aspects of illness that cannot be controlled.

There are some challenges in delivering R/S interventions in clinical care that need to be considered. First, the professional boundaries of spiritual assessments in the clinical consultation need to be clear so the health care provider neither imposes his or her beliefs on the patient nor feels compelled to reveal what his or her beliefs might be. It may be helpful for both the staff member and the patient if there is a clear understanding from the beginning that the purpose of questions relating to religion or spirituality are in order to provide appropriate support to the patient. Second, there may be some role confusion between a psycho-oncologist and priest that should be addressed. It is important to understand that roles should be made clear; a psycho-oncologist may be trained to detect clinical depression but may not be trained in the theology or well-versed with sacred scriptures and vice-versa. Third, health care providers must understand the intersection between culture, religion, and spirituality. Religion and spirituality are very personal topics. Therefore, providers need to be sensitive, discreet, and open-minded in their queries about patients’ religious or spiritual philosophies.

Kaplar, Mary, et al. “The Effect of Religious and Spiritual Interventions on the Biological, Psychological, and Spiritual Outcomes of Oncology
Retinoblastoma

Retinoblastoma is the most common childhood cancer that develops inside the eye. It is a curable condition but can cause blindness and death if diagnosis and treatment are delayed. Effective treatments fortunately do exist, and promising new therapies and protocols are under investigation. This entry will discuss retinoblastoma's epidemiology, pathogenesis, clinical features, and management.

Retinoblastoma develops in approximately one out of every 15,000 live births. Three hundred to 350 children are newly diagnosed with retinoblastoma each year in the United States. The majority of children are diagnosed before 2 years of age, and the cancer does not discriminate between sexes and races. Seventy-five percent of patients develop retinoblastoma in one eye (unilateral), while 25 percent are affected in both eyes (bilateral). Unilateral cases usually occur from a spontaneous genetic mutation only in the child. Almost all bilateral cases signify a hereditary form of retinoblastoma, as do unilateral cases with multiple tumors in one eye. These patients usually have a germ-line mutation, meaning that every cell in the body carries the mutation, and the child is predisposed to develop other non-ocular cancers throughout life. The most common secondary cancers are bone and soft tissue, which are potentially life-threatening.

Retinoblastoma arises from retina cells that grow and proliferate uncontrollably. The retina is the light-sensitive layer comprising the innermost stratum of the eye that enables visual perception. Retinoblastoma develops when mutation of a gene located on chromosome 13 called \textit{RB1} occurs. \textit{RB1} is normally responsible for restraining cell proliferation, but mutations in its DNA sequence rendering it dysfunctional or deleting it altogether can result in tumor formation. The discovery of the \textit{RB1} gene was a seminal event in medicine, as it was the first identified genetic cause of cancer, and it revolutionized our understanding of many other diseases.

Leukocoria and strabismus are common signs of retinoblastoma. Normal pupils appear red when bright light is reflected off the retina, such as in flash photography, but patients with retinoblastoma frequently present with white pupillary reflexes sometimes referred to as “cat’s eye,” a condition called leukocoria. Strabismus is a misalignment of the eyes, which can occur if there is poor vision. Diagnosis by an ophthalmologist is made via an eye examination best performed under general anesthesia. Retinoblastomas appear as white masses inside of the eye. Ultrasonography, MRI, and other imaging modalities can confirm the diagnosis and help stage the disease. CT is usually not recommended since the radiation from the scan is thought to enhance second cancers in hereditary retinoblastoma. Patients and family members are also offered genetic testing and counseling.

Retinoblastoma is best managed by a multidisciplinary team of specialists experienced in the management of retinoblastoma, including ophthalmologists, pediatric oncologists, radiation oncologists, radiologists, pathologists, nurses, and social workers. Patient survival is the primary goal of retinoblastoma treatment, and although essential priorities, salvaging the eye and vision are secondary and tertiary concerns. The mainstay of treatment for advanced tumors is enucleation, which involves the surgical removal of the entire eye and a section of the optic nerve. This is the only method to completely remove cancer tissue from the eye to prevent recurrence and metastasis to other anatomical sites. The enucleated eyes are examined under a microscope to confirm the diagnosis and to identify features that increase the risk of metastatic spread such as involvement of the optic nerve beyond the excised margin and cellular invasion outside of the eye. After the surgery, patients are fitted for prostheses (“glass eyes”). Modern prostheses are made of plastic and have realistic appearances and promote motility.

Advances have been made over the years to allow many cases of retinoblastoma that have not spread outside of the eye to be treated without
enucleation. Small tumors can be treated with local therapies such as with photocoagulation and cryotherapy. Photocoagulation uses lasers to heat and destroy tumors and their blood vessels, while cryotherapy involves freezing tumors by placing cryoprobes on the sclera adjacent to the tumor. Patients are treated during examinations under anesthesia.

The current standard of care for most cases of retinoblastoma that cannot be controlled by local therapies alone is intravenous chemotherapy. This technique is called “chemoreduction.” Chemotherapy is provided systemically using drugs to disrupt the tumor cells’ ability to grow and replicate in order to shrink the tumors. Photocoagulation and/or cryotherapy are often used to augment the effects of the chemotherapies and to treat new smaller tumors. Commonly used chemotherapies include carboplatin, etoposide, and vincristine.

If tumors do not respond well to chemotherapy, radiation therapy is usually the next step. Retinoblastoma is very sensitive to radiation, and external beam radiation therapy (EBRT) used to be the primary treatment of choice prior to the advent of chemoreduction. However, EBRT fell out of favor, because approximately 35 percent of patients with hereditary retinoblastoma developed unique cancers in the field of radiation. EBRT has undergone many advances since then, and the delivery of radiation is now more precise. However, it is still reserved for cases that have failed chemotherapy due to the side effects.

Two better options for focal delivery of radiation are proton therapy and plaque brachytherapy. Proton therapy is available at several specialized medical centers, and allows for very targeted radiation while sparing surrounding tissues. Its main limitation is the lack of availability at most...
Rhabdomyosarcoma, Childhood

Rhabdomyosarcoma is the most common form of soft-tissue sarcoma, accounting for 4.5 percent of all cases of childhood cancer. Approximately 350 new cases of rhabdomyosarcoma are diagnosed annually in the United States. The incidence is 4.5 per 1 million children with 50 percent of cases seen in the first decade of life. It is the third most common extracranial solid tumor of childhood after neuroblastoma and Wilms’ tumor. It is included in the group of small blue round cell tumors of childhood along with neuroblastoma, lymphoma, and primitive neuroectodermal tumors. The tumor cells are thought to be derived from mesenchymal progenitors that are committed to muscle-specific lineages. Most cases of rhabdomyosarcoma occur sporadically. Genetic conditions associated with rhabdomyosarcoma include Li-Fraumeni cancer susceptibility syndrome, pleuropulmonary blastoma, neurofibromatosis type I, Costello syndrome, Beckwith-Wiedemann syndrome, and Noonan syndrome.

Subtypes

Rhabdomyosarcoma is classified into five subtypes depending on clinical and pathological characteristics. The “International Classification of Rhabdomyosarcoma” created by the Intergroup Rhabdomyosarcoma Study further associated these subtypes with disease prognosis.

Alveolar rhabdomyosarcoma. Generally seen during teenage years, this subtype has an incidence of about one case per 1 million children and adolescents. They are more commonly seen in the extremities, trunk, and perineum/perianal region and have a higher risk of metastasis. Histologically, this subtype has a key defining pattern in which fibrous septa composed of collagenous fibrovascular tissue provides a scaffold for rhabdomyoblasts (small blue round cells), and this organization forms alveolar-like structures.

Molecularly, most of these tumors express a constitutively active transcription factor, $PAX3$-$FKHR$ or $PAX7$-$FKHR$, resulting from chromosomal translocations $t(2;13)(q35;q14)$ or $t(1;13)$ (p36;q14), respectively. Patients with tumors that

Further Readings

harbor these translocations have a poorer prognosis than those without.

**Embryonal rhabdomyosarcoma.** This is the most common rhabdomyosarcoma occurring in children. Embryonal rhabdomyosarcoma is 1.5 times more common in males with highest incidence (four cases per 1 million children) between birth and 4 years of age, followed by approximately 1.5 cases per 1 million in adolescents. These tumors occur mostly in the head, neck, and genitourinary region. On histology, this tumor recapitulates normal embryonal myogenesis, exhibiting cellular phases of muscle development, from undifferentiated mesenchymal cells to elongated myoblasts, multinucleated myotubes, and fully differentiated myofibers. Genetically, this group has no characteristic chromosomal translocations and its behavior resembles *PAX-FKHR* fusion-negative alveolar rhabdomyosarcoma with intermediate prognosis. These tumors may have a loss of heterozygosity at the 11p15 region.

**Spindle cell rhabdomyosarcoma.** These tumors are a variant of embryonal rhabdomyosarcoma and typically occur in young males. They occur most commonly in paratesticular soft tissue, followed by the head and neck. This neoplasm contains relatively differentiated spindle cells somewhat resembling smooth muscle tumors. They are *PAX-FKHR* fusion-negative tumors with better prognosis than the embryonal variant.

**Botryoid rhabdomyosarcoma.** A variant of embryonal rhabdomyosarcoma, this small-cell tumor abuts an epithelial surface, with condensation of tumor cells in the immediate subepithelial zone. The “bunch of grapes” appearance of this polypoid lesion led to its name as a *sarcoma botryoides*, from the Greek term *botryos*. Genetically, these are similar to *PAX-FKHR* fusion-negative rhabdomyosarcoma with good prognosis. This subtype is commonly seen in the walls of hollow, mucosa-lined structures such as the nasopharynx, common bile duct, urinary bladder of infants and young children, or the vagina in females, typically younger than age 8.

**Rhabdomyosarcoma, not otherwise specified.** Infants younger than 1 year have a higher incidence of undifferentiated sarcoma and tumors of the trunk and abdomen. This tumor is composed of poorly differentiated cells with no *PAX-FKHR* fusion and very poor prognosis.

**Diagnosis**

Rhabdomyosarcoma diagnosis is based on tumor morphology and the results of immunohistochemical stains. Rhabdomyosarcoma stains positive for desmin and muscle-specific actin but these markers are not specific for the tumors.

Myoglobin stains positive only in differentiated cells, and is hence not sensitive enough for diagnosis. Muscle transcription factors, MyoD and myogenin, are normally expressed during muscle development and are seen in high levels in rhabdomyosarcoma. These markers are both sensitive and specific for rhabdomyosarcoma. Molecular diagnostic tests such as reverse transcriptase PCR and fluorescent in situ hybridization can detect *PAX-FKHR* and chromosomal translocation status. These tests are not commonly used in practice yet.

**Prognostic Factors**

Presently, rhabdomyosarcoma is mostly curable in children with localized disease who receive multimodal therapy with greater than 70 percent five-year survival after diagnosis. Thereafter, relapses are uncommon with a 9 percent late-event rate at 10 years. Patients with metastatic disease at diagnosis have a poor 30 percent five-year survival.

The following factors are associated with favorable prognosis:

- **Age:** Children aged 1 to 9 years.
- **Tumor Site:** Cancer in head and neck along with non-bladder, non-prostate genitourinary areas.
- **Tumor Size:** Smaller tumors (<5 cm).
- **Tumor Spread:** Patients with localized disease and no lymph node involvement.
- **Tumor Resectability:** No residual tumor after surgery.
- **Histological Subtype:** Spindle, botryoid, and embryonal subtypes tend to have good prognosis.
- **Treatment Response:** Negative post-irradiation positron emission tomography (PET) scans predict improved local failure-free survival.
Stage
Staging assesses the extent of the disease before instituting therapy. This evaluation includes bone marrow aspirates and biopsy along with imaging modalities such as chest X-ray, chest computed tomography (CT) scan, bone scan, magnetic resonance imaging of the base of the skull, and abdominal/pelvis CT scan depending on the primary tumor site. PET with fluorine-18-fluorodeoxyglucose scans may help identify areas of possible metastatic disease. Rhabdomyosarcoma staging is relatively complex as it includes assignment of stage (1–4), local tumor group (i–iv), and risk (low/intermediate/high) group on a combination of various prognostic factors.

- **Stage**: Determined by primary site, tumor size (widest diameter), and regional lymph node involvement and/or distant metastases.
- **Local Tumor Group**: Determined by postoperative resection/biopsy status, with tumor margin and lymph node assessment.
- **Risk Group**: Determined by stage, group, and histology.

Treatment
All rhabdomyosarcoma patients require combined modality treatment with systemic chemotherapy, together with surgery, radiation therapy, or both to achieve maximum treatment response. Treatment strategies differ between the United States and Europe. In the United States, localized rhabdomyosarcoma is initially treated with surgery followed by chemotherapy (vincristine, dactinomycin, cyclophosphamide), with radiation reserved for residual disease. Addition of other agents such as topotecan, ifosfamide, and etoposide to date has not been shown to improve outcomes in metastatic disease. In Europe, chemotherapy followed by second-line therapy in the presence of poor response is delivered to avoid extensive surgeries. Surgical resection is preferred over radiation, which is given only for residual disease or when lymph nodes are involved. Current clinical trials are trying to target molecular alterations that are important for rhabdomyosarcoma pathogenesis.

Roche Group (Switzerland)
Roche, founded in 1896 by Fritz Hoffmann-La Roche, headquartered in Basel, Switzerland, is a globally leading pharma company. The company which is known as F. Hoffmann-La Roche Ltd. is a research-focused health care company. Its holding company, Roche Holding AG, has bearer shares listed on the SIX Swiss Exchange. The functions of Roche revolve around discovering, developing, manufacturing, and marketing innovative diagnostics and therapeutic products and services.

