Colorectal. For men and women ages 50 or over, a fecal occult blood test or fecal immunochemical test is recommended annually. Flexible sigmoidoscopy or double contrast barium enema every five years, or colonoscopy every 10 years is recommended. Computed tomography (CT) colonography may be conducted every five years as well.

Endometrial. Women at menopause with average risk should be counseled concerning risks and symptoms and encouraged to report bleeding or spotting to their physicians.

Lung. Current or former smokers ages 55 to 74 who are asymptomatic and apparently healthy, and who have at least a 30 pack-year history, may receive a low-dose helical CT (LDCT). Any current smoker or one who has quit within the last 15 years should be counseled by a clinician on the benefits, limitations, and potential risks associated with LDCT screening. A high priority should be given to smoking cessation counseling for current smokers. They should be informed of their ongoing risk of lung cancer. Screening should not be regarded as an alternative to smoking cessation.

Prostate. Men age 50-plus should receive a periodic digital rectal examination and prostate-specific antigen test (PSA). Men who have at least a 10-year life expectancy should receive information on the benefits, risks, and uncertainties associated with prostate cancer screening.

Cancer-Related Checkup. Men and women ages 20-plus at their periodic health examination should be examined for cancers of the thyroid, testicles, ovaries, lymph nodes, oral cavity, and skin. They should be counseled regarding tobacco use, solar exposure, diet and nutrition, risk factors, sexual practice, and environmental and occupational exposures.

The U.S. Preventive Services Task Force (USPSTF) recommends screening tests for breast, cervical, or colorectal cancer. Data from the 2010 National Health Interview Survey (NHIS) were analyzed to measure use of the recommended tests. The data were categorized by age, race, ethnicity, education, length of U.S. residence, and source of health care financing. The goal was to identify groups not receiving the benefits of screening and to identify possible means to increase screening rates. The breast cancer screening rate of potential patients was 72.4 percent, cervical cancer screening was 83.0 percent, and colorectal cancer screening was 58.6 percent. Screening rates for all three cancers were lower among Asians than among whites and blacks. Hispanics were less likely to be screened for cervical and colorectal cancer.

Asians were categorized as Chinese, Filipino, or other Asian. Hispanics were categorized as Puerto Rican, Mexican, Mexican-American, Central or South American, or other Hispanic. As might be expected, increased rates were observed in population segments with higher education, greater availability and utilization of health care facilities, and length of U.S. residence. For breast cancer, immigrant women who had been in the United States for 10 or more years were almost as likely as U.S.-born women to report having had a mammogram within the past two years whereas a significantly lower percentage of immigrants in the United States for less than 10 years reported being screened in the past two years. For cervical cancer among Asians, Filipinas were more likely to have been screened than other Asians. Those without insured access to health care were less likely to receive testing. In colorectal cancer screening whites were significantly more likely to report being screened than
blacks or Asians. Hispanics were less likely to have been screened than non-Hispanics. Among those who had been in the United States for less than 10 years and did not have a usual, nonemergency department source of care or did not have health insurance, less than a quarter reported having been screened within the recommended interval.

To improve availability of screening, Congress passed the Breast and Cervical Cancer Mortality Prevention Act of 1990, which directed the Centers for Disease Control and Prevention (CDC) to create the National Breast and Cervical Cancer Early Detection Program (NBCCEDP). The NBCCEDP funds all 50 states, the District of Columbia, five U.S. territories, and 11 American Indian/Alaska Native tribes or tribal organizations to provide screening services for breast and cervical cancer. The program is intended to assist low-income, uninsured, and underinsured women gain access to breast and cervical cancer screening and diagnostic services. In addition to other activities this program provides free or low-cost mammograms and PAP tests to low-income women with limited or no health insurance. The services provided include the following:

- Clinical breast examinations
- Mammography
- PAP tests
- Pelvic examinations
- Human papillomavirus (HPV) tests
- Further diagnostic testing based upon abnormal results
- Referrals to appropriate health care facilities for treatment

In 2000, Congress passed an amendment to NBCCEDP which gives the option to offer women who are diagnosed with cancer in the NBCCEDP access to treatment through Medicaid. All 50 states and the District of Columbia have approved this Medicaid option. In 2001, with passage of the Native American Breast and Cervical Cancer Treatment Technical Amendment Act, Congress further decreed that this option also applies to American Indians/Alaska Natives who are eligible for health services provided by the Indian Health Service or by a tribal organization. Federal guidelines establish eligibility for direct services to uninsured and underinsured women below the federal poverty level, ages 21 to 64, for cervical cancer screening, and ages 40 to 64 for breast cancer screening. Approximately 10 percent of U.S. women are eligible for NBCCEDP cervical cancer screening, and about 9 percent are eligible for breast cancer screening. Since 1991, NBCCEDP-funded programs have served more than 4.6 million women, provided more than 11.6 million breast and cervical cancer screening examinations, and diagnosed more than 64,718 breast cancers, 3,576 invasive cervical cancers, and 167,169 premalignant cervical lesions, of which 40 percent were high-grade.

Implementation of health care reform through the Affordable Care Act will increase access to breast and cervical cancer screening services for many low-income and underserved women through expanded insurance coverage. However barriers will continue to exist. Geographic isolation, limited health literacy, lack of provider availability, language barriers, and fear may play a part.

There are numerous examples of local programs that implement the concepts included in the NBCCEDP. In Alaska in 2007, the Breast and Cervical Health Check (BCHC) partnered with the Alaska Aces, a semiprofessional hockey team based in Anchorage, to plan a series of preseason hockey games focused on the importance of finding breast and cervical cancer early. The Aces, BCHC, and other community cancer groups contributed to awareness and fundraising events. The events continued in 2008 and 2009. In 2010, the Aces began having yearly general cancer awareness events, which included breast cancer and comprehensive cancer control.

In 2012, the Aces still had a focus on breast cancer, including ads on local TV. In Oregon the Oregon Breast and Cervical Cancer Program (BCCP) and the Oregon Health and Science University Center for Women's Health began working together in 2009 to increase the number of free breast and cervical cancer screenings for low-income women. Free breast and cervical cancer screenings were offered to women with monetary, logistical, or other barriers. Community donors and other funding paid for the screenings and for treatment if a woman was diagnosed with cervical or breast cancer. Later the program was expanded statewide to include women not eligible for BCCP.

In Mississippi, where African American women are more likely to die from breast cancer than women of other racial and ethnic groups, the Mississippi
Breast and Cervical Cancer Program (MBCCP) worked with faith-based organizations to educate African American women about their breast cancer risk and the importance of early detection. The MBCCP initiated a direct-mail campaign to faith-based organizations across the state, asking them to conduct outreach activities. In West Virginia in 2006, the West Virginia Breast and Cervical Cancer Screening Program (WVBCCSP) noticed fewer women being screened in Webster County, an area with high poverty rates. Because one clinic stopped providing services through the WVBCCSP, only one small clinic was available to screen all 900 eligible women in that area. Women found it hard to be screened because of the clinic’s small size and remote location. Communications between WVBCCSP and a community coalition resulted in a partnership with the Webster County Cancer Education Project, a coalition of more than 30 partners that offers cancer screening clinics, education programs on cancer prevention, and analysis of the benefits of the services. These and many others are examples of local programs to expand access to cancer screening.

Lung cancer will account for more than 224,000 diagnoses and 159,000 deaths in the United States during 2014. This malignancy accounts for more deaths than any other cancer in both men and women. Cigarette smoking is the primary risk factor for this disease. Unfortunately resistance to screening for lung cancer is inextricably intertwined with the tobacco habit. In addition to socioeconomic and educational barriers, resistance to smoking cessation represents an extra burden. Many smokers will avoid available screening partly through fear of discovery of the possible disease that their habit engenders, and partly through avoidance of advice on the ordeal of quitting.

The benefits of screening for lung cancer are demonstrable. In 2014 The International Association for the Study of Lung Cancer (IASLC) published results from an extensive study of the costs of screening and treatment that was conducted prospectively in the Pan-Canadian Early Detection Study. It was determined that the cost to screen patients at high risk with low-dose computed tomography, added to the cost of curative treatment of early stage lung cancer, is less than the cost to treat advanced stages of the disease. In addition treatment of late-stage lung cancer is unlikely to result in a cure.

Screening of high-risk populations offers other benefits. CT scanning can assist in development of drugs for treatment of early disease by tracking progress. Also, the images developed can identify the presence of chronic obstructive pulmonary disease (COPD) and obstructed coronary arteries. These are potential results of smoking as well.

A multitude of opportunities for lung cancer screening are available across the United States. Many hospitals and clinics are equipped to provide this service to high-risk populations. Although screening is not covered by Medicare or Medicaid, an independent government panel, the United States Preventive Services Task Force (USPSTF), has approved and recommended the procedure for those at high risk. Many private group plans and related insurance carriers have declared that such screening is “medically necessary.” Coverage however is not automatic in some instances, and cost sharing may be imposed. This is the case although it has been demonstrated that CT screening for lung cancer in a high-risk population is less costly than screening for breast, cervical, or colorectal cancer and the cost/benefit ratio favors lung cancer screening.

Smoking cessation should be considered essential in the screening and counseling process. Quitting smoking will have a greater effect upon the incidence of lung cancer than any screening program or treatment regimen. Cessation may be undertaken using a number of techniques: counseling from health care professionals, group counseling, medications or nicotine replacements such as patches, or simply through the will of the smoker alone. Studies have shown that the latter is the most common method, although a period of gradual reduction as a cessation strategy was demonstrated in at least one study to be ineffective. Avoidance of external cues to smoking and such factors as workplace and public place restrictions, as well as increasing the price of tobacco products through taxation, have a positive effect in deterring the habit. Self-efficacy to cease smoking and acceptance of the associated cravings and symptoms appear to be important contributors to success.

National surveys have shown that not all smokers receive advice on quitting from health care providers. A review has shown that only half of smokers received such advice from a physician or dentist during a 12-month period. Improvement in health care professional curricula and continuing education
were recommended. Mass media anti-smoking campaigns when evaluated by the U.S. Task Force on Community Preventive Services were deemed effective in combination with other interventions, but a review of effectiveness by Cochrane questioned their stand-alone role and value.

The health benefits of smoking cessation are beyond question. Within hours after quitting blood pressure and heart rate decrease, blood levels of carbon monoxide normalize, and sense of smell and taste begin recovery. In a period of a year circulation and lung function improve, breathing is easier, and the coronary risk is halved. After five years stroke risk is equal to that of a nonsmoker.

In summary, screening of asymptomatic and undiagnosed populations at risk for cancer can be a valuable strategy. Identification of the presence of disease at early stages allows intervention and treatment when most likely to be effective. On the other hand screening is not without some pitfalls. It is important to identify the risk/benefit ratio, since some screening procedures can cause trauma or other problems. A false positive test result can lead to unnecessary tests and procedures as well as patient anxiety. A false negative result can delay or even prevent treatment even though a cancerous condition is present. Access to and awareness of screening programs may be limited among low-income, uninsured, or underinsured patients, and less-educated population groups. Geographic isolation, limited health literacy, lack of provider availability, language barriers, and fear may all present barriers to the total success of screening programs.

Sedentary Occupations

Sedentary behavior, typically defined by activities requiring little energy expenditure such as sitting or lying down for prolonged periods, is an important risk factor associated with poor health and mortality. According to the U.S. Department of Labor’s Dictionary of Occupational Titles, sedentary occupations are those that involve sitting for most of the duration of work time including, for example, bookkeeping and computing professionals. While often used interchangeably, sedentary behavior is distinguished from physical inactivity, which encompasses both insufficient physical activity during periods of leisure as well as greater sedentary behavior both at home and in occupational settings. One of the first studies to investigate the impact of sedentary behavior in the workplace examined occupational activity and cardiovascular events among bus drivers and postal workers. In this study, researchers found a higher rate of cardiovascular events in sedentary bus drivers and mail sorters than among workers in the same industry whose occupational roles required more activity. Research has since extended to investigate the relationship between sedentary behavior in the workplace and other health-related risk factors.
A number of epidemiologic studies have identified sedentary behavior as being independently linked with chronic disease risk factors including elevated blood sugar, insulin resistance, and central adiposity. Obesity is a known risk factor for cardiovascular disease, and growing research suggests that it may also contribute to the risk for cancer. Research has shown that a body mass index (BMI | kilograms/meters²) ≥ 25 in women and ≥ 30 in men is associated with increased cancer risk, and that this association grows stronger as BMI increases. One well-known study examined the relationship between being overweight or obesity and cancer mortality in over 900,000 men and women in the United States. During a 16-year follow-up period, over 56,000 people died from cancer. Importantly, risk of cancer mortality was 50 percent and 60 percent greater for men and women with the highest BMI compared to individuals who were of normal weight.

Since the 1960s the daily amount of occupation-related energy expenditure (i.e., calories burned as result of work) has declined, which has corresponded with increases in the mean body weight for both men and women in the United States. The National Health and Nutrition Examination Survey (2008) also found that the average American adult spends approximately 55 percent (7.7 hours) of their waking time sedentary. Other studies, assessing employees that work in environments such as offices, customer service, and call centers found that 76 percent of the workday was sedentary. Thus, while sedentary workers may be less likely to be exposed to hazardous work conditions, the trade-off for prolonged periods of sitting and other work tasks with low metabolic demand may be a greater risk for obesity and subsequently cancer.

A number of biological pathways exist which may facilitate this relationship. For example, obesity is associated with elevations in blood sugar or insulin which may promote the development and growth of tumors. Adipose tissue is linked to the production of excess estrogen which at high levels is associated with increased risk of breast and certain gynecological cancers in women. Fat cells also produce hormones called adipokines, including leptin which also promotes cell growth. Obesity is also associated with chronic low-grade inflammation which may further contribute to cancer risk. Vitamin D bioavailability is also a suspected pathway independently linking sedentary behaviors to cancer risk, and recent research has linked a subset of genes related to obesity to lower levels of Vitamin D among individuals carrying these genetic variants.

Interestingly, international guidelines suggest that a reduction or return to normal body weight may reduce cancer risk. Emerging evidence suggests that people who have undergone bariatric surgery exhibit reduced cancer incidence, especially in comparison to severely obese individuals who have not had weight-loss surgery. Notably, improvement of other health-related comorbidities (i.e., hyperinsulemia) is one of the pathways thought to play a role in this post-weight loss risk reduction.

To date, several studies have evaluated the relationship between occupational sitting and cancer at multiple sites. While some studies have reported null or negative findings, others have found a positive association between mostly sedentary or sitting work histories and breast, ovarian, and colorectal cancers. Findings for breast cancer has also been noted to differ by whether women are pre- or postmenopausal, as studies have typically reported an increased risk of cancer due to sedentary work history in the latter, but not the former. More recent research suggests that occupational sitting is related to all-cause cancer mortality in women but not men.
By site, more consistent evidence has come from research investigating sedentary occupations and colorectal cancer. For example, in one study, lifestyle, physical activity, and lifetime job history were assessed in over 900 colorectal cancer patients and 1,000 control cases. In comparison to individuals with non-sedentary work histories, participants who spent 10 or more years in sedentary work had almost twice the risk of distal colon cancer and a 44 percent increased risk of rectal cancer. An important consideration from this study is that the association between sedentary work history and cancer risk remained even after accounting for leisurely physical activity. As others have proposed, this suggests that physical activity and sedentary behaviors may influence cancer risk through different mechanisms.

Despite several meta-analyses and reviews of the literature, additional research would help clarify whether sedentary work is directly linked to heightened cancer risk or merely increases the likelihood of obesity-related cancers.

Selenium comprises more than two dozen selenoproteins that the human body uses in DNA synthesis, thyroid metabolism, reproduction and to protect the body from oxidative stress and infection. This trace element, required in humans, comes in two forms: inorganic as selenite and selenate and organic as selenomethionine and selenocysteine. The soil contains the inorganic forms, and plants store the selenites and selenates so that it can be converted to organic structures.

Most of the body stores of selenium can be found in skeletal muscle where it consists of 28 percent to 46 percent of the selenium pool in the body. The plasma and serum concentrations of selenium represent the most common measurement of selenium status. Healthy people show normal selenium concentrations of 8 micrograms (mcg)/dL or higher levels.

From a historical perspective, August von Wasserman completed the first animal study that used injections of selenite to stop tumor progression in mice, in Berlin in 1911. By 1920, colloidal selenium treated breast cancer in human patients with significant results. Since the early 1900s, researchers continued to use different preparations of selenium for research treatment of many different cancers. Cancer remains the most common cause of death globally and, therefore, investigating the biology of substances like selenium may generate new possibilities for the prevention and treatment of cancers.

Food Sources of Selenium
For guidelines on the intake of selenium in food, the Institute of Medicine sets the recommended daily allowance (RDA) for adult males and females at 55 mcg per day except for pregnancy states where the selenium RDA increases to 60 to 70 mcg per day. The most abundant food sources of selenium happen to be protein foods that contain effective dietary sources of selenium, such as, egg yolks, seafood, poultry, and kidney, liver and muscle meats.
Some vegetables sources of selenium consist of asparagus, broccoli, garlic, mushrooms, onions, and tomatoes. Even whole grains (e.g., wheat germ and bran), some nuts, and seeds contain this essential mineral. In fact, one ounce of Brazil nuts contains 544 mcg; whereas, the next highest concentration of selenium is in three ounces of tuna (92 mcg).

Vegetables, grains, and seeds contain varying levels of selenium depending on the amount of selenium present in the soil. Soil with volcanic ash contains high levels and so does soil that gets its moisture from seawater. The amount of selenium in plants varies depending on the soil; factors like soil pH, presence of organic matter in the soil, and the form of selenium affect levels. Therefore, the selenium concentration in plant-based foods differs widely by geographic location. One theory indicates that the reason cancer rates remain so high in such places as Linxian, China, relates to the deficiency of selenium in the soil. Geography appears to play a significant role in cancer rates.

**Action of Selenium**

As a trace element, selenium exhibits a prominent position in maintaining a healthy state in humans. As a member of a small collection of selenocysteine-containing selenoproteins, selenium triggers both structural and enzymatic functions. Selenium deficiency amplifies infection exposure and creates alteration in mood conditions. Selenium plays a major role in redox control and antioxidant reactions, and then in membrane integrity, energy consumption, and defense against DNA damage. A group of approximately 50 diverse selenoproteins encoded by 25 separate genes facilitate the function of selenium. Selenoproteins comprise a few forms of the enzymes glutathione peroxidase, thioredoxin reductase and iodothyronine deiodinase.

Selenium exhibits a protective effect against cancer by a number of possible different methods. The mineral triggers the enzyme glutathione peroxidase, and it in turn guards against the creation of free radicals (the molecules causing damage to DNA). In laboratory studies, selenium obstructs cancer growth and helps control the normal life span of cells, guaranteeing that the cell dies when it is supposed to instead of growing wildly into a malignant cell. Selenium as an immune stimulant represents another possible mechanism. A deficiency of selenium constrains the destruction of macrophage-mediated tumor destruction and obstructs tumor necrosis factor-alpha production in animal model studies.

**Selenium and Cancer**

Laboratory and some early trials demonstrated the possibility that selenium might be effective in the prevention of a variety of cancers such as breast, bladder, esophageal, liver, prostate, and stomach. When used in combination with beta-carotene, vitamin C and E, the selenium inhibits chemical reactions that generate free oxygen radicals in the body. Free oxygen radicals damage the body’s DNA and trigger cells to produce cancers. Selenium prevents the damaged DNA particles from replicating so cancer is not produced. Consequently, the cancer is stopped before it even begins. Selenium with vitamin A and E lessens the deleterious side effects of chemotherapy drugs. It appears to augment the efficacy of chemotherapy and radiation while decreasing the damage to the body’s healthy cells. Stephen Fortmann et al. discussed the influential effects of selenium on esophageal, colorectal, lung and prostate cancers. Selenium reduces gastric and lung cancer in populations exhibiting low serum selenium levels, but individuals with normal serum levels showed no change in cancer rates.

Mahsa Jessri and colleagues conducted a case-control study of 143 subjects in Iran on the association of selenium to esophageal squamous cell carcinoma. Selenium showed a protective effect against esophageal squamous cell carcinoma with an odds ratio of 0.12 (CI 0.04-0.69).

Raluca Pais and D. L. Dumitrascu carried out a meta-analysis of clinical trials using antioxidants to prevent colorectal cancer. Many antioxidant supplements underwent review in this analysis, but only selenium appeared to possess anti-carcinogenic actions, although further research is needed.

M. Vinceti, et al., conducted a Cochrane Systematic Review of selenium cancer studies. A total of 55 observation studies found lower cancer incidence (odds ratio [OR] 0.69) and decreased cancer mortality (OR 0.60). Stomach, bladder, and prostate comprised the body sites with the most decrease in cancer occurrence. The results looked promising, but these study designs possess major limitations on quality and heterogeneity preventing accurate interpretation of the statistics.

The Cochrane Systematic Review of selenium analyzed eight randomized clinical trials (RCT).
In the eight RCTs, no clear evidence appeared that selenium supplementation lowered the risk of any of the cancers or the cancer related mortality. In fact, in the nonmelanoma skin cancer study, skin cancer risk increased (relative risk [RR] 1.44). Two other trials, the Nutritional Prevention of Cancer Trial (NPCT) and the Selenium and Vitamin E Cancer Trial (SELECT) found a possible association between type 2 diabetes, alopecia, and dermatitis to the selenium supplementation. A second NPCT found that selenium did not reduce the risk of cancers and specifically did not reduce prostate cancer.

A 2003 retrospective study showed a positive association between an initial serum selenium level and a chemotherapy delivery dose with outcome (tumor growth, disease-free survival) in non-Hodgkin's lymphoma. Earlier studies showed that many cancer patients exhibit selenium deficiency. R. Muecke and colleagues provided evidence for the positive effect of selenium supplements in patients receiving radiotherapy after surgery for cancers of the cervix or endometrium. All 81 subjects exhibited selenium deficiency by blood levels less than 84 micrograms before radiation therapy. The females underwent randomization to either the selenium treatment group (300 to 500 micrograms) or to a placebo group. The treatment group suffered significantly less radiation-induced diarrhea. The selenium produced no effect on disease free cancer survival. R. Kasseroller studied 179 post-mastectomy patients with lymphedema using a randomized controlled study design. This smaller study on selenium supplementation and lymphedema showed promising significant results of a decline in lymphedema volume and in incidence of infection at the lymphedema sites in the group treated with selenium. The action of selenium on the lymphedema remains unknown, though scientists believe selenium reduces free radicals and protects human endothelial cells from oxidative damage by inducing GPx and thioredoxin reductase as a method for reducing lymphedema.

**Selenium Neutriepigenetics**
The new term, epigenetics, describes modifications in gene expression due to heritable, but theoretically reversible, alterations in DNA methylation and chromatin structure. Epigenetic mechanisms represent new areas to investigate for cancer prevention approaches occurring early during carcinogenesis and representing potentially initiating events for cancer development. In recent years, nutriepigenetics (the influence of dietary components on mechanisms influencing the epigenome) has emerged as an exciting new field in current epigenetic research.

Carcinogenesis causes deregulation of many cellular functions and pathways. Recent evidence from in vitro studies reveal that epigenetic alterations add to the cellular defects caused by carcinogenesis, but that natural chemopreventive agents like selenium compounds potentially counteract the cancer-related epigenetic alterations by modifying the activity of DNA methyltransferases and histone transforming enzymes. The evidence so far on the anticancer effects of selenium on epigenetic mechanisms comes from animal and cell culture experiments. Future research in randomized clinical trials is needed to determine the real affect in humans.

Thomas Prates Ong and colleagues describe one study in humans showing that selenium plasma levels showed an inverse relationship with genomic DNA methylation in leukocytes. The subjects in the study comprised individuals exposed to arsenic from ground water in Bangladesh. The unknown mechanisms and significance of this study results are unclear and future research should unravel the meaning of these findings.

Juliana Xavier de Miranda and colleagues studied the use of selenium as an anti-breast cancer trace element. This laboratory study evaluated the effects of two selenium compounds, methylselenic acid (MSA) and selenite, on cell proliferation and demise and the expression of a tumor suppressor gene (RASSF1A) and epigenetic marks in MCF-7 human breast adenocarcinoma cells. Each of the selenium compounds showed diverse responses when interacting with the cancer cell line. This study demonstrated the anti-breast cancer potential of selenium, but highlighted that the response is dependent on the chemical form.

**Interactions With Pharmaceutical Agents**
Selenium possesses the ability to interact with certain medications. One medication encompasses
cisplatin, a chemotherapy agent, used to treat ovarian, bladder, lung and other cancers. Cisplatin reduces selenium levels in hair and serum. Currently, it is unknown whether the decreased levels influence the health status of humans.

Giuseppe Lippi, et al., described the interference of laboratory measurements of selenium when an injection of the contrast agent, gadolinium, transpires within two hours of using the mass spectrometry for selenium assessment. Magnetic resonance imaging (MRI) imaging uses gadolinium as a contrast agent. The contrast agent causes abnormal elevation of the selenium results.

Z. W. Liu and colleagues delineated the ability of selenium to protect against Adriamycin-induced cardiac dysfunction. Selenium supplementation protects the cardiac function with Adriamycin administration by increased expression of the KATP gene. Selenium can potentially be useful in cancer chemotherapy.

Conclusion
Selenium appears to show encouraging results for radiotherapy protection and edema treatment in cancer patients. The function of selenium for cancer prevention in healthy subjects remains controversial; though subjects with selenium deficiencies appear to benefit from supplementation. However, the recent systematic review of research on selenium and different cancers showed undisputable non-protective effects.

The recent innovation of nutriepigenetics holds the promise for novel approaches to cancer prevention and early treatment. Natural chemopreventive agents like selenium compounds can potentially counteract the carcinogenesis process.

Further Readings

The Republic of Senegal is situated in western Africa. It is bordered on the north by Mauritania, on the east by Mali, on the south by Guinea-Bissau and Guinea, and on the west by the Atlantic Ocean. It is the 24th-most populous country in Africa and 75th in the world, with a population of over 12.9 million. French is the statutory national language and there are 38 living indigenous languages still spoken by respective ethnic groups in Senegal; the most widely spoken ethnic languages include Jola, Malinke, Mandinka, Pulaar, Serer, and Wolof. Senegal has a long tradition of modern medical practice and an even much longer history of traditional healing.

Many essential medications are in short supply in Senegal. For example, morphine is an effective and relatively inexpensive medication used for treating severe pain frequently associated with certain cancers. However, Senegal only imports about one kilogram of morphine each year, only enough to treat about 200 patients suffering from pain due to advanced cancer. Human Rights Watch reports that about 70,000 Senegalese patients annually need palliative care to control symptoms related to chronic, potentially fatal diseases. In fact, morphine is reportedly only available in Dakar, the capital, and even there access is frequently limited due to shortages. In 2013, Senegal used about 0.084 mg of morphine per capita, which is 71 times less than the global average of 5.96 mg per capita.

Alongside of, and very commonly instead of, public or private health care in Senegal is traditional medicine. This includes treatment with herbal preparations and use of plant extracts, as well as use of incantations and spiritual healing ceremonies. Traditional medicine plays a significant role, particularly in rural areas. Traditional medicine is typically less expensive and more readily accessible than the public health system. Further, many Senegalese believe that traditional healers are more powerful and take a more holistic approach than Western practitioners. In Senegal, a traditional healer is called asontena by the Jola, oh pan or koumah by the Serer, and fadjcat by the Wolof.

Traditional healers prescribe an array of medicinal plants to treat ailments, including cancers. For instance, Never-die (Morenga oleifera) leaves, referred to as nebedaye in Wolof, are used for treating over 300 diseases, including cancers. Most of these traditional medicinal preparations incorporate use of myriad local plant materials, many of which have shown medicinal properties in laboratory studies. For example, extracts of Hibiscus sabdariffa have demonstrated antitumor activities. Analysis of extracts of Peristrophe bicalyculata, which the Serer call luben and the Wolof call moto, show it as a potential source of a chemotherapeutic agent. Thus, a rather wide array of traditional medicinal preparations is available for potentially treating cancer and associated problems in Senegal.

There are serious deficiencies of modern pharmaceutical supplies, as opposed to traditional preparations, and in modern medical services for cancer and similar conditions in Senegal. According to the World Health Organization's "Health System Response and Capacity" as of 2010 there was no general availability of either chemotherapy or radiotherapy in the public health system in Senegal.

Senegal is a signatory to the Single Convention on Narcotic Drugs, Convention on Psychotropic Substances, and U.N. Convention against the Illicit Traffic in Narcotic Drugs and Psychotropic Substances. Consequently laws exist to control narcotic and psychotropic substances and precursors. The annual consumption of controlled substances is highly regulated to curtail abuse. Accordingly, the annual consumption of morphine is 0.047 mg per capita, and fentanyl is 0.0007 mg per capita. In 2010, the annual prevalence of use of all opiates as a percentage of the population aged 15 to 64 years in Senegal was 0.08 percent, which ranks it as the 116th highest country. This, as noted, makes the delivery of palliative care problematic, and the experience of living with and dying from cancers is very different in Senegal from parts of the developed world.

The average number of cancer cases annually in Senegal is 103.1 per 100,000 of the population. Cancers account for a substantial amount of disability and suffering among impacted populations. According to the World Health Organization's report "Disease and Injury Country Estimates," the age-standardized disability adjusted life year estimates for 2004, the 10 most prevalent cancers in Senegal were led by liver cancer at 388 per 100,000 population; cervical and uterine cancers at 128 per 100,000 population; breast cancer at 112 per 100,000 population; lymphomas at 89 per
Serbia

The Republic of Serbia is a central-eastern European country located in the Balkans region. The capital, Belgrade, is one of the oldest and largest in eastern Europe. Serbian history is very rich and varied, as it was influenced by many different cultures throughout the ages. The first Kingdom of Serbia was established during in 1217, under Byzantine authority and control, later to be conquered by the Ottoman Empire during the 16th century, until their annexation under the Hasburgic Crown. After World War I Serbia was part of a federation of six republics that founded Yugoslavia in 1918, but numerous ethnic, political and religious tensions arose during the 20th century, causing it to breakup. The Kosovo War, from 1998 to 1999, ended a 10-year period of political isolation that caused economic collapse, the effects of which are still felt today.