The company’s products and services address the prevention, diagnosis, and treatment of diseases, and improve the well-being and quality of life of patients. Roche specializes in in-vitro diagnostics and drugs for cancer and transplantation. The company classified its operations into two reportable business segments: Pharmaceuticals and Diagnostics. Roche has operations in various countries across North America, Latin America, Europe, Asia, Africa, Australia, and Oceania. The company’s main strategy for establishing itself in the market is through new product launches, network expansion, internal development, in-licensing of technology, and products, acquisitions, and strategic alliances.

Through acquisitions, Roche owns the Japanese biotechnology company Chugai Pharmaceuticals,
the American biotechnology company Genentech, and Ventana, based in Tucson, Arizona.

During the fiscal year 2013, the company's revenues were 46.78 billion Swiss francs. Roche is owned by three entities. Descendants of the founding Hoffmann and Oeri families own slightly over half of the bearer shares with voting rights: a pool of family shareholders 45 percent; and the Oeri family a further 5 percent. The Swiss pharma firm Novartis owns a third of the company's shares. Roche is the fifth-largest pharma company worldwide, as per 2013 rankings. It is one of the few companies increasing their dividend every year. The fiscal year 2013 was the 27th consecutive year of the company realizing increasing annual dividends.

Roche is a full member of the European Federation of Pharmaceutical Industries and Associations (EFPIA). Soon after its establishment in 1896, the company established itself as a leader in the market through the production of various vitamin preparations and derivatives. Roche was the first to produce, on large scale, synthetic Vitamin C with the brand name Redoxon. In 1957, the company introduced into the market the class of tranquilizers known as benzodiazepines, with Valium and Rohypnol being the best known brand names. In 1992, the company bought the patents for the polymerase chain reaction (PCR) technique. It has produced various HIV tests and antiretroviral drugs. In the field of cancer, Roche manufactures and sells several cancer drugs and is a leader in this field.

In 1982, the United States arm of the company acquired Biomedical Reference Laboratories located in Burlington, North Carolina, for $163.5 million. By the early 1990s, Roche Biomedical, which was formed after Hoffmann–La Roche mixed its laboratories, was one of the largest clinical laboratory networks in the United States, with 20 major laboratories and $600 million in sales. In 1994 and 2002, Roche acquired Syntex and Chugai Pharmaceuticals respectively. In 2009, the company acquired Memory Pharmaceuticals Corp. and Genentech. In 2010, the companies acquired were Medingo Ltd. and Biolimagene, Inc. In 2013, the company acquired PVT Probenverteiltechnik GmbH, mtm laboratories AG, and Anadys Pharmaceuticals, Inc.

Due to the wide infrastructure and firm grip on the market, the company has a wide variety of drugs in their product line. Some of these products include Avastin (bevacizumab) for certain malignant tumors, Erivedge (vismodegib) for basal-cell carcinoma, Herceptin (trastuzumab) for HER-2 positive breast cancer, Kytril (granisetron) for chemotherapy-induced nausea and vomiting, MabThera (rituximab) for lymphocytic leukemia, non-Hodgkin's lymphomas, rheumatoid arthritis, a number of solid tumors (including Kaposi's sarcoma), genital lesions, hepatitis C, Tarceva (erlotinib) for various cancers, Xeloda (capecitabine) for breast and colorectal cancer, and Vesanoid (tretinoin) for acute promyelocytic leukemia, among others.

Despite the obvious successes and achievement made by Roche, the company has had to overcome challenges too. In 1999 the firm pled guilty to participation in a worldwide conspiracy to raise and fix prices for vitamins sold in the United States and globally.

Roche undertakes intensive research and development (R&D). In addition to internal research and development activities the company is involved in publicly funded collaborative research projects, with other industrial and academic partners. One example is InnoMed PredTox in the area of non-clinical safety assessment. In joint research, Roche is expanding its activities within the framework of the Innovative Medicines Initiative of EFPIA and the European Commission.

In the area of oncology, Roche Group is the world's leading provider of cancer care products. (Some of the cancer products have been listed above.) The company's anticancer medicines are saving lives and significantly advancing the way some cancers are treated. Moreover, the company is developing new diagnostic tests that will have a significant impact on disease management for cancer patients in the future. This is being done through a broad portfolio of tumor markers as well as a range of molecular oncology tests. Through such advances, it is obvious that Roche will continue to be one of the leaders in providing cancer-focused treatments and diagnostics. As a show of its commitment in the field of oncology, the company has four oncology research sites (two in the United States and one each in Germany and Japan) and five development sites (two in the United States and one each in the United Kingdom, Australia, and Switzerland).

Roche's R&D in the area of oncology is focused on providing effective cancer therapies through the
discovery and development of novel therapeutics that target the specific molecular pathways associated with cancer. By understanding the molecular mechanisms of tumor development and how tumors spread, scientists are able to target the processes that lead to cancer. The area of oncology covered by Roche is one where a number of antibodies can be important. The objective of the company is to get more technologies ready to make all functions for treatments easier to manage.

According to the company, the key to successful treatment of cancer lies with precise diagnosis. Biomarkers enable doctors to determine which cancer type a patient has much more quickly and specifically. The company is also working to identify tumor markers that will detect tumor cells long before the first symptoms become apparent. In such a way, physicians will be able to initiate targeted and effective treatment without delay, therefore enhancing patient well-being and bringing down the cost to the health care system.

Romania

Located in the southeast of central Europe, Romania was a communist country until the revolution of December 1989, when it started a long and challenging transition toward a democratic political system and a market economy. The country is a member of the North Atlantic Treaty Organization (NATO), the World Trade Organization (WTO), the Council of Europe, and the United Nations (UN). While it has also acquired full membership in the European Union (EU), since January 2007, and has undertaken substantial socioeconomic transformations, Romania has, however, an inferior life expectancy and general health status when compared to EU and regional averages (average life expectancy is six years shorter in comparison with EU average). Cancer is among the three leading causes of death in terms of noncommunicable diseases (17.6 percent of all deaths in 2006), surpassed by cardiovascular diseases (62.1 percent) and followed by digestive diseases (5.5 percent). The country needs to further advance the health and social protection system, including cancer control and prevention programs, in order to align its performances with the mandatory EU levels.

Data on cancer mortality from the last 20 to 40 years (1969–2004) in Romania show an increasing trend in cancer mortality rates among men, and an unchanged pattern among women. Standardized cancer incidence rates for all types of cancer increased almost two times from 1990 to 2005 (from 120.10 per 100,000 in 1990 to 240.66 in 2005). Fifty-two thousand new cancer cases are estimated to be diagnosed annually, and the number of deaths from the disease is expected to be almost the same.

With 240.66 cancer cases per 100,000 population, Romania currently ranks below the cancer average rate in Europe (460.12 cases per 100,000 inhabitants). In contrast with this relatively lower cancer incidence, cancer mortality shows a rising trend (179.8 per 100,000) equal to the European average (182.79 per 100,000).

The most common leading types of cancer in Romania with regard to new cancer cases in 2012 among men of all ages were lung cancer, colorectal cancer, and prostate cancer, while among women breast cancer incidence was first, followed by colorectal cancer and cervix cancer. In terms of cancer deaths, lung cancer was first, colorectal cancer second, and stomach cancer third among men, while, among women, breast cancer was first, colorectal cancer second, and lung cancer third.

In terms of cancer incidence in women of all ages in Romania in 2013, breast cancer ranked first, with an annual crude prevalence rate of 81.5 per 100,000, colorectal cancer ranked second (40.8 per 100,000), and cervical cancer ranked third (39.4 per 100,000). Also, while 4,343 cervical cancer cases are identified every year, cervical cancer
represents the second most common cancer in women 15 to 44 years old. High cervical cancer rates among Romanian women can be explained by both lack of information about the need for periodical testing as well as hesitancy to be tested. (The incidence of women who have never been tested for cervical cancer is expectedly higher in rural areas and among women with a lower socio-economic status).

The occurrence of colorectal cancer also shows a rapid rise as its incidence and mortality have increased two times over the last 20 years (for instance, 4,150 patients died of colorectal cancer in 2010, and 4,860 in 2012). Although colorectal cancer is considered a disease more frequent among the elderly, the average age of newly diagnosed patients has dropped during recent years.

Similar to other former communist countries in southeastern Europe, Romania still has incomplete and unreliable national or regional cancer registration coverage, and limited cancer control programs. Because of poor access to cancer education, prevention, and screening programs, the diagnosis for more than two-thirds of cancer patients occurs during the advanced stages of the disease, which leads to more complex and traumatic treatment. This current situation calls for intensive prevention and screening programs in view of early diagnosis.

Another issue within the Romanian health care system is that psychosocial support and cancer rehabilitation services are not included in the cancer control programs, mainly because of a poor cooperation between the health and social care sectors. Also, there is a general public reluctance for psychosocial oncology services that may be explained by both stigma of cancer and the Romanian culture of care.

Rosenberg, Barnett

When President Richard Nixon famously declared a national war on cancer in 1973, much research focused on prevention through minimizing
behaviors that created the greatest risks for cancer and its growth, as well as establishing keys to maintaining a healthy lifestyle that would make the diagnosis of cancer rarer. However, in the same era, groundbreaking work was done in heavily funded cancer research facilities that tested new methodologies for treatment as a way, if not to cure the cancer, then to put the often aggressive disease into remission and, in turn, guarantee a quality of life unimaginable for patients just 75 years earlier. It is one of the ironies of the era of cancer research that a physicist working at a state university lab, and with no background in oncology or even chemistry, would be responsible for isolating a chemical compound that actually stopped tumor growth, a revolutionary, even landmark drug patented as cisplatin. The story of Dr. Barnett Rosenberg and the discovery of cisplatin is a story of remarkably diligent observation, persistent research in the face of skepticism within the cancer research field, and ultimately of the kind of serendipitous luck that has always been a part of groundbreaking scientific research.

Barnett Rosenberg was born November 16, 1926, in the working-class environs of Brooklyn. Remarkably gifted early on in science and math, he attended Brooklyn College and graduated in 1948 with a Bachelor’s in Science. He completed his doctoral work in physics at nearby New York University (NYU) in 1956. After two years in the public sector (working in the research department of Westinghouse Electric), Rosenberg returned to academia; after a brief stint back at NYU, he accepted a position at Michigan State University (MSU) to establish a biophysics department, a daunting task as Rosenberg had no background in biology. But Rosenberg thrived in the research freedom his directorship provided as well as the resources and the lab teams available at a major state university. He would remain in East Lansing for the rest of his career. Rosenberg decided as an initial project to examine the implications of work he had completed during his doctoral term when he had noticed that bacteria exposed to an electrical field grew exponentially but did not, indeed could not, divide. How might electricity introduced through the controlled agency of an inert heavy metal, such as platinum, impact cells? Using a bacterial soup of E. coli, he exposed it to electromagnetic pulses. When he disengaged the electromagnetic impulses, what he noticed was odd: the bacteria had indeed grown, far beyond normal parameters, but had not divided.

Once the electric impulse was removed, however, the bacteria resumed its normative division processes. Rosenberg inferred that some element of the process had actually stopped cell splitting; he also realized the potential implications to cancer and specifically the often rapid cell division responsible for the growth of inoperable tumors. Rosenberg, with his background in physics, knew electrical impulses could not be responsible for prohibiting cell division. He focused on the platinum compound, although decades of cancer research to that point had dismissed such heavy metals in treatment regimens.

Meticulously, the research team led by Rosenberg, certain they were onto something potentially groundbreaking, devised numerous research protocols to isolate the actual causal process that, in turn,
resulted in the effects they had observed. Each table of results eliminated some possibilities and created new avenues to research, a classic application of the rigorous protocols of the scientific method. Unlike so many cancer research facilities and drug companies at the time that sought quick results and the resulting headlines, Rosenberg worked quietly, carefully, and under the radar of far more well-known cancer research programs. What he found through the careful process of elimination was that the cis form of platinum had the observed effect. In 1968, the research team tested cis-platinum on laboratory mice and found a stunning result: in a simple eight-day trial, a nearly 100 percent success rate. Tumors could actually be stopped, in essence cured. Certain now of cisplatin's potential, Rosenberg immediately sent the results and his conclusions to the National Cancer Institute.

Given Rosenblatt's comparative lack of specific oncological expertise, the NCI was dubious over such extraordinary claims. However, Rosenberg invited the Institute's researchers to replicate his research. When his results were confirmed and later duplicated in laboratory animals both in the United States and in Britain, Rosenberg understood the full implications. He went public—publishing his findings in the prestigious journal *Nature*, and news of cisplatin electrified the oncology research field.

In 1972, as part of the application for FDA approval, cisplatin was introduced initially to cancer patients who had exhausted all other treatment protocols. Then in numerous research projects, cisplatin was introduced to set appropriate dosage levels and to evaluate side effects. The side effects were harsh—nausea and vomiting, disorientation, hearing diminishment, brain dysfunction, and, most alarming, significant damage to the kidneys. However, the results were undeniable. Pharmaceutical giant Bristol-Myers Squibb acquired the patent, and the FDA moved quickly to approve the drug in 1978.

Over the next decade, in conjunction with research teams internationally, new drugs were introduced to help minimize the side effects. Cisplatin had its greatest effect on testicular cancer (more than 95 percent success rate), but it has been introduced to treat other cancers, including ovarian, bladder, neck, and stomach. Millions of cancer patients benefited from Rosenberg's discovery, and cisplatin became a standard in cancer treatment regimens.

Rosenberg himself was recognized for his landmark achievement and awarded the Charles F. Kettering Prize in 1984 presented by General Motors for the outstanding achievement in cancer research. A year later, he was recognized with the $75,000 Harvey Prize, awarded annually by the Israeli Institute of Technology in a variety of medical, scientific, and technology fields to acknowledge major contributions.

Rosenberg remained modest, quietly working in the research laboratories of MSU—the royalties from the drug patent were used to establish cutting-edge biomedical research facilities on the campus. Rosenberg died August 8, 2009, in East Lansing, Michigan.

**Roswell Park Cancer Institute**

Roswell Park Cancer Institute (RPCI) is America’s first cancer center. It was founded in 1898 by Dr. Roswell Park. Dr. Park created a multidisciplinary approach to the treatment of cancer that required scientists and clinicians to work and consult together. This approach has become the standard used by many modern-day comprehensive cancer centers across the country.

RPCI holds the National Cancer Institute (NCI) designation of “comprehensive cancer center” and serves as a member of the National Comprehensive
Cancer Network (NCCN). A large number of the faculty members at RPCI are also members of NCCN panels that create the Clinical Practice Guidelines in Oncology, which creates internationally recognized standards for clinical policy in oncology. These guidelines also provide comprehensive clinical practice guidelines that are updated on a continuous basis. The patient satisfaction rating at RPCI is in the 97th percentile nationwide, with overall nursing and physician's ratings both in the 99th percentile nationwide.

Throughout its history, RPCI has been instrumental in reducing the cancer burden and has successfully maintained an exemplary leadership role in setting the national standards for cancer care, research, and education. Recently, RPCI has gone through a period of expansion, adding jobs and creating new and innovative programs, including a hospital facility dedicated to Phase I cancer research studies. RPCI has been a proponent of surgical robotics, vitamin D research, immunotherapy, and vaccine therapy, and has conducted studies targeting tumor microenvironment and cancer prevention.

The RPCI campus is comprised of 28 acres in downtown Buffalo and consists of 15 buildings with about 2 million square feet of space. Buildings on the campus include a comprehensive diagnostic and treatment center and a new medical research complex, in addition to educational facilities, with plans for continued growth and development.

The RPCI mission is to understand, prevent, and cure cancer. RPCI would like to be among the top 10 of the nation's leading cancer centers. The values associated with this organization are innovation, integrity, teamwork, commitment, and compassion and respect. RPCI seeks to develop research that helps inform current and future generations about cancer. They are committed to making each decision, whether related to patient care, research, education, or administration, based on standards that are thoughtful, informed, honest, transparent when appropriate, and always respectful of privacy. The members of RPCI work as a team, encouraging the input and constructive feedback of all people within the organization. The RPCI organization is devoted to creating progress for patients and families, scientists and clinicians, and students who seek knowledge about cancer. RPCI prides itself on diversity, and appreciates differences as staff members establish research goals, develop care plans, and interact with one another.

RPCI is a founding member of the Blue Distinction Center for Complex and Rare Cancers created by the BlueCross BlueShield Association. This program provides information to patients who have complex, aggressive, or rare cancers to help support their decision making. Complex and rare cancers comprise approximately 15 percent of new cancer cases each year, and these patients have difficulty finding research facilities with oncology teams experienced in treating these specific types of cancers. This designation lets patients and family members know that the specific range of cancers identified as rare and complex are handled at RPCI using the best care and research available.

RPCI is one of the oldest National Cancer Institute–designated Comprehensive Cancer Centers in the United States. It was founded as an offshoot of the University of Buffalo School of Medicine. In the early 1900s, RPCI engaged in important research on immunological reactions with malignancies, and in 1946 was home to the first-ever studies on the effects of atomic radiation on humans. Research, development, and treatment progressed throughout the 20th century.

In 2006, RPCI opened the University at Buffalo's New York State Center of Excellence in Bioinformatics and Life Science and Roswell Park's Center for Genetics and Pharmacology. This was the first facility in Buffalo, and one of the first facilities in the country, to utilize robotic-assisted surgery for patients with bladder cancer. The pioneering technique offers these patients a less invasive treatment option that has several potential advantages over traditional open surgery. By this time in 2006, more than 1,000 patients had undergone blood and marrow transplantations for treatment of cancer and blood disorders at RPCI since its inception in 1991.

RPCI has also expanded service locations by signing a regional affiliation network agreement with Bradford Regional Medical Center, a rural hospital in Pennsylvania, to enhance oncology and hematology programs through research, education, and patient care in the northwestern Pennsylvania and southern tier of New York regions. RPCI continued to expand and reach more patients by launching an international effort to develop new and innovative programs in the prevention, detection, and treatment of lung cancer by establishing
the Stacey Scott Lung Cancer Registry. Joining lung cancer experts representing 11 leading research institutions around the world, this program is organized and stored at Roswell Park and draws from other member institutions’ research data to help scientists understand how lung cancer develops and evolves. Additionally, RPCI recently opened the Amherst Center in Williamsville, New York, to help meet the increasing demand for chemotherapy and infusion services and to help meet the needs of cancer patients in upstate New York.

In 2007, RPCI received the best Cancer Center Support Grant score in its history, and enjoyed the renewal of a five-year grant. New technology was added, including a Trilogy System installed in the Department of Radiation Medicine, which has significantly increased the treatment options available to cancer patients in the Buffalo-Niagara region. This fully integrated powerful image-guided radiation therapy technology delivers precise high-dose radiation therapy to tumors.

Recently, the Minimally Invasive Surgical Center at Roswell Park performed its 100th robot-assisted radical cystectomy for advanced bladder cancer using the da Vinci Surgical Robotic System. This event distinguished RPCI as one of the world’s premier academic institutions for the procedure. RPCI has also created programs that would involve younger generations in the pursuit of a cancer cure by launching an awareness campaign and supportive Web site, http://www.yroswell.com. This site uses a social networking approach by introducing videos, blogs, and other interactive media elements in an attempt to encourage youth to pursue careers in science and medicine.

RPCI continues to aggressively work to help patients and families. They are continuously engaged in research and development of state-of-the-art technology and treatment methods. The care and concern provided by staff members continued to provide them with high-ranking reviews by patients and governing medical agencies. RPCI is committed to continuing the fight to treat and cure all forms of cancer.

Russia

The northeastern Eurasian nation officially termed the Russian Federation became a modern state in 1992. Contemporary Russian historians usually consider the beginning of Russian history to have started in 862 C.E., when a Slavic leader by the name of Rurik created the country of Gardariki. Gardariki eventually dissolved over time, but in the ensuing centuries, the territories that make up modern Russia became important hubs of trade and culture. Tsars ruled the Russian Empire from 1712 until 1922, when the Communist party came to power and created the Union of Soviet Socialist Republics. Since the collapse of the Soviet Union in 1991, the modern Russian Federation has been a republic.

Recently, incidences of cancer account for over 15 percent of all mortalities in Russia, which is much higher than in certain other parts of the world such as Europe and North America; based on cancer statistics in the country, if you are diagnosed with cancer in Russia you have only a 40 percent chance of surviving, whereas in the United States you would have a 67 percent chance of surviving and in the United Kingdom you would have a 60 percent chance. Furthermore, over 25 percent of all Russian cancer patients will pass away in less than 12 months after their diagnoses. Cancer is currently a large problem for the nation for various reasons. For instance, many in the Russian population simply cannot afford the cancer care that comes along with a diagnosis.

Additionally, nearly all of the nation’s advanced treatment facilities are amassed within the largest cities of the country, like St. Petersburg or Moscow.
If a patient does not live close to these areas, then their chances of being adequately treated drastically decrease. After the collapse of the Soviet Union in the early 1990s, it has become much harder for patients to receive even basic radiation treatment. It is now estimated that only about 30 percent of all cancer patients in Russia can garner access to such treatment.

Moreover, Russia is only one of two nations in the entire world with a negative population rate. This negative population rate has largely been attributed to the popularity of alcohol and tobacco usage in the country, which consequently is believed to have a drastic effect on the rate of cancer incidences there. With regard to Russia’s high levels of alcohol and tobacco consumption, the World Health Organization declared the nation one of the most precarious places to live in the entire world. In countless studies conducted by numerous institutions around the world, alcohol and tobacco usage have been strongly correlated with high levels of cancers, such as lung cancers, esophageal cancers, and stomach cancers. As of 2014, there are almost 50 million Russian smokers. Since lung cancer is the most common form of cancer in Russian men, domestic health advocates are calling for much more intensive public campaigns against the use of tobacco. And since cancers linked to high amounts of alcohol use like esophageal and liver cancer are quickly increasing in the country, health activists are striving for more public awareness regarding reducing such behavior.

Diagnosing and screening practices are an aspect of cancer treatment in Russia that can be greatly improved. There are no national screening initiatives in the country for bowel or uterine cancers, though these types of cancers are extremely prevalent in the country. Domestic data seems to suggest that the average Russian cancer patient is diagnosed with the disease when it is already at a very advanced stage, which also indicates that much more can be done in the nation to identify the disease earlier and more effectively within the Russian population. If steps are taken at the regional and federal level to improve and increase diagnosing efforts, then many Russian cancer patients can be given a much better opportunity to survive the disease.

Currently, the most prevalent forms of cancer incidences in Russia are bowel cancer, breast cancer, cervical cancer, lung cancer, and prostate cancer. Lung cancer accounts for the most common incidences in Russian males, followed by cases of prostate cancer and bowel cancers. And while breast cancer rates in Russian females are significantly lower than those of many other modern nations, it is still the leading cancer incidence in women here, followed by cases of cervical cancer and bowel cancer.

Conversely, within the past 10 years certain cancers such as bladder cancer, kidney cancer, and ovarian cancer have seen a nationwide increase in prevalence, while incidences of skin cancer have steadily but consistently been declining. Industrial and manufacturing portions of the nation experience much higher rates of cancer than other parts of the country, and this is believed to be because of the large amounts of radioactive and chemical pollutants that are produced by industrial operations in those regions.

Unfortunately, many citizens of the Russian Federation have had cancer throughout its history. The popular and acclaimed Russian actor Yevgeny Zharikov passed away from an undisclosed cancer in 2012. Mstislav Rostropovich, a Russian cellist who many critics claim was perhaps the best cellist to have ever lived, died in 2007 after a brief battle with intestinal cancer. Elena Donaldson Akhmilovskaya, a female Russian grandmaster of chess who was once one of the great technicians of the game, succumbed to her bout with brain cancer in 2012.

While it is difficult for many Russians to receive cancer treatment for financial and geographic reasons, there is still a good amount of advanced cancer treatment centers in the country, especially in the larger cities of the nation. There is a lot of promising cancer research being conducted in facilities countrywide, such as at the Russian Institute of Experimental Diagnostics and Cancer Treatment. There, scientists are studying various methods of using chemicals extracted from plants to fight the disease. For example, the Australian tobacco plant has been shown to produce a particular kind of antibodies that seem to display anti-cancerous properties. Russian researchers are hoping to find a breakthrough in the global fight against the disease in the midst of such promising research.

Rwanda

The Republic of Rwanda is a central-eastern African country situated in the Great Lakes region. Rwandan culture is divided into three different ethnic groups: the Hutu, Tutsi, and Twa (pygmy people). Until the late 1800s, the Kingdom of Rwanda was ruled by Tutsi people, who kept their power after German and Belgian colonization in 1884 and 1916 respectively. The Hutu population revolted in 1959, causing a vast massacre of Tutsi people and establishing a new independent Hutu state. In 1990, Tutsi revolted, launching a civil war that culminated in the 1994 Rwandan Genocide. During this 100-day genocide, 500,000 to 1 million Tutsi were brutally massacred by Hutu extremists. The Tutsi eventually won the civil war, but the Rwandan economy suffered a tremendous blow. In addition to deaths from the war, more than 2 million Hutu fled the country for fear of reprisal.

Most of the Rwandan population is comprised of very young people: almost half of its inhabitants are under the age of 15, and less than 3 percent are more than 65 years old. The population is predominantly rural, with more than 85 percent of Rwandans living off subsistence agriculture. Kigali is the largest city, with 1 million citizens, followed by Gitarama, Butare, and Gisenyi, all with less than 100,000 inhabitants. Health care in Rwanda is decentralized and has four referral hospitals which are Centre Hospitalier Universitaire de Kigali (CHUK), Centre Hospitalier Universitaire de Butare (CHUB), King Faisal Hospital (KFH), and the Kanombe Military Hospital. The Bamako Initiative, a joint World Health Organization/United Nations Children’s Fund (WHO/UNICEF) initiative aimed at providing African populations with health care services and essential drugs, gave support to the Rwandan health care system in the pre-genocide era, but much of the progress was lost after the massacre. For example, the national cancer registry, established in the Department of Pathology at the University Hospital of Butare in 1991, stopped functioning.

Before the 1994 massacre, the most commonly diagnosed cancers were liver cancer (12 percent), cervical cancer (12 percent), stomach cancer (9 percent), and HIV-related cancers such as Kaposi’s sarcoma (6 percent). A retrospective study of children admitted to the Butare Teaching Hospital
between 1999 and 2005 found that the most common pediatric cancers were Burkitt’s lymphoma, non-Hodgkin’s lymphoma, and Hodgkin’s lymphoma. In 2008, the International Agency for Research on Cancer (IARC) and the WHO estimated that Rwanda had 34.5 cases of cervical cancer and 25.4 deaths attributable to cervical cancer per 100,000 inhabitants. Significant cancer risk factors in Rwanda are HIV, HPV (human papillomavirus), malaria (a possible risk factor for Burkitt’s lymphoma), and high alcohol consumption. Tobacco use was assessed as rare by demographic surveys.