During the Republic of Yugoslavia period, healthcare was technically free because of the communist regime politics, but was practically unavailable to most people due to widespread corruption, general abuse of services, and inadequacy of equipment and supplies due to poor funding. Today’s reforms still fail to achieve a basic level of health services for all people, and only those who possess some form of health insurance can access treatment and hospitalization, although the National Health Insurance Fund (NHIF) is responsible for financing the system. Even though health structures such as

Further Readings
hospitals and clinics are relatively well staffed with qualified doctor and nurses, the overall quality of health care is poor because of the absence of proper organization and communication between facilities, bribes and corruption, a lack of equipment, and the poor condition of buildings. Similarly, the health care system in Kosovo is organized in three sectors including primary, secondary, and tertiary health care, and shares the same economic and organizational problems of its Serbian counterpart, albeit to a lesser extent.

After World War II, in Kosovo there were only five hospitals with just nine doctors in total. Living conditions were terrible, and the illiteracy rate reached 98 percent. Today the largest tertiary care institution, the University Clinical Center of Kosovo (UCCK), houses more than 400 doctors and consists of many clinics and institutes. Among these, the National Institute of Public Health (NIPH) is Kosovo’s largest and highest medical and scientific institution, whose duty is to organize and improve public health by defining hygienic-sanitary measures and promoting medical and health education.

In Serbian men, lung cancer showed the highest incidence, followed by colorectal, prostate, and bladder cancer. Breast cancer was the most common form of cancer in women, followed by cervical, colorectal, and lung cancer. After NATO bombings in 1999 with radioactive depleted uranium (DU) ammunitions, cancer incidence and mortality in Serbia saw a progressive increase. Also, incidence and mortality are significantly higher compared to other neighboring European countries, and Serbia has the highest mortality for lung cancer in the world. Although two United Nations Environment Program (UNEP) and World Health Organization (WHO) missions from 2000 to 2001 did not find detectable widespread contamination of the ground surface by DU, a significant increase of all types of cancer was reported by local doctors and internationally recognized medical figures such as Dr. Slobodan Cikaric, president of the Association to Fight Cancer. For example, after the 1999 bombings, the rate of childhood leukemia in Kosovo was found to be 10 times higher than previous reports. Many important Serbian and Kosovar personalities died of cancer, such as the Albanian leader and former president of the Republic of Kosovo Ibrahim Rugova, and the politician Mahmut Bakalli.

Recent studies tried to find a correlation between specific genomic variations among Serbian population, and prostate cancer risk and progression. Meta-analysis studies demonstrated association between single nucleotide polymorphisms (SNPs) at locus 17q12, and at the nitric oxide synthase NOS3 gene locus, suggesting they are both genetically susceptible factors for the progression of prostate cancer and patient outcome.

Because of the generally subpar conditions of the health care system, cancer prevention is often lacking, and patients often refer to hospitals in later stage malignancies, which are difficult to treat. To solve this problem and increase early cancer diagnoses, government authorities issued prevention programs, such as a wide cervical cancer screening project that ran from 2002 to 2007 and a National Day Against Breast Cancer, launched by Fund B92 in March 2013. In 2006, the Ministry of Health of Serbia appointed the Institute for Oncology and Radiology of Serbia to write and implement a set of national guidelines for cancer prevention, designed for primary health care doctors in the country. In 2012, it was established NALOR, the National Association of Cancer Treated Patients, which is comprised of 14 member organizations among nine different cities that help support and improve the quality of life of cancer patients throughout the country.

Further Readings
Thanks to the many advances of modern medicine, there are more and more patients who survive a cancer diagnosis. As a result, there is new focus on the long-term goals of living with and surviving cancer, including healthy sexual functioning after a cancer diagnosis and treatment. There are many, many factors that contribute to healthy sexual functioning for the cancer survivor. These include such things as the physical effects of treatment, the patient’s body image, and the impact on the patient’s partner.

The Effects of Treatment
Much of the literature on sexual health and cancer treatment has focused on breast and gynecologic cancers for women, and prostate cancer for men. Sexual problems can exceed 50 percent in these populations. However, there are some common ailments that affect sexual functioning that occur across all types of cancer. A primary effect of treatment can be overwhelming fatigue. This can be a very disabling factor when discussing sexual functioning. If fatigue prevents one from performing regular day-to-day activities (e.g., showering, eating), sexual arousal may be the furthest thing from one’s mind. There are, however, several things that can be done to mitigate the effects of fatigue on sexual functioning:

Keeping a consistent sleep schedule. Having a structured sleep/wake cycle is one of the best stabilizers of fatigue.

Developing a daily schedule of activities (including sex). Returning to the normal activities of life after dealing with cancer, whether it’s an afternoon of work, or participating in the soccer practice car pool, can take some time. If one is given a finite energy supply each day, it helps to reserve enough energy to enjoy sex.

Adjusting premorbid behavioral patterns. It is important to assess the level of precancer sexual health activities and behavioral patterns. If sex occurred only once a week before the diagnosis, it is certainly not a reasonable expectation that sex will occur more often during and after cancer treatment. Additionally, other adjustments such as extended foreplay,
use of sexual aids ("toys," film, written media) may be needed to jump-start the libido, and so forth.

Decrease the level of performance expectations. Adjusting to a new body, especially if one feels "betrayed" by one's body, takes time. Deconditioning happens quickly. The effects of surgery can limit one's range of motion or sexual sensitivity, bowel and bladder issues may be factors, or negative body image (due to scars) may be a factor. Relaxation and communication can help the survivor ease back into healthy sexual activity. Sometimes "cuddling" is enough to maintain intimate contact with one's partner.

Impact on the Partner
It may be hard for the partner of a cancer survivor to navigate a new sexual relationship. Partners need to be aware that that they may be with a person that does not, in any explainable way, resemble the individual to which they were initially attracted, and there may be concerns over interest in or ability to engage in sexual activity.

Communication with one's sexual partner is the key. Often there are long periods of time for couples dealing with cancer treatment during which sex does not occur. The disease often occupies a central role in the relationship. The physical and emotional needs of the partner are often put on the back burner—perhaps resulting in feelings of resentment and anger. These feelings should be explored, so that the survivor and his/her partner can move forward. Living a new life means taking care of any baggage from one's old life so that misperceptions can begin to be healed. There is often anticipatory anxiety related to resuming one's sex life, post-cancer. It is important to realize that intimacy does not begin and end with intercourse. In time, the survivor's desire for intercourse will resume, but it may not be in the same timeframe as the partner. Stop, listen, and explore are three tips for getting a couple to reinvigorate their intimacy efforts.

Effect on Body Image
The effects of surgery, radiation, and chemotherapy can leave the survivor looking different than before treatment. For some partners, the change will not impact their sexual attraction. For others, the loss of hair, an impaired physical appearance due to surgery, and radiation burns can modify the survivor's physical appearance: sometimes to such a degree that the survivor may not feel attractive to the partner and may feel self-conscious about disrobing—and the partner may have trouble adjusting to the survivor's new body as well. In addition, the stress of having one's body poked and prodded during physical examinations may compromise one feeling like a sexual being.

Conclusion
Sexual health is a multidimensional concept and often very complicated. The health care team, along with the survivor and his/her partner, need to be open and honest all through diagnosis, treatment and post-treatment. If the treatment team addresses the sexual health of the survivor and his/her partner throughout the treatment process—from assessment through to discharge—sex may be less of an obstacle to conquer once treatment has concluded. For a couple dealing with cancer, communication and creativity can go a long way in preserving intimacy.

Sézary Syndrome
Sézary syndrome is a rare but very aggressive kind of cutaneous lymphoma, or skin cancer, that affects
for the most part those over the age of 60, and as data has shown most often affects men. Because the primary symptom of the early stages involves red rashes in thick itchy patches in different areas of the body, the disease early on is often mistaken for psoriasis or eczema and treated with topical lotions and Benadryl-based or Cortisone-based over-the-counter products. Once the correct diagnosis is made—after a biopsy of the bumps that appear in the rashes (known as erythroderma), patients have a variety of options for treatment. But none actually permits remission—the prognosis for patients with Sézary syndrome is not encouraging. The disease is particularly aggressive and resists most conventional cancers treatments, including chemotherapy. The median survival rate is only two to four years.

Sézary syndrome is a particularly insidious kind of lymphoma as it masquerades as other far more benign conditions (the chemical processes behind the reddening of the skin are also responsible, for instance, for nervous or excited blushing); thus for an extended period of time when the disease is just forming, time critical to effective treatment, its symptoms raise few questions about possible cancerous involvement in patients who most often believe the red patches and the itching are simple treatable run-of-the-mill infections. Indeed, the initial research into SS was begun as part of a larger research study into tracking the signs and symptoms of venereal diseases. Algerian-born physician and dermatology researcher Albert Sézary (1880 to 1956) pioneered groundbreaking investigations into treatments of venereal diseases in the last era before the availability of penicillin.

Living in Paris, Sézary described the spread of venereal diseases, particularly syphilis, as a critical public health crisis, the moral dimension of which often convinced patients not to seek help. In studies completed between 1938 and 1949, even as France struggled within the chaos and brutalities of war and German occupation, Sézary worked with more than 5,000 syphilitics. What Sézary noticed, however, was that in rare cases the generalized erythroderma resisted conventional treatments and in fact when cells of it were put under a microscope revealed what are called transportable cells, that is infected T cells (white blood cells) that can move in turn to other parts of the body's internal systems, most notably the lymph nodes. At that point, Sézary noted, far more specific symptoms were manifested, symptoms not associated with venereal diseases, including rapid hair loss; pronounced enlargement of the lymph nodes; a thickening of the skin on the palms of the hands and the soles of the feet; loss of fingernails and toenails; unusually rapid weight loss; prolonged fevers; loss of appetite and a general malaise; and most peculiarly a tendency of the lower eyelids to flip outward. Sézary also tracked an alarming one- to three-degree drop in average body temperature as if the body were responding to a far more insidious viral invasion. In addition, the mortality rates of these isolated cases, Sézary noted, were nearly triple the mortality rates of patients diagnosed with venereal diseases, and death in these cases occurred far more rapidly. Sézary, although he had no specific medical training in oncology, suspected that this handful of cases pointed less toward the spirochetes associated with syphilis and more to the aggressive cellular self-destruction then associated with the spread of cancers.

Sézary conjectured that the impacted T cells had become cancerous and in turn had caused the massive reddening of the skin and the characteristic lumps. Although the T cells were found in the rashes and bumps, they only became a problem when they moved from the blood to the skin, the skin in a way importing the cancer itself from the T cells in the blood. Decades after Sézary’s groundbreaking theorizing, and following his lead, cancer researchers have still not been able to account for the T cell anomaly—although research in the late 1980s suggested the influence at the genetic level, specifically chromosomal abnormalities consistent with other cancer patients. But even that was conjecture. The reality is that close to a century after Sézary first isolated this type of virulent skin cancer, there is little known of its cause and advice for its prevention is the advice that generally relates to cancer-prevention (monitoring nutrition, visiting the doctor regularly, inspecting the body periodically, maintaining a general healthy lifestyle). SS is rare. It accounts for less than 3 percent of skin cancer diagnoses annually worldwide, often mistaken for the far more prevalent non-Hodgkin cutaneous lymphoma known as mycosis fungoides. World Health Organizations estimate that SS affects one in every 20 cases of mycosis fungoides.

The stages of SS are fairly typical and patterned: from itchy red patches and skin inflammation
(the condition was long known as Red Man’s Disease), the infected blood cells move from the blood to the skin surface and from there to the lymph nodes and from there grow into the ulcerated patches on the skin’s surface (tumors) that characterize the advanced stages of the disease. Although the syndrome can spread to the entire internal organ system, that is rare. It is largely manifested in the skin inflammation and in the major compromising of the lymph system.

At that point, after treating the spread with drugs including psoralen and bexarotene, three primary aggressive treatments can be applied. First, a process known as photopheresis that involves cleaning the blood entirely twice a month by filtering it through a machine as in dialysis and then recycling it back to the patient. The blood itself is shot with UV light before it is returned to the body in an effort to remove the infected T cells early on. In nonresponsive cases, chemotherapy can also be used—not only the traditional soup of chemical poisons regularly injected into cancer patients but also a special kind of chemotherapy skin lotion targeted to specifically attack the inflamed scaly body patches that have the widest and most aggressive range. And as a last stage, radiation can be used to blast the cancer cells; if the T cells have invaded the entire lymph system, doctors use total skin electron treatments, debilitating to the patient but the most effective way to target large areas of tumor growth in the lymph system. Failing that, physicians can recommend more unorthodox medical treatments that are essentially clinical trials, including the use of interferon and retinoid. At this point, however, patients are willing to try these treatments as a way for doctors and researchers to learn more about how best to approach the terminal stages of Sézary syndrome.

Shire UK

Shire UK in the United Kingdom is an indirect wholly owned subsidiary of Shire Plc. It is a global specialty biopharmaceutical company that works closely with various professionals in the health care system, among them nurses, physicians, and home care givers. This close linking with health care professionals is intended to help develop and market medicines that improve quality of life for patients, their families and care givers. Shire UK was started in 1986, when a team of entrepreneurs began to capitalize on a number of unmet medical needs in the society. Within its first two years of operation the UK-based specialty pharmaceutical company had launched a range of supplemental calcium products for patients seeking to treat or prevent osteoporosis. Following the successful marketing of these initial products and positive consumer feedback, the company undertook innovative drug development programs. These programs saw the development of drugs on behalf of patients facing such challenging conditions as Alzheimer’s and end-stage renal failure.

The company’s operations in the UK currently comprise the original range of products, additional specialty pharma products, and therapies for genetic disorders. The operations by Shire UK are primary to the United Kingdom, especially in Basingstoke. Currently operations by the company are focused in a number of therapeutic areas which are: ulcerative colitis, seizures and epilepsy, chronic kidney disease, Alzheimer’s disease, chronic constipation, essential thrombocythaemia, Gaucher’s disease, Fabry disease, Hunter syndrome, attention-deficit/hyperactivity disorder (ADHD), and hereditary angioedema. The company has also managed
to successfully establish itself as a market leader in providing adjunctive therapies for patients with osteoporosis through a range of calcium-based supplements available. The company has a focus and dedication to gastrointestinal and renal (kidney) diseases, with products for the treatment of mild to moderate ulcerative colitis, a type of inflammatory bowel disease, and a phosphate binder for use in some patients with chronic kidney disease. Currently, Shire UK has a number of products in the UK pharma market.

Shire UK has a reputation for having a strong commitment of its employees, who aim to make a difference in the lives of patients, their families, and caregivers, as well as to the medical community. In addition to the products available in the market, Shire UK has an active community initiative that provides support to a variety of charitable events held each year. The company employees are an active part of Shire’s global Volunteer Day program whereby the company allows employees to use a day of work in a voluntary capacity. Through these, several events have been launched.

The Basingstoke Alzheimer’s Society Christmas lunch is a key event in which Shire participates. During the event, Shire UK volunteers service residents in the Alzheimer’s wing with a Christmas meal and will celebrate the day with patients.

Shire’s donation of Christmas gifts for the elderly has been running for some years and is very successful. During the event, Shire UK employees have the opportunity to accompany the organizers and hand out gifts personally.

Volunteer days that benefit local schools and charities include accompanying disabled children from a designated school with the local Rotary Club for a day of outdoor learning where students can, for example, create garden space where they can learn to grow their own vegetables.

The company supports additional charity events such as Wear it Pink Cancer Relief, Comic Relief, Macmillan’s Big Coffee Morning appeal, and the annual Jeans for Genes fundraising day where the company matches employees’ donations.

Shire’s environmental conservation activities include encouraging company employees to actively “Think Recycling” at home and at work. In the company facilities, recycling facilities are used in the office to ensure all paper, cardboard, some plastics, and office waste such as printer cartridges are recycled. In addition, all the Shire UK offices in Basingstoke have energy efficient heating and lighting that automatically switches off.

Through a partnership with a local volunteer service called “The Link,” unwanted materials such as books, CDs, clothing, household equipment, and small items of furniture are passed on to worthy causes such as children’s home, scout groups, and the local archaeological society.

Other initiatives include allowing employees to donate to their chosen charities each month directly from their paychecks, opportunities for employees to donate blood to the National Blood Service that visits the Basingstoke area twice a year, and a matching-funds program for employee fundraising activities.

In early 2014, Shire UK acquired ViroPharma, a high growth, rare disease biopharmaceutical company.

Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins

The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins began in 1973. Formerly the Hopkins Cancer Center, it was renamed in honor Sidney Kimmel, the founder and chairman of Jones Apparel Group, to acknowledge his $150 million donation to Johns Hopkins University. The Johns Hopkins Kimmel Cancer Center is a pioneer in deciphering
the mechanisms of cancer and new ways to treat it. It was recognized early on as a “Center of Excellence” by the National Cancer Institute (NCI), and was one of the first to earn Comprehensive Cancer Center status.

The Center is currently headed by Director William Nelson, M.D., Ph.D., recognized nationally as an expert in the translational research of prostate cancer. The Johns Hopkins Kimmel Cancer Center is one of the 41 cancer centers in the United States designated as the Comprehensive Cancer Center by the NCI. Its mission is to be a leader in scientific and medical research, and translate the discoveries into the very best cancer therapies. It has active programs in clinical research, laboratory research, education, community outreach, and prevention and control. It has 33 different specialty centers and clinics for consultancy.

The main clinical building at the Sidney Kimmel Cancer Center is the Harry and Jeannette Weinberg Building, a 350,000-square-foot facility housing the ambulatory services, an inpatient and outpatient surgical center, 16 operating suites, 62 medical oncology beds, 72 surgical beds, and 20 intensive and intermediate care beds. The Weinberg Building offers a specialized inpatient-outpatient clinic for stem cell and bone marrow transplant patients, as well as outpatient chemotherapy and inpatient units for solid tumors and hematologic malignancies.

Sidney Kimmel Comprehensive Cancer Center is internationally recognized for excellent programs in molecular genetics of cancer; brain tumor research and treatment; bone marrow transplantation; new drug development; pediatric oncology; radiation oncology; and esophageal cancer research, treatment, and prevention. The center is also known for its research in gene therapy and development of novel therapeutic approaches for the treatment of breast cancer. It provides comprehensive information and genetic counseling for patients at a high risk for the development of breast, colon, and ovarian cancers.

Patients are treated by multidisciplinary teams at specialty clinics for individualized treatment plans. The center pioneered research on cancer as a genetic disease, resulting in the development of genetic tests for hereditary cancers and the development of a stool test for colon cancer. The center was also the first to develop therapeutic cancer vaccines, especially the pancreatic cancer vaccine, and those for cervical cancer, prostate cancer, and leukemia. Research at the Sidney Kimmel Cancer Center linked DNA methylation to the leukemia precursor myelodysplastic syndrome and resulted in the approval of the first DNA demethylating agent. This work also earned recognition from the NCI for most outstanding research in the Specialized Programs of Research Excellence (SPORE), an honor that has been granted to the center multiple times. Currently, the Kimmel Cancer Center runs specialized research programs on lung cancer, gastrointestinal cancer, head and neck cancer, prostate cancer, breast cancer, cervical cancer and lymphoma.

The Kimmel Cancer Center offers fellowship programs in Hematology/Medical Oncology, Neuro-Oncology, and Pediatric Hematology/Oncology. It also offers several additional fellowship and training opportunities in Anti-Cancer Drug Development (ACDD), Training Program in the Pathobiology of Cancer, Cancer Training Fellowships in Epidemiology, and Molecular Biology & Genetics for health professionals. The center also operates several communication channels to inform the general public as well as specialists about the latest advancements in cancer research.

The Sidney Kimmel Cancer Center has a unique fellowship program called CUPID (Cancer in the Under-Privileged Indigent or Disadvantaged) with the mission to promote the discipline of Oncology to medical students interested in caring for the underserved. It is a seven-week summer fellowship and includes laboratory-based research and lectures on topics ranging from basic oncology to health care disparities. The program also includes clinician shadowing in the medical, surgical, and radiation oncology clinics. The fellows visit the NCI and interact with the researchers addressing the issues of health care disparities at a national level.

In addition, the Martin D. Abeloff Scholars Program at the Sidney Kimmel Cancer Center is a mentoring program that offers training and support to the next generation of cancer specialists.

The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins has initiated a partnership program with the Howard University Cancer Center, working toward a strong national cancer program addressing the disparity in cancer rates and outcomes in minority populations. The current
studies include translational research on the genetics of cancer in African Americans in order to identify the factors that would help eliminate cancer health disparities. It also aims to conduct research on cancer prevention and control research, and to develop novel therapeutics which could reduce the existing disparities associated with cancer treatment in African Americans.

The center is also recognized as having a highly professional nursing environment. The cancer center has an elite designation as a Magnet hospital, the highest nursing honor in the world. Over the last decade, attempts have been made to reduce hospital stays and treatment-related complications at the Sidney Kimmel Cancer Center. This move has led to a reduction of costs, even for the most intensive treatment modalities.

The Sidney Kimmel Comprehensive Cancer Center is committed to its mission of teaching, research, and patient care. The nurses working at the Kimmel Cancer Center work on the cutting-edge of clinical care and are also responsible for conducting research and developing models for patient care. The nursing teams are trained not only to work in the inpatient units, they also participate in diagnosis and therapy at outpatient clinics, and carry out detailed monitoring of the clinical trial research. The center regularly offers new courses, mentorships, seminars, and classes to the nurses.

The center provides exhaustive information on the clinical trials offering new drugs, new surgery approaches, and new treatments to patients.

Sierra Leone

The Republic of Sierra Leone is a western African country rich in natural resources such as diamonds, gold, and titanium. Despite its vast natural wealth, most of Sierra Leone’s population—around 70 percent—still lives in poverty conditions. With an estimated population of 1.2 million, Sierra Leone’s largest city is Freetown, its capital. Freetown was founded in 1787, when the British Crown attempted to resettle freed black slaves after the American Revolutionary War. Through the 19th century, Freetown was the major port for liberated Africans (the so-called “Recaptives”) and African Americans and West Indians freed from slavery, giving birth to a new mixed-blood ethnicity called Creoles or Krio people.

Following the end of British Colonialism, in 1961, Sierra Leone declared its independence. After a brief period of democracy, a series of armed military coups in 1967 led to the reign of Siaka Stevens as prime minister (and later president). Stevens’ remained in power despite multiple coups attempts, and amid accusations of mismanagement and corruption, until he stepped down in 1985. Authoritarian rule survived in various forms in Sierra Leone until 1991, when Civil War erupted. The war lasted 11 years, leaving over 50,000 dead and hundreds of thousands of refugees. In 2002, United Nation military forces intervened and the rebels were disarmed. In 2007, Sierra Leone held presidential and parliamentary elections.

Today Sierra Leone is one of the least developed countries in Africa; more than two-thirds of the population is illiterate and the health care system is severely lacking in resources. In 2010 Sierra Leone Government launched a “Free Health Care Medical Insurance” system to cover all medical expenses for women who are pregnant and breastfeeding and children under five. However, in spite of the program, medical services are often charged a fee or are simply unavailable to those living in rural areas. Over 100 nongovernmental organizations (NGOs) operate in the health care sector in Sierra Leone, and funds from the United Kingdom and United Nations helped rebuild many hospitals destroyed during civil war. Among these, the most important national hospitals in Sierra Leone are Connaught Hospital, Masanga Hospital, Princess Christian Maternity Hospital, and St John of God Hospital.
In Sierra Leone cancer services are still very primitive, with almost no forms of screening or prevention, and a widespread absence of modern equipment to treat cancer patients. In 2012, a National Cancer Registry program was launched in Connaught Hospital, Freetown, with the help of World Health Organization (WHO) funds, to assess local cancer burden and major risk factors. Also a 24-bed palliative care center for patients with terminal conditions including cancer was created. Because of the absence of a national cancer registry up until very recent times, there is little statistical information about cancer incidence in the region. However, in surrounding countries in western Africa, the highest rates of cancer are of the cervix and breast cancer in women; liver and prostate cancers, and Kaposi’s sarcoma in men; and Burkitt’s lymphoma in children. Known risk factors are Human Papillomavirus (HPV) and Human Immunodeficiency Virus (HIV), alcohol consumption, smoking, and malaria. About 23.3 percent of women in the general population are estimated to harbor the HPV infection at a given time.

Getting cancer treatment in Sierra Leone is often very hard if not impossible for families that struggle even to obtain water and other basic needs. The few who can afford the trip, travel to Ghana to seek out much higher quality treatment. Cancer is often considered a taboo due to the widespread belief that it is a transmittable diseases like HIV, and radiation therapy is not available. Plans to build a radiotherapy center in 2014 and 2015 were made through various partnerships between the government, NGOs, and the International Atomic Energy Agency (IARC), however a massive Ebola outbreak in 2014 placed an enormous burden on the country’s already fragile health care system.

Public awareness projects such as “Breast Week,” which took place in 2006, provided free screenings, and education on breast cancer and importance of breast health for 1,200 women. In addition, starting in 2013, the government of Sierra Leone joined in with cancer groups around the world to commemorate “World Cancer Day,” which takes place every year on February 4.

In addition to provided education through health-awareness campaigns, many NGOs collect data about cancer patients who seek treatment inside their clinics. For example, the Thinking Pink Breast Cancer Foundation, in Freetown, built a Well Woman Clinic that provides clinical breast screenings and cancer prevention programs, and cancer support and treatment. Another important cancer center is the Lady Deborah Berewa Hospital in Lakka, a free outpatient clinic, built in 2012 by Greatest Goal Ministries, that also conducts health education and training for local health care providers.

Traditional African medicine is still a part of the primary health care system in Sierra Leone, and the Ministry of Health and Sanitation founded the construction of training schools and healing centers in Makeni and Kono. While most of the traditional African medicine consist of religious and spiritual rituals that aim to heal both the soul and the body, many practitioners claim they can assist in the treatment of cancer through herbal remedies, such as Sutherlandia frutescens (cancer bush) which is often used as a cancer tonic. Some plants used in traditional African medicine were actually found to contain alkaloids that showed antiblastic and antitumor effects, for example vincristine and vinblastine in Catharanthus roseus (Madagascar periwinkle).

Others possess a significant antioxidant power which may be used as complementary cancer therapy, such as Sorghum Bicolor (sorghum) and Moringa Oleifera (drumstick tree). Moringa leaves contain nutritional properties that have also been very useful in combatting malnutrition, especially among infants and nursing mothers, as well as for patients under cancer treatment when malnutrition is an issue.

Singapore

Singapore is a city-state and island country in Southeast Asia which is on the southern end of the Malay Peninsula near the equator. The country's territory consists of a main island called Singapore Island plus about 60 small islets. The country is mostly urban with minimal vegetation. Singapore is known worldwide for its strong business and shipping functions. Manufacturing is a particularly important industry in Singapore. The population of Singapore is approximately 5.4 million based on 2013 June estimates and approximately 2 million of these are foreign-born. Seventy-five percent of the population is Chinese.

The health care system of Singapore is generally efficient, but health expenditures are relatively low for a developed country. According to the World Health Organization's (WHO) World Health Report, Singapore health care system is ranked sixth overall in the world. Singapore has had the lowest infant mortality rate in the world for the past two decades. Life expectancy is 80 and 85 for males and females respectively, placing the country fourth in the world for life expectancy. The government's health care system includes a program called Medifund for those who need help with paying for health services, Medisave to help people save for their health expenses and the government-backed Medisheld helps patients with insurance navigate the system.

With the efficient health care system, cancer is the number one cause of death in Singapore, constituting 29.3 percent of total deaths in 2009. The number of deaths caused by cancer increased from 78.2/100,000 (78.2 deaths for every 100,000 deaths) in 1970 to 111.9/100,000 in 1995. This reached a peak in 1997 with 122/100,000 rate and over the past 10 years has shown a slow decline with a rate of 94.9/100,000 in the period of 2006 to 2010. The country has the highest age-standardized rate (ASR) of cancer in southeast Asia. The incidence rates in males and females has increased for the period 2006 to 2010, compared with that reported for the period 2005 to 2009 and currently stands at 229.6 and 208.0 per 100,000 person-years in males and females, respectively. This translates into a total number of 51,657 cancer cases diagnosed in the resident population during the period 2006 to 2010. Of these cases, 48.6 percent were reported in males.

For specific cancer types, lung cancer and breast cancer had the highest mortality rates in males and females respectively. In the country, lung cancer accounted for 27.6 percent of cancer deaths among males and breast cancer accounted for 17.9 percent of cancer deaths among females. Given the high number of Chinese among the country's population, the incidence of cancer was highest among the Chinese for ethnic groups, with 23,164 males and 23,925 females suffering from the disease. For the resident population, prostate cancer lung, and colorectal were the top ranked cancers among males while lung cancer, colorectal, and breast were the top-ranked cancers among females.

Singapore Society of Oncology (SSO), founded in 1981, is a professional medical organization for all Singapore health care professionals who treat and manage cancer patients. The objectives of the SSO is providing an active platform to promote the practice of oncology through education, research, collaborations, and partnerships with allied local, regional, and international organizations. To ensure practitioners in the field of cancer are skilled for effective care, the SSO provides continued medical education and other opportunities for the cancer medical specialist community to further enhance their knowledge, skills and expertise in the rapidly changing practice of oncology.

As Singapore transitioned from a developing country to a developed country, the pattern of illnesses in the country changed within a space of a few decades. This was due to advancement in the economic status of the country and the creation of a more effective health care. However, given the complexity of cancer, it soon overtook cardiovascular...
diseases as the number one cause of deaths in the country. As a result of this, in 1992, the Review Committee on National Health Policies suggested the overall development of a national cancer center that can focus on many critical aspects of care. The national cancer center is also responsible for training oncologists and other allied health workers, facilitating and conducting cancer research, and developing cancer databases.

Currently, the country has five public and 12 private hospitals that are equipped to diagnose and initiate the treatment of newly diagnosed cancers. There also are two public institutional centers that specialize in cancer care in Singapore: the National Cancer Centre Singapore (NCCS) and the National University Cancer Institute. In addition to public institutions and facilities, the private sector has several small cancer centers. The objective of these institutions is to function as a comprehensive cancer center, providing multidisciplinary services, within their organizations. The NCCS is located at the same location as the general hospital, the largest in Singapore, with 1,600 beds. The NCCS began its operations in the country in 1996. And to effectively deliver on its operational objectives of clinical service, research and education, the center has five clinical departments: medical, surgical, oncology, radiation oncologic imaging, and palliative medicine. It also has three research divisions: clinical trials and epidemiological sciences, medical sciences, and cellular and molecular research. In its education program, the NCCS has students from the two medical schools in Singapore, local and overseas fellows, as well as pre- and postdoctoral graduate students. Through the years, the NCCS has grown in strength and numbers, and currently treats 60 percent to 70 percent of all subsidized patients and 50 percent of all cancer patients in Singapore.

The effort toward fighting cancer has seen more entrants. In Singapore, there are many charitable and welfare organizations that provide support for patients and their families. One of these is the Singapore Cancer Society (SCS) established in 1964 and endorsed by the Ministry of Health. The society plays a prominent role in the support of patients with cancer by, for example, organizing public education forums and screening clinics.

Further Readings

Singapore Cancer Society

The Singapore Cancer Society (SCS) is a cancer advocacy organization established in 1964 that addresses cancer-related issues through multiple platforms across diverse population groups in Singapore. Its vision is to become the leading charitable cancer organization in Singapore, and in the Asia-Pacific region. To target the problem of cancer in a holistic manner, SCS’s strategy is to involve both cancer patients and the general public in its outreach efforts. Specifically, SCS has seven core programs that drive its vision to become effective in combating cancer. The seven core programs are (1) community partnerships, (2) cancer screening, (3) cancer research, (4) hospice care, (5) public education, (6) cancer support service, and (7) welfare services.

Community Partnerships
SCS recognizes the important role of the community in the fight against cancer as they help raise awareness and provide financial support for its programs. An annual “Flag Day” dispatches students to different locations in Singapore to raise funds for SCS. SCS also organizes an annual “Race against Cancer” run that is a highly publicized event and “Tee for Cancer” (a charity golf event) with many participating sponsors. These community networks increase the visibility of SCS’s works.

Cancer Screening and Research
SCS offers a spectrum of affordable cancer screenings to the population. In line with its objective of minimizing the impact of cancer on health, it encourages the public to go for early screening. To increase the screening uptake, SCS offers free clinical breast examinations, Faecal Immunochemical Tests (FIT) for colorectal cancer, and Pap smears for cervical cancer throughout the year.

SCS is an active supporter of cancer research in Singapore. Since 1973, SCS gives awards and grants to cancer research in both science and social science to improve cancer treatment and patient care to enhance the quality of life for cancer patients. Some of the research areas it supports include: tumor biology, genetics, and clinical (e.g., clinical pharmacology) studies. SCS also supports social science research such as statistical analyses on factors associated with cancer patients’ psychosocial needs and well-being, as well as factors related to employers’ intent to hire and retain cancer survivors.

Hospice Care
SCS has a Hospice Care department that provides care for terminal cancer patients through a team of doctors, nurses, occupational therapists, and case workers. One of the goals of the hospice is to provide quality care to cancer patients at the last stages of their illness to ensure that they live comfortably. Since its inception in 1987, SCS Hospice Care has grown from providing basic clinical care and pain relief to include support services that target the psychosocial well-being of cancer patients. It has a structured home rehabilitation program to provide outpatient support in helping cancer patients...
gain confidence and control over aspects of their lives that were temporarily hindered because of the illness.

Public Education
SCS is active in raising public awareness of various forms of cancer in Singapore through campaigns, dialogue sessions, symposiums, and talks. SCS conducts regular talks at community centers, schools, and business corporations. To raise public awareness of risk factors as well as availability of screening and treatment options, SCS has dedicated certain months for a specific form of cancer. For example, annually the month of May is dedicated to raising awareness for cervical cancer while the month of October is for breast cancer. These campaigns are often reported in the mainstream media because of the creative and catchy campaign theme. The theme for colorectal cancer awareness month in February 2013 was “Don't Flush Away Early Detection,” while the cervical cancer awareness month in July 2013 was themed “Lift your skirt, save your life.” Some of the other cancers that are featured in the monthly awareness publicity are ovarian, prostate, gastric, and lung cancers.

Cancer Support and Welfare Services
As the process of cancer treatment can be traumatic, SCS offers rehabilitation support to help cancer patients. Cancer patients are placed in support groups. Members often meet regularly (monthly or weekly) and share coping strategies and discuss the challenges faced—professional health care providers and therapists are often present to give patients additional insights and to correct any misconceptions. These support groups also engage in activities such as workshops and recreational activities.

The welfare services arm of SCS seeks to provide financial aid to help needy cancer patients buffer treatment and living costs through various funding schemes. The SCS Cancer Treatment Fund helps cancer patients offset part of the cost of chemotherapy drugs while the SCS Welfare Aid Fund provides support for necessary medical products such as colostomy bags. SCS Hospital Transportation Services provides free transportation for low-income patients from their homes to the hospitals. The SCS Help the Children and Youth Program helps reduce the cost of education by providing children and adolescent patients with free tuition, school allowance, and awards for academic achievement.

Conclusion
SCS has grown to become one of the largest cancer advocacy groups in Singapore. To achieve its vision of becoming a stellar resource for the cancer community, it has expanded beyond raising public awareness and education to include wide-ranging patient care and welfare services, as well as contributing to cancer research locally.

Siteman Cancer Center
The Siteman Cancer Center is a cancer treatment and research facility located in St. Louis, Missouri. It is affiliated with Barnes-Jewish Hospital and Washington University School of Medicine. The center specializes in imaging, genomics, and prevention strategies that have contributed significant advances to cancer research and treatment. Through its partnership with the Washington University School of Medicine, researchers at the center have developed an interdisciplinary approach to cancer care. Patients and survivors are treated by multidisciplinary teams of doctors. Significant fields of research include breast cancer research,
cancer and developmental biology, oncologic imaging, tumor immunology, as well as cancer prevention and control. The center is a leader in gene therapy, clinical trials, vaccines, chemoprevention, and nanotechnology.

The Siteman Cancer Center opened in 1995 and serves over 40,000 patients annually. The center has operated under the direction of Timothy Eberlein, M.D., since it was founded. In 2004 it was designated a Comprehensive Cancer Center (CCC) by the National Cancer Institute (NCI). In 2006 it became one of the 25 members of the National Comprehensive Cancer Network (NCCN), a non-profit group of cancer centers committed to the improvement of cancer care and treatment.

A collaboration between the Siteman Cancer Center and the Genome Institute at Washington University has led to groundbreaking research on cancer and genetics. The center has identified genetic mutations that can reduce the efficacy of conventional cancer therapies and lead to increased mortalities. By sequencing the complete genome of patients with acute myeloid leukemia (AML), scientists at the center discovered that a single gene mutation can inhibit the efficacy of treatment. AML patients with a mutation of the gene DNA methyltransferase 3A (DNMT3A) lived on average just over a year, while patients in the study without the mutation lived for an average of 3.5 years. The identification of the DNMT3A mutation could lead to new drug research and therapies for the AML patients for whom current treatments are less effective.

Partnering with the Mallinckrodt Institute of Radiology at Washington University, researchers at the center developed new methods for diagnosing cancer and for monitoring cancer treatments. The Mallinckrodt Institute of Radiology’s Cancer Center for Clinical Imaging Research (CCIR) is dedicated to the advancement of research in clinical imaging. Located within Barnes-Jewish Hospital, the CCIR serves the combined goals of imaging research and patient care. The CCIR employs a state-of-the-art scanner that combines positron emission tomography (PET) and magnetic resonance imaging (MRI) scanning capabilities. The scanner simultaneously performs both PET and MRI scans, and produces finely detailed images. The PET/MRI reduces the radiation exposure risk to patients by emitting about half of the radiation of combined PET/computed tomography (CT) scanning. The CCIR builds upon a long history of PET scanner research at Washington University where Michel Ter-Pogossian developed the first PET scanner in the 1970s.

The Siteman Cancer Center’s Program for the Elimination of Cancer Disparities (PECaD) was established in 2003. PECaD works to remove social barriers from cancer education, prevention, diagnosis, and treatment. Through community outreach in the St. Louis region, PECaD is developing a national model for reducing and eliminating the uneven distribution of cancer resources among minority populations and the medically underserved. Studies show that demographic factors such as income, age, race/ethnicity, and access to health insurance have an effect on rates of cancer prevention and treatment resources among patients. Medically underserved women, for example, cited variables including fear of cost, lack of transportation, and lack of childcare as obstacles to mammogram screening. Siteman Cancer Center’s Mamography Outreach Registry was developed in 2006 to determine the effectiveness of mobile mammography among underserved urban and rural women of Missouri.

PECaD has developed a network of cancer community partnerships that bring together cancer survivors, advocates, community representatives, and academic faculty to create program strategies to eliminate cancer disparities. These cancer community partnerships include the Breast Cancer Community Partnership (BCaP) in North St. Louis County, the Prostate Cancer Community Partnership (PCCP), and the Colorectal Cancer Community Partnership (CCCP). These community partnerships help connect cancer patients to existing services and educate the community about cancer prevention. PECaD engages in public service messaging campaigns through local newspapers, billboards, radio stations, and public libraries in the St. Louis area. The center has been instrumental in the development of interactive technologies such as a free mobile app for mobile devices that evaluates risk factors for cancer, diabetes, and other diseases.

The institution is named for Alvin J. Siteman, former president of Flash Oil Corporation and former director of Barnes-Jewish Hospital. In 1999, Alvin J. and Ruth Siteman donated $35 million to Barnes-Jewish Hospital and Washington University School of Medicine for cancer patient care, research, and community education. In 2001 Alvin J. Siteman committed a further $1 million per year to fund prevention and diagnostic programs. Along
with the CCC designation, the center receives yearly research grants from the NCI.

Skin Cancer, Childhood

Childhood skin cancers are exceedingly rare, accounting for 1 percent to 3 percent of all cancers diagnosed in the pediatric population. In order of incidence, malignant melanoma, basal cell carcinoma (BCC), and squamous cell carcinoma (SCC) account for the overwhelming majority of cutaneous pediatric malignancies. In most cases, children with skin cancer possess an underlying risk factor such as a precursor lesion or other predisposing condition. Given that the prognosis of skin cancer is highly dependent on early detection, it is crucial that clinicians have adequate familiarity and index of suspicion for skin cancer in children.

Malignant Melanoma
Malignant melanoma is a tumor of melanocytes, the cells responsible for the production of the dark pigment that accounts for the color of skin. Malignant melanoma is the most common skin cancer in the patients under the age of 20, with approximately 400 new cases diagnosed in the United States each year. Though malignant melanoma may arise de novo, it is estimated that up to 65 percent of cases in children arise from a preexisting nevus. Malignant melanoma most commonly affects children with fair skin, blonde or red hair, and blue eyes, though cases of pubescent malignant melanoma are more frequently observed in non-Caucasian patients.

Pediatric malignant melanoma is frequently found on the head and trunk region in boys, but is more common on the arm and leg region in girls. It typically presents as an enlarging, raised papule that is brown or black. However, pediatric cases of malignant melanoma are frequently amelanotic, signifying a lesion that is red, pink, or white in color. In contrast to benign lesions, malignant melanomas tend to be asymmetric with irregular borders, heterogeneous in color, and larger than 10mm in diameter. It is common for patients to report associated itching, ulceration, bleeding, crusting, or pain. On diagnosis, examination of regional lymph nodes is critical, as palpable lymph nodes suggest metastatic spread and are an indication for more extensive workup.

Several conditions are associated with a significantly increased risk for the development of malignant melanoma in the pediatric population. The most common among these conditions are xeroderma pigmentosum, giant melanocytic nevi, and Werner syndrome. Additionally, increased numbers of melanocytic nevi, dysplastic nevi, or freckles portend heightened risk for malignant melanoma. Other risk factors include immune system deficiency or suppression, fair complexion, red hair, blue eyes, freckles, inability to tan, high levels of ultraviolet (UV) light exposure, and blistering sunburns. Finally, a family or personal history of melanoma or retinoblastoma is indicative of higher risk for malignant melanoma among children.

With suspicion of malignant melanoma, full thickness excision is required to assess depth of the lesion, which then guides all further treatment. The treatment of choice for localized melanoma is surgical resection, with margins that range from 0.5 centimeter (cm) to 2 cm, based on the thickness of the lesion. Sentinel node biopsies are offered to patients at increased risk of spread, with complete lymph node dissection indicated with a positive initial test. Patients who are found to have regional lymph node involvement are offered treatment with adjuvant interferon alfa-2b.
For patients with metastatic disease, prognosis is poor, but potential treatment options include dacarbazine, temozolomide, sorafenib, or interleukin-2. Newer therapies that have specifically shown promise in pediatric trials include ipilimumab and vemurafenib. As in adults, the prognosis of malignant melanoma is based on thickness, depth of invasion, and presence of ulceration. Over 75 percent of pediatric cases are localized with excellent prognosis. Overall, five-year survival in individuals under 20 years old with malignant melanoma approaches 90 percent.

**Basal Cell Carcinoma**

BCC is a tumor of the basal cells of the epidermis. Lesions typically present as raised growths that are lumped or ulcerated. Pediatric BCC is most common on the upper, central portion of the face, as well as other uncovered regions that have high predilection for sun exposure. In general, BCCs are locally invasive tumors with slow growth that are highly unlikely to exhibit metastasis.

Risk factors for pediatric BCC include prolonged UV sunlight exposure, and exposure to radiation therapy for the treatment of other malignancies. The diagnosis of BCC should prompt further workup for common underlying conditions, such as xeroderma pigmentosum, albinism, BCC nevus syndrome, Gorlin syndrome, Bazex syndrome, or Rombo syndrome. As in malignant melanoma, diagnosis of pediatric BCC is often delayed due to a low index of suspicion in children. Regional lymph nodes should be inspected extensively with diagnosis, in order to rule out local invasion. The treatment of choice is complete excision, but curettage and electrodessication may be considered in smaller lesions. The prognosis of SCC is variable. Smaller lesions stemming from normal skin are highly unlikely to metastasize. On the other hand, lesions secondary to radiation exposure, scars, or chronic wounds tend to be more aggressive.

**Squamous Cell Carcinomas**

SCC is a malignant tumor of squamous epithelial cells within the epidermis. SCC is very rare in children, with only a handful of cases reported each year. Lesions are characteristically red, scaly, and raised, with variable induration. They may be associated with telangiectasias, crusting, ulceration, or necrosis. The most common location of SCC in the pediatric population is the lower face, including the lower lip and pinna of the ear, as well as the dorsal aspects of the hand and forearm. In the pediatric population, lesions are frequently mistaken for sites of eczema, infection, or trauma.

SCC may arise in normal skin, but is frequently observed on skin with prolonged sun exposure, or with damage due to trauma, burns, or chronic inflammation. As with malignant melanoma and BCC, SCC is associated with a number of underlying conditions that include xeroderma pigmentosum, immune system deficiency or suppression, chemotherapy, radiation therapy, and HPV infection, particularly in the context of immunosuppression.

Histological evaluation of SCC is based on lesion depth and the cytological features of malignant cells. As in BCC, the treatment of choice is complete excision, but curettage and electrocautery may be considered in smaller lesions. The prognosis of SCC is variable. Smaller lesions stemming from normal skin are highly unlikely to metastasize. On the other hand, lesions secondary to radiation exposure, scars, or chronic wounds tend to be more aggressive.

**Further Readings**

**Skin Cancer, Melanoma**

Melanoma is a tumor produced by malignant transformation of pigment-producing cells (melanocytes)
found primarily in the skin, but also located in the eyes, gastrointestinal tract, mucous membranes, brain, and meninges. The epidemiology, risk factors, and clinical presentation of skin lesions suspicious for melanoma are important determinants in diagnosis and prognosis, and help dictate appropriate management.

**Epidemiology**

Melanoma is the sixth most common form of cancer in the United States, and its incidence has nearly tripled in the Caucasian population in the last 20 years. Incidence in Caucasian men and women has increased significantly by approximately 1.6 percent in the last decade, but remained level among other races. Caucasian individuals are at significantly greater risk for disease development; however, mortality rates are higher for African Americans and Hispanics due to the subtype of melanoma that affects these races, as well as more advanced disease at presentation. Although melanoma accounts for only 4 percent of all skin cancers, it is the leading cause of skin-cancer related deaths, accounting for over 75 percent.

The current lifetime risk for developing melanoma in the United States is one case per 33 Americans. Outside of the United States, the highest incidence is reported in Australia and New Zealand, owing to high ultraviolet light exposure in a predominately white population. Invasive melanoma has a higher predilection for females in patients under 39 years of age, whereas in patients aged 40 and older, there is a higher incidence in males. Yet, the median age at diagnosis is 59 years, and mortality risk increases significantly in persons older than 50.

**Risk Factors**

Certain personal characteristics place individuals at higher risk for the development of melanoma. These include blue eyes, fair/red hair, pale complexion, skin that is easily sunburned, high number of melanocytic nevi (colloquially referred to as moles), and various immunosuppressive states, such as solid organ transplant patients. Furthermore, lifetime exposure to UVB and UVA radiation, number of blistering sunburns, use of tanning beds, positive family history, the presence of an evolving skin lesion (the most important clinical warning sign), and older age, all confer greater risk for the development of melanoma.

Prevention of melanoma centers on sun protection: specifically, avoiding the sun during mid-day, wearing sunscreen year-round, wearing protective clothing, avoiding tanning beds, and becoming familiar with one’s own skin in order to notice changes that may require attention. Nevertheless, these prevention strategies have yielded only modest results as the incidence continues to increase in Caucasians and has remained stable among other races.

**Presentation**

The most common warning sign for the development of melanoma is a new or evolving skin lesion. Characteristics that are suggestive of malignancy are summarized by the acronym “ABCDE,” which include the following:

- A: Asymmetry
- B: Border irregularity
- C: Color variations (especially blue, red, or white tones in a black or brown lesion)
- D: Diameter greater than 6mm
- E: Evolving over time or an elevated surface

Lesions demonstrating these characteristics are suspicious for melanoma, and diagnostic accuracy increases when these criteria are found in combination. Although symptoms such as bleeding, ulceration, itching, and pain are less common, a pigmented lesion with such characteristics warrants evaluation as well.

In Caucasian patients, lesions are typically found on the trunk and lower legs, while in African Americans, Hispanics, and Asians, lesions are typically located on the palm, plantar surface of the foot, subungal, and mucosal sites. There are four major subtypes of cutaneous melanoma, with each subtype portending a different race predilection and prognosis. These subtypes include superficial spreading melanoma, nodular melanoma, acral lentiginous melanoma, and lentigo maligna melanoma; differentiation between these subtypes depends primarily upon histologic growth pattern.

**Workup**

A careful history, review of systems, and physical exam are important factors in accurate clinical diagnosis of melanoma, and all lesions suggestive of melanoma should be biopsied to confirm the diagnosis. The approach to skin biopsy varies depending on the size of the lesion and the anatomic site, but a general guiding principle is that the thickest part of the lesion should be sampled and a low threshold for biopsy should be maintained.
Histologic classification of the biopsy specimen facilitates diagnosis of the particular subtype of melanoma and allows for staging of the malignancy. Various classification schemes for disease staging have been proposed, including the Breslow classification, Clark classification, and TNM (tumor, node, metastasis) staging system; each of these classification schemes stage the tumor based on the thickness of the lesion or the anatomic level of invasion into the skin layers. The TNM system further stages the disease based on the presence of lymph node metastasis and metastasis into distant organs. Lesions greater than 1mm in thickness, and the presence of metastasis are poor prognostic factors.

Management: Medical and Surgical
Following biopsy-confirmed diagnosis of melanoma, a wider excision of the tumor is employed, although further surgery is usually required to reduce the risk of recurrence. Indeed, surgical excision is the standard of care for localized cutaneous melanoma, and surgical margins vary depending on the stage of the tumor. Current recommendations suggest surgical margins of 5mm for melanoma in situ, 1cm for melanomas ≤ 2mm in depth, and 2cm margins for melanomas greater than 2mm thick.

Adjuvant therapy may be required for patients with high-risk melanomas, including high-dose interferon, various chemotherapy agents, immunotherapy, and radiation therapy following resected advanced-stage melanoma. Although adjuvant medical therapies may prolong the time until relapse, a survival benefit has not been consistently demonstrated. Clinical trials are currently underway exploring the benefits of interferon alfa, melanoma vaccines, and biologic response modifiers. Basic and translational research has generated multiple novel therapeutic modalities that have demonstrated promising early results, such as the BRAF inhibitor Vemurafenib.

Patients are monitored regularly after a diagnosis of cutaneous melanoma, because most metastases occur within the first three years after treatment of the primary lesion. Regular skin examinations are recommended for the rest of the patient’s life to detect recurrent/metastatic disease and to evaluate for new primary melanoma.

Prognosis
Prognosis after diagnosis depends on several factors, including the thickness of the tumor, presence or absence of histologic ulceration, and, most importantly, lymph node involvement and distant metastasis. Survival is quantified by the five-year survival rate, which is the percentage of patients who live at five years after cancer diagnosis, excluding those that died of other causes.

Cutaneous melanomas (stage I and II) with thin primary lesions (≤1mm) have a five-year survival of 94 percent to 97 percent, intermediate thickness (1.01mm to 4mm) have a five-year survival rate of 68 percent to 91 percent, and high-risk tumors (>4mm) have a 71 percent five-year survival rate without ulceration and a 53 percent survival rate with ulceration of the primary tumor. Indeed, ulceration confers a significantly reduced five-year survival at every tumor stage, regardless of lymph node involvement. Regional lymph node involvement (stage III) is associated with a five-year survival of 38 percent to 78 percent depending on the number of nodes involved. Patients with distant metastasis (stage IV) have a grim prognosis, with median survival of seven to eight months and a five-year survival of <20 percent.

Further Readings

Skin Cancer, Non-Melanoma

Nonmelanoma skin cancer is the most prevalent type of cancer in the United States and can be
diagnosed by a physician through clinical examination of the skin, with biopsy of suspicious lesions for histological confirmation. Among this subset of cancers, up to 80 percent occur as basal cell carcinomas while nearly 20 percent occur as squamous cell carcinomas. The development of both cancer types is highly associated with ultraviolet (UV) sun exposure and therefore proper sun protection is the most effective risk reduction strategy. Treatment options are dependent on the location and severity of the lesion in question. Overall, prognosis is typically favorable, especially when the lesion is discovered and treated early.

**Epidemiology**
Basal cell carcinoma (BCC) is the most common type of nonmelanoma skin cancer, responsible for up to 80 percent of cases. Its prevalence is largely dependent on geographic location. Populations closer to the geographical equator are at higher risk of BCC and Australia has the highest reported incidence rates of BCC, between 1 percent and 2 percent per year, followed by the United States and Europe. In particular, individuals with fair skin, history of sun-damaged skin, and high exposure to UV radiation are more commonly affected. The lack of organized cancer registries in many countries makes it difficult to approximate the number of patients worldwide suffering from BCC.

Squamous cell carcinoma (SCC) is the second most common type of nonmelanoma skin cancer in the United States after BCC, responsible for nearly 20 percent of cases. The incidence of SCC has increased during the past 20 years due to an aging population, increased sun exposure, and improved detection. Similar to BCC, SCC is more prevalent in areas closer to the equator with more UV exposure, and in the older population, and less common in darker skinned individuals. Studies suggest that people with intermittent sun exposure are at higher risk for BCC, while individuals with chronic sunlight exposure have an increased risk of developing SCC.

**Etiology and Prevention**
The development of BCC is associated with genetic factors, such as individual skin phototype, and exposure to ultraviolet radiation in the UVA and UVB spectrum. It is postulated that mutations in the p53 tumor suppressor gene in the basal cell layer of the epidermis play a role in BCC development. Tumorigenesis of BCC is also linked to constitutive activation of the sonic Hedgehog cellular signaling pathway, though the exact mechanism is not yet well understood. Similar to BCC, SCC is believed to primarily develop from UV-induced mutations in epidermal keratinocytes. Mutations in the p53 tumor suppressor gene, as well as inhibition of the Raf kinase, have also been demonstrated in cases of SCC. These mutations are believed to prevent apoptosis and allow for proliferation of genetically mutated keratinocytes.

Measures for preventing BCC and SCC include reducing exposure to ultraviolet radiation from the sun. This can be accomplished by avoiding sunlight during peak hours of the day, wearing sunscreen that protects against both UVA and UVB radiation with a sun protection factor (SPF) of 40 or greater, routine self-skin examinations for early detection of potentially malignant lesions, and regular visits to a dermatologist for professional skin examinations. In addition, wearing sunglasses, a brimmed hat, and avoiding tanning salons can also help reduce the risk of these skin cancers.

**Diagnosis**
Patients who are fair-skinned, have had a history of considerable sun exposure or skin burns,
and anyone with concerning skin lesions, should undergo a regular whole body skin examination by a dermatologist to check for skin cancers. The dermatologist checks for skin findings such as pink pearly papules, nonhealing scabs or ulcers, nodules with rolled borders, and other lesions that may be suggestive of skin cancer. A skin biopsy is typically performed to provide histological confirmation of the diagnosis. The histological findings can further provide information about the tumor grade, prognostic factors such as tumor differentiation, depth, presence of perineural invasion, and risk of recurrence. Even though skin cancers can develop on any region of the skin, physicians can expect to find most lesions in sun-exposed parts of the body such as the head, face, and extremities.

**Treatment**

Once diagnosed, treatment of nonmelanoma skin cancer depends on multiple factors, including the location, size, and histological grading of the lesion, in association with findings such as poorly defined lesion borders, rapid growth, and tendency of the tumor to recur.

Surgical excision is typically the treatment of choice, in patients who are an appropriate surgical candidate. Other treatment options such as electrotherapy, cryotherapy, topical medicines, and radiation therapy may also be used in certain patient populations. Mohs surgery may be utilized, especially when the lesion is on a cosmetically sensitive area such as the face. This surgery consists of complete examination of the surgical margin using intraoperative sectioning and histological staining to confirm tumor removal. Complete circumferential peripheral and deep margin assessment is another surgical option, especially for SCC. For unresectable or metastatic SCC, chemotherapeutic agents can be utilized, and if the cancer has infiltrated the lymph nodes, aggressive surgical resection may be necessary with potential adjuvant radiation therapy.

**Prognosis**

The prognosis for patients with BCC is excellent if proper treatment is carried through in the early stages of the lesion. BCC rarely metastasizes and is a very slow growing tumor. Studies indicate that the metastasis rate of BCC is as low as 0.05 percent. If a non-metastasized lesion is left untreated it may ulcerate and pose wound-healing issues. When metastasis occurs, the lesions are usually deeply invasive or large in area, and can spread to regional lymph nodes, lungs, and bones. If metastasis occurs the prognosis is tends to be poor, with a median survival time of approximately 10 months after diagnosis of metastatic BCC. Approximately 20 percent of treated patients may develop a new BCC within one year, and 40 percent within five years, of the initial diagnosis. Frequent follow-up is recommended to check for recurrences or new malignancies.

The prognosis for SCC is also favorable. SCC generally has a low recurrence rate with appropriate treatment and management. Approximately 75 percent of recurrences occur within one year of the initial treatment, and metastasis occurs in 2 percent to 5 percent of cases. If the tumor metastasizes, it commonly infiltrates local lymph nodes or spreads to distant sites, with 10-year survival rates of 20 percent and 10 percent, respectively. Furthermore, patients treated for SCC are at an increased risk of a second skin cancer, as well as cancers elsewhere in the body, thereby making regular visits to the physician very important for surveillance of their condition.

**Skin Carcinoma, Merkel Cell**

Merkel cell carcinoma is an aggressive form of skin cancer and neuroendocrine tumor, also known as primary small cell carcinoma of the skin, primary neuroendocrine carcinoma of the skin, or trabecular carcinoma of the skin. Most—about 80 percent—of Merkel cell carcinomas are caused by the Merkel cell polyomavirus (MCV). MCV was discovered in 2008 at the University of Pittsburgh, and is one of seven viruses that have been discovered to cause cancer in humans. Polyomaviruses are small double-stranded DNA viruses, and only five have been discovered that infect humans—MCV is closely related to a polyomavirus that infects African green monkeys, supporting the hypothesis that MCV has coevolved with primates. The discovery of the virus may lead in turn to a vaccine which, like the human papillomavirus vaccine, could prevent the development of Merkel cell carcinoma, or could assist the immune system in fighting existing tumor cells. The cause of MVC-negative Merkel cell carcinomas is unknown.

Merkel cells are oval receptor cells found in the skin, and are involved in the sense of touch, especially our ability to distinguish shapes and textures through touch. They’re clear cells found at the bottom of sweat duct ridges, and can especially be found in association with sensory nerve endings. Much about Merkel cells remains unknown, from the mechanisms of their involvement with the sense of touch to their possible neuroendocrine function to whether their origin is in the epidermis or the neural crest.

MCC is twice as common in men as in women, and is more common in whites than non-whites. Advanced HIV, chronic lymphocytic leukemia, and other immune disorders greatly increase the odds of developing it. It typically presents in white men ages 60 to 80. Because it’s so rare, accounting for about one in 1,000 skin cancer cases, it is often initially mistaken for another skin cancer like basal cell carcinoma or malignant melanoma, or for a benign cyst. The first symptom of MCC is usually a visible dome-shaped tumor on the surface of the skin that is red, blue, or flesh-colored. Firm and painless, they can appear anywhere on the body, about half of them appearing on sun-exposed parts of the head and neck. Usually starting small—the size of a pimple or insect bite—they expand quickly. This often leads to rapid metastasis as the cancer infiltrates subcutaneous fat, muscle, or fascia, and expands beyond the skin to the lymph nodes, or through the blood vessels to the liver, lung, bone, or brain.

MCC is similar enough to other skin cancers that frequently it is not until the pathological examination after it has been removed surgically that it is identified, because so little differentiates it from other skin cancers. Usually a margin or “cuff” of healthy tissue is removed from the surrounding area in order to help prevent local recurrence; if the lesion has developed beyond one centimeter in diameter, lymph nodes may be removed as well. Sentinel lymph node biopsy is important because it has detected the spread of MCC in one-third of patients whose cancer had been underestimated.