Today Rwanda’s government focuses significant attention on improving its health care system, considerably increasing the funds for the Ministry of Health, leading to considerable improvements in life expectancy in just 10 years. Rwanda’s economic and health development has been so rapid, that actually it’s the only country in sub-Saharan Africa on track to meet most of the United Nations’ Millennium Development Goals. A community-based health insurance program called Mutuelles de Santé was launched in 1999, allowing the government to grant universal health insurance and to provide for the poorest and most vulnerable individuals. In 2010, thanks to the funding provided by the National Cancer Institute (NCI) at the United States National Institute of Health (NIH), a new cancer registry was developed to assess Rwandan cancer burden.

In 2012 Rwanda’s Ministry of Health, together with charity organizations such as Partners in Health (PIH), opened the first comprehensive cancer referral facility in rural east Africa, the Butaro Cancer Center of Excellence. This Cancer Center has delivered high-quality cancer care to many
patients from Rwanda and its neighboring countries, endorsed national protocols for cancer care, expanded Butaro’s pathology lab into a national referral facility, and implemented an electronic medical record system to support national registry inputs.

Since 2009 a national strategic plan for cervical cancer prevention, care, and control was developed and implemented. In 2010 Merck & Co. donated two million doses of the HPV vaccine Gardasil, which were distributed over a period of three years covering 93.2 percent of the eligible girls in the first year, and 96.6 percent in the subsequent year. Vaccines were delivered through a series of designated “health days” each year, which have also been used for a nationwide health and hygiene education campaign aimed at adolescents, and programs designed to deliver iron and folic acid to pregnant women and vitamin supplements to children. Nurses and physicians received intensive training on how to perform screening tests such as the Papanicolaou (Pap) test, visual inspection with acetic acid (VIA), colposcopy, and biopsy on precancerous lesions.

Options for cancer treatment in Rwanda are still somewhat limited: there are currently just a small number of oncologists in the country, and radiotherapy is not yet available.

However, the Faculty of Medicine of the National University of Rwanda is training many new pathologists, and in March 2012 the First National Baseline Cancer Training was held at the Rwinkwavu Training Center. Rwanda became a member of the International Atomic Energy Agency in 2012, a first step toward the construction of a radiation facility, and National Palliative Care Policy was launched in April 2011 to ensure palliative care to terminally ill patients. All health centers can also provide antiretroviral therapy to prevent HIV-related cancers, and cryotherapy and loop electrosurgical excision procedures (LEEP) are available to surgically remove cancerous lesions.

SAGE was founded in 1965 by Sara Miller McCune to support the dissemination of usable knowledge by publishing innovative and high-quality research and teaching content. Today, we publish more than 850 journals, including those of more than 300 learned societies, more than 800 new books per year, and a growing range of library products including archives, data, case studies, reports, and video. SAGE remains majority-owned by our founder, and after Sara's lifetime will become owned by a charitable trust that secures our continued independence.

Salivary Gland Cancer

Salivary gland cancer is considered to be one of the rarest forms of cancer that affects the mouth or the respiratory tract. Salivary glands are composed of tissue that can develop into malignant cells that can affect the mucus production in the glands to aid in digestion and protect the mouth from over dryness.

The salivary glands consist of two parts: the major and the minor. The major section of the salivary glands is divided into the following three parts:

- The parotid glands where most of the cancerous cells are detected. These glands are situated in the front of the ears in the human body.
- The sublingual glands are small and are situated near the back of the jaw.
- The submandular glands are near the sublingual glands.

The minor section of the glands is a less-common site for tumors, though tumors that materialize can be cancerous. Minor salivary glands appear in the tongue, sinuses, larynx (or voice box), nose, and inner cheeks.

The World Health Organization (WHO) has broken down the different types of salivary gland tumors into the following five parts:

- Cancerous epithelial skin tumors
- Noncancerous epithelial skin tumors
- Cancerous cells in soft tissues
- Tumors that are not primary cancer sites
- Lymphomas, such as non-Hodgkin’s lymphoma

Risks Associated With Salivary Gland Cancer

Although salivary gland cancer is rare, medical professionals still warn individuals about the associated risks. Exposure to radiation, such as in the treatment of other head and neck cancers causes a greater risk of developing salivary gland cancer. Researcher indicates that exposure to X-rays can increase risk.

Other factors that affect the risk for salivary gland cancer include age, the cancer is more common in older populations, though it can develop at any time; family history; and environmental factors, such as exposure to toxins.

Some researchers have suggested that diet, alcohol or tobacco consumption, and the use of cell phones also increase risk, but these causes have not been definitively proven.

Symptoms and Diagnosis

Symptoms of salivary gland cancer can include being unable to open the mouth fully, or feeling chronic pain or inflammation in the salivary gland.
region. This may cause a lump to form on the jaw mouth, or neck. Patients may also feel numbness on one or both sides of the face, and facial muscles may feel weak and awkward.

In order to diagnosis salivary gland cancer, medical professionals will conduct a thorough examination that includes noting any problems or abnormalities with the head, mouth, neck, and face. The examination will help detect any presence of enlarged lymph nodes or weakness in the muscles of the face.

Medical imaging tests that help detect the cancer include such as X-ray, magnetic resonance imaging (MRI), computed tomography (CT) scan, and positron emission tomography (PET) scan. In addition the medical imaging diagnostic tools, a fine needle aspiration (FNA) biopsy is performed to expel fluid from the tumor in order to test tissue and cells. This test can be done under general anesthetic. Surgery can also be performed to remove malignant cells and tissue from the affected area.

**Treatment**

With less invasive cases of salivary gland cancer, there may be the opportunity to excise the malignant cells out of the infected area. However, there are some side effects to this type of treatment, such as the inability to heal quickly, continual wound invasions, problems with dealing with aftermath of anesthesia, uncontrollable bleeding, pain that needs to be managed with medication, potential damages to the nerves in the mouth and a condition referred to as Gustatory swelling or Frey syndrome. This condition involves the development of swelling over the nerves exposed during surgery.

Radiation therapy is helpful to direct treatment to the affected area. Side effects of radiation include constant dry mouth, extremely sore throat and trouble swallowing, nausea and vomiting, feeling tired and withdrawn, possible loss of taste, pain and damage to the bone in the face and thyroid gland pain.

Salivary gland cancer can also be treated with a biopsy that involves making a small cut while the patient is under anesthesia so the doctor is able to take the tumor away.

Depending on the location of the cancer—whether it is located within the parotid, submandibular, or sublingual glands—there are special treatments for each of the cancers.

Parotid gland, the gland that is closest to the face, is where most tumors occur. Surgery is performed on the gland remove the tumors, though this it is a tricky procedure as they can be hard to reach. However, if the tumors spread from the parotid gland to the superficial lobe they can be even harder for the surgeon to remove.

Submandibular gland surgery, otherwise referred to as the sublingual gland surgery, is done when the tumor is located in one or both of these areas. Unfortunately, the whole gland is usually removed. There is a risk of having to take pieces of bone and tissue, and there is a strong possibility that nerves of the tongue may also be removed.

Minor salivary gland surgery involves the removal of the cancers from areas in the mouth such as the tongue, lips, and throat.

Chemotherapy is a treatment that is used for any type of cancer. There are medications that are used in addition to chemotherapy such as methotrexate, paclitaxel, cisplatin, carboplatin, 5-fluorouracil, and doxorubicin.
Reconstructive surgery will replace and repair any tissue or nerves damaged from surgery to excise cancer from the salivary gland.

Further Readings

Salivary Gland Cancer, Childhood

The salivary gland is an exocrine gland that produces saliva and amylase, an enzyme the body uses to turn starch into maltose sugar. Each gland includes salivons, consisting of an intercalated duct, striated duct, and excretory duct, and termini acini (berry-shaped cell clusters where the secretion of saliva is released). There are about 1,000 salivary glands in the oral cavity, both major and minor.

Major salivary glands include a pair of parotid glands, the largest salivary glands, wrapped around the mandibular ramus (part of the lower jawbone). These glands secrete serous saliva to begin digesting starch and make swallowing easier. Lesions here can have an impact on the patient’s facial expressions, because of the proximity to the relevant facial muscles and nerve branches. Beneath the lower jaws is a pair of submandibular glands, about two inches above the Adam’s apple and two inches below the chin, which produce most of the saliva, about 70 percent. Under the tongue are the two sublingual glands, which produce mucous saliva. The salivons of the sublingual glands are simpler, lacking intercalated and striated ducts. Though we are often more aware of salivating from near the tongue, these glands are actually responsible for only 5 percent of saliva.

The remaining salivary glands are minor glands located throughout the oral cavity, in the submucosa of the labial, lingual, and buccal tissue, the soft palate, the hard palate, the muscle fibers of the tongue, and the floor of the mouth. Their ducts are also simpler, and they sometimes share an excretory duct among several minor glands. Each is only about a millimeter or two in diameter.

Saliva production is important to oral health (dry mouth can lead to tooth loss and significant gum problems in the long term, and increases incidence of cavities and especially gum disease in the short term). Saliva production is sometimes jeopardized by chemotherapy treatments and radiation therapy.

Salivary gland cancer is rare, and most salivary gland tumors in children are benign. Very young children, though, have a greater chance of developing malignant salivary gland tumors. In other cases, salivary gland cancer is a known side-effect of radiation treatment for other cancers, and so may be a side effect of childhood leukemia, for instance. Cumulative incidence of salivary gland cancer is low even among children with other cancers, but childhood cancer survivors treated with radiation face an elevated risk (positively associated with the dose of radiation) for two decades after exposure.

Salivary gland cancers include acinic cell carcinoma, found in the parotid gland and accounting for most childhood salivary gland cancers in first-time cancer patients; mucoepidermoid carcinoma, characterized by mucus-secreting and squamous cells, occurring more often in adults but sometimes striking late adolescents; adenoid cystic carcinoma, the most common form of submandibular gland cancer; and salivary duct carcinoma, which is very aggressive and usually painful, and found mainly in adult men. There are a variety of benign tumors that can develop, including the soft-tissue tumor hemangioma, a swelling of endothelial cells that
line blood vessels and usually occurs in young children; sebaceous lymphadenoma; Warthin’s tumor, a benign cyst that is more often found in heavy smokers; myoepithelioma, found in the parotid gland or palate; and pleomorphic adenoma, the most common tumor found in the parotid gland.

Symptoms of salivary gland cancer usually begin with a painless lump inside the mouth or near the cheek, jaw, lip, or even ear. Fluid may drain from the ear, or parts of the face may feel numb or weak, or experience pain that does not go away. Mouth trouble may be experienced, from difficulty swallowing to difficulty chewing or opening the mouth wide. Of course, all of these symptoms may be caused by other conditions, and salivary gland cancer’s rarity—accounting for only 2 percent of head and neck cancers—can lead to it escaping initial diagnosis, if it is not a side effect of cancer treatment. Diagnosis is usually performed with imaging.

The prognosis for salivary gland cancer in children is good, and the tumor(s) can usually be removed surgically. Sometimes radiation therapy or chemotherapy follows in order to eliminate surviving cancer cells and prevent recurrence. Acinic cell carcinoma has a 20-year survival rate of more than 50 percent.

Further Readings
Research
From the beginning, the Salk Institute envisioned creating a research environment where scientists and researchers could interact and exchange ideas, studies, and projects. The institute was especially interested in developing expertise in the then-new fields of molecular and cellular biology, as these fields promised to reveal better understanding of human life processes. Although arranged into specific research units, the Salk Institute encourages collaboration between groups. Specific research units at the Salk Institute include:

- Cancer research
- Cellular neurobiology
- Chemical biology and proteomics
- Computational neurobiology
- Gene expression
- Genetics
- Immunobiology and microbial pathogenesis
- Molecular and cell biology
- Molecular neurobiology
- Peptide biology
- Regulatory biology
- Structural biology
- Systems neurobiology

These groups work in independent laboratories, although Kahn’s design of the institute consists of a minimum of walls so that members of different groups can easily communicate with each other.

Salk Institute scientists have examined a range of critical issues related to the underlying causes of cancers. Their discoveries have led to new therapies and directions of research. In 1971, the National Cancer Act dramatically increased funding for cancer research. Since that time, Salk Institute scientists have been leaders of the “war on cancer” initiated by President Nixon. Researchers at the institute have studied the diverse genetic mutations that drive the development of individual cancers. These studies have resulted in important contributions that have increased understanding and helped change cancer treatments offered to patients facing the disease. A series of important discoveries have been made at the Salk Institute that continue to shape new treatments and pave the way for future research.

Nobel Prize–winner Renato Dulbecco, who was a member of the Salk Institute from 1962 until shortly before his death in 2012, conducted studies involving the identification and characterization of mammary gland cancer stem cells. Also involved in the human genome project, Dulbecco believed cancer represents a disease of acquired mutations, and that epigenetic modification of a cell might contribute to the development or progression of cancer. The Cancer Center was established at the Salk Institute in 1970, and originally focused on studying tumor virology. As the center grew, it began to explore other areas, including identifying nuclear hormone receptors and determining their role in physiology and development; characterizing transcription factors that control gene expression and cell growth, differentiation, and patterning; and developing viral vectors for gene therapy.

The Cancer Center currently makes up about half of the research at the Salk Institute, and includes 30 members, about 200 postdoctoral researchers, 40 graduate students, and 100 research assistants. A grant from the National Cancer Institute helps support many shared resources at the Salk Institute, including shared equipment, bioinformatics, functional genomics/quantitative PCR, proteomics, cytometry, imaging, peptide synthesis, transgenic facilities, and viral vector production.