Radiation therapy is a common treatment for MCC, usually with a very large field of exposure, because of the cancer’s aggressive metastasis. Radiotherapy has been shown to significantly reduce the rate of recurrence, and a patient with a negative sentinel lymph node biopsy and no distant metastases has a 90 percent five-year survival rate with postsurgical radiotherapy.

MCC risk factors probably include sun exposure and exposure to UV light through artificial sources like tanning beds, though this isn’t known for certain. Merkel cell carcinomas have a 60 percent five-year survival rate overall.

Johannessen, J. V. and V. E. Gould. “Neuroendocrine Skin Carcinoma Associated With Calcitonin
Skipper, Howard E.

When Dr. Howard Earle Skipper was born in Avon Park, Florida, at the height of World War I (on November 21, 1915), the idea of treating cancer by injecting toxic chemical compounds directly into the blood stream in an attempt to stop the furious cell division and uncontrollable tumor construction typical of the disease was dismissed by the most respected cancer specialists as crude medicine that often caused the patient more agony than the cancer, and seldom stopped the cancer’s spread. Ironically, it was during World War I that Allied doctors first noticed the particular killing strength of chemical compounds, specifically nitrogen mustard, that went into producing that war’s most controversial weapon responsible for massive civilian casualties—mustard gas. Nitrogen mustard worked by simply killing all the cells it contaminated with a nearly 100 percent rate. More than 40 years later, after his own stint in the biochemical division of the Army during World War II, Skipper would be among the first and certainly the most prominent research oncologists to glimpse the potential and to test the viability of nitrogen mustard not as a weapon but rather as a potent, potentially lifesaving anticancer medicine.

Little in Skipper’s early years would have predicted a nearly 40-year career in the quiet of a research laboratory—he grew up in Sebring, in central Florida’s rich farmlands, working on his father’s cattle ranch and earning extra money performing daring diving exhibitions for tourists in the summer. At the University of Florida, he earned a full athletic scholarship, a commanding presence on both the football team and the swim team. But science was his passion. He completed his B.S. in 1938, his master’s the following year, and his doctorate in biochemistry and nutrition in 1941, all in Gainesville. After completing his doctorate, he immediately enlisted in the army and served in the toxicology section of the army’s medical division in Bethesda, Maryland. He had a keen interest in chemical weapons, particularly the strength of nitrogen mustard. He was convinced that the compound could be used in the chemical treatment of certain cancers. There was at the time no specific research to back up his intuition. Much later he would credit that spark of informed guessing, which he called inductive reasoning, as the cornerstone of his revolutionary reconceptualization of chemotherapy.

However, he needed a laboratory. He was offered a position to help start and then direct a biochemistry department at the Southern Research Institute in Birmingham, Alabama. When Skipper made it clear he would take the position only if he could follow his hypothesis about nitrogen mustard, the Institute agreed. Skipper quietly, methodically went about recruiting a staff of researchers, including virologists, organic chemists, biologists, and oncologists. It was a revolutionary idea, to secure different fields of research to work together, but Skipper, with his unassuming demeanor and his general disdain of the egoism of leadership, preferring the camaraderie of teamwork, was in many ways the perfect choice for director.

Skipper began by having the team gather hard data that his intuitive leap lacked. The research team at Southern Research earned a national reputation for its groundbreaking use of animal models, in this case mice, to trace the effects of different combinations of nitrogen compounds on cells. They studied the cells that survived the chemical doses and those that did not. They measured different levels of dosage and kept meticulous records on the progress of the cancers and the tumors and most importantly, measured the necessary intervals between dosages. Using mice models, Skipper led his team to creating what became among the first protocols for the contemporary conception of chemotherapy. He directed his team to evaluate the impact of chemical treatment on mice artificially injected to create leukemia, lymphomas, and a variety of solid tumors. He was certain that nitrogen compounds, because of their high toxicity, would be effective in halting the growth and spread of cancerous cells. Conventional wisdom at the time held that chemical treatments were most effective if they killed a
percentage of the cancerous cells and then left the body’s natural immune system to get the idea and in turn kill the rest of the cancerous cells, as if cancer were some bacterial presence, a dicey proposition as the malignant cancer cells could divide so rapidly. Further, Skipper found out that hospitals seldom measured the dosages and that most of the data was therefore inconclusive.

Skipper devised a protocol for measuring exact amounts of chemicals necessary to completely kill the cancer cells. Although he often modestly dismissed his pioneering research work by dismissively referring to himself as the “mouse doctor,” he understood that he was onto a major revision of long-held notions about the chemical treatments of cancers. If traditional chemotherapy held that cancer was a kind of generally benign bacteria that the body, if assisted, could ultimately overcome, like some uninvited guest, Skipper redefined the cancer itself, using his background in warfare, to view it as a massive invasive agency, like some menacing foreign military occupation, that could not be controlled by partial resistance. Rather the body, the cells themselves, had to fight off the cancerous invasion with no goal less than total annihilation. The body had to be helped through chemical infusions to destroy the cancerous invasion entirely. His conception, indeed his research data, redefined the import of chemotherapy—by using compounds derived from mustard gas, Skipper introduced the idea of chemotherapy as a kind of all-out war against the cancer—a far more militant conception of treatment than any before him. For his efforts he was awarded the 1974 Albert Lasker Award, which annually recognizes significant advances in the treatment of diseases, and the 1982 Kettering Prize for outstanding contribution to cancer research.

Although his introduction of nitrogen compounds into chemotherapy regimens was not without controversy within the field of oncology treatment (patients would often experience heightened side effects from the treatments, including intense nausea and a debilitating fatigue), there was little doubt as to the success of Skipper’s tested
protocols. Even when he was named director of the Southern Research Institute in 1974, Skipper never left the research division, determined to track and measure the impact of aggressive chemotherapy. He wanted only to reassure cancer patients that treatment was available and offered authentic hope, and although he authored more than 200 research documents in refereed journals, he also produced a line of booklets designed to inform and reassure cancer patients of the promise of chemotherapy. After he retired in 1989, he continued his own research protocols. He died, January 2, 2006, at the age of 90, in Mountain Brook, Alabama.

Slovakia

The Slovak Republic is one of the landlocked countries at the heart of the European continent with the boundaries covering about 49,000 km². More than 85 percent of the population in the country is Slovaks. The country has been a signatory to the United Nations and the other associated agencies; it is also a member nation in the European Union and NATO, the Council of Europe, and the Organization for Security and Co-operation in Europe (OSCE). One of the most interesting things about this country is that when compared with other Organisation for Economic Co-operation and Development (OECD) states, in 2006 they reached the highest growth rate in the economy, though the global economic crisis in 2008 slowed this growth.

As far as health and development are concerned the Slovak constitution institutes the right to every citizen to receive health care a fundamental right. In the Slovak Republic cancer in the society is as much of a concern as in other countries.

Comparative studies between the United Kingdom and countries such as Slovakia and Turkey indicate that the Slovak Republic has made significant strides toward the ability to detect and handle cancer. Of special note is the fact that in Slovakia there is equipment at hand to scan patients for cancer early. The availability of high-tech equipment is a signal of just how far the republic has come in the battle against cancer.

Osteoporosis
This metabolic skeletal disease has been a significant challenge to the health care industry in Slovakia for a very long time. Over the past few years the epidemiologic data that is available in the industry has shown that there is a steady increase in the number of people that are continually being diagnosed with the condition. As a matter of fact, reports suggest that by the year 2050, it is expected that there will be more than 6 million reported bone fractures as a result of osteoporosis in the country, which marks a significant growth from the figures in 1990 of 1.5 million.

Cancer patients in the country, especially those that are dependent on hormone therapy, such as those suffering from breast cancer and prostate cancer, or even those that are getting treatment in hormonal metabolism, ovarian cancer, thyroid cancer, germ cell tumor, and other associated conditions, are at a higher risk of suffering from osteoporosis.

Breast Cancer
According to 2011 reports, breast cancer accounted for 1.8 percent of the overall deaths in the country. According to the statistics, this puts the figure at 823 individuals who died of breast cancer alone, ranking Slovakia 64th in the whole world for deaths from the disease.

Industry experts have reported that those suffering from breast cancer are also at a very high risk for osteoporosis as a side-effect of anticancer therapy. Postmenopausal women are at an even higher risk.
In order to deal with the cancer situation in the country that is fast getting out of hand, the government, in partnership with the other organizations, has been working on bone mineral density measurement for postmenopausal women. Such patients are commonly treated with tamoxifen or aromatase inhibitors at the St. Elisabeth Cancer Institute. The procedure often takes more than one year because the density of the bones is measured at the beginning of the treatment, in the course of the therapy, and as soon as the therapy is completed.

One of the most important features of this study in the industry was to lay an emphasis on the fact that it is important to consider the evaluation and the relation between osteoporosis and cancer in the Slovak Republic.

Testicular Cancer
Testicular cancer is not just a problem in the Slovak Republic, but it is a problem all over the world. However it is worth noting that when detected early enough, it is possible to treat testicular cancer, and as a matter of fact the healing rate currently stands at 90 percent. The catch however is in making sure that the diagnosis is done at a very early stage, and most importantly done correctly.

In the Slovak Republic, more than 1 percent of the male population is currently suffering from malignant testicular cancer. The worst thing about this is that the number of those who are suffering from testicular cancer is on the rise, with reports indicating that the increase has multiplied more than five times.

Most of those who are affected are men between the ages of 20 and 40 years. A good number of those in this category have their testicular cancer as a result of germ cell tumors, which have been further classified as under seminoma and nonseminoma germ cell tumors. More than half of those who have testicular cancer in the Slovak Republic have it as a result of nonseminomatous germ cell tumor.

The Cancer Research Institute SAS has been around since 1946, and is at the moment the oldest research institute in the country devoted to cancer research. The institution is tasked primarily with studying and understanding molecular mechanisms of the cancerous cells, and with this in mind they have also focused on running the inquiries under a multidisciplinary approach. There are a lot of scientists that work under this institute to further the objectives, including a number of high-profile molecular biologists, chemists, and geneticists.

In as much as this is primarily a research facility, the institute has also been working together with the oncology unit at the Bratislava St. Elisabeth Institute. They also actively published Neoplasm, an oncology-based journal.

Small Intestine Cancer
There are five types of small intestine cancer, with the most common type being adenocarcinomas. All forms of small intestine cancer are fairly rare, affecting only a small percentage of the population. This disease tends to be prevalent in those who have Cohn's or celiac disease, cystic fibrosis, and those with a history of adenomatous polyps.

The following are types of small intestine cancer:

- Adenocarcinomas: This form of small intestine cancer is the most common
Small Intestine Cancer

type, and it usually forms in the cells that live in the walls of the small intestine. Much of the time, adenocarcinomas will develop from noncancerous polyps, which are small growths on the intestinal walls.

- **Carcinoid**: When suffering from this type of cancer, a person will endure slow-growing cancerous tumors within his or her small intestine.
- **Sarcoma**: Cancer that forms within the connective tissue found in the small intestine is known as sarcoma.
- **Lymphomas**: Although this form of cancer is known as an immune system disease, it often begins its development in the small intestine.
- **Gastrointestinal Stromal Tumors**: Much like sarcoma, this form of cancer starts out by attacking the soft tissue in the intestines.

**What Does the Small Intestine Do?**

To understand small intestine cancer, it’s first important to understand the function of the small intestine in the human body. The small intestine is part of a major system within the body, which is most commonly referred to the digestive system; this system is composed of the mouth, throat, esophagus, stomach, small intestine, large intestine (colon), rectum, and anus.

It is the digestive system’s purpose to remove and process foods. It separates nutrients from waste, allowing the “good” material to stay in the body, and the “bad” material to be excreted. The small intestine itself lies between the large intestine and stomach, connecting the two organs.

**Factors That Influence Development of Small Intestine Cancer**

Though cancer of the small intestine is rare, there are certain factors that increase risk. Those with a history of Crohn's or celiac disease, those with cystic fibrosis, and those with a family history of adenomatous polyps are considered at a higher risk. In addition, there are certain behavioral and environmental factors that can increase the risk of small intestine cancer, such as eating foods high in fat, tobacco and alcohol use, and exposure to certain chemicals, including vinyl chloride.

**Signs and Symptoms**

Being aware of the symptoms of small intestine cancer increases the likelihood that person will seek medical attention at the first signs of the disease. As with other cancers, early detection and treatment increases the changes for a positive outcome. Signs and symptoms of small intestine cancer include the following:

- Weight loss for an unknown reason
- One or more lumps in the abdomen
- Blood in the stool
- Abdominal pain and/or cramps

If a person notices any of these signs or symptoms, it is highly recommended that he or she visit a physician as soon as possible.

**Methods for Detection and Diagnosis**

If a physician believes that a patient may be suffering from small intestine cancer, certain tests will be administered. It is through these tests that the exact form of small intestine cancer can be identified, which then makes it possible to carry out the proper treatment methods. The processes that are used to identify cancerous cells within and around this area of the body are most commonly referred to as staging. The following is a list of tests that are often administered to identify and diagnose small intestine cancer:

- **Physical Exams**: A simple yet very effective way to see if there are signs of small intestine cancer is a physical exam. A physician will assess a patient’s past medical history and risk factors, as well as check for any lumps are present in the abdomen.

- **Liver Function Tests**: This type of test is carried out by collecting a blood sample. The sample is then checked to see how much of certain substances are being released into the human body by the liver. If higher than normal amounts of certain substances are noticed, this is a good indication that small intestine cancer is present.

- **Blood Samples**: A blood test checks for a wide array of substances in the blood. If higher or lower than normal amounts of certain substances are noticed, this is a good indicator of the presence of small intestine cancer.
Endoscopies. This type of test allows a physician to look at the small intestine and identify whether there are any abnormalities. There are three types of endoscopy that can be performed, which include an upper endoscopy, capsule endoscopy, and a double balloon endoscopy.

Other tests used to identify the presence of small intestine cancer include laparotomy, biopsies, upper GE series with small bowel follow-through, computed tomography (CT) scans, or magnetic resonance imaging (MRI).

Treatment for Small Intestine Cancer
There are three primary ways that physicians treat small intestine cancer, which are surgical removal of the cancerous lump or polyp, chemotherapy, or radiation therapy if the cancer has spread to other parts of the body.

Survival Rates of Small Intestine Cancer
The survival rates for small intestine cancer are largely dependent on the stage of cancer that a person suffers from. According to the American Cancer Society, the following rates apply:

- Stage I: 55 percent
- Stage IIA: 49 percent
- Stage IIB: 35 percent
- Stage IIIA: 31 percent
- Stage IIIB: 18 percent
- Stage IV: 5 percent

Smokeless Tobacco
Smokeless tobacco includes a variety of tobacco products that are consumed (or otherwise used) recreationally in some way other than smoking. It generally excludes electronic cigarettes, which simulate the experience of smoking and include nicotine. All forms of tobacco consumption pose carcinogenic risk, and in some cases the additives used in various forms of tobacco increase the risk of cancer and other health-related problems.

Chewing Tobacco
Chewing tobacco is perhaps the best known form of smokeless tobacco. For a long period in the 19th century, chewing tobacco was made with cigar clippings, but today it uses loose leaf or scrap tobacco, pellets of tobacco, or loose leaf tobacco bundled into a plug with an added sweetener. Chewing tobacco is one of the original forms of tobacco consumption, dating to the pre-Columbian period, and it was developed commercially by the tobacco plantations in the Southern colonies of North America. In the antebellum south and much of the frontier, chewing tobacco was an almost universal habit among men over 10 years of age, and practiced by over half the women as well. In contrast, daily smoking never enjoyed such widespread use. Chewing tobacco continues to be popular in the south, midwest, and mountain states, and is common in certain professions such as commercial trucking. Long associated with baseball, it has been displaced in that sport by dipping tobacco.

Chewing tobacco is known to be linked to oral cancers. Several well-known ball players developed cancer associated with chewing tobacco, including notably Babe Ruth, who died of nasopharyngeal cancer, and Tony Gwinn, who died of salivary cancer. After Babe Ruth’s death, cigarettes gained popularity among ballplayers, but the federal push
Smokeless Tobacco

Smokeless tobacco to warn the public of the dangers of smoking in the 1970s brought back chewing tobacco. Dipping tobacco or moist snuff is finely ground tobacco that is moistened, known by a variety of names in different parts of the country, including dip, rub, chew (though it is not chewing tobacco), snuff (though dry snuff is different), chaw, and daps. Skoal and Copenhagen are popular brands. Dipping tobacco was introduced by Copenhagen in 1822, and is primarily popular in the south and rural Canada, as well as in professions where smoking is banned. Dip is consumed by placing a pinch of tobacco between the lower lip and the gum, and letting it sit there for 10 to 30 minutes. Nicotine and other substances are absorbed through the inferior and superior labial arteries, as well as under the tongue. Both chewing tobacco and dipping tobacco cause excess saliva that needs to be spat out, since swallowing saliva infused with tobacco can cause nausea and vomiting. Dipping tobacco is associated with tongue, lip, cheek, gum, throat, and salivary gland cancer, as well as tooth loss and gum disease, and probable cardiovascular problems.

In parts of Alaska, Blackbull is a form of dipping tobacco mixed with the ash of Phellinus igniarius, a fungus that infects black walnut trees. It’s consumed by some Alaska Natives and sold in general stores.

In central Asia and the Indian subcontinent, and among immigrants from that region, naswar is a moist powdered tobacco similar to dipping tobacco. It is stuffed under the lower lip or inside the cheek, and requires periodic spitting. It is processed with lime (which helps make the nicotine bioavailable), air-cured and dried, sometimes flavored with juniper, and dyed with indigo. The National Institutes of Health have established a positive link between naswar and mouth and throat cancers.

**Snuff**
Snuff or dry snuff is also made from ground tobacco, which is inhaled through the nose for a quick nicotine buzz and accompanying scent, if the snuff is flavored. The tobacco is absorbed through the mucus membranes of the nose, so does not need to be inhaled deeply enough to reach the sinuses. Not surprisingly, snuff is associated with nasal and throat cancers.

Dry snuff originated with Native Americans and became popular in Europe after the colonization of North America, remaining popular there long after chewing tobacco and cigarettes had overtaken snuff’s popularity in the United States. “Medicated” snuff is made with menthol to clear the sinuses. Numerous flavors of snuff are offered, from traditional spice, fruit, and floral flavors to modern whiskey- and cola-flavored snuff. Snuff boxes became popular in Europe when snuff was in its heyday, designed to fit in a pocket and protect snuff from drying out. Members of the British House of Commons continue to be provided with rose-scented snuff because of the centuries-long ban on smoking in the building.

**Snus**
A similar product to dipping tobacco is snus, a finely ground moist tobacco powder developed in Sweden in the early 1700s. Unlike most American tobacco products, Swedish snus is not fermented during the curing process, and it is not sweetened. Placed under the upper lip rather than the lower, it does not stimulate the production of excess saliva, and does not require spitting. It is linked to oral, pharyngeal, and pancreatic cancers, as well as hypertension and tachycardia. The European Union banned snus in 1992, except in Sweden and Norway. Recently, American companies like Camel have started selling snus as an alternative to other smokeless tobaccos, though it is prepared slightly differently and contains less bioavailable nicotine. Swedish snus often comes in smoked, juniper, bergamot, or citrus flavors, while American snus comes in various mint and fruit flavors.

**Creamy Snuff**
One of the more unusual smokeless tobacco products in the United States is creamy snuff, a blend of tobacco, clove oil, spearmint, menthol, camphor, and glycerin, with a texture like that of toothpaste (and sold in a similar tube). The paste is rubbed on the inside of the mouth or gums and allowed to linger before rinsing. This too is linked to oral cancers and hypotension.

**Conclusion**
Health professionals do not agree on the relative merits or dangers of smokeless tobacco. There is no doubt that compared to avoiding all tobacco use, smokeless tobacco is dangerous. However, many health professionals, citing the doctrine of harm reduction, credit smokeless tobaccos with being
significantly less dangerous than cigarette smoking. While the carcinogenicity is undeniable, research is fairly compelling that smoking, especially smoking cigarettes, is far more carcinogenic, and more likely to lead to death by cancer, than smokeless tobacco usage. Furthermore, even if risks to the user were completely equal, smokeless tobacco poses a lesser public health concern since there is no analogue to secondhand smoke, the dangers and carcinogenic contributions of which many researchers believe are still understated. In Sweden, snus is widely used in smoking cessation programs, and tobacco-related mortality among men is lower in Sweden than in any other European country. However, the use of smokeless tobacco in smoking cessation programs has a noncarcinogenic alternative as well, in the form of nicotine gum or nicotine replacement therapy. Such treatments are considerably more expensive, though.

Smoking and Society

The World Health Organization (WHO) forecasts that up to 1 billion people could die this century from smoking or from being exposed to tobacco, if current smoking rates continue. Around 6 million people die every year due to smoking or exposure to secondhand smoke. In spite of these rates, consciousness about the health risks associated with smoking is on the rise in many countries thanks to widespread antismoking campaigns. However, in developing countries such as India, tobacco accounts for about 40 percent of all cancers.

Smoking increases the risk of acute hypertension, tuberculosis, heart diseases, lung cancer, oral cancer, and diabetes. Passive smokers (those exposed to secondhand smoke) are also at risk. Prolonged cigarette-smoking can rob a decade of life, on an average. Smoking during pregnancy can lead to everything from low birth weight and birth defects to stillborn births. The cost of cigarettes can have an economic impact on smokers, and the litter from smoking can contaminate the waterways and the soil. Smoking can create clashes among smokers and nonsmokers, as the general public may oppose smoking in public places. There are more than 50 countries that have banned indoor smoking in workplaces, hotels, restaurants, etc.

The World Health Organization has opposed passive smoking, which also affects the health of pets. Children of smoking parents are at greater risk of becoming smokers themselves. The social learning
theory supports that conceptions of behaviors among children guide their future actions. Children learn that smoking is a normative behavior, which can impact their willingness to smoke in the future. Even if parents make it a point not to smoke in the sight of children, the ill-effects of smoking still affect families.

There are several myths which are prevalent in developing societies which may prevent people from seeking treatment for cancer. For example, according to a *Lancet* report, around 80 percent of cancer patients in India seek treatment from unqualified medical professionals before going to reputable doctors, in part because many of people prefer cheaper methods of care. Even today, many people believe that cancer is incurable and that a diagnosis an automatic death sentence. But, this fear still does not deter people from smoking.

There has been a rise in smoking among women. Researchers state that excessive smoking among women may lead to a rise in infertility and cancer. Research conducted by the *British Medical Journal*, from 1980 and 2012 among smokers in 187 countries, confirmed this trend. Women in China and India are increasingly turning to cigarettes as a form of socialization. Moreover, cigarette manufacturers have realized that India and China are good markets which need to be targeted. That will lead to less dependence on Western markets for cigarettes where antismoking laws are becoming more stringent. The tobacco companies have diverted their targets to middle- and low-income countries. In a paper published by the Mumbai-based Tata Memorial Centre, it has been observed that the cost of tobacco consumption in 2002–2003 exceeded the total combined government revenue and capital expenditure on medical and public health, water supply, and sanitation.

To curb smoking, France is considering the option to support unbranded packaging. France is also considering instituting one of the toughest antismoking policies in the world. Plain packaging has been successful in reducing smoking rates in France. Less than one-third of the population is now engaged in smoking in France. Australia has pioneered plain packaging for cigarettes since 2012. Britain, New Zealand, and Ireland have also planned similar bans. Nicotine-replacement therapy has proven to be a success in Europe and the United States in the drive for antismoking. But, to date, poverty-stricken, developing societies have failed to understand the benefits of the therapy.

Strong antismoking laws are a starting point to creating a smoking-free society. Taking stern action against tobacco companies may affect local economies, but it is necessary for the greater good of the community.

Advertisement of cigarette brands plays a significant role in influencing smokers to continue with the addiction and has been proven to encourage young people to start smoking. Aggressive anti-smoking ad campaigns can have just as much influence in preventing people from starting smoking in the first place. In India, for example, where smoking and tobacco use are the leading causes of cancer, movie halls show short public service announcements that encourage smokers to quit.

Many societies have started engaging in aggressive campaigns against smoking, although it is worth noting that these campaigns have been less successful, as measured by the rate of smokers quitting, in developing countries as compared to industrialized countries. Public awareness on exposing children to secondhand smoke is growing. Bans on household smoking will have favorable effects on children. Long before children start smoking, prevention programs for adolescents are required.

Quitting smoking can take an enormous amount of one’s determination and will. Family members may play an important role by becoming the
Smoking Cessation

Nicotine replacement therapy (NRT) is used to aid in the transition from cigarette smoking to smoking cessation. NRT is a temporary means of replacing the nicotine from cigarettes in an attempt to reduce an individual’s motivation to smoke, and to ease nicotine withdrawal symptoms. The nicotine in cigarettes is the active ingredient that often leads to physical dependence on smoking. If someone tries to quit smoking, the physical dependence can result in withdrawal symptoms. Nicotine dependence occurs early and easily as people begin to smoke cigarettes. It does not take much use before withdrawal symptoms and cravings occur. Nicotine is a substance that increases the levels of the brain chemicals dopamine and norepinephrine. When people stop smoking, the chemical levels drop, causing the body to experience withdrawal symptoms, including anxiety, irritability, and hunger.

NRT supplies the body with a lower dose of nicotine to help reduce nicotine withdrawal and resulting cravings. NRT uses about one-third to one-half as much nicotine as cigarettes. Nicotine from NRT also increases dopamine and norepinephrine levels, like cigarettes, which reduces withdrawal symptoms while reducing the level of nicotine ingested. The NRT process helps as a temporary replacement for the nicotine received from smoking cigarettes, and can be adjusted so that the smoker can decrease the amount of the medicine they use in a steady decline until it is no longer needed and they have been weaned from nicotine. Inhalation of tobacco smoke moves quickly into the lungs and bloodstream. The nicotine replacement products take longer to enter into the lungs and bloodstream, and are much less likely to cause dependence on nicotine. NRT is safe when properly used, and is not as harmful as smoking because NRT does not provide the tars, carbon dioxide, and other harmful chemicals present in tobacco. NRT delivers nicotine in the form of gums, patches, sprays, inhalers, or lozenges, but does not contain the other harmful chemicals in tobacco. NRT can help relieve some of the physical withdrawal symptoms so that an individual can focus on the psychological aspects of quitting.

Nicotine replacement therapy has been an effective means of helping people try to quit smoking, but there are some limitations. According to the U.S. Agency for Healthcare Research and Quality Clinical Practice Guideline on Smoking Cessation in 2000, this medicine should not be used when someone is pregnant or suffers from heart disease. This was revised in 2008, as the agency stated that the nicotine patch could be safely used with a doctor monitoring the process. NRT products have been linked to low birth weight in children born to...
mothers who use it during pregnancy. While this risk is present, smoking during pregnancy is also an important risk to consider. Although NRTs expose the fetus to nicotine, smoking exposes the fetus to nicotine and additional harmful chemicals. The effects of smoking while pregnant could also have long-term effects on subsequent child development. It is best to quit smoking, or at least reduce the amount smoked, before becoming pregnant. If an individual becomes pregnant, or plans on becoming pregnant, they should contact their physician and discuss possible safe options. They will likely need to try other methods during the pregnancy.

A physician should also be consulted if an individual has heart disease, has had a recent heart attack, or has serious heart problems like irregular or rapid heartbeat or chest pain. Studies indicate that the benefits of quitting smoking outweigh the risks for individuals with cardiovascular disease. Risks are still present, but the greater risks seem to be with smoking cigarettes. When looking at NRT use, the benefits of quitting smoking must outweigh the potential health risks of NRT for each person. NRT products are not recommended for people under the age of 18 because they have not been tested on younger populations. The side effects of nicotine replacement therapy for young people are unknown. It is always better to consult with a physician before beginning any type of NRT, healthy or otherwise. This allows the physician to recommend products that would be most useful and monitor the effects. NRTs have not yet been proven to help people who are lighter smokers. Individuals who smoke fewer than 10 cigarettes a day might not see the effects of NRTs as easily as heavier smokers. Light smokers might want to talk with a doctor about a lower dose of NRT if they smoke less than that, but feel that they need nicotine replacement.

In many cases, research indicates that using some form of nicotine replacement therapy increases an individual’s chances of quitting smoking. NRT can help with the withdrawal symptoms and cravings that the majority of smokers indicate as the reason they have either not tried to quit smoking, or have been unsuccessful in efforts to quit smoking. All forms of nicotine replacement products appear to be about equally effective, when properly used. In some cases, combining the use of products, such as the nicotine patch and another form of NRT, can increase efficacy. As with any other medication, this option should be discussed with a physician before beginning, and should be monitored by the doctor throughout. It is believed that NRT treatments work best for quitting smoking when combined with a behavioral program of smoking cessation. These programs often include setting goals for quitting, creating plans for dealing with triggers to smoking, and working with a doctor, counselor, or other support system.

It is often possible to quit smoking without resorting to NRT treatments, but there are usually multiple attempts because most people do not succeed on the first attempt. In most cases, smokers need many tries before they are able to permanently quit smoking. Most smokers who try to quit end up smoking again within the first three months without nicotine. This lack of success can usually be attributed to the accompanying withdrawal symptoms. The reduction of withdrawal symptoms with NRT can reduce the negative physical effects. Smokers seem to have the best chance of quitting and remaining smoke free if they have the help of a professional and personal support network.

NRT treatments only work on the physical dependence, and do not address psychological feelings of dependence and reliance. It only works on one part of the smoking problem, and often cannot be successful without addressing the other elements of the issue. Smokers will need to utilize other treatment methods to address the psychological (emotional and mental) part of smoking, such as a stop-smoking program or support group. People seeking to quit should use these resources during treatment with NRT, and stick with them for at least a few months after quitting to help them remain smoke free. Studies have shown that pairing NRT with a program that helps to change behavior can improve the likelihood of successfully quitting and staying quit compared to approaches that only use one method. The best time to start NRT is when an individual first stops smoking. Smokers often try to quit without the aid of NRT therapy first, and then find that they need extra help, which leads them to try NRT shortly after the initial attempt to quit. This does not give the process the greatest likelihood of success.