Training
Although not a degree-granting institution, the Salk Institute uses the titles of assistant professor, associate professor, and professor for its members. Through an affiliation agreement with the nearby University of California, San Diego (UCSD), the Salk Institute runs a graduate program that permits students to work toward a Ph.D. or M.D./Ph.D. degree. The Salk Institute also runs a well-regarded postdoctoral program, where graduates from other institutions of higher learning receive training in research skills, grant writing, and leadership. In several areas of biology, the Salk Institute is regarded as one of the globe’s premier organizations of its type, as its research output is among the highest in the world.

The Salk Institute has received support annually through monies awarded to its members in the form of research grants. Most of these research grants have been awarded from the National Institutes of Health (NIH), as well as from private foundations, organizations, and individuals. The March of Dimes has continued to provide funds to the Salk Institute
for every year of its existence, in addition to the monies given for the original structure. The organization of the Salk Institute consists of a board of trustees, a president and CEO, an academic council, and a chairman of the faculty. Together, these individuals help to guide the direction of future research endeavors at the Salk Institute.

Further Readings

Sanford-Burnham Medical Research Institute

Sanford-Burnham Medical Research Institute is a nonprofit medical research institute with operations in La Jolla, California; Orlando, Florida; and Santa Barbara, California. The institute has over 850 scientists who work on the fundamental molecular causes of various diseases, with research including topics such as cancer, neuroscience, stem cell research, diabetes, and obesity. Being a nonprofit institution, research is supported by funding from National Institutes of Health (NIH), National Cancer Institute (NCI), and Juvenile Diabetes Research Foundation among others. In addition, the institution is in partnership with pharmaceutical companies such as Johnson & Johnson Pharmaceutical Research and Development. In 2008 Sanford-Burnham was awarded a $97.9 million grant by NIH to establish a high-throughput screening center.

The Institute was founded in 1976 as the La Jolla Cancer Research Foundation. It was founded by William H. Fishman and his wife, Lillian Waterman Fishman. The cancer center first received its NCI-designation in 1981. In 1996, the Foundation was renamed The Burnham Institute following a substantial donation from Malin Burnham. A decade later, it was renamed the Burnham Institute for Medical Research. After receiving a $20 million donation from Sanford Health in 2007, followed by an additional $50 million a few years later, “Sanford” was added to the name.

The Sanford Burnham Institute is known for paradigm-shifting research in prevention, treatment, and causes of diseases. The Institute’s collaborative, multidisciplinary research on cancer has led to new cancer therapies. In addition, the center remains active in educating and training the next generation of cancer scientists.

The primary objective of the Sanford-Burnham since its inception has been to focus on cancer research. To reach this objective, the institution has more than 1,000 employees among them about 850 scientists. These scientists include biophysicists, chemists, engineers, computer scientists, and biologists. The center currently houses five research centers and is able to conduct research in a wide array of medical areas. The five centers housed in the institution are the Infectious and Inflammatory Disease Center, the Sanford Children’s Health Research Center, the Del E. Webb Center for Neurosciences, Aging and Stem Cell Research, the Diabetes and Obesity Research Center, and the NCI-designated Cancer Center. The Cancer Center has a variety of specific research programs, including the following:

- **Tumor Initiation and Maintenance** seeks to identify the cells that cause tumors and the signals that allow these cells to expand uncontrollably.
- **Cell Death and Survival Networks** focuses on the study of how cancer cells reprogram their metabolism and protein homeostasis to survive nutrient stress conditions associated with tumor progression, and how they might use autophagy
The Ewing family of tumors (EFT) is a group of cancers that occur in bones or adjacent soft tissues. EFT includes Ewing sarcoma of bone, extrasosseous Ewing tumors, peripheral primitive neuroectodermal tumors (pPNET or peripheral neuroepithelioma), and Askin's tumors (pPNET of the chest wall). EFT is characterized by morphologically similar round-cell neoplasms and the presence of common chromosomal translocation that is unique to this group.
First described in 1918, pPNET is a rare tumor with undifferentiated round cells that form rosettes. It occurs in children and young adults under 25 years of age and has a five-year survival rate of about 53 percent. In 1921, James Ewing reported the first case of Ewing sarcoma as a “diffuse endothelioma of the bone.” In 1975, Angervall and Enzinger identified the first case of Ewing sarcoma arising from soft tissue. Ewing sarcoma can occur in all age groups, but is most commonly seen in people in their 20s. Five-year survival for localized disease is 70 percent, while metastatic disease is about 20 percent. Askin's tumor, initially described in 1984, is a malignant small-cell tumor of the thoracopulmonary region with histologic features similar to pPNET. These tumors have a poor prognosis.

Ewing sarcoma is the third most frequent primary sarcoma of the bone, after osteosarcoma and chondrosarcoma. In children, it is the second most common bone tumor after osteosarcoma accounting for 3 percent of pediatric malignancies and approximately 10 percent of primary malignant bone tumors. In the European Intergroup Cooperative Ewing’s Sarcoma Study 86 trial, only 10 percent of cases were diagnosed in patients over 20 years old. Overall annual incidence is about one case per million but this increases at pubertal age group to about five cases per million. It is slightly more common in males than females (1.6:1).

**Clinical Features**

**Tumor Site.** While almost any bone can be involved, Ewing sarcoma occurs more commonly in both flat and long bones followed by pelvic bone involvement (25 percent of cases). Older patients have more aggressive disease with pelvic and generally large-sized tumors. Fifteen percent of patients may have pathological fractures.

**Signs and Symptoms.** Pain, swelling, and a mass (mostly in extremities) are the most common presenting symptoms. Patients with large pelvic tumors may present with bowel/bladder disturbances in addition to pain. Paraspinal tumors may be associated with neurological impairments. Patients with Askin's tumors may present with shortness of breath, chest pain, cough, and pleural effusion. They may have systemic signs and in some cases, fever. Laboratory studies are nonspecific but may reveal anemia, leukocytosis, or increased erythrocyte sedimentation rate. It is common to have a delay between onset of symptoms and diagnosis. This may be because the mass has to become large enough to be palpable.

**Imaging Features.** Ewing sarcoma of the long bones arises from diaphysis or metadiaphysis. It appears as an ill-defined, focally mottled, destructive lesion on X-rays. Periosteal reaction with a multilayered “onion skin” appearance is commonly seen. Other features that may be present are sunburst or spiculated pattern, as well as Codman’s triangle due to periosteal lifting from the bone at the site of detachment. The major radiological differential diagnoses include osteosarcoma, osteomyelitis, and eosinophilic granuloma.

**Pathological Features.** EFT grossly presents as gray-white tumors with variable amount of necrosis, hemorrhage, or cyst formation. The tumors are composed of small round cells with high nuclear-cytoplasmic ratio. Cells have glycogen in their scant cytoplasm that stains positively with periodic acid-Schiff stain, and round nuclei with little mitotic activity. Tumor histology varies from undifferentiated cells in Ewing sarcoma to more differentiated cells in pPNET. Neural differentiation pattern in the form of Homer Wright rosettes may be visible under light microscopy in pPNET. Electron microscopy may detect neurosecretory granules. CD99 expression is detected at high levels in EFT but is not pathognomonic of this disease. Depending on the extent of differentiation, neuron-specific enolase, S-100 protein, and neurofilaments may be expressed. EFT is reactive to anti-Vimentin antibodies. These immunohistochemical stains help distinguish EFT from other small blue round cell tumors.
**Molecular Features:** EFT is characterized by a \( EWS-ETS \) fusion gene arrangement. Ninety percent of cases harbor a \( EWS-FLI1 \) translocation; \( t(11;22) \) (q24;q12). Other ETS members involved in genetic rearrangements with \( EWSR1 \) are \( ETV1 \) and \( EIAF \). These molecular features can be identified by techniques such as fluorescent \textit{in situ} hybridization and polymerase chain reaction.

**Risk Factors and Staging**

Studies have identified gender, age, tumor size, site, fever, serum lactate dehydrogenase levels, anemia, histological response to chemotherapy, and treatment variables as prognostic factors. Children's Oncology Group studies classify patients into three risk groups: those with localized tumors, with lung metastasis only, and with other or multiple metastases. Pretreatment staging allows for determining the limits of tumor involvement and ruling out metastatic disease. Tissue biopsy with cytogenetic and immunohistochemical studies is paramount in diagnosing EFT. Magnetic resonance imaging (MRI) can be used to detect primary lesions and computed tomography (CT) scans are better at diagnosing metastatic disease. Positron emission tomography (PET) imaging highlights metastatic spread to lymph nodes, bone, and bone marrow.

**Treatment**

Most patients have subclinical micrometastatic disease when they present with apparently localized disease at diagnosis. Chemotherapy and radiation are necessary adjuncts to surgery for EFT treatment. Chemotherapy regimens have significantly improved outcomes in patients with pPNET. Current recommendations suggest surgical resection whenever possible, adjuvant or neoadjuvant chemotherapy, and radiotherapy. Recommended chemotherapeutic regimen includes vincristine, doxorubicin, and cyclophosphamide with ifosfamide and etoposide. Outcomes in metastatic disease have not improved with current therapy. Radiotherapy, though sensitive, has a high risk of second malignancy. Ongoing clinical trials in EFT are designed to use targeted therapy against molecular pathways that are essential to EFT pathogenesis. These trials may help identify drugs that have the most treatment response with the least toxicity such that outcomes can be improved for patients with metastatic disease.

**Research**

While basic research studies help identify crucial survival and growth pathways for EFT, translational research is investing efforts into developing tools that can be used for targeted EFT therapy. Antibodies, peptides, and nucleic acid molecules that block critical molecules in EFT are being currently studied. Drug-delivery vehicles such as nanoparticles are being designed to incorporate chemotherapeutic agents so that maximum delivery occurs to the tumors rather than adjoining normal cells.

**Sarcoma, Soft Tissue, Adult**

Adult soft tissue sarcoma is a sarcoma that develops in connective tissue. Cancers are classed according to the type of cell from which they develop: carcinomas develop from epithelial cells, lymphomas and leukemias from hematopoietic cells, and sarcomas from non-hematopoietic mesenchymal cells. In humans, sarcomas are far less common than carcinomas, and the major cancers are all carcinoma type cancers. Mesenchymal cells are cells that make up tissue lacking polarity, such as the tissues of the circulatory and lymphatic systems, bones, cartilage, and connective tissues.
Connective tissue is often fibrous, though adipose tissue is non-fibrous and often considered connective tissue. Connective tissue typically includes type I collagen—which constitutes about a quarter of the protein content of the body—as well as ground substance, a clear viscous fluid composed of glycosaminoglycans and proteoglycans, which fix collagen fibers in intercellular spaces. Connective tissue literally connects parts of the body to one another: collagenous fibers bind bones and tissues to each other, elastic fibers provide the elasticity of certain organs (like lungs), and reticular fibers create a scaffolding for other cells, made up of type III collagen and found in the liver, marrow, and lymphatic organs. Connective tissue functions to protect organs, help to provide a framework for the body, supply hormones, repair tissues, and provide defense reactions.

Soft tissue sarcomas are uncommon, accounting for less than one in 100 new cancer cases, in part because soft tissue cells are not continuously dividing, and so the opportunity for mutation is less frequent. Not all soft tissue sarcomas are associated with known risk factors, and their etiology remains little understood. There are a handful of exceptions, like the link between exposure to high doses of radiation and the development of soft tissue sarcoma (which was discovered in the early history of radiation therapy, when it was used to treat non-cancerous conditions like tonsillitis). The hereditary disease Li-Fraumeni syndrome predisposes the individual toward soft tissue sarcomas, among other cancers.

Most soft tissue sarcomas occur in the upper body, but there are exceptions. One case study detailed a 21-year-old man who came to the emergency room with a swollen foot that he believed had been caused by a drunken slip on the walk home weeks earlier, but an X-ray of the foot showed a distinct mass to the side of one of the metatarsals. A subsequent biopsy showed tumor cells in nests surrounded by fibrous stroma and small areas of necrosis.

Soft tissue sarcomas are asymptomatic in their early stages. Because of the physical characteristics of soft tissue, tumors are usually able to form and grow large before they cause any symptoms or become noticeable through swelling. When soreness does finally occur, it is the result of the tumor growing large enough to press against

*Soft tissue sarcoma photographed through an electron microscope. Soft tissue sarcomas are uncommon, accounting for less than one in 100 new cancer cases, in part because soft tissue cells are not continuously dividing and so the opportunity for mutation is less frequent. Not all soft tissue sarcomas are associated with known risk factors. (National Cancer Institute/Timothy Triche)*
adjacent muscles or pinch nerves. Abdominal soft tissue sarcomas can be mistaken for constipation, digestive problems, or menstrual cramps. In such cases, only the failure of the discomfort to respond to treatment or a worsening of symptoms as the tumor grows will lead to the discovery of the tumor.

Whether the tumor is cancerous (malignant) is determined through a biopsy, either surgically, in which case a surgeon removes the tumor and a pathologist diagnoses it under the microscope, or through fine-needle aspiration, in which a hollow needle is inserted in order to obtain a tissue sample. If malignant, a sarcoma is classified as either low-grade or high-grade, depending on whether it is likely to metastasize. If it does, the lungs are the most common site to which soft tissue sarcomas spread.