**Side Effects**
The different NRTs work equally well. As a result, smokers can choose a treatment based on how it
fits with the individual’s lifestyle and comfort zone. Each person needs to create a program that works best for them, including taking into account the potential side effects. All NRTs have side effects, but the types of side effects differ across NRTs, and are based on each individual. Very few people (less than 5 percent) have to stop using a nicotine replacement product altogether because of side effects, but a smoker should contact their doctor to make sure which therapy would work best based on their overall health and ability to deal with the possible side effects. As with cigarette use, the sudden cessation of nicotine replacement therapy may cause some of the same withdrawal symptoms that occur when an individual stops smoking cigarettes. Individuals are less likely to have withdrawal symptoms with a gradual reduction of the dose or number of uses of the specific NRT each day. Although rare, it is possible for an individual to become dependent on a nicotine replacement product.

The U.S. Food and Drug Administration (FDA) has approved five forms of nicotine replacement therapy, including gums, patches, nasal sprays, inhalers, and lozenges. Nicotine gum and lozenges release nicotine through the mouth. Nicotine patches stick to the skin and release nicotine through the skin into the bloodstream. A nicotine inhaler delivers a puff of nicotine vapor into the mouth and throat. No prescription is necessary for nicotine gum, patches, and lozenges, but a prescription is necessary to buy nicotine inhalers. Non-prescription NRTs cannot be sold to individuals under 18 years of age, although a doctor can prescribe an NRT for an underage nicotine user.

**Gum**

Nicotine gum is a fast-acting form of replacement in which nicotine is taken in through the mucous membrane of the mouth. Individuals can buy it over the counter without a prescription, and it comes in 2 milligram (mg) and 4 mg strengths. The gum should be chewed slowly until the individual experiences a peppery taste or tingle. The gum should then be held against the inside of the cheek until this taste fades. The gum is chewed again until the taste or tingle returns, it is held against the side of the mouth until it fades, and the process continues to repeat for about 20 to 30 minutes. Users should not eat or drink anything from about 15 minutes before gum use through 15 minutes after gum use so that the nicotine can be absorbed in the proper proportion.

The gum dose that an individual uses will be based on how many cigarettes he or she is currently smoking per day, whether or not they smoke within 30 minutes of waking up in the morning, and how much trouble they have when they are in a position where they cannot smoke for a period of time. If any of these symptoms are present, the individual should start with the higher 4 milligram gum dose. Individuals cannot chew more than 24 pieces of gum in one day, and the process is normally recommended for six to 12 weeks, up to a period of six months. Users are advised to begin tapering down the amount of gum used at about three months. The gum has some advantages. The gum allows individuals to control the doses of nicotine that are ingested, and it can be used as needed or on a convenient fixed schedule during the day. This flexibility allows users to determine when they need it the most, and to use it accordingly. Additionally, if an individual has sensitive skin, they might prefer the gum to the patch.

Some possible side effects of nicotine gum include a residual bad taste, throat irritation, mouth sores, hiccups, nausea, jaw discomfort, and racing heartbeat. The gum also has a tendency to stick to dentures or dental work, potentially causing damage. Symptoms related to the stomach and jaw are usually caused by improper use of the gum, such as swallowing the nicotine or chewing too fast. No one has all of the side effects, and some people have none. If an individual experiences a racing heart or irregularity in the beat, they should stop using the gum and talk to their doctor. If the NRT dose is too low, it is also possible to experience withdrawal symptoms. Long-term dependence is one possible drawback of nicotine gum. Some research indicates that a few gum users who are able to quit smoking keep using the gum beyond 6 months. Nicotine is addictive, and people can transfer their dependence from cigarettes to the gum.

**Patch**

Patches give a measured dose of nicotine through the skin. Individuals move from higher to lower dose patches over the course of a few weeks. Patches can be bought with or without a prescription, and come in different types and strengths. Packages contain instructions on how to use them, and list special
considerations and possible side effects. Directions should be carefully followed. Light-to-average smokers can use the 16-hour patch, which is less likely to cause adverse side effects. It does not deliver nicotine overnight, which means that individuals with early morning withdrawal symptoms might have trouble and need a different patch. The 24-hour patch provides a steady dose of nicotine, and helps reduce the withdrawal symptoms in the morning. Users tend to experience additional side effects, like disrupted sleep patterns and skin irritation.

Most smokers should start using a full-strength patch daily for four weeks, and then use a weaker patch for another four weeks to begin to wean off of it. Quitters would put a new patch on in the morning after cleaning and drying the area thoroughly. A good place to put the patch is an area without much hair, below the neck and above the waist—for example, on the upper arm or chest. The FDA has determined that it is safe to use the patch for a total of three to five months. Side effects of nicotine patches may include skin rashes from the sticky backing of the patch or the ingredients in the patch. Other side effects could include redness and itching, dizziness, racing heartbeat, headaches, nausea, or muscle aches and stiffness. Individuals might also experience problems sleeping when they use the 24-hour patch. These side effects could be influenced by the strength of the dose of nicotine, the brand of the patch, presence of skin allergies, length of time the patch was used, and how the patch was applied.

No one has reported having all of the side effects, and some people have none. Some side effects, such as racing heart, may occur because the dose of nicotine is too high. It is also possible to experience nicotine withdrawal symptoms during this time, if the NRT dose is too low. Quitters can reduce side effects by keeping from smoking while using the patch. They can also try a different brand if the skin becomes irritated, try a patch with a lower dose, switch to a patch with a shorter time length, or move to a different NRT.

**Nicotine Nasal Spray**

The nasal spray is easy to use, and delivers nicotine to the bloodstream quickly because it is absorbed through the nose. This type of NRT is prescribed by a physician. The nasal spray provides quick relief of withdrawal symptoms and control of nicotine cravings. One negative to this is that the quick-fix approach of the nasal spray can increase the risk of developing dependence issues. As a result, nasal sprays should only be used as long as needed, and should be taken by the direction and prescription of a physician. The FDA recommends that the spray be prescribed for three-month periods, and that it not be used for longer than six months. Side effects can include nasal issues, watery eyes, sneezing and runny nose, sore throat, and coughing. These side effects normally only last about one or two weeks, but people who have respiratory issues such as asthma or allergies, along with sinus problems, might not be appropriate for this method and should look into other forms of NRT. It is also possible to use too much of the nasal spray.

This form of NRT should be carefully handled and securely stored because it poses a more serious risk to small children and pets. Even empty bottles of the spray can contain enough nicotine to harm them, if ingested or absorbed. Nicotine absorbs through the skin as well as mucous membranes like the mouth or eyes, and can cause serious harm. If there is any skin contact, the user should rinse thoroughly with plain water right away. If a bottle breaks or liquid leaks out, put on plastic or rubber gloves.
to clean it up. Call Poison Control and get emergency help if there is any question of an overdose.

**Nicotine Inhalers**
Inhalers are controlled and only available by prescription. Inhalers consist of a thin plastic tube with a nicotine cartridge inside. When an individual takes a puff from the inhaler, the cartridge puts out a pure nicotine vapor. Most types of inhalers deliver medicine to the lungs. Nicotine inhalers, however, send most of the nicotine vapor to the mouth, where it is absorbed into the bloodstream. Nicotine inhalers are the FDA-approved nicotine replacement method that is most like smoking a cigarette, which some smokers find helpful. The recommended dose is between four and 20 cartridges a day, which are slowly tapered off over six months. The most common side effects, especially when first using the inhaler, include coughing, mouth and throat irritation, and upset stomach. Nicotine inhalers pose a significant risk to small children and pets because the used cartridges still have enough nicotine in them to cause harm if it gets on skin or mucous membranes. It is not a good choice if an individual has asthma, allergies, a sinus condition, or any other respiratory problems. Inhalers are also the most expensive form of NRT on the market. They are not electronic cigarettes, which are not approved by the FDA.

**Nicotine Lozenges**
Nicotine-containing lozenges are not controlled substances, and can be purchased over the counter without a prescription. The lozenges are somewhat similar to nicotine gum. They come in two strengths: 2 and 4 milligrams. Smokers choose their dose based on how long after waking up they normally have their first cigarette. Lozenges should be used as part of a 12-week program, with the recommended dose of one lozenge every one to two hours for six weeks, then one lozenge every two to four hours for weeks seven to nine, and finally one lozenge every four to eight hours for weeks 10 to 12. It is helpful to follow a few guidelines in the use of lozenges. Individuals should stop smoking when using the lozenges. Users should not eat or drink for 15 minutes before using a lozenge. The lozenge should be sucked for the full time until it is dissolved. It should not be bitten, chewed, or swallowed because the nicotine should be absorbed through the mucous membranes of the mouth. No more than five lozenges should be used in any six-hour period, with no more than 20 lozenges total for a 24-hour period. The lozenges should only be used for 12 weeks, with additional use approved by a doctor. Possible side effects of the nicotine lozenge could include trouble sleeping, nausea, hiccups, coughing, heartburn, headaches, and excessive gas.

**Information to Consider**
It is normal to begin coughing within the first week after quitting smoking, regardless of the method used. It is the body’s means of trying to clear the lungs. Acidic beverages ingested at the same time as use of NRT can prevent the absorption of the nicotine. They should be avoided for 15 minutes before use through 15 minutes after use. Choice of NRT is a matter of personal choice, and if one form is not desirable because of side effects, switch to another and see if it works better. Nicotine overdose is rare, but possible. NRT products are labeled to provide a dose of nicotine fairly close to what an individual has been receiving from cigarettes. Higher doses of nicotine can cause harm. To avoid this, dosing instructions must be carefully followed, and keep the NRT product away from children and pets.

Most NRT product dosages are recommended on the basis of how much an individual smokes. A light smoker would be someone who smokes fewer than 10 cigarettes per day, whereas a heavy smoker would smoke a pack or more a day. The average smoker would fall somewhere in between. A pack year would be calculated by multiplying the number of years that an individual has smoked by the number of cigarettes smoked per day. An individual who smokes 20 cigarettes, or the number of cigarettes in a pack, per day for one year would smoke one pack year. This figure is used to determine the risk of smoking-related disease. For heavier smokers, it is possible to combine the patch with other shorter-acting nicotine replacement products. The idea is to receive a steady dose of nicotine with the patch, and then use one of the shorter-acting products when they have strong cravings. Combining NRTs is thought to be relatively safe, and might work better. This type of use has not yet been approved by the FDA, and additional research will provide a better picture of this process. For now, it would be best to consult a physician before doing so. Heavy smokers might also use higher doses of NRTs, but should be monitored by a physician.
NRT use can begin as soon as an individual stops smoking. There is no waiting period before beginning use of the patch, gum, lozenges, nasal spray, or inhalers. NRT products should not be used while an individual is still smoking. They are also used for limited periods of time, during which the individuals taper down and eventually cease their tobacco use. For example, the patch is used for 3 to 5 months, so use should begin to be reduced by the second or third month, and continually reduced from there to avoid withdrawal symptoms and reduce risk of relapse. Continued research will pinpoint more specific time periods, and the most important suggestion is to keep in contact with a physician and consult before creating any changes.

Society of Gynecologic Oncology

The Society of Gynecologic Oncology (SGO) is a medical specialty society for health care professionals trained in gynecologic cancers. The SGO encourages research, education, raising standards of practice, advocating for patients, and collaboration with national and international organizations. There are five main types of gynecologic cancer: cervical, ovarian, endometrial, vulvar, and vaginal. Cervical cancer is one of the most common cases of cancer deaths in women. Approximately 12,360 women are diagnosed with cervical cancer each year, and 4,020 will die from the disease. Cervical cancer is most common among Hispanic women, then African American women, followed by Asians, Pacific Islanders, and whites. If caught early, women diagnosed with cervical cancer have an excellent survival rate of 92 percent (first five years following diagnosis). Most cases are diagnosed in women aged 30 to 60, but about 20 percent will be over the age of 65.

The two main types of cervical cancer are squamous cell carcinoma and adenocarcinoma. Cancer found in the outer surface of the cervix is called squamous cell carcinoma. Adenocarcinoma cancer occurs in the glandular cells, usually located higher in the cervical canal. Ovarian cancer forms in the ovaries. Approximately 21,980 cases of ovarian cancer will be diagnosed each year in the United States, and 14,270 deaths will result. Ovarian cancer is 9th of the top 10 cancers among women, and is the most lethal of gynecologic cancers. Cancer that occurs in the inner lining of the uterus (that sheds with monthly menstrual cycles) is called endometrial. This is the most common cancer in the female reproductive system. Approximately 52,630 cases are diagnosed annually, and 8,590 deaths will occur in the United States.

Vulvar cancer originates in the outer portions of the female reproductive system (i.e., the clitoris, vaginal lips, and opening of the vagina). Less than 1 percent of all female cancers are vulvar. Approximately 4,850 new cases occur annually, and 1,030 will die from the disease. Cancer of the vagina occurs in 1 out of every 100 cancers of the female reproductive organs. Malignant cells are found in the tissue of the vagina in about 3,170 cases annually, and about 880 women will die from this form of cancer. Most of the time, vaginal cancer occurs when cancer in another part of the body invades the vagina.

SGO members provide a variety of cancer treatments, including chemotherapy, surgery, supportive care, and radiation therapy. There are more than 1,700 members nationally and internationally.
Members are allied health care professionals, hematologists, surgical oncologists, obstetrician/gynecologists, physician assistants, radiation oncologists, pathologists, nurses, and medical oncologists. Members are present in a variety of settings, including academia, cancer centers, hospitals, and private practice.

The SGO was founded by doctors Averette and Mikuta with likeminded fellows of the American College of Obstetricians and Gynecologists in 1968. The SGO was formalized in 1969. In 1970, the first annual meeting was held. That same year, the SGO was incorporated, and its first committees were formed. In 1974, the first written and oral examinations for certification for Special Competence in Gynecologic Oncology were given. In 2012, the SGO became a nonprofit organization, and the Foundation for Gynecologic Oncology was created. The foundation is responsible for education, fundraising, research, and development. The SGO assumed responsibility for membership activities, government relations, and clinical practice at that time.

The mission of the SGO is to promote the highest quality of comprehensive care through research and education in the treatment and prevention of gynecologic cancers. Its vision is to eradicate gynecologic cancers. The strategic goals of the SGO include education, research, advocacy, communication, collaboration, and leadership. The SGO plans to be the authoritative source of gynecologic oncology education. It identifies the educational needs of members and other audiences while enhancing the program quality and content during educational activities. The SGO provides e-learning opportunities and explores and develops continuing medical educational topics and credits. The SGO also explores credentialing and delivery of public education internationally. The SGO promotes research in gynecologic oncology. It fosters quality research and database development to advance care. The foundation supports increased funding for basic, clinical, and translational research through public and private partnerships, including a research summit. It represents the interests of patients and members through a leadership role that defines quality of care and facilitates reporting of findings. The SGO explores and promotes practice models that are new and methods to secure adequate funding and reimbursement for gynecologic cancer care. It advocates for all facets of research and raises awareness by developing and operationalizing effective and user-friendly strategies that include social media. The SGO seeks to collaborate with organizations that advance similar missions and visions by building, leading, and joining together in advocacy. The SGO also aligns and joins organizations that support and promote gynecologic cancer prevention and treatment. Finally, the SGO leads through identification and response to the needs of members and to continue to increase and diversify revenue. A plan for outreach to allied health professionals and international organizations is aligned with and supports the SGO’s philanthropic, communicative, research, and educational strategies.

The SGO’s purpose is defined by its bylaws, to (1) promote and further common goals among cancer clinicians and scientists, (2) develop and promote high practice standards and ethical practice, (3) cooperate and interact with other allied health professional organizations, (4) develop educational programs and professional materials to enhance allied health professionals’ ability to meet the needs of gynecologic cancer patients, (5) communicate with the public about gynecologic cancer both directly and through allied health professionals, (6) work independently with groups to influence state and federal agencies to further the interests of patients and families that cope with gynecologic cancer, and (7) operate as a professional association.

Society of Surgical Oncology

The Society of Surgical Oncology (SSO) was founded in 1940 by the James Ewing Society. It is a premier organization for surgeons and allied health professionals who are dedicated to advancing and promoting the science and treatment of cancer. The society participates in the Annual Cancer Symposium, promotes educational initiatives, and produces a monthly scientific journal, the Annals of Surgical Oncology. James Stephen Ewing M.D. is widely regarded as the father of oncology. The primary focus of his nonprofit foundation is to support education and research in surgical oncology. The foundation relies on contributions from SSO members, patients, other individuals, and organizations to sponsor lectureship and awards, including the James Ewing Lecture, the Harvey Baker Traveling Fellow Award, the Clinical Investigator Awards, and the James Ewing Layman's Award.

The mission of the SSO is to improve multidisciplinary patient care by advancing the education, science, and practice of surgical oncology worldwide. Key values include professionalism (advocacy for the cancer patient with integrity and ethical conduct), quality (improved understanding of the biology of cancer, compassionate communication, and optimization of outcomes across the continuum of care), lifelong learning (ongoing multidisciplinary education), leadership (developing disciplines and providers for the future and leading the public and health professional on the importance of surgery in multidisciplinary care), and discovery (innovative patient care). Along with the mission of the SSO in clarifying the role of the surgical oncologist, the SSO also recognizes that managing a surgical oncology practice is complex. With that in mind, the SSO assists the practicing surgeon with evidence-based clinical guidelines in breast cancer, gastrointestinal cancers, melanoma, biliary cancer, endocrine cancer, and sarcoma.

In 2007, the SSO began the Clinical Investigator Award Program (CIA) with a goal of encouraging patient-oriented research by training surgical oncologists in clinical and translational sciences. The award is $50,000 annually for two years. Beginning in 2013, the administration and management of the program was moved to the James Ewing Foundation. The foundation also assumed solicitation of grant funding and support. Applicants must be surgical oncologists within 10 years of the completion of training and SSO members for at least six months prior to application.

The SSO strongly encourages its member surgeons to recruit patients for appropriate trials. The Alliance for Clinical Trials in Oncology, consisting of the American College of Surgeons Oncology Group, Cancer and Leukemia Group B, and the North Central Cancer Treatment Group, is a center for information regarding surgical oncology trials. Also, the Annals of Surgical Oncology promotes high-quality surgical oncology management by disseminating advances in research that are relevant in the provision of multidisciplinary care of patients with cancer. The Annals of Surgical Oncology is the official journal not only for the SSO, but also for the American Society of Breast Surgeons.

As a leading provider of continuing education, the SSO was awarded the designation of Accreditation with Commendation by the Accreditation Council for Continuing Medical Education (ACCME). This is the highest accreditation, extending the reaccreditation period from four to six years. Only 15 percent of the 2,000 accredited providers receive this distinction. The SSO was found to exhibit compliance in all 19 of ACCME’s criteria.

The SSO’s accomplishments include a comprehensive consensus guideline on margins for conserving breast tissue during surgery, an international exchange program, and assistance with the development of the first qualifying exam in complex general surgical oncology. In 2013, the SSO approved the short-term International Career Development Exchange Program. In its first year, participants were from the Indian Association of Surgical Oncology, Japanese Society of Gastrointestinal Surgery, and Sociedad Mexicana de Oncologia.

In February of that year, the SSO released the comprehensive consensus guideline on margins for conserving breast tissue during surgery with the American Society of Radiation Oncology. The guidelines were developed, in part, from a grant from the Susan G. Komen foundation. It is endorsed by the American Society of Clinical Oncology and the American Society of Breast Surgeons. Supporting documentation for the guideline is available in the SSO’s Annals of Surgical Oncology with complimentary access to increase...
the impact of the research. The guidelines are available on the SSO’s Web site. Collaborating with the American Board of Surgery, the Accreditation Council for Graduate Medical Education, and the American Board of Medical Specialties resulted in the Complex General Surgical Oncology Exam, which first was offered in September 2014.

The SSO is currently promoting two fellowships. The Breast Oncology Fellowship Match matches qualified applicants with positions in breast oncology fellowship training programs approved by the SSO. The Surgical Oncology Fellowship Match is coordinated by the National Resident Matching Program, and SSO members are encouraged to apply.

The SSO is also promoting an opportunity to experience the United Kingdom as a visiting professor. The Royal Society of Medicine and the Royal Society of Medicine Foundation also promote this opportunity. The successful candidate receives $10,000 to cover travel and living costs, with support from the trustees of the L.W. Froehlich Charitable Trust. The opportunity enables the candidate to spend two weeks in the United Kingdom and visit three to four prearranged centers to deliver lectures.

Solar Radiation

The sun accounts for cutaneous synthesis of vitamin D in humans; however, the sun’s light also carries dangers. Sunlight at the top of the Earth’s atmosphere is 50 percent in the infrared spectrum, 40 percent in the visible spectrum, and 10 percent ultraviolet (UV). Although the atmosphere filters out more than 70 percent of the UV, enough reaches the surface to form the primary cause of skin cancer. More than 90 percent of skin cancer incidence is caused by exposure to UV radiation from the sun. Solar UV is composed of two components, 95 percent UVA and 5 percent UVB. UVB exposure carries greater danger of producing sunburn and cancer in humans through deoxyribonucleic acid (DNA) damage. Such solar exposure, and incidental other exposures such as tanning beds, are recognized as increasing the risk of all three primary types of skin cancer, basal cell, squamous cell, and melanoma. Skin cancer is the most common form of cancer in the United States, with approximately 3.5 million diagnoses in over 2 million patients annually. Basal cell and squamous cell cancers, often termed nonmelanoma skin cancers, are unlikely to spread beyond the skin to other areas of the body, in contrast to the more aggressive melanomas.

Types of Skin Cancer
Basal cell cancers account for approximately 80 percent of nonmelanoma skin cancers. This is the most common form of skin cancer, with an estimated 2.8 million annual diagnoses in the United States. This lesion is slow growing, and may damage the surrounding tissues, which can present a small inflamed area around the margin. The lesion usually appears as a shiny raised area of the skin, sometimes with an associated ulcer. Treatment can usually be performed on an outpatient basis in the office of the physician or clinic. The first step after visual examination is a biopsy. Under local anesthesia, a small sample of tissue is removed and microscopically examined. If basal cell cancer is confirmed, the tumor is usually removed surgically, again under local anesthesia. The extent of the surgery is determined by the size, location and depth of penetration of the tumor. Pain or discomfort during and following the procedure is rare, and the outcome is normally positive.

Squamous cell cancer is the second most common type of skin cancer, with an estimated 700,000 annual diagnoses in the United States. Squamous cell cancers are more likely to spread, but like basal cell cancers, they are unlikely to result in death.
In the United States, these two nonmelanoma cancers cause less than 0.1 percent of all cancer deaths. Squamous cell cancer usually presents as a raised lesion with a scaly top, again possibly with an ulcer. A margin of inflamed tissue surrounding the lesion may also be present. As with basal cell cancer, treatment is usually by surgical removal. One of several surgical techniques may be employed. With ordinary excisional surgery, a scalpel is used to remove the growth, along with a surrounding margin of apparently healthy tissue. If the wound is extensive, it may be closed with sutures, otherwise it is simply bandaged. The tissue is sent to a laboratory for microscopic examination to insure that all cancer cells have been removed. In some cases, additional surgery may be required, although this is uncommon.

In Mohs micrographic surgery, a scalpel or curette is used to remove the lesion along with a thin layer of surrounding tissue under local anesthesia. The layer of tissue is microscopically viewed to determine if tumor cells are present. If so, succeeding layers are viewed until the final layer is free of tumor cells. Electrosurgery, or electrocautery, may be used. Here, the lesion is excised with a curette, and then the burning heat of an electrocautery needle is used to eradicate any additional tumor cells and to control bleeding. The procedure is repeated on a layer-by-layer basis to eliminate any residual tumor cells. This procedure is primarily used in basal cell cancers, and may not be as effective in squamous cell tumors. Two less-employed surgical techniques are cryosurgery and laser surgery. In cryosurgery, the tumor is frozen with liquid nitrogen. No anesthesia is required. The application is repeated several times to destroy malignant cells. The area develops a scab that usually sloughs off in a matter of days or weeks. In laser surgery, a laser is used to remove the outer epidermal layer and some deeper tissue. Since the laser seals blood vessels as it cuts, the procedure is bloodless. Currently, this technique is primarily limited to patients with basal cell cancer and comorbid bleeding disorders.

Cutaneous melanoma is becoming a more common disease. An estimated 76,000 new cases representing 4.6 percent of all new cancer cases were diagnosed in the United States during 2014, with 9,700 estimated deaths. The increasing incidence may be attributed to increased recreational exposure to sunlight, an increasing amount of UVB making the descent through Earth's atmosphere to the surface, or more alert early detection of the disease. About 2.1 percent of men and women will be diagnosed with cutaneous melanoma at some point in their lifetime. The male to female ratio of diagnoses is roughly 3:2, and is most frequently diagnosed in patients between 55 and 64 years old. Typically, the melanoma patient is fair in complexion and light eyed, with red or blond hair and a tendency to sunburn, rather than tanning.

Identification and Treatment
The most common site for cutaneous melanoma lesions in men is the back; in women, the legs. The first step in diagnosis is visual, using the acronym ABCDE to identify signs and symptoms: the cancerous lesion is Asymmetrical in shape; the Border of the lesion is irregular, ragged, or notched, rather than smooth; Color—melanomas usually have multiple shades of black, brown, or tan;
Solar Radiation

Diameter—moles greater than 6mm are more suspicious than smaller lesions; and Enlarging—the lesion is enlarging or growing. The initial diagnosis is confirmed with a biopsy. Metastatic melanomas may be detected by X-rays, computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), or ultrasound scans. Treatment options, depending on the stage of the disease, may include surgery, chemotherapy, immunotherapy, or radiation therapy. Evaluating the stage of the disease is important in order to determine the treatment modality or modalities to be employed. Melanoma stages are determined based on the size or thickness of the tumor, whether it has spread to the lymph nodes or other organs, and the rate at which the lesion is growing. The stages and potential treatments are:

Stage 0. The cancer cells are confined within the epidermis and have not spread or penetrated. Treatment is usually by surgical excision alone, with adequate margins to reduce the possibility of recurrence at the original site.

Stage I. Cancer cells have penetrated deeper into the skin, but have not spread to the lymph nodes or other organs. Subcategories involve penetration less than 1mm without ulceration, or ulceration and rapid division, or one to two millimeter penetration without ulceration. Treatment is usually by wide surgical excision. In some cases involving the subcategories that make the possibility of spread to nearby lymph nodes more likely, a sentinel node biopsy is recommended. If positive, surgical removal of all nearby lymph nodes may be recommended.

Stage II. Cancer cells have penetrated more deeply into the skin, but have not spread to the lymph nodes or beyond. Subcategories involve depth of penetration, one to two millimeters, two to four millimeters, or deeper than four millimeters with or without ulceration. The treatment is wide surgical excision, and may include sentinel node biopsy and lymph node dissection. Adjuvant therapy with interferon may also be employed.

Stage III. Cancer cells have spread to nearby lymph nodes, but not distant organs. Subcategories include spread to one to three nearby lymph nodes, or nearby areas of skin or lymphatic channels, but not to lymph nodes, or the above and four or more nearby lymph nodes. Wide surgical excision, lymph node excision, and adjuvant therapy may be employed, as well as radiation therapy to the area of lymph node removal. Other possibilities for treatment may include targeted therapy, immunotherapy, chemotherapy, or a combination of these.

Stage IV. The cancer cells have spread beyond the epidermal layers and regional lymph nodes to distant organs such as the liver, lungs, or brain, or distant lymph nodes and areas of the skin. Curative therapy at this stage is unlikely, but many modalities have been sought to prolong survival. Chemotherapy may include administration of drugs like dacarbazine or temozolomide. A combination of chemotherapy with interleukin-2 or interferon may be used. Clinical trials with new targeted drugs, immunotherapy, and combination chemotherapy are ongoing. In a few short years, the approved drug armamentarium has been expanded to include newer agents such as vemurafenib, ipilimumab, dabrafenib, and trametinib. These and other agents currently in trials offer hope at least for prolonged survival and improved quality of life for late stage melanoma patients.

Even with improvements in therapy, a primary weapon against the scourge of skin cancer is prevention. Measures to minimize the exposure of the skin to ultraviolet radiation should be taken, although with a sense of balance toward the necessity for outdoor occupations and the pleasures of recreational activities. When practical, protective clothing should be worn, including such wardrobe items as long sleeves, long trousers, sunglasses, and wide-brimmed hats. If possible, exposure to sunlight at peak radiation hours between 9 A.M. and 3 P.M. should be avoided or minimized. A guideline can be to avoid exposure when an individual's shadow is shorter than their height. A broad spectrum sunscreen with a sun protection factor (SPF) rating of at least 30 should be applied to exposed areas. Beyond 30, the incremental protection achieved is minimal. Some clinicians question the value of sunscreens in long-term exposure, but definitive studies have not been conducted.

Solvents

A solvent is a substance used to dissolve another chemically or physically different one, called a solute, such as a gas dissolved into a liquid, to form a solution. Commonly used solvents are found in nail polish and hair extension removers (acetone, acetonitrile), paint and lacquer thinners (turpentine, naphtha), spray and aerosol pressurized liquids (propane, isobutane), perfumes (ethylic alcohol), and detergents (various terpenes). Solvents are roughly classified into polar and nonpolar, depending on their dielectric constant and their ability to dissolve ionic compounds. Other important physical properties of solvents are boiling point, which defines the temperature and speed at which a given substance will evaporate, and density. Whereas the first is helpful to predict if that solvent will instantly transform into a gas at room temperature (e.g., in sprays), the second will define its partitioning when mixed with other liquids such as water (i.e., if it will form a separate layer on top, or if it will sink to the bottom of the container).

Direct or chronic exposure to organic solvents constitutes a well-known health hazard in many industrial facilities, shipyards, and workplaces, such as in painting, printing, dry cleaning, and rubber manufacturing. To address this problem, various standards to ensure worker safety have been defined through the years. Direct exposure to large amounts of organic solvents may cause severe acute reactions including toxicity to the nervous system, liver, or kidneys; dermatitis; respiratory impairment; sudden loss of consciousness; and even death. Chronic exposure to even small quantities of solvents may cause long-term adverse effects such as neuropsychiatric effects, eye cataracts, and an increased risk of cancer.