Soft tissue sarcoma is usually treated with surgery, preferably with a large margin of healthy tissue in order to decrease the odds of local recurrence. In some cases this can result in the need for amputating part of a limb, depending on where the tumor is located and how big it is. Radiation therapy and chemotherapy are both means of reducing the size of the tumor before surgery, and can be used to eradicate surviving cells after surgery. Radiation therapy can also treat tumors that cannot be safely removed by surgery; chemotherapy is not effective in this regard, but can be used to shrink tumors in patients that are not eligible for surgery.

Soft tissue sarcomas are more common in adults than in children, and adults tend to develop different types of soft tissue sarcomas than children do. In the arms, legs, and trunk, sarcomas may develop as fibrosarcoma, malignant fibrous hystiocytoma, or dermatofibrosarcoma, all of which are sarcomas of fibrous tissue; liposarcoma, developing in the fat; rhabdomyosarcoma, developing in the muscle; hemangiosarcoma, developing in blood vessels; and malignant peripheral nerve sheath tumor, developing from peripheral nerves. In the uterus or digestive tract, leiomyosarcoma can develop from smooth muscle tissue. Lymph vessels can develop into lymphangiosarcoma. Additionally, in the legs, synovial tissue (lining joint cavities) can develop into synovial sarcoma or cartilage can form into extraskeletal chondrosarcoma.

Further Readings

Sarcoma, Soft Tissue, Childhood

Soft tissues are composed of connecting and supporting structures that surround organs and the skeletal system. This includes fat, muscles, nerves, tendons, synovial tissues around joints, tissues with admixture of bone and cartilage, blood vessels, and lymph nodes. Malignant tumors arising in these structures in adults or children are called soft tissue sarcomas (STSs). Childhood soft tissue sarcomas (STSs) account for 7 percent percent of all pediatric tumors.
Types of Pediatric STSs

Rhabdomyosarcoma is the most common STS in children aged 0 to 14 years and accounts for 50 percent of tumors in this age group. The remaining STSs are commonly referred to as nonrhabdomyosarcomatous STS and account for about 3 percent of all childhood tumors.

**Skeletal Muscle STS.** Rhabdomyosarcoma is the most common malignant childhood STS and has various subtypes depending on histology and genetic features. Prognosis is associated with tumor stage and grade.

**Connective Tissue STS.** Liposarcomas are rare tumors that arise from fat cells deep in regions such as the thigh or retroperitoneum. Most pediatric liposarcomas are low-grade, spread very slowly, and respond well to treatment. Pleomorphic high-grade liposarcomas, however, have poor treatment response and an unfavorable prognosis.

Desmoid tumors (aggressive fibromatosis) are low-grade fibrous tissue tumors that recur near primary site but rarely metastasize. Most occur sporadically, however 10 percent may occur in individuals with Gardner’s syndrome, a type of familial adenomatous polyposis.

Fibrosarcoma originates in bony fibrous tissue and invades long or flat bones, and may involve the periosteum and overlying muscle. Congenital or infantile fibrosarcoma occurs in children under 4 years of age and may be detected by perinatal ultrasound. Most of these tumors have a chromosomal translocation, t(12;15), and the associated fusion gene ETV-NTRK3 is useful for its diagnosis. Fibrosarcoma in older children and adolescents do not have this genetic change.

Dermatofibrosarcoma protuberans is a skin dermis tumor, 90 percent of which harbor a genetic translocation, t(17;22). The fusion gene COL1A1-PDGFB produces a self-stimulatory growth signal that allows tumor growth. Less than 5 percent of tumors metastasize.

Inflammatory myofibroblastic tumors are characterized by a mix of inflammatory cells localized to a soft tissue area, and may have genetic rearrangements involving the ALK gene. Tumors have random areas of cell growth and death, calcification, and bleeding. They can recur after treatment but rarely metastasize.

**Low-grade fibromyxoid sarcomas** are associated genetic rearrangements, t(7;16) or t(11;16). They have a long clinical course with potential local recurrence or distant metastasis to the lung, sometimes decades after primary diagnosis.

**Peripheral Nervous System STS.** Malignant peripheral nerve sheath tumors affect the covering of nerves that are not part of the brain or spinal cord. About half the cases are seen in patients with a genetic condition termed neurofibromatosis type I.

**Smooth Muscle STS.** Leimyosarcomas are tumors associated with smooth muscles lining blood vessels and hollow internal organs such as stomach, intestines, bladder, and uterus. They are commonly associated with Epstein-Barr virus in HIV-positive children. Children with inherited retinoblastoma are at secondary risk for this disease.

**Vascular STS.** Angiosarcomas grow very rapidly from cells lining the inside of blood vessels and have a tendency to metastasize.

Epithelioid hemangioendotheliomas occur most often in livers of infants although they can be seen elsewhere. In infants, the tumors may go away without treatment and are generally benign. Benign tumors can be treated with liver transplants but may become malignant and spread to lungs, lymph nodes, bones, abdomen, and pelvis in some cases.

Hemangiopericytomas occur in lining of the blood capillaries. It can be very aggressive if found within the nervous tissue. Patients under one year of age have favorable prognosis when compared to older children where the tumor is more likely to metastasize to lymph nodes and lungs.

**Extraskeletal Bone and Cartilage STS.** Extraskelatal chondrosarcoma and osteosarcoma are cartilage and bone tumors that can grow quickly and metastasize.

**Fibrohistiocytic STS.** Plexiform fibrohistiocytic tumors appear as a painless nodule in skin of arm, wrist, or hand and rarely spread.

Undifferentiated pleomorphic sarcoma may be seen in children if they have received radiation previously or have retinoblastoma. They are usually found on extremities and can metastasize.
**Other STS.** Alveolar soft part sarcomas are rare tumors that can spread to other organs. Prognosis is favorable if the tumor is completely resected or is 5 cm in size or smaller. Histologically, the cells are arranged in a similar fashion as lung alveoli.

Desmoplastic small round cell tumors predominantly occur in boys and young adults, and can be aggressive. They occur as an abdominal or pelvic mass and can spread to lungs and other organs.

Perivascular epithelioid cell tumors such as renal angiomyolipomas and pulmonary lymphangioleiomyomatosis commonly occur in children affected with tuberous sclerosis.

Extrarenal (extracranial) rhabdoid tumors are rare, fast-growing cancers that usually occur in young children. They are frequently associated with 22q11.1 chromosomal deletions resulting in loss of SMARCB1 tumor suppressor gene.

Extraskeletal myxoid chondrosarcoma is a rare tumor often characterized by a translocation resulting in the fusion gene EWSR1-CHN. This generally indolent tumor may relapse after treatment with a 40 percent chance to metastasize.

Primitive neuroectodermal tumors are derived from neuroectodermal cells that have not completed differentiation. These rare tumors belong to the Ewing family of tumors and are seen in children and adults under 25 years of age.

Synovial sarcomas occur in soft tissues near joints in extremities, but may also form in the trunk, head or neck. Most cases are associated with a translocation t(x;18) resulting in the SS18-SSX fusion gene that promotes tumor development. Age under 10 years and tumors 5 cm or smaller have good prognosis. Large tumors can spread to other organs.

**Presentation**
Children usually present with painless lumps under the skin over the arm, leg, or trunk. There may be no more symptoms until the tumor grows large enough to press on other surrounding structures or organs.

**Diagnosis**
Imaging can help identify bone involvement and calcification seen in extraskeletal bone tumors, and can detect metastasis. Tumor biopsy can be used for conventional histology, immunocytochemical analysis, cytogenetics, fluorescence in situ hybridization, and molecular pathology given the diagnostic importance of translocations in almost all STSs.

**Treatment**
Treatment is based on age, tumor type, stage, and grade. Childhood STSs have better outcomes with multimodal therapy including surgery, with pre- or post-surgery chemotherapy and radiation therapy that is only reserved for unfavorable cases. Most STSs do not respond to chemotherapetry alone. Radiotherapy is associated with long-term morbidity in children as most organs can be damaged during their development years.

**Sarcoma, Uterine**

Uterine sarcoma is a cancer that forms from the smooth muscle or connective tissue of the uterus. Sarcomas form from mesenchymal cells rather than epithelial cells as carcinomas do, and are the rarer form of cancer in humans. All sarcomas combined comprise only about 1 percent of American cancer diagnoses each year. Uterine sarcomas are largely found in postmenopausal women, especially those who have taken tamoxifen over a long-term period. Pelvic radiation is another risk factor—and so uterine sarcoma is very often the second cancer the patient has developed in her life—and African American women are twice as likely to develop a uterine sarcoma than white or Asian women.
Beyond these risk factors, causes of the disease are not yet understood.

There are several kinds of uterine sarcomas depending on where they originate. Tumors originating in uterine muscle cells are uterine leiomyosarcoma (LMS), accounting for 5 percent to 10 percent of soft tissue sarcomas. Resistant to both chemotherapy and radiation treatment, leiomyosarcomas are also unpredictable in their recurrence, sometimes recurring years later. The best prognoses are for patients who discover the tumor early and in whom surgery with wide margins can be performed. The widest possible margins are preferred when excising uterine sarcomas, in order to ensure that the whole tumor is removed—partly because of the cancer’s tendency to recur and partly because of any surviving cancer cells’ high odds of surviving both chemotherapy and radiation. Hormone treatments have had some success.

LMS are staged using the 2009 FIGO staging system, in which stage I is a tumor limited to the uterus; stage II, extending beyond the uterus but within the pelvis; stage III, infiltrating the abdominal tissue; stage IVA, infiltrating the bladder or rectum; and stage IVB, distant metastasis.

Uterine sarcomas originating in the stroma (connective tissue) of the uterine lining are endometrial stromal sarcomas. Low-grade endometrial stromal sarcomas resemble phase endometrium, but behave more aggressively, and express estrogen and progesterone receptors. Undifferentiated high-grade endometrial stromal sarcoma does not resemble normal endometrial tissue, and is even more aggressive. Either type can metastasize, though undifferentiated sarcoma is more likely to. The sarcoma is visible under a microscope as a tongue-like infiltration of tissue between muscle bundles, with prominent arterioles and 10 to 15 mitotic figures per 10 HPF. Foam cells may be visible in the stroma.

Uterine carcinosarcomas are one of a few types of tumors that are a combination of carcinoma and sarcoma, consisting of both epithelial and mesenchymal cells. Similarly, uterine adenosarcoma combines both uterine cancer of the mesenchymal tissue and a benign glandular component. Uterine adenosarcomas and endometrial stromal sarcomas are staged the same as LMS.

A mixed Mullerian tumor is a type of carcinosarcoma that is found in the uterus, ovaries, or fallopian tubes, and may be either homologous or heterologous. A heterologous tumor includes sarcomatous tissue from outside the uterus, including skeletal muscle, bone, or cartilage. About 2 percent to 5 percent of uterine cancers are mixed Mullerian tumors, found mainly in postmenopausal women.

Uterine sarcoma symptoms may include unusual or postmenopausal vaginal bleeding, pelvic pain or pressure, discharge, or an enlargement of the uterus. There is no specific screening test, and diagnostic tools include computed tomography (CT) or magnetic resonance imaging (MRI) scans, biopsy, and hysteroscopy. Surgery usually involves a total abdominal hysterectomy. Radiation therapy, chemotherapy, and hormonal therapy are all options either following surgery or in lieu thereof. Prognosis is poor for leiomyosarcoma and undifferentiated sarcomas, except in patients who are diagnosed early (in which case the five-year relative survival rate is over 60 percent), but the relative survival rate for endometrial stromal sarcoma is very high.

The uterus can also develop noncancerous tumors in the connective tissue, including leiomyomas, adenofibromas, and adenomyomas, known collectively as fibroid tumors. Most require no treatment, but some may need to be removed because their presence is causing bleeding, pain, or constipation. In such cases, surgery (either a myomectomy or a hysterectomy) is common, but killing the tumor with electricity, freezing it with liquid nitrogen, or blocking the blood vessels until it withers and dies, are all options.

Sarcoma Foundation of America

The Sarcoma Foundation of America (SFA) advocates for sarcoma patients by funding research and increasing awareness. The foundation funds research for new sarcoma therapies, advocates for government funding, and encourages alliances with the pharmaceutical and biotechnology industries. In addition the SFA advocates for early detection, optimal patient care, and early access to newly developed treatments.

Incorporated in 2000, the SFA was founded by Dr. Mark Thornton and Mrs. Patricia Thornton. It is a nonprofit organization. SFA has thousands of members in all 50 states. Since 2003, SFA has funded 57 sarcoma research grants. SFA started the Sarcoma Patient Registry, which gathers data that can be used as a resource for oncologists and researchers. Anyone diagnosed with any sarcoma subtype can join the registry for free.

Cancerous tumors found in connective tissues—such as cartilage, muscles, bones, fat, blood vessels, nerves, and deep skin tissues—are sarcomas; they are typed by either bone sarcomas or soft tissue sarcomas. Pediatric patients account for about 15 percent of all sarcomas. Approximately 14,000 new cases are diagnosed per year in the United States. Soft tissue sarcomas, a rare form of cancer, occurs about one percent of the time among all cancer diagnoses. About 3,900 people die each year from this disease. Common causes associated with soft tissue sarcomas include: exposure to phenoxyacetic acid (in herbicides), exposure to clorphenols (in wood preservatives), exposure to high doses of radiation, genetic abnormalities, and chromosome mutations.