Many studies provide detailed information about the correlation between casual or occupational exposure to organic solvents and cancer outcomes. For example, in Canada, 40 percent of male cancer patients in Montreal experienced exposure to solvents, and occupation as a painter has consistently been associated with a 40 percent increased risk of lung cancer, and a 20 percent increased risk of all cancers. Scientific literature has primarily focused on exposure to specific compounds, including benzene, trichloroethylene, tetrachloroethylene, and methylene chloride, but many studies on mixtures of unspecified organic solvents have also been made.

Benzene

Benzene is probably the most thoroughly investigated solvent because it is commonly found in the environment, coming from industrial discharge, motor vehicle exhaust, burning oil and coal emissions, and even indoor tobacco smoking. Many organic solvents used in industrial manufacture contain benzene, or are broken into byproducts that form it. Benzene is nonpolar, colorless, and very volatile, yet is able to dissolve in water, and thus can pass through the soil into underground water, further contaminating the environment. Everyone is exposed to a small amount of benzene every day, mainly through breathing air containing small percentages of it. Benzene has been determined as a known carcinogen by many sources such as International Agency for Cancer Research (IARC), U.S. Environmental Protection Agency (EPA), and U.S. Department of Health and Human Services (DHHS). It has repeatedly been shown to induce hematopoietic cancers such as acute myeloid leukemia (AML) and cancers of the ovaries, mammary glands, pancreas, and liver. A vast retrospective
cohort study conducted in China during the early 1980s among 28,460 benzene-exposed workers showed a relative risk for leukemia of 5.74, and for lung cancer of 2.31. Also, mortality for malignant neoplasms was more than doubled among the exposed subjects. Benzene exposure has also been directly linked to birth defects, and it is a known teratogen.

**Chloroform**
Chloroform (trichloromethane) is a colorless dense liquid with a pleasant odor and sweet taste. It was one of the first inhaled anesthetics used through the 19th and 20th centuries during surgery practices, but was later abandoned in favor of ether. Today, it is mostly used in the chemical industry as a precursor to refrigerants and Teflon, and its only medical use is as a solvent in nuclear magnetic resonance (NMR) spectroscopy. Chloroform may be found in small amounts in chlorinated drinking or swimming pool water, and may pose a risk for people who work with it, especially if inhaled. Acute inhalation exposure to chloroform in humans causes central nervous system depression and possible liver and kidney damage. Chloroform is suspected of causing cancer because liver and kidney tumors have been reported in laboratory animals exposed to this substance. Even if epidemiologic studies on human subjects suggest an association between cancer of the large intestine, rectum, and bladder and chlorinated water, data is still incomplete and not yet consistent enough to confirm these claims. Nonetheless, the DHHS determined that chloroform may reasonably be anticipated to be a carcinogen, while the EPA determined that chloroform is likely to be carcinogenic to humans by all routes of exposure, but only under high-exposure conditions.

**Formaldehyde**
Formaldehyde is a colorless flammable gas with a characteristic pungent smell. It has a broad range of uses, ranging from the production of fertilizers, glues, paper, pressed-wood household furniture, and insulating materials to a wide variety of other industrial uses such as fungicide, germicide, preservative, embalming fluid, and as an important precursor to many other materials and chemical compounds. Formaldehyde is normally present in both indoor and outdoor air at low levels (ranging from 0.02 to 0.04 parts per million), but various materials containing formaldehyde (such as plywood, furniture, and carpets) can release formaldehyde gas or vapor into the air. Other sources of this substance include cigarette smoke, automobile exhaust, gas and wood stoves, heaters, and glues/resins. Exposure primarily occurs by inhalation of formaldehyde gas and vapor, and by absorbing liquids containing it (such as formalin) through the skin. Effects of acute exposure to formaldehyde usually include eye and mucous membrane irritation, coughing, asthma, and headaches. Formaldehyde has been classified by both the IARC and EPA as a known human carcinogen, confirmed by various epidemiological studies. Professionals exposed to formaldehyde in their occupation, such as funeral industry workers and embalmers, showed an increased risk of leukemia and brain cancer compared with the general population. Other cohort and case-control studies found an association between formaldehyde exposure and nasopharyngeal and nasal sinus cancer.

**Methylene Chloride**
Methylene chloride (dichloromethane, or DCM) is an organic colorless liquid compound used in degreasing metal parts, as a paint stripper, industrial solvent, aerosol and pesticides propellant, and in the manufacture of photographic film, textiles, and plastics. DMC is highly volatile, constituting a potential acute inhalation hazard that may lead to a carbon monoxide poisoning, hepatitis, and chemical skin burns. In many laboratory animal studies, methylene chloride showed various degrees of carcinogenicity, inducing liver, lung, and pancreas tumors in various rodents. Several cohort studies of potential occupational hazards examined many workers daily or occasionally exposed to dichloromethane for up to 20 years, showing mixed results. However, the World Health Organization (WHO), EPA, and DHHS classified methylene chloride as a probable cancer-causing agent in humans.

**Styrene**
Styrene is an organic compound that appears as a colorless, somewhat volatile liquid, with a sweet pungent smell. Its main use comes from its ability to polymerize, a chemical property that allows styrene to act as a precursor for many other substances such as polystyrene and other copolymers (acrylonitrile butadiene styrene, or ABS; styrene-butadiene rubber, or SBR; and styrene-acrylonitrile, or SAN). These polymers and styrene are used to
manufacture rubber, plastic, carpet backing, synthetic foams, fiberglass, automobile and boat parts, pipes, and shoes. Effects of acute exposure to styrene usually manifest with nervous system toxicity symptoms like concentration problems, hearing loss, or change of color vision. Both the IARC and DHHS classify styrene as reasonably anticipated to be a human carcinogen, an assessment that has recently been backed up by the U.S. National Toxicology Program's findings.

**Tetrachloroethylene**
Tetrachloroethylene (perchloroethylene, or PCE) is a volatile nonflammable liquid with a distinctively sweet odor. It is widely known worldwide for its use as dry-cleaning fluid. Tetrachloroethylene exposure may cause skin irritation through direct contact because it dissolves epidermal fats, and can act as a central nervous system depressant if inhaled in large doses. Many studies that assessed the effects of chronic tetrachloroethylene exposure on dry-cleaning workers suggested that this compound may increase the risk factor for cancer in humans. Also, tetrachloroethylene has been shown to cause liver tumors in mice and kidney tumors in male rats. For these reasons, the IARC and DHHS classified it as probably a carcinogen.

**Trichloroethylene**
Trichloroethylene is a clear nonflammable liquid used as an industrial solvent to remove grease from metal parts, and as dry-cleaning spot remover. In the past, it was also used to extract vegetable oils (e.g., soy, palm, and coconut oil), for coffee decaffeination, and as a volatile anesthetic together with nitrous oxide. Although Europe and North America replaced its pharmaceutical and food industry uses because of its acute and chronic toxicity, it still saw some use as a potent inhaled obstetrical analgesic in less-developed African countries. It enters the body mainly through inhalation of its vapors or direct skin contact, but it can also be ingested by drinking contaminated water in areas near factories or waste disposal sites. Other than the acute toxic effects reported after ingestion or inhalation of high levels this substance, such as kidney and liver damage and arrhythmias, trichloroethylene is considered probably carcinogenic to humans. Epidemiologic meta-analysis showed a relative risk (RR) of 1.7 for kidney cancer, 1.9 for liver cancer, and 1.5 for non-Hodgkin's lymphoma. Recent molecular epidemiology studies confirmed its supposed carcinogenicity by showing specific renal cell mutations primarily found in renal cell carcinoma patients exposed to trichloroethylene.

**Somalia**

The Somali Democratic Republic is situated in eastern Africa. It is bordered on the north, east, and south by the Indian Ocean, and on the west by Djibouti, Ethiopia, and Kenya. It is the 27th most populous country in Africa, and 89th in the world, with a population of over 8.3 million. The two statutory national languages are Arabic and Somali, while English and Italian are statutory working languages, and there are 14 living indigenous languages still spoken by respective ethnic groups in Somalia. The most widely spoken include Kiswahili, Maay, and Oromo.

Somalis have depended upon traditional medicine, particularly medicinal plants, for a long time, and they still largely depend on this practice, augmented by medieval Arabic medical practices. Each ethnic group has a rich tradition of ethnomedicine. For example, a traditional healer who uses...
medicinal plants for treating ailments is known as wadaad in Arabic, mganga in Kiswahili, and dofa in Oromo.

There are many traditional medicinal preparations used in Somalia for treating cancers and other conditions. Most of these traditional medicines incorporate the use of local plant materials, many of which have shown medicinal properties in laboratory studies. For example, myrrh or Commiphora myrrha, which is used in Somali traditional medicine as a panacea for many ailments, including cancers, has demonstrated antitumor, antibacterial, and anti-diarrheal efficacy. Research suggests that use of certain plants may help protect against cancer by reducing oxidative stress and stimulating enzymes and other processes that help the body fight carcinogens. For example, an extract from Boswellia serrata, referred to as yagar or yigaar in Somali, demonstrated antioxidant properties.

Medicinal plants are prescribed by traditional healers to treat respective ailments, including cancers. For instance, juice from Commelina forskoolii is used by traditional healers in Somalia for treating uterine cancer. A root decoction of Adenium obesum, which in Arabic is called sim-es-samak and in Somali is called warrab-karon, dun-durwa, or habaarticaa, is traditionally used to treat rhinitis. Commiphore guidottii is traditionally used to treat stomach problems, including diarrhea. The leaves of Sansevieria bagamoyensis are pounded, squeezed, and then filtered; the resulting liquid is drunk, and the residue is topically applied for treating convulsive fevers.

Somalia is a signatory to the Single Convention on Narcotic Drugs, Convention on Psychotropic Substances, and U.N. Convention Against the Illicit Traffic in Narcotic Drugs and Psychotropic Substances; consequently, laws exist to control narcotic and psychotropic substances and precursors. The annual consumption of controlled substances is highly regulated to curtail abuse. Accordingly, the annual consumption of morphine in 2009 was 0.000285 milligrams per capita, and pethidine was 0.16131 milligrams per capita. In 2010, the annual prevalence of use of all opiates as a percentage of the population aged 15 to 64 years in Somalia was 0.16 percent, which ranks it as the 19th-highest country. These factors make the provision of palliative care for cancers and other ailments problematic. Further, there are serious deficiencies of modern pharmaceutical supplies, as opposed to traditional preparations, and in modern medical services for cancer and similar conditions in Somalia. According to the World Health Organization (WHO), in 2010, there was no general availability of either chemotherapy or radiotherapy in the public health system in Somalia.

Partly because of the shortage of medical services and supplies, health problems are endemic in Somalia. The five leading causes of morbidity, in rank order, are malaria, respiratory infections, dyspepsia, parasitic diseases and infections, and pneumonia. The average number of cancer cases annually are 113.5 per 100,000 of the population. Cancers account for a substantial amount of disability and suffering among impacted populations. According to the WHO, in 2004, the 10 most prevalent cancers per 100,000 population in Somalia were led by liver cancer at 258; lymphomas at 242; cervical and uterine cancers at 234; esophageal cancer at 233; breast cancer at 135; mouth and oropharynx cancers at 120; stomach cancer at 119; leukemia at 92; colon and rectal cancers at 80; and trachea, bronchial, and lung cancers at 77.

Modern medical supplies and services are in short supply in Somalia. Both prescription and over-the-counter products are often unavailable. Consequently, health problems are endemic and limit development. For example, an estimated 43,000 people live with human immunodeficiency virus (HIV) in Somalia, which ranks the country 38th highest in Africa, and 65th highest in the world. The mortality rate for HIV/acquired immunodeficiency syndrome (AIDS) is 81 per 100,000 population. Debate continues on the relative risks in Africa for respective cancer types for those infected with HIV. The mortality rate for tuberculosis is 64 per 100,000 population, and that for malaria is 51 per 100,000 population.

Skin cancers are the 11th most-common cause of age-standardized cancer deaths in Somalia, and occur at a rate of 3.57 per 100,000 population, which ranks 13th highest in the world. Furthermore, according to the WHO, in 2008, the age-standardized estimates of deaths from all cancers was 105 per 100,000 population for males and 97 per 100,000 population for females. As a consequence, life expectancy is only 47.71 years, which ranks Somalia 32nd in Africa and 203rd in the
With this ethnic diversity come a variety of languages (official and other home languages), cultures, and religious beliefs, all of which challenge cancer control in the country. Cancer treatment and education were not available to most South Africans until the end of apartheid in 1994. Most quality health care and cancer treatment was only available to whites; however, that continues to change over time with the work of the Cancer Association of South Africa (Cansa). Another major challenge is the availability of health care workers; World Development Indicators report that there are 80 physicians (generalists and specialists) for every 100,000 people, and 490 nurses per 100,000 people, for a population approaching 53 million and a growing cancer burden.

Approximately one in four South Africans are affected by cancer in their lifetime, with more than 100,000 South Africans diagnosed with cancer yearly, and more than 60,000 dying from cancer each year. About one in six South African men and one in seven South African women will have cancer during their lives. In South Africa age, race, gender and socioeconomic status play an important role in determining the prevalence of certain cancers. The prevalence of behavioral and environmental factors related to smoking, alcohol consumption, and diet are also salient. For example, the grinding process of homegrown maize has been linked to esophageal cancer. It is believed that the silica produced from the grinding process injures the esophagus and prolonged inflammation increases the risk of cancer. This phenomenon has resulted in the former Transkei region on the eastern Cape being identified as an esophageal cancer hotspot. The rate of this cancer type is six times the national average when compared to the rest of the country.

The cancers affecting all South African men, in order of prevalence, are prostate, lung, esophageal, bladder, and colorectal cancer. The cancers that are more prevalent among black South African men are esophageal, lung, liver, and larynx cancer. The cancers affecting all South African women, in order of prevalence, are breast, cervical, colorectal, lung, and esophageal cancer. Cancers that are more prevalent among black South African women, in order of prevalence, are cervical, breast, esophageal, uterine, and lung cancer. The cancers most prevalent among South African children, in order of prevalence, are leukemia, brain tumors,
South Korea

The east Asian nation officially called the Republic of Korea is one of the newer nations in the world, authoritatively established in 1948 after Japan's withdrawal from the country in 1945. An agreement at the United Nations led to Korea's split in half along the 38th parallel north, with the top portion of the territory turned into the Democratic People’s Republic of Korea, and the bottom portion becoming the modern Republic of Korea. Presently, the nation has one of the top 25 most bustling economies in the world, and it is composed of a population of over 50 million citizens.

In recent times, South Korea has been the site of extremely promising research in the battle against cancer. In January 2014, researchers at Chonnam National University in Gwangju, South Korea, claimed to have created the first nanobots capable of fighting cancer. More specifically, the researchers genetically altered salmonella bacterium to train the bacteria to seek out cancer cells to destroy them. The bacteria are able to locate a patient’s cancer cells as a result of the bacteria searching for a particular secretion that only cancer cells emit. Although the technique is still in development, and the bacteria can only seek out certain kinds of cancers, the discovery is potentially a huge breakthrough in cancer research. Recently, South Korean scientists have also conducted research regarding the possibility of using magnets to eradicate cancer cells. Magnetic fields might be a viable way to combat the disease.

Further Readings

Every year, cancer is estimated to cause over 50,000 deaths in South Korea, and information collected from regional cancer registries within the nation suggests that mortality incidences related to cancer will continue to increase in coming years. In 1980, the Korean Ministry of Health and Welfare established the nation’s first nationwide cancer registry, the Korea Central Cancer Registry. In 1995, with the Ten Year Plan for Cancer Control, the Korean government mounted a concerted national effort to combat the rise of the disease, which has now become the leading cause of death in the country. Fortunately, the vast majority of the Korean population has health insurance, which has allowed Korean physicians to effectively and quickly diagnose cancer cases in the nation.

Currently, the most prevalent forms of cancer in South Korea are bowel, breast, lung, stomach, and thyroid cancer. Bowel, liver, lung, and stomach cancers account for over two-thirds of all cancer incidences in males in South Korea, whereas breast, bowel, stomach, and thyroid cancers make up over one-half of all cancer incidences in females there. The Republic of Korea has the highest rate of stomach cancer incidences in the entire world, with over 40 Koreans diagnosed annually with the disease per every 100,000 Korean citizens; scientists believe that the reason for such high stomach cancer rates within the Korean population is a result of certain nutrition factors, such as high levels of sodium in the average Korean’s diet. Incidences of uterus cancer in females are increasing within the nation, whereas incidences of lung cancer in both genders is declining.

Many famous South Korean citizens have been diagnosed with cancer during the nation’s history. For instance, Jang Jin-Young, an actress and former winner of the Miss Korea beauty contest, died in 2009 at the age of 35 after losing her brief battle with stomach cancer. John Tae-Suk Lee, a prominent South Korean Catholic missionary who spent many years providing medical services in Africa, passed away in 2010 as a result of bowel cancer. Moreover, South Korean Myung Jae Nam, who created the famous martial arts styles of Hankumdo and Hankido, died in 1999 after succumbing to stomach cancer.

South Korea has an excellent health care system, highly trained specialists, and numerous world-class medical facilities. For example, Dr. Kang Hyun Lee became the sixth president of the Korean National Cancer Center on July 18, 2014. Dr. Lee has long contributed his expertise to the Republic of Korea’s battle against cancer, and he even worked at the Seoul National University Hospital in the nation’s capital. The Seoul National University Hospital is one of the most advanced medical facilities in the world, and is home to 26 separate cancer treatment centers. This allows patients at the hospital access to incredibly personalized and specialized treatment regimens.

Spain

Spain has a population of 47 million inhabitants, with one of the lowest birth rates in Europe. As a country from the southwestern area, Spain has specific features related to cancer, its registries, control, and incidence. In that Mediterranean region, the number of cases and deaths is lower than in western Europe, and much lower than in eastern Europe. In general, the population from Sweden, Spain, Switzerland, and France has a lower mortality rate compared to southeastern countries in Europe. However, cancer is still a big killer in the old continent—the incidence of cancer in men in Spain is one of the highest in the world.

According to data from the International Agency for Research on Cancer, in 2012 the most common cancer among men was prostate cancer (as in the rest of Europe), but with a very low mortality rate. The second-most common among men is lung and trachea cancer, with a high mortality rate. The most common among women is breast cancer, with a high incidence and low number of deaths for that cause. The second-most common among women is large bowel cancer, also with a low mortality rate. Also in 2012, about 215,534 cases were diagnosed, and there was an estimated risk of 21 percent suffering cancer before 75 years old. The expected number of cases for 2015 is 227,076, a higher rate because of the aging of the population. In absolute figures, the incidence of cancer is higher among the male population (135,954) than among females (91,122). According to the Spanish Institute of Statistics, malignant tumors are the first cause of death among men, and the second among women. In men, the five-year relative survival was 44 percent for all kind of cancers, and for women 59 percent. The mortality rate remains low thanks to early diagnosis and the efficacy of treatments, although it is still far from other countries like the United States.

With the conviction that prevention is the first step to fight cancer, priority to prevention programs was given in the last decades. Those programs are organized according to two categories: primary prevention (actions meant to prevent disease occurrence, such as informing people about good health habits) and secondary prevention (activities mean to reduce the impact of a disease through early detection and treatment, such as screening programs to facilitate early detection of the disease). The benefits of screening are successful when a high participation of the population is involved—and for that purpose everyone has to be properly informed, even about the negative effects of Control of Smoking was created in 2003 with the purpose of reducing the prevalence of tobacco consumption and protecting the population against the dangers of smoke. The mortality rate from lung cancer has decreased compared to 20 years ago, but it has increased for women, especially those between 46 and 64 years old. From the point of view of exposure to carcinogen agents, about 25 percent of the working population in Spain is susceptible of suffering from cancer because of external (occupational or environmental) elements.

Spain is a member of the European Network of Cancer Registries, established in 1990 by the European Commission within its program Europe Against Cancer. It organizes activities and coordinates projects of collaboration between different European national registries. Spain is one of the first European countries to have created a registry of cancer patients between 1902 and 1908, following the German attempt to register all cancer patients under treatment. However, the first modern registry was created in 1960 in Zaragoza, and 1976 the National Population-based Cancer Registration Plan was launched. Current registries meet the quality indicators established by the Agency for Research on Cancer. Progressively, all registries became involved in collecting detailed data on patients’ treatments, diagnosis, or disease stage. Currently, there are a total of 23 regional cancer registries and 63 hospital cancer registers in the country. Other reliable sources of data are provided by the White Paper of Spanish Oncology that offers a general vision of the situation in Spain, or the Directory of Resources for Palliative Care, edited by the Spanish Society for Palliative Care. The National Catalogue of Hospitals is an inventory of what kind of equipment and treatments are offered at each hospital.
Squamous Neck Cancer With Occult Primary, Metastatic

Metastatic squamous neck cancer with occult primary is a form of cancer where cancerous squamous cells spread to lymph nodes in the neck. (Lymph nodes are small bean-shaped structures that are found throughout the body and are responsible for the production and storage of immune cells in the body.) Squamous cells cover the skin surface and the lining of body cavities and hollow organs like the uterus and blood vessels, as well as the lining of the respiratory (breathing) and digestive tracts. The mouth, esophagus, lungs, kidneys, and uterus all have a lining of squamous cells. Once the cancer has spread (metastasized), it is not possible to know the site of cancer initiation in the body. Metastasis in the upper and middle neck regions is generally attributed to head and neck cancers, whereas metastasis in the lower regions of the neck is believed to have a primary tumor site below the clavicle.

Squamous cell cancer of the neck, whose site of origin cannot be diagnosed, is referred to as the occult (hidden) primary tumor. Such cancers constitute about 5 to 10 percent of all patients with cancers of unknown primary site. Squamous cell cancer of the head and neck is one of the most common cancers worldwide. It constitutes about 4 percent of all cancers in the United States, and 5 percent in the United Kingdom. In cases where the primary tumor is occult, the primary tumor generally regresses either because of a slower growth rate or an impaired neovascularization. In such events, the result is the formation of a biologically adapted tumor with a metastatic phenotype. Metastatic tumors are extremely aggressive and resistant to systemic therapies. A known primary site of the carcinoma enables administration of focused therapy to the primary site. However, in case of an occult primary carcinoma, the treatment is targeted at all secondary sites, resulting in a significantly higher morbidity, predominantly from radiation and chemotherapy.

Head and neck squamous cell carcinomas are differentiated depending on the histological appearance, as well differentiated, moderately differentiated, or poorly differentiated, depending on the difference in appearance from a normal squamous epithelium. Poorly differentiated squamous carcinomas are more aggressive, and have been associated with poor prognosis. The incidence of squamous cell carcinoma has risen, although there has been a fall in the number of cases with head and neck cancer because of public health efforts against the use of tobacco. Alcohol consumption is also associated with an increased risk. High-risk human papillomavirus (HPV) subtypes have been identified in a number of squamous cell cancers, and include HPV strains 16, 18, 31, and 33. Higher risk has also been associated with having multiple sexual partners, and engaging in high-risk sexual behavior.
Typical presentation of an occult primary squamous cell carcinoma of the neck is the presence of a painless neck mass. According to the patient, the neck mass has usually been present for weeks to months. Other associated symptoms may be the feeling of a lump in the throat or throat pain. Sometimes, the condition may remain asymptomatic during the early stages of the disease. Analysis of fine needle aspirate may reveal metastatic squamous cell carcinoma of the neck. After a metastatic squamous neck cancer with occult primary has been diagnosed, further evaluation is performed to check the spread of cancer to other sites in the body. The tumor is classified either as untreated or recurrent because there is no standardized staging protocol for metastatic tumors. Several clinical tests such as chest X-ray, computerized tomography (CT) scan and magnetic resonance imaging (MRI) are used to evaluate secondary tumors in other parts of the body.

Surgery alone can be used for patients with early-stage neck disease, followed by post-operative radiation therapy in cases involving multiple lymph node and connective tissue invasion. However, curative surgical removal of an occult primary is limited to the removal of the affected lymph nodes, followed by radiation therapy of the head and neck. Advanced stages may also require a combination with systemic chemotherapy as a palliative measure. As large areas of tissue are radiated, the treatment can have severe side effects, and may result in debilitating morbidity in the long term. Untreated metastatic squamous neck cancer with occult primary may be treated by surgery where the affected lymph nodes are resected.

Depending on the individual case, a physician may decide to give radiation therapy in combination with surgery. Chemotherapy is another option to treat metastatic squamous neck cancers with primary occult. Several clinical trials also offer options for treatments that are novel and may involve a combination of chemotherapy and radiotherapy with new drugs or a cocktail of drugs. Some trials also test the efficacy of novel drugs that block specific cellular pathways in cancer cells.

Further Readings

Sri Lanka

The Democratic Socialist Republic of Sri Lanka, formerly known as Ceylon, is an island country south of the Indian subcontinent, home of many different cultures and religions. Moors, Kaffirs, Sinhalese, Tamils, Burghers, and many other ethnic groups live together in its capital, Colombo, which has more than 4.5 million inhabitants. Sri Lanka was colonized by Portuguese and Dutch explorers from the 17th century until the early 1800s, when Great Britain occupied and then conquered the country. The British started cultivating vast plantations of coffee, tea, cinnamon, and rubber, changing the country’s economy into a major commodities exporter. Following the end of colonialism and the fall of the British Empire, in 1972, Sri Lanka repudiated its dominion status and declared independence, becoming a republic.

Tensions between the ruling Sinhalese culture and the Tamil community started to rise in 1983, with a series of insurgencies against the government by the Liberation Tigers of Tamil Eelam (LTTE). The Sri Lankan Civil War erupted, lasting until 2009, when the LTTE front was finally defeated with the help of the Indian Peace Keeping Force (IPKF). These 26 years of war caused over 150,000 refugees, almost 300,000 displaced people, and 60,000 to 100,000 deaths.
Sri Lanka provides free universal health care and education to all its citizens. Government hospitals and other health care facilities such as laboratories are very well equipped, and all doctors and nurses are properly qualified and trained. There are 555 government hospitals in Sri Lanka, together with many private luxury clinics and Ayurvedic system facilities. The National Cancer Institute (NCI) in Maharagama is the most important cancer treatment facility in the country with a 742-patient capacity, more than 40,000 patients admitted every year, and many modern facilities providing cancer screening and diagnostic services, chemotherapy, surgery, and radiotherapy. The NCI is also the major training center for medical students of the Postgraduate Institute of Medicine (PGIM), a training program of the University of Colombo's Faculty of Medicine.

A national cancer registry, called the National Cancer Control Programme, was established in 1980, but it is partly incomplete because cancer cases from the Jaffna District between 1985 and 1995 were missed because of the civil war. The data collected was registered with all modern methodologies, and comes from the NCI, the teaching hospitals in Kandy, Karapitiya, and Jaffna, and the General Hospitals in Badulla and Anuradapura. Cancer is the second-leading cause for death in Sri Lanka, followed by ischemic heart diseases, and its incidence per 100,000 population showed an increase in 10 years, from 31.8 to 37.3 in the male population, and from 31.5 to 43.5 in the female population. A female preponderance is also shown in the crude incidence rate of cancers: 63.8 in males, and 72.2 in females in 2007.

The five leading cancer sites among males were oropharyngeal cancer; trachea, bronchus, and lungs cancer; esophagus cancer; colorectal cancer; and lymphoma. Among females, the top five cancer sites were breast cancer, cervical cancer, thyroid gland cancer, esophagus cancer, and ovary cancer. The pattern of cancer incidence in Sri Lanka is thus very different than that of Western countries. The preferred treatment routes for cancer were chemotherapy (52 percent), radiotherapy (50 percent), surgery (40 percent) and hormone therapy (14 percent).

Together with other common risk factors for cancer such as smoking, high animal fat consumption, alcohol abuse, and a sedentary lifestyle, in Sri Lanka some peculiar regional habits could represent additional sources of cancer. For example, betel leaves and areca nuts are chewed as mild stimulants and for their breath-freshening effects, even if they pose a serious risk of developing oral submucosal fibrosis (OSF), cancers of the mouth and esophagus, and many other systemic diseases such as type 2 diabetes and hypertension. High habitual consumption and chewing of betel liquid may account for the higher percentage of oropharyngeal malignancies diagnosed in south and southeast Asia regions: of the 390,000 cancers of this type estimated to occur in the world every year, 228,000 (58 percent) occur in these regions alone.

To improve cancer prevention and early detection, the Sri Lankan government issued a series of screening projects. Among these, many screenings of the oral cavity for oral cancer were issued among tea estate workers, identified as a high-oral-cancer-risk group. Also, sensitization and awareness campaigns against breast cancer were organized, and October was designated as breast cancer awareness month. Many volunteer national and international organizations also help by increasing public awareness about cancer prevention, and by providing psychological support for adults and children fighting cancer.

Some specialist clinics in Sri Lanka also offer Ayurvedic and traditional herbal immune therapies as complementary cancer therapies. Ayurveda medicine tries to maintain or reestablish harmony between the mind, body, and forces of nature, and while its effectiveness has not been proven by scientific literature, some of the herbs used may possess therapeutic value. Also, Ayurvedic treatment promotes body detoxification through cleansing, massage, exercise, and meditation, which in turn may improve immune response among cancer patients and reduce the side effects of chemotherapy. Ayurveda therapy may nonetheless pose a danger to health because potentially poisonous heavy metals such as arsenic, lead, and mercury are often used in excess in Ayurvedic medicines.

St. Jude Children’s Research Hospital

Research hospitals have a significant influence on the treatment, control, and prevention of cancer. Located in Memphis, Tennessee, St. Jude Children’s Research Hospital opened its doors on February 4, 1962. Upon entering the hospital, a warm atmosphere greets families, their littlest patients, and visitors. Vibrant colors adorn the walls, and a variety of small red wagons are available to transport patients through the corridors. A bright blue telephone perches atop a counter, allowing visitors who do not speak English to access support for language translation. A bust of founder Danny Thomas reveals a nose that has been worn down over the years by all the people who have rubbed the nose for good luck. Patient artwork decorates many of the walls, including a corridor of the ABCs of cancer, with entries that depict topics such as “C is for cure,” “J is for joy is everywhere,” and “N is for needles.”

According to the late founder, Danny Thomas, the hospital stands as a shrine to St. Jude Thaddeus, the patron saint of hopeless causes. Thomas was at a turning point in his life, not yet a star and with a growing family, when he contemplated giving up his dream of show business success to pursue a more stable job. He prayed to St. Jude for guidance, with the promise to build a shrine in gratitude. Shortly thereafter, Thomas was discovered and went on to become a successful entertainer and producer, best known for the television sitcom Make Room for Daddy. Thomas kept good on his word and traveled extensively to raise money to build the hospital, even going door to door in apartment complexes to ask for donations. The dedication and combined efforts of Thomas, Memphis resident Ed Barry, Dr. Lemuel Diggs, Michael F. Tamer, and the American Lebanese Syrian Associated Charities (ALSAC), and others led to fulfillment of the promise and the opening of the hospital.

Based upon a suggestion from Dr. Lemuel Diggs, the hospital was targeted toward childhood catastrophic diseases, rather than general care. Two of founder Thomas’s core beliefs guide the mission and vision of the hospital, that “no child should die in the dawn of life,” and that no child should be denied treatment based on race, religion, or a family’s ability to pay. Families do not receive a bill from the hospital for treatment, travel, housing, or food. In June 2012, the daily operating cost of the hospital was $1.9 million, predominantly covered by individual contributions.

In 1957, Danny Thomas founded ALSAC, a non-profit organization that is the fundraising partner of the hospital. Additionally, many high schools, colleges, and universities around the country actively participate in fundraising efforts for the hospital. Fraternities such as Tau Kappa Alpha and Kappa Alpha Sigma, and sororities such as Delta Delta Delta and Lambda Theta Alpha are also fundraising partners for the hospital. The campus includes housing for short-term care, Grizzly House for up to one week; medium-term care, Ronald McDonald House for one week to three months; and long-term care, Target House for more than three months. Since its inception, the hospital has treated patients from every state in the United States, as well many countries from around the world, and on average has more than 67,000 patient visits each year.

St. Jude Children’s Research Hospital has become a leader in the research, treatment, and care of pediatric patients facing catastrophic illnesses. Through the work of its dedicated staff, survival rates for acute lymphoblastic leukemia (ALL), which in 1962 were 4 percent, are now 94 percent. It is the only...
comprehensive cancer center specifically devoted to children, as designated by the National Cancer Institute. In addition to its leading role in cancer treatment, the hospital also helps pediatric human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) patients, and has created one of the largest programs to treat pediatric sickle cell disease patients. It was the first pediatric cancer research center in the United States housing a good manufacturing practice (GMP) facility onsite, which creates biopharmaceuticals for use in clinical trials.

Ranked as one of the top pediatric cancer hospitals in the country, St. Jude Children's Research Hospital has also been ranked as one of the top 10 places to work in academia by the Scientist, and as one of the 100 best companies to work for by Fortune magazine. The hospital is partnered with Washington University School of Medicine in St. Louis for the Pediatric Cancer Genome Project. This project is geared toward understanding the genetic origins of childhood cancers, and thus far has completed whole genome sequencing of over 700 pediatric cancers. The faculty includes Nobel Prize winners, members of the National Academy of Sciences, members of the Institute of Medicine of the National Academy of Sciences, and Howard Hughes Medical Institute investigators. Founder Danny Thomas died on February 6, 1991, two days after he celebrated the 29th anniversary of the hospital with caregivers, patients, and families at the hospital. He is buried near his wife, Rose Marie, on the grounds of the hospital where a memorial garden and pavilion are located. The hospital that originally was built as a shrine to honor the patron saint of hopeless causes continues to provide hope to pediatric patients from around the world.

Stainless Steel

The term stainless with respect to steel came about early in the development stages of steel that was in use for cutlery applications. This was a generic term that has since come to be associated with different types of steel, in particular the grades that are resistant to oxidation or corrosion. Stainless steel is available in three main categories: austenitic, ferritic, and martensitic. Stainless steel is an alloy made up of at least 10.5 percent chromium. There are other alloy elements that may have been added into the metal structure to help in supporting the supposed properties, and in particular properties such as strength, formability, and the cryogenic toughness that is associated with the metals. Some of the common alloys include nickel, copper, titanium, and molybdenum. Besides metallic additives, there are also some nonmetallic additives that are included into the metal structure of stainless steel, such as carbon and nitrogen. One of the main elements of stainless steel is that it is supposed to be resistant to corrosion within a given environment, or for a particular application. There are different grades of stainless steel, based on different corrosion resistance requirements.

In metallurgical terms, stainless steel is known as inox, or inox steel, which comes from the French term inoxydable, meaning the inability of the metal to be affected by oxidation, or corrosion. Stainless steel does not readily stain with water, rust, or corrode like other types of steel. However, when in an environment where there is high salinity, low oxygen, and poor circulation, even the highest grade of stainless steel will corrode. Therefore, there are different grades and surface finishes that are applied to stainless steel to suit particular environments.

Numerous studies, as summarized by Sørensen and colleagues, have found that welders are at increased risk for lung cancer. Some studies have also found that welders are at increased risk of other types of cancer, including nasal and larynx cancer.

A cohort study by Sørensen and colleagues found increased risk for lung cancer for Danish men
working as welders in the stainless steel and mild industries, even after controlling for tobacco use and exposure to asbestos. They studied 4,539 men who worked in the stainless steel or mild steel industries in Denmark for at least one year between 1964 and 1984, using information drawn from questionnaires (work history and smoking status) and from the Danish Cancer Registry (through December 2003). Lifetime exposure to welding fumes was estimated for each worker, using information about the occupational history of each worker and measurements of fume particulates in different welding processes. They found an increased risk of lung cancer among the welders (standardized incidence ratio 1.35, 95 percent CI 1.06–1.70) and, for stainless steel welders, an increasing risk of lung cancer associated with increased exposure to welding particulates. The increased risk with exposure may be due to the fact that stainless steel welders are exposed to water-soluble nickel and hexavalent chromium during their work, with the latter being a known lung carcinogen.

Statistics
There are many different cancer statistics, but only a few basic ones are needed to understand a nation’s or other collectivity’s general cancer experience. The first population statistics were measures of population size and identification of citizens for government purposes through a census. Citizens were not especially happy to be counted and identified, because they would then be taxed, and for men, be subject to induction for military service and/or forced labor in public works projects. Suspicion about the intentions and use of statistics continue to this day in some quarters, which makes the gathering of valid statistics problematic in some countries.

Vital statistics, literally measures of life and death, are a later development and the basis of many government programs involving planning and provision of services according to age cohorts, such as schooling for the young and services for the elderly. Vital statistics at first were simply measures of each person’s date of birth and date of death. Spread into columns of the years of birth on one axis, and the years of death on the other axis, a life table reveals such statistics as life expectancy, or the average of the intervals from life to death along the birth columns. In its simplest form, this merely involved gathering the dates of birth and death inscribed on tombstones or church records of christenings and funerals. Practical applications, such as life insurance premiums, are calculated from these numbers. These vital statistics form the basis of the sociological field of demography, the study of human populations. Vital statistics provide basic information for public health and government planning. Calculation of birth rates and death rates led to the theory of demographic transition from the traditional society with high birth rates and high death rates, to the modern society with low birth rates and low death rates.

Mortality
When the cause of death is included, mainly from the physician’s filling out of a death certificate, then the vital statistics include mortality from the various causes given across a population. This is simply the number of deaths from such causes as heart attack, cancer, stroke, or pneumonia. However, this very common procedure suffers from a number of problems. Different physicians may disagree about the cause of death, the cause may not be clear to the observer without an autopsy, and in the absence of a clear diagnosis, the physician or other official may simply characterize the death as from “natural causes.” This is particularly the case for a deceased elderly person, the group most likely to suffer from cancer. The problem of agreement has been resolved
by the development and use of standard categories in the International Statistical Classification of Diseases (ICD), which is regularly evaluated and updated. The next updating is scheduled for 2017. However, the problem of classification when the cause is not apparent is more difficult to manage.

Some causes of death are hidden (occult), whereas others appear directly on observation. Also, causes of death vary along such axes as proximate to ultimate. Decades ago, the vital statistics of Australia were used to investigate the cause of prostate cancer, mainly a condition of very elderly men. The study compared the cause of death (a prostate cancer diagnosis) with the number children of the deceased in the medical records. It was found that men without children were less likely to be diagnosed with prostate cancer. This finding led to speculation that prostate cancer was caused by male virility, high levels of testosterone, or an active sex life. More likely, considering that the prostate is an occult organ, autopsies were more frequently performed on elderly males when there were interested offspring present who were attending their deceased parents’ affairs. The conclusion is that even carefully recorded causes of death may have hidden biases that reduce the validity of the resulting statistics.

Cancer mortality “ultimate causes” that are not directly physiological, such as smoking, sedentary life style, obesity, and alcohol abuse are not included on death certificates. However, it is just as important to know the risks of cancer from these causes as the more proximate causes described on death certificates. So, mortality statistics on these ultimate causes are calculated, but through an elaborate process of estimation from the more directly observable proximate causes. For example, lung cancer can be attributed to smoking in general and exposure to irritants such as asbestos for certain occupations, and stomach cancer to ingestion of carcinogens in the diet of specific ethnic groups. To a certain extent, these estimates are more controversial and subject to debate than other statistics. Yet, all statistics are a product of human activity, and may contain hidden biases.

Incidence

Compared with the mortality statistic, there are more complex statistics of incidence and prevalence. Incidence is defined as a cancer diagnosis on a patient during a specific time period. Each diagnosis is a count, and the total count is the incidence of the population or cohort for that time, such as a year. A related static, prevalence, is the total count of all patients alive at a specific time who are afflicted with that type of cancer. For nations with a modern health system, the ICD is very useful in practice because it equalizes counts among different physicians and hospital records. With a national cancer registry to record these counts, each form of cancer can be calculated, compared, and monitored over time. One of the most interesting of these specialized registries has been the linkage of the medical records of the mother during pregnancy to the health condition of her offspring in later life. Through those registries, a daughter’s likelihood of contracting clear cell adenocarcinoma (CCA) of the vagina and cervix was linked to the mother’s ingestion of the synthetic estrogen drug diethylstilbestrol (DES). Now, there is a DES Cancer Registry to carry on this work.

Cancer incidence and prevalence statistics are different from mortality statistics. The medical technology used for the discovery of cancer in normal healthy people changes over time. There is no IDC for modern screening and technology, so earlier detection and more extensive screening will alter incidence and prevalence statistics by continually expanding their findings. Cases will increasingly be found where the cancer is small, not growing, or growing so slowly that it will not be a threat to the individual’s life or health. Autopsy studies of elderly men, for example, have found that most men over 80 years of age have some form of prostate cancer, but they do not die from it, or even experience symptoms. A smaller but significant proportion of women from 40 to 80 years of age have been discovered to have breast cancer on autopsy after dying from other causes. Studies of these women found up to 15 percent with undiagnosed breast cancer. There is no statistical baseline for defining small and slowly growing, non-life-threatening cancers. As a result, the meaning of incidence and prevalence will change through an inflation of cases as medical diagnosis and screening continues to advance.

Calculated together, mortality and incidence provide another vital statistic, the life expectancy of the patient, not from birth to death, but from diagnosis to death. This particular life expectancy is called survival. While life expectancy is calculated as the
number of years of expected life, as from the time of the purchase of a life insurance policy, survival is calculated somewhat differently. It is the proportion (expressed in percentages usually) of patients still living within a period of time after diagnosis, such as five years. While useful at present, this statistic will lose its meaning as inflation of incidence continues. Lifetime risk is calculated from mortality and prevalence statistics. Two versions of lifetime risk are calculated. Risk of contracting cancer in one’s lifetime comes from prevalence life tables for each type of cancer. The risk of dying from cancer is calculated from cancer mortality tables. Individuals can calculate their risks in great detail from the National Cancer Institute Web site. While extraordinarily useful in monitoring the forms of cancer and their treatment, statistics can be misleading. They must be interpreted with care and with a certain degree of skepticism.

Stomach (Gastric) Cancer

Gastric (stomach) cancer is a disease in which malignant (cancer) cells form in the tissue lining the stomach. Stomach malignancy is linked to Helicobacter pylori (H. pylori) bacterium infection, or Epstein-Barr virus (EBV) infection. H. pylori is a pathogen responsible for the development of chronic gastritis, peptic ulcer disease, and gastric cancer. It seems to be neither genotoxic or mutagenic. H. pylori infection tends to be correlated with poor socioeconomic conditions. EBV (also called human herpes virus 4, HHV-4) belongs to the herpes family, and is one of the most common viruses in humans, causing various types of diseases.

Gastric cancer was the most common neoplasm in 1975, and was the second cause of cancer deaths worldwide in 1985 and 1990. According to GLOBOCAN 2012, gastric cancer is now the fifth most common type of cancer worldwide, after lung, breast, colorectum, and prostate cancers. In cancer-related deaths, gastric cancer is the third-leading cause worldwide (723,000 deaths, or 8.8 percent of the total). High mortality rates occur in eastern Asia (the highest, 24 per 100,000 in men and 9.8 per 100,000 in women), central and eastern Europe, Latin America, and the Caribbean, while Africa and North America have the lowest (2.8 per 100,000 in men, and 1.5 per 100,000 in women in the United States). The eastern Asian region includes China, Japan, Mongolia, North Korea, South Korea, and Taiwan. South Korea had the highest rate of stomach cancer, followed by Mongolia and Japan.

Whereas cases of gastric cancer have increased because of population growth, mortality rates of stomach cancer have rapidly declined, especially in developed countries in recent decades. Some researchers (e.g., M. Amiri and colleagues) have projected that with this consistent trend, stomach cancer is likely to become far less deadly in Europe in the future. Middle-aged or older males residing in eastern Asia are still at high risk of gastric cancer.

Risk Factors
Most gastric cancer cases are associated with H. pylori infection. In 1995, the International Agency for Research on Cancer (IARC) of the World Health Organization classified this organism as a Group 1 human carcinogen for stomach malignancy. Patients with H. pylori infection are significantly more likely to develop stomach cancer than those who do not. However, only about 1 percent of infected individuals will develop gastric cancer. Other factors such as gender (male), socioeconomic condition at the time of birth, age at first H. pylori infection, different strains of H. pylori (genetic structure and virulence), family history of stomach cancer, previous stomach
Surgery, some types of stomach polyps, genetic conditions, diet, dietary supplements, tobacco use, certain occupations (coal, metal, and rubber industries), and exposure to radiation can also affect the risk of stomach cancer.

Demographic Factors
GLOBOCAN 2012 reports that more than 70 percent of stomach cancer cases (677,000 cases) occur in developing countries (456,000 in men, 221,000 in women). Half of stomach cancer cases worldwide take place in China. However, this is because of the sizable Chinese population. Age-standardized incidence rates (per 100,000) indicate that South Korea has the highest (62.3 in men, and 24.7 in women, followed by Mongolia (47.4 and 20.2, respectively), and Japan (45.7 and 16.5, respectively). Asian males are vulnerable to gastric cancer, whereas western Africans have a very low risk of stomach cancer (3.3 in men, and 2.6 in women). In the United States, the National Cancer Institute estimates that there will be 22,220 new cases of stomach cancer, and more than 10,990 Americans will die of the disease, in 2014. Between 2004 and 2010, the five-year survival rate of stomach cancer survivors in the United States was 28.3 percent.

Types
The most common type of stomach cancer is adenocarcinoma, comprising 90 to 95 percent of cases. The cancer starts in the gland cells that form the innermost lining of the stomach, known as the mucosa. Other less common types include lymphoma non-Hodgkin (cancer of the immune system tissue in the wall of stomach, about 4 percent of cases), gastrointestinal stromal tumors (GIST, cancerous tumors that start in the digestive system, and about 60 percent of the tumors are in the stomach), carcinoid tumors (they grow in the hormone-producing tissues in the digestive system, about 3 percent of cases) and others (such as squamous cell carcinoma, small cell carcinoma, and leiomyosarcoma).

Symptoms and Stages
The general signs and symptoms of stomach cancer include stomach pain, loss of appetite, weight loss for unknown reason, nausea, vomiting, a change in bowel movements (constipation or diarrhea), weakness, and anemia. These symptoms could be similar to that of other diseases (such as stomach flu, chronic fatigue, or food allergy) and may go unnoticed until the cancer spreads. In early-stage stomach cancer, symptoms include indigestion and stomach discomfort, a bloated feeling after eating, mild nausea, loss of appetite, and heartburn. The signs and symptoms in advanced stages are blood in the stool, vomiting, weight loss for no known reason, stomach pain, jaundice (yellowing of eyes and skin), ascites (build-up of fluid in the abdomen), and trouble swallowing. To compound the difficulty in detection, many stomach cancer patients are asymptomatic, especially in early stages.

Screening and Diagnosis
In addition to commonly used medical tests (physical exam and medical history, X-ray of the abdomen, blood chemistry studies, computed tomography or CT scan, biopsy, and complete blood count), two procedures are particularly useful for screening stomach cancer. Upper endoscopy is a procedure to check if there are abnormal areas inside the esophagus, stomach, and duodenum (first part of the small intestine). A conventional endoscope is a thin tube-like instrument with a light and a lens that is passed through the patient’s mouth and down the throat into the esophagus. It helps physicians see the inside of the stomach; however, it is invasive to patients.

Advances in imaging technology have invented a new procedure—capsule endoscopy. The capsule is the size of a large vitamin pill that has a camera inside. The patient swallows the capsule; once it is activated, it starts taking thousands of pictures while traveling through the patient’s digestive tract. The pictures are transmitted to sensors attached to the patient’s chest and the recorder on a belt the patient wears around the waist area. Eventually, the capsule is discharged by the patient into the toilet and flushed away. Barium-meal photofluorography (or upper gastrointestinal or GI series) refers to a series of x-ray films of liquid-coated esophagus and stomach. The patient drinks a liquid that contains barium (a silver-white metallic compound) in advance to produce the coating effect. The barium swallow test seems to be less effective than endoscopy.

Treatment and Side Effects
Stomach cancer is strongly linked to H. pylori infection, therefore, a H. pylori screen-and-treat strategy is one solution. Treatment with antibiotics to
eradicate *H. pylori* infection may prevent gastric cancer. However, because many factors contribute to a person’s risk of stomach cancer, elimination of the infection alone may not produce expected results. Another example is anti-*Helicobacter* therapy; it has shown potential in the treatment of low-grade gastric mucosa-associated lymphoid tissue (MALT) lymphomas, yet its long-term effect is unclear.

Once stomach cancer (mostly adenocarcinoma, or in some cases squamous cell cancers) is diagnosed, the most common treatment method is surgery. In the early stage of stomach cancer, when it has not spread, endoscopic resection is an effective procedure by using an endoscope to cut out a tumor or cancerous cells. Subtotal or partial gastrectomy is used to remove the affected areas of the stomach, and some lymph nodes and tissue near the stomach. In some cases, total gastrectomy is needed to remove the whole stomach. If the cancer is advanced, and cannot be removed, palliative surgery is the option. The purpose of palliative surgery is to help control the cancer or relieve symptoms or problems (such as bleeding); it rarely cures the disease. Palliative surgery includes several options, such as subtotal gastrectomy, gastric bypass (gastrojejunostomy), endoscopic tumor ablation, stent placement (a hollow metal tube is placed by using an endoscope), and feeding tube placement.

Side effects of surgery include bleeding from the surgery, blood clots, and damage to the nearby organs. Post-op recovery also includes side effects such as risk of infections during the healing process, pain, nausea, heartburn, abdominal pain, and diarrhea (especially after eating), and shortages of some vitamins. If part of the stomach is removed, dietary habits have to be changed in terms of portion and frequency (smaller portions eaten frequently) to manage upset stomach. A feeding tube placement may also be needed. If the whole stomach is removed, it leads to a lifestyle change, in addition to a change of diet. Individuals without a stomach will not be able to absorb B12; they will need regular shots (of B12) to maintain healthy blood and nerves. Total gastrectomy presents a special challenge to pediatric cancer patients and their life expectancy. Side effects of radiation and chemotherapy are nausea, vomiting, diarrhea, skin reactions, and tiredness.

Side effects of radiation and chemotherapy are similar to those of treating other types of cancer. They include nausea, vomiting, diarrhea, skin reactions, and tiredness. Because chemotherapy kills the fastest-growing cells in the body (e.g., the stomach lining, hair, and blood cells), its side effects also include hair and weight loss.

All these side effects can be managed with medication and diet, and they phase out after treatment is completed. A new targeted drug for treating advanced stomach cancer recently received approval from the U.S. Food and Drug Administration in April 2014. Cyramza (ramucirumab) was developed to treat patients with advanced stomach cancer that cannot be surgically removed (unresectable) or has spread. The new drug is an angiogenesis inhibitor that blocks the blood supply to tumors. In a clinical trial of 355 participants (median age was 60) with unresectable or metastatic stomach or gastroesophageal junction cancer, Cyramza showed evidence of slowing the tumor growth and extending survival (participants’ lives). Common side effects of using Cyramza during clinical testing were diarrhea and high blood pressure.

**Prognosis and Five-Year Survival Rate**

Prognosis (chance of recovery) of gastric cancer depends on if it is detected in an early stage, or if it has spread at the time of diagnosis. The five-year survival rate refers to the percentage of cancer survivors who live beyond five years after initial diagnosis. Many factors contribute to the five-year survival rate, including the type and location of the stomach malignancy, the stage of development, the patient’s age, the patient’s general health, and the patient’s response to treatment. For any type of cancer, early detection is vital to the five-year survival rate. In stomach cancer, the early stage five-year rate is as high as 90 percent (Stage 0) and 78 percent (Stage 1A). The survival rate drops to 58 percent (Stage 1B, where stomach malignancy has spread into the lymph nodes or under the main muscle layer), and it further deteriorates to the point of 34 percent (Stage II), 20 percent (Stage IIIA), 8 percent (Stage IIIB, where malignancy has grown through all the stomach layers and wall, infecting between 7 and 15 lymph nodes), and 7 percent (Stage IV, where cancerous cells have spread to other organs and have metastasized). The sad reality is when gastric cancer is diagnosed, it is often in an advanced stage (such as Stage IIIB or later). The prognosis is poor, and long remissions are rare.
Stomach (Gastric) Cancer, Childhood

Conclusion

The stomach is a delicate and complex organ. As a result, screening and treating gastric cancer is challenging. It is difficult to detect early gastric cancer until it is too advanced with a poor prognosis. Screening and detecting stomach cancer in moderate- to high-risk populations via endoscopic screening programs are effective in reducing mortality rates in eastern Asia (China, Japan, and Korea). This type of population screening or targeted screening is also cost effective in regions where incidence rates of stomach cancer are high. However, mortality rates in developed countries (such as Europe) exist without such screening programs. Regional differences are evident in gastric cancer. Innovative approaches (such as imaging technology and endoscope, better diagnostic skills, targeted drugs, clinical considerations for high risk groups, biomarkers of the blood of stomach cancer patients, DNA sequencing, and genetic inheritance factors) are under development. They bring hopes that one day stomach cancer can be detected early, and patients will be able to have a better outlook in life expectancy.

Stomach (Gastric) Cancer, Childhood

Cancer in children is less common than in adults. According to the National Cancer Institute, approximately 1 in 285 children (0.35 percent) in the United States will develop cancer before the age of 20. Pediatric cancers represent 1 percent of all new cases of cancer in the United States. In 2014, there were an estimated 10,450 new cases of pediatric cancer, and 1,350 children died of the disease. Pediatric cancers are the second-leading cause of deaths in children ages 5 to 14 (accidents are the first cause). The most common types of cancers among children (ages 0 to 14) are acute lymphocytic leukemia (26 percent), brain and central nervous system (CNS) (21 percent), neuroblastoma (7 percent), and non-Hodgkin’s lymphoma (6 percent). Gastric cancer is a rare cancer in children, according to the Physician Data Query (PDQ). The most common type of stomach cancer is adenocarcinoma, comprising 90 to 95 percent of cases. The cancer starts in the gland cells that form the innermost lining of the stomach, known as the mucosa.

The signs and symptoms of stomach cancer are usually difficult to diagnose, especially for children. A child might be diagnosed as having stomach flu if these symptoms (of stomach cancer) are present, such as stomach pain, loss of appetite, diarrhea, and weakness. In early-stage stomach cancer, symptoms may include indigestion and stomach discomfort, a bloated feeling after eating, mild nausea, loss of appetite, and/or heartburn. The signs and symptoms in advanced stages are blood in the stool, vomiting, weight loss for no known reason, stomach pain, jaundice (yellowing of eyes and skin), ascites (build-up of fluid in the abdomen), and trouble swallowing.
Screening and Diagnosis
Many commonly used medical tests may be helpful in screening for and diagnosing lung cancer, including taking a medical history, doing a physical exam, performing blood chemistry studies, and conducting tests such as a biopsy, a complete blood count, a CT (computerized tomography) scan, and an abdominal X-ray. In addition, upper endoscopy and capsule endoscopy exams are particularly useful in screening for pediatric stomach cancer.

Upper endoscopy is performed using a conventional pediatric endoscope, a thin, tube-like instrument including a light and a lens, which is passed through the mouth and down the throat into the patient’s stomach. Upper endoscopy allows the physician to check for abnormal areas within the esophagus, stomach, and duodenum (first part of the small intestine) but carries the disadvantage of being invasive and possibly traumatic to the patient.

Capsule endoscopy is a more recently developed procedure that requires the patient to swallow a capsule (that is about the size of a large vitamin pill) containing a camera. While the capsule is passing through the individual’s digestive tract, the camera records thousands of images that are transmitted to sensors and a record outside the patient’s body. Eventually, the capsule passes out of the patient’s body and is discarded. Because it is experienced as less invasive, capsule endoscopy may be particularly useful with child patients.

An alternative test, barium-meal photofluorography, is less effective than endoscopy. In barium-meal photofluorography, the patient drinks a liquid containing barium, a silver-white metallic compound, and a series of X-ray films are taken of the patient’s liquid-coated esophagus and stomach.

Treatment and Side Effects
The treatment of a childhood cancer brings up physical, psychological, emotional, cognitive, and social challenges to the child and the family. Because children are still growing and developing while having cancer, it is highly recommended that child cancer patients seek treatment at pediatric oncology centers that offer comprehensive cancer care and clinical trial programs. Stomach cancer is linked to Helicobacter pylori (H. pylori) bacterium infection. The infection is often acquired in childhood, and is considered a risk factor for the development of gastric malignancies in adulthood. Early age at first infection may determine a gastric neoplastic outcome in adults (H. pylori infection is most common where socioeconomic conditions are poor). To detect H. pylori infection in children, however, is challenging because they usually show no symptoms of the infection (except peptic ulcers in a very small number of infected children).

The most common treatment method for stomach cancer is surgery. Endoscopic resection, a procedure in which an endoscope is used to remove a tumor or cancerous cells, is commonly used if the cancer is in an early stage and has not spread. In subtotal or partial gastrectomy, the affected areas of the stomach and some lymph nodes and tissue near the stomach are removed. In some cases, total gastrectomy is needed to remove the whole stomach. If the cancer is advanced and cannot be removed, palliative surgery is the option. The purpose of palliative surgery is to help control the cancer or relieve symptoms or problems (such as bleeding); it rarely cures the disease. Palliative surgery includes several options, such as subtotal gastrectomy, gastric bypass (gastrojejunostomy), endoscopic tumor ablation, stent placement (a hollow metal tube is placed by using an endoscope), and feeding tube placement.

Surgery carries the risk for side effects, including damage to nearby organs, blood clots, and bleeding. Side effects may also occur during the post-operative recovery period, including infection, pain, heartburn, diarrhea (especially after first eating), and vitamin deficiencies. If part of the stomach is removed, dietary habits have to be changed in terms of portion and frequency (smaller portions eaten frequently) to manage upset stomach. A feeding tube placement may also be needed. If the whole stomach is removed, it leads to a lifestyle change, in addition to a change of diet. Individuals without a stomach will not be able to absorb B12; they will need regular shots (of B12) to maintain healthy blood and nerves. Total gastrectomy presents a special challenge to pediatric cancer patients and their life expectancy.

Radiation and chemotherapy can also produce side effects, including fatigue, nausea, vomiting, diarrhea, and skin reactions. These side effects taper off after the treatment is completed and can be managed with medication and diet but may still have a substantial impact on a child’s health and development. A new, targeted drug for treating advanced stomach cancer received approval from the U.S. Food
and Drug Administration in April 2014. Cyramza (ramucirumab) was developed to treat patients with advanced stomach cancer that cannot be surgically removed (unresectable) or has spread. The new drug is an angiogenesis inhibitor that blocks the blood supply to tumors. In a clinical trial of 355 adult participants (median age of 60) with unresectable or metastatic stomach or gastroesophageal junction cancer, Cyramza showed evidence of slowing the tumor growth and extending survival (participants’ lives). Common side effects of using Cyramza during clinical testing were diarrhea and high blood pressure. The safety and effectiveness of Cyramza in pediatric patients, however, are unknown.

Prognosis and Five-Year Survival Rate
Prognosis (chance of recovery) of gastric cancer depends on if it is detected in an early stage, or if it has spread at the time of diagnosis. The five-year survival rate refers to the percentage of cancer survivors who live beyond five years after initial diagnosis. Many factors contribute to the five-year survival rate, including the type and location of the stomach malignancy, the stage of development, the patient’s age, the patient’s general health, and the patient’s response to treatment. Early detection is vital to the five-year survival rate. In stomach cancer, the early stage five-year rate is as high as 90 percent (Stage 0) and 78 percent (Stage IA). The survival rate drops to 58 percent (Stage IB, where stomach malignancy has spread into the lymph nodes or under the main muscle layer), and it further deteriorates to the point of 34 percent (Stage II), 20 percent (Stage IIIA), 8 percent (Stage IIIB, where malignancy has grown through all the stomach layers and wall, infecting between 7 and 15 lymph nodes), and 7 percent (Stage IV, where cancerous cells have spread to other organs and have metastasized). Because childhood stomach cancer is rare, the five-year survival rate of the disease has not been established. The most common causes of death in childhood cancer are recurrence of the primary cancer, a second primary cancer, and heart and lung damage.