Soft tissue sarcomas rarely cause any symptoms in the early stages because soft tissue is very elastic. Tumors tend to grow quite large before any lumps are noticed. It is when the tumor presses on nearby muscles and nerves when pain or soreness occurs. A surgical biopsy is the only form of diagnosis. The following are subtypes of soft tissue sarcomas:

- **Liposarcoma:** Usually develop in deep fatty tissue in the thigh, the gluteal area, the groin, behind the knee, or behind the abdominal cavity.
- **Fibrosarcoma:** Usually found in the arms, trunk, or legs.
- **Dermatofibrosarcoma Protuberans:** A lesion that protrudes out of the skin usually on the back or abdomen;
- **Synovial Cell Sarcoma:** Most often found in the arms or legs next to a joint in young adults.
- **Epithelioid Sarcomas:** Usually found in the hand or foot of young adults.
- **Rhabdomyosarcomas:** Found in the striated or skeletal muscle and most often found in children.
- **Leimyosarcoma and Uterine Sarcoma:** Found in smooth muscle of the uterus and GI tract.
- **Mycomas:** Most often found in the arms and legs of men and women about 50 years of age.
- **Mesenchymomas:** Found throughout the body.
- **Vascular Sarcomas:** Contain many blood vessels.
- **Neurilemmomas:** Found in peripheral nerves and are most common in young to middle aged male adults.
- **Alveolar Soft-Parts Sarcoma:** Found in the extremities and usually occurs in female adolescents and young adults.
- **Kaposi's Sarcoma:** Usually found in the tissues under the skin or the mucous membranes of the mouth, nose, and anus.

Several of these subtypes of soft tissue sarcomas also have their own subtypes.

Surgery, radiation, and chemotherapy are the typical treatment methods used in soft tissue sarcomas. Any of these methods can be used singularly or in combination depending upon the location, growth rate, and size of the tumor. Biological
therapy and targeted therapy continue to be methods available with improvements in prognosis as science advances.

Bone cancer sarcomas have three subtypes: chondrosarcoma (found in the cartilage), Ewing’s sarcoma (found in bone or soft tissue), and osteosarcoma (found in bone). Approximately 2,890 people are diagnosed with bone cancer sarcomas in the United States each year; of those there are approximately 1,410 deaths. Bone sarcomas are much more likely to be diagnosed in children. Symptoms vary depending on size and location of the tumor, but pain is the most common symptom. Other symptoms can be anemia, fatigue, bone fractures, and weight loss.

Surgery and chemotherapy are the most common treatment methods. Amputation is sometimes necessary but limb-saving treatments are available with the use of chemotherapy before surgery to remove the tumor. In this case, chemotherapy or other anti-cancer drugs will also follow surgery.

SFA supports the American Society of Clinical Oncology’s (ASCO) mission to improve cancer care and prevention and that all patients receive the best possible care. The ASCO’s research and education goals includes the Conquer Cancer Foundation. The SFA has helped to fund nine Conquer Cancer Foundation grants, two Advanced Clinical Research Awards in Sarcoma, and four Young Investigator Awards. The Career Development Award supports clinical investigators in their first to third year of a faculty appointment whose goal is to establish an independent cancer research program. The Advanced Clinical Research Award supports researchers who have designed original research that does not yet have funding. The Young Investigator Award is designed to promote research in clinical oncology for researchers during their transition from a fellowship program to a faculty appointment.

Advocating for persons impacted by sarcoma is a core principal of SFA. Active engagement with public policy is a high priority for SFA, especially with regard to access to quality patient care, drug development, and cancer research. The SFA has urged Congress to fully fund the FDA and National Institutes of Health (NIH) since drastic cuts have had a significant impact on the budgets of science and health programs. A bill introduced by Representatives Cliff Stearns (R-FL) and Ed Towns (D-NY) called the Unlocking Lifesaving Treatments for Rare-diseases (ULTRA) Act has been supported by the SFA. The Act would allow the FDA more flexibility to approve drugs for rare diseases. The Creating Hope Act, also supported by SFA, proposed in the U.S. Senate, creates incentives in the development of treatments for rare diseases that have a disproportionate impact on children.

Saudi Arabia

Saudi Arabia is an absolute monarchy founded upon the tenets of Islam. The King of Saudi Arabia is the head of the government but his decisions are made after consultation among the senior princes of the royal family and the religious establishment. All references noted herein are government agencies.

Saudi Arabia has kept careful records of incidences of cancer in the country. Per the Cancer Incidence and Survival Report 2007 by the Saudi Cancer Registry, 12,309 cases of cancer were diagnosed in Saudi Arabia in 2007. Saudi Arabia’s population at the time was approximately 17 million. Breast cancer ranked first (13.8 percent), then colorectal (9.9 percent), non-Hodgkin lymphoma (7.7 percent), thyroid (6.4 percent), leukemia (6.2 percent), liver (4.8 percent), and lung cancer (4.5 percent). Most common cancers in women were breast, thyroid, colorectal, non-Hodgkin lymphoma, and leukemia; in men non-Hodgkin...
lymphoma, leukemia, lung, and liver. Female age-standardized incidence rate (ASR) was 84.7 per 100,000 compared to 282.8 per 100,000 for the United States. The ASR for males was 80 per 100,000 compared to 353.4 per 100,000 for the United States.

While the cancer rate is now projected to be lower than the rate in the United States for the next two to three decades, it is still likely to increase. A main reason for this is an aging population, which will bring more people into the “cancer zone.” Another reason is the recent introduction to the country of the Western (U.S.) lifestyle. This is characterized by both a more sedentary lifestyle and an increase in the consumption of Western junk food. In Saudi Arabia, fast-food restaurants are now as popular as they are in the U.S. The number of smokers in the country is also increasing; therefore the prevalence of lung and other smoking-related cancers is projected to increase in the next 20 to 30 years.

The Kingdom of Saudi Arabia is fighting this expected increase in cancer with many facilities where treatment of stages of disease can be given equal care with the highest international standards. Previously, modern cancer treatment could only be found in three major cities: Riyadh, Jeddah, and Dammam. Recently, however, cancer centers have appeared in smaller cities, including Makkah, Madina, and Qaseem, with several more on the way.

Saudi Arabia has also made training physicians a top priority. Most of the practicing oncologists in Saudi Arabia were educated in North America. Ambitious health sciences universities in Saudi Arabia now educate medical, nursing, and other related health science staff to be prepared for the expected increase in cancer diagnoses.

Another unique part of Saudi cancer care is that Saudi law guarantees that all patients with cancer receive free care. There are multiple governmental and nongovernmental organizations dedicated to cancer control, such as reducing tobacco use and screening and early detection programs.

Cancer Organizations
The Saudi Cancer Registry (SCR) is responsible for the collection, maintenance, and dissemination of population-based cancer data. There are over 170,000 cancer cases that were reported from 1994 to 2010 from over 500 governmental and private hospitals, physician’s offices, cancer treatment centers, and pathology laboratories. The SCR collects information on cancer cases such as the types of cancers, the infection sites and extent of cancer at the time of diagnosis. Patient characteristics and predications of cancer are also studied.

The SCR began reporting cancer cases beginning in January 1994. In 2013 the SCR became part of the council of health services. The foremost goal of the SCR is to continue to define population-based rates of cancer occurrence in Saudi Arabia. Additional objectives include programs for early detection and cancer screening, as well as cancer research projects.

A later report from the SCR tracks the incidence of cancers for one year 2010. The total number of cancers reported to the SCR was 13,706. Overall cancer was more prevalent among women than men. Cancers affected 6,579 (48 percent) males and 7,127 (52 percent) females, with a male to female ratio of 92:100.

Childhood Cancers
As part of the SCR 2010 study, childhood cancers were evaluated. The total cancer cases reported among children (0 to 14 years) in 2010 was 796. This figure represents 5.8 percent of the total cancers reported. The incidents show that cancer was more prevalent among boys than girls—482 (60.6 percent) cases reported were boys and 314 (39.4 percent) among girls, with a male to female ratio of 154:100. Childhood cancer is most important because 41.7 percent of the Saudi population is under 15 years of age. In addition to this, there has been a major breakthrough in the cure of childhood cancers. The leading cancer among Saudi children was leukemia, which accounted for 33.3 percent, followed by brain, 12.9 percent, Hodgkin’s disease, 9.2 percent, non-Hodgkin lymphoma, 8.1 percent, and kidney, 6.1 percent. This report has many charts and tables illustrating the above findings.

Cancer Incidence for Most Common Sites, 2010
According to the data collected from January through December 2010, statistics for the top four cancer diagnosed are as follows:

Breast Cancer. There were 1,473 female breast cancer cases. Breast cancer ranked No.1 among females, accounting for 27.4 percent of all newly diagnosed
female cancers (5,378) in 2010. The ASR was 24.9 per 100,000 population for female population.

**Colorectal.** There were 1,033 cases of colorectal cancer equaling 10.4 percent of all newly diagnosed cases. This cancer ranked first among males and third among females. It affected 541 (52.4 percent) males and 492 (47.6 percent) females with a male to female ratio of 110:100. The overall ASR was 9.6/100,000. ASR for males was 9.9/100,000 and for females 9.2/100,000.

**Non-Hodgkin Lymphoma.** Non-Hodgkin lymphoma is any of a large group of cancers of lymphocytes (white blood cells). Non-Hodgkin lymphomas can occur at any age and often present with enlarged lymph nodes as well as fever and weight loss. There are many types of non-Hodgkin lymphoma. There were 703 cases of non-Hodgkin lymphoma, 7.1 percent of all newly diagnosed cancers. This cancer ranked second among male population and fourth among female population. It affected 407 (57.9 percent) males and 296 (42.1 percent) females with a male to female ratio of 138:100. The overall ASR was 5.7/100,000. ASR for males was 6.2/100,000 and 5.2/100,000 for females.

**Thyroid.** There were 697 reported cases of thyroid cancer or 7.0 percent of all newly diagnosed cases. This cancer ranked second among the female population and 12th among the male population. It affected 149 (21.4 percent) males and 548 (78.6 percent) females with a male to female ratio of 27:100. The overall ASR was 4.9/100,000. ASR was 2.3/100,000 for males.

The remaining reported cases of cancers was as follows: leukemia, liver, lung, Hodgkin disease, skin (nonmelanoma), stomach, kidney, prostate, bladder, and ovarian cancer.

**Conclusion**
Saudi Arabia will likely become a giant in the care and cure of cancer. They have the money to invest in facilities and top physicians. However, as noted, they may need all they can get. The forecast is for the cancer rate to rise significantly in the next 20 to 30 years.

**Further Readings**

**Screening**

Early detection is key to preventing and treating many cancers as it provides doctors a better chance to outline effective treat and ensure better survival rates. Promoting awareness of these screening tests is an important part of improving outcomes for patients.

**Evidence-Based Recommendations and Implications for Care**

The U.S. Preventive Services Task Force (USPSTF) is responsible for many of the cancer screening recommendations in existence today. Made up of 16 volunteer members who are experts from a variety of medical backgrounds, this task force continually reviews scientific evidence on preventative health care services and develops recommendations for clinicians. The USPSTF not only evaluates the research on services in terms of preventing or detecting a disease, but also evaluates the benefit/harm ratio of the service. The preventive services recommended by the USPSTF cover many diseases and conditions, and generally fall into four categories: screening tests, immunizations, counseling, and preventive medications.

The USPSTF recommendations are important for a number of reasons. The recommendations are based on a continual, systematic review of many studies over a long period of time, meaning no single study will influence their recommendations.
The task force does not simply approve or reject a preventative service; instead, each recommendation is given a letter grade based on the evidence and the benefit/harm ratio of the preventative service, and the recommendations provide specific information regarding age, gender, medical history, and health behaviors. Fourth, the USPSTF recommendations have implications for health care delivery. Because the task force has the support of the Federal government (and is convened by the Agency for Healthcare Research and Quality), the recommendations often affect which preventative clinical services are covered by Medicaid, Medicare, and even private health insurance plans. In fact, one important component of the Affordable Care Act requires that most preventative clinical services recommended by the USPSTF be covered by the health insurance plan at no additional cost to the patient (i.e., no cost-sharing for the patient).

Cervical Cancer Screening
Cervical cancer is one of the easiest cancers to prevent. There are two cervical cancer screening tests that women can receive, and each comes with different recommendations depending on a patient’s age, medical history, and frequency of test.

The first is the Pap test (sometimes called a Pap smear). The Pap test is one of the most widely used cancer screenings in the world. Developed by an American Obstetrician/Gynecologist around 1930, the Pap test is extremely successful in detecting precancerous cells on a woman’s cervix. The test is performed by a doctor, usually in conjunction with a pelvic exam. A speculum is used to widen the vagina, then a small brush is inserted to collect a sample of cells and mucus from the lining of the cervix in order to determine if any abnormal cells are present. An unclear or abnormal result typically means that there are cell changes or abnormalities on the cervix and that the patient may need further follow-up tests to see if those abnormalities are cancer-related.

For many years the recommendation for cervical cancer screening was once a year. In 2012, however, the USPSTF changed the recommendation for screening (via a Pap test) to once every three years for women aged 21 to 65, or once every five years for women ages 30 to 65 if the Pap test is done in combination with the test for human papillomavirus (HPV). Additionally, women were previously advised to begin screening within three years of onset of sexual activity, or no later than 21 years of age. However, the new recommendations advise women to begin screening at age 21 and not any earlier, essentially eliminated the consideration of sexual activity as a risk factor in determining the necessity for the test. One recommendation that did not change is that healthy women without a history of negative test results should stop screening at age 65. While these changes to the recommendations for cervical cancer screening initially caused concern among doctors and patients, the USPSTF has determined that risks of more frequent screening (or screening at younger ages) outweigh the benefits. In any case, women with a history of repeated negative test results should continue to receive annual screening for 20 years from the date of the last negative result, even if this means going past age 65. The second screening test is the human papillomavirus (HPV) test.

Persistent infections of several high-risk strands of HPV are known to cause more than 90 percent of cervical cancers. Because of this, detecting a high-risk HPV infection early can alert doctors and patients to the need for more frequent testing and monitoring, in case cervical cancer does develop (although most HPV infections do clear up on their own). The HPV test is usually, but not always, performed in conjunction with a Pap test. Both tests use a similar technique in which cells are collected from the cervix using a small brush, the sample is sent to a lab, and then for this specific test, a computerized system assesses the cells for the presence of high-risk HPV. Even though the HPV can be present in both men and women, the test is only available to women because it is designed to assess cells taken from the cervix.

Prior to 2012 the USPSTF did not have any recommendations for regular HPV testing because the task force did not have enough evidence to create guidelines for this test. However, in 2012, the task force recommended that women under 30 need not have an HPV test, because most HPV infections clear on their own in young, healthy women. Additionally, as previously mentioned, the USPSTF designated that women over the age of 30 can reduce the frequency of Pap tests they receive, from every three years to every five years, if they also have an HPV test every five years.
Breast Cancer Screening

There are three general types of breast cancer screenings that can be done. The first two are very similar and can be completed without any medical equipment; they are the clinical breast exam (CBE) and the breast self-exam (BSE). The main difference between the CBE and the BSE is that a doctor performs the BSE. This is important to note for two reasons.

First, the doctor may detect something that the patient misses, as they are highly trained to detect symptoms. Second, the CBE provides an excellent opportunity for the doctor to teach the patient how to perform a correct BSE. In either case, the individual performing the test first checks for a change in breast appearance, such as color, shape, and size. Next, using various levels of pressure, the breast tissue is felt for any lumps or abnormalities. If one is discovered, the doctor may discuss further screenings or procedures with the patient, such as a biopsy. However, the doctor may also be able to decide if a suspicious lump is merely a cyst or, by knowing a patient’s history, that this particular patient has fibrocystic breasts (which often have small bumps throughout them). Because both of these screening procedures are non-specific and have much room for error, and no literature exists supporting their efficacy in comparison to no screening activity, the USPSTF actually recommends against teaching BSE to patients, and concludes there is insufficient evidence to support CBE. However, anecdotal evidence abounds in support of the value of these screening tests. Hence, many health organizations recommended monthly BSEs and regular CBEs with a doctor.

The main tool used by health care professionals for breast cancer screening and diagnosis is the mammogram. A mammogram is performed by taking an X-ray (using very low levels of radiation) of each breast, making it possible to see small tumors or lumps that cannot be felt. During a mammogram, the breast is compressed between two metal plates in order to spread out the breast tissue for a better X-ray view. If the doctor determines that the X-ray shows abnormalities, a follow-up biopsy of any lumps may be performed. It is important that the doctor have access to previous patient mammograms for comparison, as this will allow him or her to see if any changes have occurred in the breast tissue.

At the time of this writing, the USPSTF was in the process of reviewing the scientific evidence on breast cancer screening practices. The recommendations from 2009 state that healthy women begin receiving biennial mammograms (every 2 years) starting at age 50; after age 75, the recommendation is that women receive no benefit from continued screening. In addition, because breast cancer is linked to genetics and family history, the USPSTF specifically recommends that women at a higher risk for breast cancer speak with their individual doctor about beginning regular mammogram screening earlier in life.

The USPSTF’s 2009 guidelines differ widely from the recommendations for early detection from the American Cancer Society which recommends CBEs and mammograms once a year for all women over the age of 40, and CBEs alone every three years for women in their 20s and 30s. Additionally, counter to the USPSTFs discouraging BSE, the American Cancer Society encourages all women to perform self-exams starting in their 20s, as a way to familiarize themselves with the normal look and feel of their breasts as a way to better identify any changes that may occur. For women considered high-risk,
due to genetic or other factors, magnetic resonance imaging (MRI) may also be recommended.

**Colon Cancer Screening**

There are several types of colon cancer screenings recommended by the USPSTF; these screenings vary in terms how the test is done and how often a person needs to get screened.

The colonoscopy is the most comprehensive and invasive colon cancer screening test. The colonoscopy is performed in a doctor’s office. The doctor uses a long, lighted tube with a small camera, called a colonoscope to see inside the rectum and the entire colon for polyps, tumors, or inflamed areas. The image is transmitted to a large screen in the examining room, which allows the doctor a clear view of the area. The tube may also be equipped with a small device for taking tissue samples of the colon, in order to further examine the tissue for cancerous markers; this is known as a biopsy. Polyps may also be removed during the colonoscopy.

Though the colonoscopy is an in-office procedure, patients do undergo mild sedation and generally need some time to recover before going home. While the colonoscopy itself only takes about 30 to 45 minutes, a patient does have to engage in several pre-colonoscopy tasks that ensure his or her bowel is empty (which is necessary for a clear view of the colon). This includes, but is not limited to: limiting solid food intake for a day before the test, drinking a bowel preparation solution that helps to clean out the bowel, and receiving one or two enemas before the procedure. Many patients report the preparation for the colonoscopy is more uncomfortable than the procedure itself.

The USPSTF recommends that healthy people begin regular colonoscopy screening at 50 years of age and receive follow-up screenings every 10 years. The task force also recommends that routine colonoscopy screening is unnecessary for healthy patients age 76 and older, and no screening is recommended for patients over 85. However, high-risk patients of any age with certain gastrointestinal conditions, a family history of colon cancer, or other high-risk factors are advised to talk with their doctor about more frequent screening.

The flexible sigmoidoscopy is similar to the colonoscopy and is also performed in a doctor’s office. After the patient participates in the same bowel cleaning tasks described above, the doctor uses a lighted tube called sigmoidoscope (which is significantly shorter than the colonoscope) to see into the rectum and the lower third of the colon. The doctor will look for polyps, tumors, and other inflamed areas, and may take a biopsy. There are two main differences between the colonoscopy and the sigmoidoscopy. First, the sigmoidoscopy is considered slightly less invasive than the colonoscopy. Many patients do not need the mild sedation during this test and therefore have quicker recovery time; they can drive themselves home. Second, the sigmoidoscopy is not as comprehensive a test as the colonoscopy, because it only examines the lower third of the colon. This portion of the colon may appear healthy, but there could be problems in the upper two-thirds of the colon.

The USPSTF recommends that healthy people should begin regular flexible sigmoidoscopy screening at 50 years of age and should have the test once every five years. Because it is a less thorough test than the colonoscopy, the task force recommends that those relying on the sigmoidoscopy screening every five years should complement their care with a fecal occult blood test every three years (described below). The sigmoidoscopy is not recommended for patients over 76 years of age (and especially those over 85 years of age), though high-risk patients should discuss more frequent screenings with their doctor as necessary.

The fecal occult blood test (usually just called FOBT) can be done at home. Patients are given a test kit by their doctor and are instructed to use the provided stick or brush to take one or more samples of their stool; they then return the test kit containing the obtained sample to their doctor. The stool sample is sent to a lab and is tested for traces of blood, which may be a symptom of colon cancer. If the test gives a positive or inconclusive result, a follow-up procedure such as a colonoscopy is usually recommended. Some newer tests, such as the fecal immunochemical test (FIT) or immunochemical fecal occult blood test (iFOBT) even allow the patient to perform the blood test at home by adding certain chemicals to the sample to detect if blood is present. However, these tests are more expensive than the regular FOBT. The USPSTF recommends that healthy people should begin regular FOBT screening at 50 years of age and should be screened every year.
Promoting Use of these Screening Tests

One of the biggest challenges to successful cancer control is underutilization of these screening procedures. Each of the screening tests described in this entry comes with its own unique challenges. In addition, different patient population characteristics, such as education, race/ethnicity, and geographic location, can affect whether these screening procedures are used.

The Pap test, and to a lesser extent, the HPV test, have been extremely useful tools in the early detection of cervical cancer. These tests alert doctors and patients to early symptoms of the disease, which allows for earlier diagnosis, treatment, and monitoring.

While cervical cancer rates are still relatively high, the U.S. Department of Health & Human Services reports that between 1955—soon after the introduction of the Pap test—and 1992, cervical cancer rates fell more than 60 percent. In 2010 (before the new USPSTF recommendation for starting Pap tests at age 21), the CDC reported that only 73.2 percent of women aged 18 years and over had received a Pap test in the last three years. This means that more than a quarter of American women were not following recommended Pap test screening guidelines, putting themselves at risk of not detecting the early signs of cervical cancer. Extant literature cites lack of knowledge, lack of health care coverage, uncomfortableness, and embarrassment as some of the main reasons women forego regular Pap testing. However, with the recent USPSTF recommendation for regular HPV testing combined with recent advances in cervical cancer prevention through the use of a vaccine that targets high-risk strains of HPV, cervical cancer rates are expected to continue to fall in the United States.

Despite frequent media coverage and popular awareness campaigns (i.e., pink ribbons) of breast cancer, the rates for mammography screening are still relatively low: the CDC reports only 67.1 percent of women 40 years and older had a mammogram in the past two years. Breast cancer incidence rates have remained stable from 2001 to 2010, though there was a small but significant decrease in the number of breast cancer deaths in the same time period. Research reveals that lack of health care coverage, uncomfortableness, pain from the test, and fear are all reasons women forego regular mammograms. Less research has focused on breast self-exams and clinical breast exams, though many believe these are important screening procedures in the early detection of breast cancer.

According to the CDC, the combination of the colon cancer screening tests described above have resulted in a significant decline in colon cancer incidence and mortality rates from 2001 to 2010 in the United States. Despite this, colon cancer remains the second leading cause of cancer-related death in this country, and it is estimated that 60 percent of those deaths could have been avoided if the individuals had participated in regular colon cancer screenings.

In fact, as recently as 2008, only about 10 percent of adults 50 years and older had received a FOBT in the past year and only 50.2 percent had received either a sigmoidoscopy (in the past five years) or a colonoscopy (in the past 10 years). There are many barriers to colon cancer screening including lack of health care coverage (cost), inadequate education from primary care providers about the importance of these screening procedures, discomfort, inconvenience, and fear. Improved awareness of these screening procedures, especially through community outreach programs that encourage at-home FOBT tests and improved patient-provider communication about the importance of these screenings, will help to improve the adoption of these screening procedures.

Conclusion

Patients have access to effective screening tests for cervical, breast, and colon cancers. The USPSTF provides an important service to both doctors and patients by evaluating evidence-based preventive services and providing clear recommendations for those who should receive specific cancer screenings.

For cervical, breast, and colon cancers, a number of cancer screening tests exist that are effective at detecting precancerous symptoms or early cancerous symptoms in the body. The education about these screening tests among the appropriate populations is important for ensuring they are used to promote early detection in order to give those diagnosed with cancer the best possible outcomes. As medical technology continues to develop, newer screening procedures may prove...
to be more effective and perhaps less invasive than what is available to patients today.

Screening, Access to

Screening, as it relates to cancer, is a strategy employed to identify undiagnosed disease. It is directed toward asymptomatic individuals or those who have symptoms that are not recognized. The goal is to identify disease early in its course when intervention and treatment are likely to be more effective than in later stages when symptoms appear. Access to and awareness of screening programs may be limited among low-income, uninsured, or underinsured patients, and less-educated population groups. In 1968 the World Health Organization established criteria for screening programs. In brief these are, as follows:

1. The condition for which screening is conducted should represent an important health problem.
2. Effective treatment for the condition should exist.
3. Facilities for diagnosis and treatment should be available to the population screened.
4. There should be a latent, asymptomatic stage of the disease.
5. There should be an effective, sensitive, and specific test for the disease.
6. The test procedure should be acceptable to the population.
7. The natural history and progression of the disease should be understood.
8. A policy on patient selection for treatment should exist.
9. The cost of screening and diagnosis should be in balance with the total medical expenditure.
10. Screening should be ongoing rather than a one-time activity.

There are numerous modalities that may be employed in screening for disease. A physical examination may be conducted and patient history taken including health habits, prior illnesses, and disease history of close relatives. Laboratory testing of blood, tissue, urine, and other substances may be done. Imaging as X-rays, computed tomography (CT), or magnetic resonance imaging (MRI) may be employed. In some cases tests for gene mutations may be conducted.

Not all screening tests are beneficial. It is important to identify the risk/benefit ratio of testing. Certain screening procedures can cause trauma or other problems. Colon cancer screening with a sigmoidoscopy or colonoscopy can cause tears in the lining of the colon or rupture. A false positive test result can lead to unnecessary procedures as well as patient anxiety. A false negative result can delay or even prevent treatment even though a cancerous condition is present. The American Cancer Society has published screening guidelines for early cancer detection in average risk and asymptomatic patients. The following is a summary.

Breast. In the population of women ages 20-plus, three modalities are specified. Breast self-examination (BSE) is regarded as optional. Education on the technique to employ, and benefits of, this procedure should be explained by a health care professional.
to women in their early 20s. For women who chose BSE the importance of reporting any symptoms should be stressed. The second modality, clinical breast examination (CBE) for asymptomatic women in their 20s and 30s should be done as a part of a periodic health examination, at minimum every three years. After 40 this should be done annually. The third modality is mammography which should be conducted annually after age 40.

Cervix. Two tests are recommended, the PAP test and the HPV DNA test. Women ages 21 to 29 should be screened with the PAP test every three years. For women ages 30 to 65 both tests should be administered every five years or the PAP alone every three years. Women over 65 with a history of normal test results or a total hysterectomy may discontinue cervical cancer screening. Women with a serious history of abnormal results continue being tested for 20 years, even if that testing continues past the age of 65.