Late Effects
Late effects are a special condition for child cancer survivors, from a developmental perspective. After
Stress

A review of the literature on stress and cancer reveals that cancer can be seen as a result of environmental stressors and as a cause for further stressors among patients. Results of cancer-related stressors may include anxiety, feelings of depression, cancer worry, and even post-traumatic stress disorder (PTSD). Cancer is a life-threatening disease, with uncertain survival in the near and more distant future. Cancer recurrence looms in one's arena of fears and anxieties. Stigma, based on the reaction of friends and acquaintances, can add to stressors experienced by the patient. PTSD is often discussed as a result of being diagnosed and treated for cancer, but epidemiological evidence is inconclusive. The effects of cancer on personality, self-concept, and world outlook are described in many

Stigma, based on the reaction of friends and acquaintances, can add to stressors experienced by the patient. PTSD is often discussed as a result of being diagnosed and treated for cancer, but epidemiological evidence is inconclusive. The effects of cancer on personality, self-concept, and world outlook are described in many
articles within the journals of psycho-oncology and psychosocial oncology.

Cancer stress is often a function of the nature of symptoms, cancer site, severity of the cancer, type of treatment (e.g., surgery, radiation, or chemotherapy), and its side effects. Stressors may also be posed by the patient’s concerns about the uncertainties of survivorship. Other variables that can influence stress levels include stage of the patient’s life course and their family circumstances. For example, breast cancer has a different meaning for a young mother than for a retired grandmother. A prevalent theme in many psychosocial studies of survivorship is the concept of posttraumatic growth (PTG).

The stress-buffers-outcome model is useful for understanding the effects of stressors on diverse outcome variables. The factors that can buffer cancer-related stress include the patient’s coping styles and strategies. Instrumental and emotional social supports from family and friends offer major survival and psychological benefits to patients facing cancer-related stress. There are also formal resources, such as ties with health care personnel and access to legal and educational resources that can serve valuable buffering functions. Of particular note are mental health professionals who specialize in oncology, including social workers and psychologists.

**Studies on Cancer Stress**

In a national health survey, participants who developed cancer and a cancer-free control group were reinterviewed 10 years later. Cancer survivors demonstrated adverse effects, compared to the control group, in mental health, mood, and other aspects of psychological wellbeing. Nevertheless, the cancer survivors also showed resilience, reflected in social wellbeing, spirituality, and personal growth. Younger survivors demonstrated higher levels of anxiety and depression than their age-matched peers. In contrast, older survivors reported few adverse psychological effects, consistent with others their age.

In another study, comparing eight-year survivors of breast cancer to a suitable control group, small differences were found, favoring controls in positive quality-of-life outcomes. When limited to women who remained disease free over the entire follow-up period, survivors’ quality of life was similar to controls. In contrast, survivors who developed recurrence or a new primary cancer experienced worse quality of life in all domains, except social functioning. A study of quality of life and mental health in cervical and endometrial cancer patients found no significant differences in depressive symptoms between survivors and controls. However, cervical cancer survivors reported significantly higher levels of anxiety than endometrial cancer survivors. Cancer survivors who were unemployed or living alone were found to be at special risk for mood and mental health difficulties.

A large-scale study of quality of life in patients with colorectal cancer one year after diagnosis revealed that in comparison to the general population, the colorectal patients scored only slightly worse on a quality of life (QOL) global-health measure. More severe limitations were observed on the emotional and social functioning scales, including financial difficulties, and on the physical symptom subscales of fatigue, dyspnea, insomnia, constipation, and diarrhea. These differences predominantly affected younger patients. As in other cancer studies, older cancer survivors fared better than younger survivors.

**Focus on Long-Term Survivors**

A study by Boaz Kahana explored life perspectives of older adults who were long-term cancer survivors. Interviews were conducted with 321 survivors, age 60 and over, who were at least 5 years post diagnosis and treatment. The sample included survivors of breast, colorectal, and prostate cancers. The majority looked back upon their past cancer as a traumatic experience (57 percent). Approximately 40 percent worried about their cancer coming back. However, only 15 percent stated that cancer had changed the person that they were, and 13 percent said that they felt that they were not a whole person since they had cancer.

These data underscore that even older long-term cancer survivors recognize the stressful nature of the cancer experience. However, the essential personhood of survivors remains intact. It is also notable that African American survivors in this study found cancer to be less of a stressor than Caucasians. They portrayed lower scores on a depression scale, scored higher on an optimism scale, and had fewer cancer worries. This might relate to more positive appraisals of illness, in the context of lives that are fraught with many social stressors, including economic disadvantage. Also, older adults no longer grapple with the disruption of role obligations.
that face younger survivors. Although older people are always facing the possibility of their cancer reemerging, they nevertheless strive to normalize the world in which they live.

Factors That Exacerbate and Ameliorate Cancer Stress
The stressors posed by cancer can challenge cognitive functioning and information processing that is necessary to understand the course of treatment, to comply with health maintenance regimens, and to engage in health-promoting behaviors. Depression can impair the patient's ability to learn and maintain health behaviors, or to undertake complex tasks that require planning for one's recovery. Poor coping strategies often lead to inability to adhere to treatment regimens and poor management of one's illness. Low motivation to monitor one's illness and feelings of pessimism, based on fears of recurring illness, can delay the adoption of new salutary health practices. Negative coping strategies in responding to the stressors of cancer may be manifested in adverse health habits such as smoking, alcohol consumption, eating foods containing high fats or sugars, poor sleep patterns, and a decline in exercise.

External obstacles to coping with cancer include poor doctor-patient communications that may lead to poor illness management. Doctors and nurses are often pressed for time, and may not be sensitive to the psychological needs of their cancer patients. Patients need to receive general education about cancer and education specific to their type of cancer and different methods of treatment. Health care consumerism and patient advocacy can reduce cancer related stress and improve patient outcomes. Patients also need to learn which medical centers are most knowledgeable and experienced when dealing with the patient's particular cancer. Adverse effects of cancer, including PTSD, are greatly exacerbated among terminally ill cancer patients. Patients with advanced or terminal cancer need the full support of a palliative care setting to minimize the stress for both patient and family.

Economic pressures can also exacerbate cancer-related stress. Financial problems, job loss either before or after cancer diagnosis, and inadequate health insurance all pose added burdens for patients coping with cancer. Low income is a strong risk factor for many negative outcomes, including illness, disability, lack of transportation to visit the doctor, inability to pay for medical visits or to purchase medications, or even to visit support groups or travel to the grocery store and pharmacy. In one study, socially isolated breast cancer patients had a 66 percent higher rate of dying from all causes compared to socially integrated women.

Optimism and self-efficacy are related to emotional resilience and better coping with one's illness. Adaptive and useful coping strategies to deal with cancer-related stress include information seeking, problem solving, and positive reframing, such as seeing the cup as half full rather than half empty. At least 83 percent of breast cancer survivors found at least one benefit following diagnosis and treatment of their illness. Despite the stressful nature of cancer, many patients respond with highly protective coping and survival skills.

Sudan

For most of its history, the north African country of Sudan was ruled and influenced by Arab and Nubian cultures. In 1821, it was conquered by the Ottoman Empire, which annexed it to Egypt.
In 1890, Sudan was liberated by the British, who treated it as a colony, sowing the seeds for revolution, which erupted after the Egyptian Revolution in 1952. Sudan’s cultural and religious mix generated much internal conflict during its modern history, culminating in the 2011 separation of South Sudan, which claimed independence.

Its numerous civil wars, including the war in the Darfur region, and the authoritarian theocratic government brought about a widespread disrespect for human rights. Thus, even if Sudan is a somewhat modernized nation, with more than 30 million inhabitants, much of the population (46.5 percent, according to United Nations Development Programme) live in poverty, with very little or no access to health care, and a lack of hospital facilities. Except for some free clinics and hospitals managed by international humanitarian organizations such as Emergency and Doctors Without Borders (Médecins Sans Frontières), there are very few doctors available (16 per 100,000 inhabitants), so underdiagnosing of all types of cancer is a major issue. Also, much of the rural population still believe in traditional shamanistic healing and herbal remedies, and they are often reluctant to seek modern medical treatment to properly treat even the most common diseases.

Even though in 1982 a National Cancer Control Programme (NCCP) was initiated, until 2009, data about cancer research and incidence in Sudan was sparse because there was no population-based cancer registry, except for a very incomplete early 1967 register that was discontinued in the early 1980s. All data available came from the patient cases evaluated by the only two existing cancer centers in this country: the Radiation and Isotope Center in Khartoum (RICK), and the Institute of Nuclear Medicine Molecular Biology and Oncology (INMO) in Wadmedani. Nonetheless, according to hospital reports, cancer was the third-leading cause of death after malaria and viral pneumonia, accounting for 5 percent of all deaths. In 2009, the first National Population-based Cancer Registry (NCR) was established in Sudan, collecting all data from cancer patients in Karthoum State.

From 2009 to 2010, 6771 new cancer cases were registered. The data from NCR indicated that prostate and breast cancer were the most commonly diagnosed cancers in men and women in Khartoum, while cancer of the cervix trailed behind, portraying a cancer picture similar to that of the developed world. In children less than 15 years of age, leukemia was the most common cancer, followed by lymphoma. A very recent study suggested a strong association between Epstein-Barr virus (EBV) and breast carcinoma in Sudanese patients, and considerable epigenetic silencing of tumor suppressors that may likely be an outcome or an association with viral oncogenesis.

The data available is incomplete because most of the patients from the South Sudan region seek treatment in cancer facilities in neighboring countries such as Uganda because of the long distance from the only two available centers, lack of road safety, and scarcity of financial means. Only 5 percent (1,135 out of 20,954) of the registered cases in the National Cancer Registry for 2009 to 2010 were found to be from South Sudan. Recent government surveys indicate a high prevalence (10.7–13.1 percent) of human immunodeficiency virus (HIV), and a high hepatitis B surface antigen (HBsAg) endemicity (more than 8 percent) in the South Sudan population. They both constitute a significant regional risk factor for cancer, together with the high prevalence of human papillomavirus (HPV) and high consumption of alcohol among South Sudanese people.

Sudan has initiated a series of educational strategies that aim to dispel many of the misconceptions about cancer among the general population (who are 80 percent either nomadic or rural), such as superstitious beliefs and fears, or the misperception that cancer is transmissible. Booklets and posters have been distributed within schools, hospitals, and work places, together with radio, newspaper, and television educational programs. Some attempts to improve cancer prevention through early detection have also been made, by training some local populations to perform breast cancer screening in Keremet County in 2012.

One of the most prominent figures in cancer treatment and research is Dr. Sulma Mohammed, a native of Sudan and an associate professor of cancer biology at the Department of Comparative Pathobiology, Purdue Center for Cancer Research, Purdue University and Indiana University School of Medicine. Dr. Mohammed is a council member of the African Organization for Research and Training in Cancer (AORTIC), a nongovernmental organization that is dedicated to the promotion of cancer control, increasing public awareness, and reducing
the stigma associated with cancer. Dr. Mohammed has received a number of awards, including the African American Institute award, African women leaders in science award, and many American Association for Cancer Research travel awards.

Sun Exposure (Australia)

The interaction of human skin and the sun’s rays is complex. While sunlight warms the skin and aids in cooling the body through evaporation, it also contains energetic ultraviolet wavelengths (UVW) that harm the skin’s deoxyribonucleic acid (DNA). They also destroy folate, an essential nutrient in the body. Fortunately for life on Earth, the shortest UVWs below 100 nanometers and the next most energetic, between 100 and 280 nanometers (UVC), are screened out by the oxygen and ozone of the atmosphere, while UVB, between 280 and 315 nanometers, is 90 percent screened out. The rest of UVW (UVA, above 315 to 400 nanometers) passes through, but how much arrives at the planet’s surface depends on a variety of factors, including moisture in the atmosphere, the incidence of the sunlight (latitude), and the height above sea level (thickness of the atmosphere). Each of these factors has been registered on human skin when a people has lived in a place for enough human generations to reflect the evolutionary pressures on the skin, as noted by the biologist Nina G. Jablonski.

Humans require solar radiation in order to produce an essential nutrient, vitamin D. Thus, there is evolutionary pressure to have light skin that allows sunlight to enter. The alternative interaction is that certain ultraviolet rays are carcinogenic, and produce skin cancer, including life-threatening melanoma. The degree of melanin in a person’s skin is a testament to that individual’s ancestry. Extremely light skin that never darkens on sun exposure will only burn, and is most often a demonstration of ancestral origins in the far northern latitudes. However, a condition of albinism can occasionally appear in the tropics of Africa, and the unfortunate inheritor of genetic loss of all skin melanin yields a 1,000 times greater incidence of skin cancer for the albino over the dark-skinned African. Light skin that contains melanocytes that darken on direct sun exposure is one evolutionary adaptation to changing sunlight intensity over the annual cycle of seasons. The original peoples of northern Europe and Asia have this adaptation, as do their descendants across the planet. The peoples of the tropics have varying degrees of brown to black skin tones that let in enough sun to produce vitamin D.

The continent of Australia is exposed to the sun more than most because of modern technology, the use of chemicals that destroy the polar ozone that impedes the transmission of UVB. As displayed in the dark skin tone of Australia’s indigenous people, the aborigines, there has long been enough UVW arriving to cause major harm. The arrival of light-skinned people from Great Britain two centuries ago laid the foundation for an epidemic of skin cancer in Australia. The country is now among the world leaders in skin-cancer incidence, with 400,000 new cases each year in a population of
about 20 million. This is a major expense for the Australian health system, accounting for about 1 million physician visits a year, with a high proportion for skin diagnosis and treatment.

**Responses**

There have been two responses to this situation. The first was a campaign to stop the industrial and consumer use of chlorofluorocarbons. This came about when scientists determined that these chemicals were destroying the ozone layer. The unanticipated discovery of an ozone hole over the South Pole began the process, and when it was monitored and found to migrate northward to cover Australia, the alarm grew. An international agreement to prohibit the use of chlorofluorocarbons was made, and has proved effective. After some years of enforcement of the agreement, the ozone returned to the atmosphere. However, the actual size of the damage from this unanticipated exposure of the Australian people to a carcinogen that they could not see, hear, or feel will not be known for some time. The exposure of young people under age 30 has been found to be a major cause of these skin cancers, with most cases appearing years to decades after this critical exposure. The concern for public health is that the ozone hole years have caused a hidden threat of skin cancer that has yet to fully appear. With the aging of the Australian population that was exposed decades ago, a crisis will be at hand. It is estimated that two out of three Australians will contract skin cancer by the age of 70. The one positive is that there will be time to prepare and educate the public on the need for early detection and treatment. Skin cancers are visible and treatable in most cases. The need is for a many-sided effort to educate the public for prevention and early detection.

The second response includes increasing public awareness of the vulnerability of the white population to skin cancer, about the clear prevention techniques available, and the need for constant monitoring of one's skin. The education campaigns are targeted to specific populations, with emphasis on the protection of young people from exposure, and close monitoring of the skin of older Australians. In 1980, the Australian public health campaigns began. The Sun Smart campaign of 1980 to 1981 was the first national Australian social media campaign for cancer prevention. It featured a simple message, “Slip, Slap, Slop” to children, with a seagull cartoon singing for the audience to “slip on” sun proof clothing, “slap on” sunscreen with application instructions, and “slop on” a broad-brimmed hat. It was also directed to adults. Later campaigns also targeted specific populations who had been identified as at high risk for cancer or for low use of preventive methods. These later campaigns were less about using preventive methods, instead emphasizing the dramatic side of cancer incidence.

The tragic case of a young woman dying of melanoma at age 26 was transformed into a media awareness campaign, featuring the woman before her death. Clare Oliver gave her message in 2008 as a personal appeal to her young viewers: “No tan is worth dying for.” Other messages have been given during the dramatic removal of a skin cancer on screen. These messages have targeted teenagers and young adults who are less concerned about their sun exposure.

**Protection Measures**

Media campaigns are not the only part of the process of social change in a population at risk from a danger that they cannot see. Protection efforts begin by identifying problems of sun exposure and then responding to them. Public places where people gather can be provided with sources of shade. School children can be required to wear suitable hats when playing outside, and shade provided with shade sails. Workplace policies can do the same general monitoring for adults. Behavior (such as wearing appropriate hats and protective clothing) can be observed and counted before and after a campaign. However, behavior has generally been measured by surveys, not observation. Attitudes and awareness of educational messages can be tracked by surveys. Ideally, survey responses can be connected to studies of observed behavior rather than substituted for it. Campaigns can be segmented by people's place in the sun, their age, and other demographics.

Perhaps the most important of the techniques developed in Australia is the establishment of a sun exposure baseline. This statistic can be used to compare exposures at different venues. The baseline of 22 percent of the participants being sunburned was set from surveys, which are less valid than studying people on Australian beaches, but behavior has also been directly observed, as at schools. Then campaigns can be evaluated by how much they reduce reported sunburn at that venue. In a second
use of the baseline, studies of sports venues found an unexpectedly high rate of sunburn there, also 22 percent. So, this became the basis of a campaign directed at sports fans. Finally, the daily monitoring of the level of UVW, with published alerts when the index reaches dangerous levels, helps cue protective behavior while maintaining awareness of the risk.

The success of these efforts has been seen in a number of outcomes. Concerned parents have demanded that their children's schools take responsibility for monitoring children's sun exposure. The government's irregular appropriations for the media campaigns have been tracked, and decreases in media exposure are followed by an increase in reported sunburn, a direct indicator of risk. An economic analysis concluded that 24 cents per capita spending on educational campaigns saves 2.32 health dollars. These campaigns appear to have been successful in more than public awareness. The incidence of skin cancer in Australia in the most recent report demonstrated a decline.

**Sunlamps or Sunbeds, Exposure to**

Sunlamps and sunbeds are a known risk factor for developing basal cell carcinoma, squamous cell carcinoma, and melanoma. Indoor tanning exposes the skin to a spectrum of ultra violet (UV) radiation that creates a cosmetic tanning of the skin. This exposure also induces mutations in the skin cell's deoxyribonucleic acid (DNA) leading to the development of skin cancers. The use of indoor tanning has increased the prevalence of skin cancers at an earlier age. Besides the known risk of skin cancers, individuals using sunlamps or sunbeds are at risk for premature skin aging, developing cataracts, photokeratitis (arc eye), and immunosuppression. Sunlamps and sunbeds are occasionally used in the treatment of psoriasis and vitamin D deficiency. This treatment is not intended for cosmetic self-use and is only used under strict medical supervision. There has been an increase in indoor tanning use since the first sunbed was brought to the United States in 1979. Women between the ages of 18 and 29 years old are most likely to regularly use indoor tanning methods, and are at highest risk for skin cancers at earlier ages. The use of sunbeds and sunlamps can become addictive in nature. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM) outlines how to diagnose dependencies, which are modifiable for the diagnosis of indoor tanning dependence and abuse. Guidelines and regulations on sunbed use, along with education on their dangers, are needed to decrease sunbed use, and thus decrease the risk of skin cancers.

**UV Exposure**

Sunbeds and sunlamps are methods of indoor tanning that individuals use to attain a cosmetic tanning of their skin. The amount of cosmetic tanning depends on the individual's skin phototype, likelihood of sunburn, and melanocyte class. Those who always burn tend not to tan, and those who are melano-compromised will burn in both natural and artificial UV exposure. Sunlamps create a tanning effect in the skin by emitting UV radiation. The bulbs used in indoor tanning are fluorescent lights with phosphor mixtures, or quartz lights that emit a spectrum of UV radiation. UV radiation is a known human carcinogen that increases risks of certain cancers. The most common UV radiation emitted from sunlamps is UVA, with a minor portion of UVB rays. The sunbed industry once claimed that sunlamp use was safer than natural sunlight because of the high degree of UVA rays. However, UVA rays are now known as a Class I carcinogen, with exposure causing an increased incidence of melanoma,
and should also be avoided. Recently, sunlamp manufacturers have started using UVB rays, in addition to UVA rays. These lights are marketed to mimic the natural solar spectrum and speed up tanning. No UVC rays should be emitted from any sunlamp. Certain sunlamps are capable of exposing individuals to UV rays that are up to five times stronger than the UV rays in midday Australia.

**Increased Risk of Skin Cancers**

Sunbed and sunlamp exposure to UV radiation increases an individual's risk of developing skin cancer via DNA mutagenesis. The use of sunlamps and sunbeds before the age of 35 has been shown to have a 75 percent increased risk of developing melanoma. Childhood exposure to UV radiation is a known risk factor for developing melanoma in adulthood. The National Institute of Health found that the incidence of melanoma among women in the United States has almost tripled during the last 30 years, positively correlated with the increased use of sunbeds. The melanomas diagnosed in recent years have become thicker and more lethal, also possibly linked to sunbed usage.

Sunbeds also expose a larger area of skin to UV radiation than sunbathing in natural sunlight. This creates a larger area for skin cancers to develop. Along with the increase in skin cancers, artificial tanning increases the risk of precancerous skin lesions, such as actinic keratosis and Bowen's disease (squamous cell carcinoma in situ). These lesions may develop into cancers, and can be risk factors for developing cancerous lesions elsewhere on the body. Certain medications and cosmetics can increase photosensitivity, causing increased damage to skin and burning with sunlamps and sunbed exposure. These products should be avoided during sunlamp use to prevent accelerated skin damage and cancer risk. Overall, sunlamps and sunbeds emit the same UV rays as the sun, a known carcinogen, thus they should be avoided or used in moderation.

**Methods to Regulate Sunbed and Sunlamp Exposure**

Each state has individual laws regulating the use of sun lamps and sunbeds for minors. The U.S. Food and Drug Administration (FDA) prohibits the indoor tanning industry to use the words “safe” and “safer than” when promoting sunbeds and sunlamps. Sunbed salons are not allowed to claim health benefits from sunbed use. The government also requires all indoor tanning salons to post warnings about the effects of UV radiation, as well as the risk to eyes if individuals do not wear protective goggles. Additional warnings required to be displayed in sunbed establishments include “no one under 18 should use sunbeds” and “sunlamps increase aging of the skin and may cause skin cancers.” Signs in commercial sunbed salons also need to include warnings that “people with skin that does not tan should not use sunbeds,” and “exposure to sunlight or sunlamps should be avoided 48 hours after previous use of a sunbed.” These warnings also need to be printed on a consent form that the client must read, sign, and date, acknowledging the risks of sunbed use.

UV protective eyewear is mandatory during the use of sunbeds and sunlamps to prevent permanent damage to vision. Additional methods to decrease UV exposure include training workers at salons to educate tanners about the risks of sunlamps, and not having unattended sunbeds. The sunbeds should also comply with the regulations set by national standards, and supply exposure recommendations based on sunlamp strength. The International Commission on Non-Ionizing Radiation Protection has developed recommendations for individuals who should avoid sunbed and sunlamps. They include individuals less than 18 years of age, individuals with melano-compromised skin types, individuals with multiple nevi or freckles, individuals with history of frequent childhood sunburns or premalignant skin lesions, and individuals who wear cosmetics or take medications that may cause photosensitivity.

**Increase in Sunlamp/Sunbed Usage**

The first sunbed was brought to the United States in 1979. Since then, indoor tanning has grown into a billion dollar industry. The increase of sunbed use is partly because of the change in culture. Popular culture promotes a tanned skin as desirable, healthy, and attractive. The tanning industry has marketed a tan as a symbol of wealth, beauty, and health. Many young women say that they feel and look better with a tan. These messages have led to an increase in sunbed use. The risk of UV exposure from sunbed and sunlamp use is increased when the bed is unregulated, at home, or if the salon staff is not
trained in educating customers about UV exposure for each type of sunbed and skin type. There is also an increase in sunbed use when salons are competing by having the lowest prices for those who tan more frequently, and offering unlimited tanning for specific amounts of time.

**Indoor Tanning Dependence**

Indoor tanning dependence can develop, with the continued use of sunlamps and sunbeds mirroring substance dependence. Dependence on indoor tanning can be identified in individuals who are frequent tanners and fail to cut back on tanning, along with tolerance, withdrawal, and physical and psychological problems. One can use a tanning-adapted model of *The Structured Clinical Interview for DSM IV Axis I Disorders* to identify individuals who have indoor tanning abuse and addictions. One method of screening for tanning dependence is using the CAGE questionnaire that is frequently used in identifying alcohol dependence. This questionnaire assesses if the tanner has ever tried to Cut back on tanning, if those around them become Annoyed with their tanning habit, if they ever feel Guilty for tanning, and if they ever woke up feeling the urge to tan (an Eye opener). Two or more affirmative answers to these questions identify a tanning dependence. Some psychiatrists consider that tanning dependence is similar to, or a component of other psychiatric disorders, such as body dysmorphic disorder and obsessive-compulsive disorder.

Theories supporting sunbed and sunlamp dependence suggest that the mechanism of dependence could be from the release of endogenous opioids during use. Other researchers have shown that tanning increases cerebral blood flow to the same areas in the brain as a drug reward. The degree of dependence can be seen when individuals risk their health after the diagnosis of a sunbed related cancer. There has been evidence of continued sunlamp use, even after the diagnosis of skin cancers, despite knowledge that this increases risks of future skin cancers. A similar model can be seen in individuals with nicotine dependence continuing to smoke after the diagnosis of lung cancers and other nicotine-related cancers.

**Conclusion**

Sunbeds and sunlamps are currently being used for cosmetic tanning of the skin, but these devices are additionally exposing users to dangerous UV radiation. The increased use of sunlamps over the years mirrors the increase in melanoma diagnosed in the United States.

These melanomas are more lethal in nature, and are occurring at younger ages, especially in women who have known sunlamp exposure. Because most skin cancers are related to UV exposure, regulating sunbed and sunlamp use can decrease the incidence of skin cancers. The need to regulate sunlamp and sunbed use is currently a nationwide issue. The FDA, along with the World Health Organization, is working to educate the population on the risks of sunlamp exposure and to eliminate the use for those under the age of 18. There is also a need to educate the public on tanning dependence.

**Sunscreen**

Exposure to ultraviolet (UV) radiation in sunlight has both beneficial and harmful effects on human health. Sunlight stimulates the synthesis of Vitamin D, sets biological rhythms, and has favorable effects on mood. On the other hand, exposure to UV radiation is also responsible for photoaging, sunburns,
and skin cancer. Sunscreens are topical agents that reflect or absorb UV radiation, and thereby help mitigate the deleterious effects of UV light. There are a variety of types of sunscreens, with some formulations better suited for a given individual than another; however, sunscreen should be used by all individuals regardless of skin type. The proper use of sunscreen is a critical component in preventing skin cancer and photoaging, and is generally regarded as having an excellent safety profile.

Public health messages have generally focused on the health hazards of excessive sun exposure. Approximately 95 percent of the UV radiation that reaches the Earth is in the form of UVA radiation, which penetrates deeply into the skin and can damage deoxyribonucleic acid (DNA) molecules, thereby promoting the generation of skin cancer and leading to photoaging. The contribution of UVA radiation to the formation of sunburn is thought to be minor, thus some sunscreens do not block UVA radiation. On the other hand, UVB radiation accounts for only 5 percent of the total UV radiation that reaches the Earth, but is the primary cause of sunburns, and includes the most biologically active wavelengths. In addition to causing sunburns, UVB is the primary determinant of hyperpigmentation, photoaging, and skin cancer.

All individuals need sunscreen, regardless of race or skin color. People of all skin types get skin cancer, with 2 to 3 million non-melanoma skin cancers and 132,000 melanoma skin cancers worldwide occurring each year. Many of these skin cancers could have been prevented by the use of sunscreen and other sun-protective measures. However, sunscreens are particularly beneficial for people with lighter skin types and those who are more susceptible to sunburns. Sunscreens should be used daily, especially when performing outdoor activities in sunny weather. Sun tanning is unsafe and is not recommended by the American Academy of Dermatology.

Types
Sunscreens can be classified into two major types: chemical (organic) and physical (inorganic). Chemical sunscreens contain a variety of special ingredients that act as filters to absorb UV radiation and convert it to a negligible amount of heat, thereby reducing the amount of UV radiation that penetrates the skin. These types of sunscreens primarily block UVB radiation; however, newer compounds also block UVA. Physical sunscreens, also referred to as sunblock, are able to reflect and scatter UV radiation from both UVA and UVB wavelengths. They contain mineral compounds such as titanium dioxide or zinc oxide, and are considered more stable and less irritating than chemical sunscreens.

However, older preparations are considered cosmetically unacceptable by many people because they produce a visible white film on the skin and do not easily wash off. Newer nanoparticle preparations produce a transparent film on the skin while maintaining a high level of UVA/UVB protection; however, the use of nanoparticle formulations of titanium dioxide or zinc oxide have raised concerns regarding the systemic absorption and toxicity of these substances.

Sunscreens are labeled using a standardized sun protective factor (SPF), which is a measure of a sunscreen's capacity to protect against UVB radiation and a sunburn. SPF is the ratio of the minimal amount of UV radiation needed to produce skin redness in sunburned and nonsunburned skin. However, SPF does not describe a sunscreen's protection against UVA radiation, which constitutes over 90 percent of the UV radiation that reaches the human skin. The American Academy of Dermatology recommends that all individuals wear sunscreen when they will be engaging in outdoor activities, even on cloudy days because more than 80 percent of the sun's harmful UV rays can still reach the skin. Sunscreens should be applied at least 15 minutes before going outdoors, applied liberally to all sun-exposed areas, and reapplied every 90 to 120 minutes. The amount necessary to cover the entire body is about one ounce, or the size of a shot glass. It is best to use a sunscreen with an SPF of 30 or higher, and because skin cancer can also form on the lips, it is recommended to also use a lip balm with an SPF of 30 or greater. Broad-spectrum sunscreens that offer both UVA and UVB protection should be used because both of these forms of UV radiation are involved in photoaging and carcinogenesis.

Efficacy and Safety
There is strong evidence to suggest that the use of sunscreen protects against various photodermatoses, such as actinic keratoses or “pre-skin cancer,” and squamous cell carcinoma. Additionally, some randomized trials have demonstrated decreased incidence of melanoma with the regular use of sunscreen, and a systematic review by the U.S. Preventive Services Task Force found that regular sunscreen use was associated with decreased squamous cell carcinoma. However, the role of sunscreen in the prevention of basal cell carcinoma (BCC) is less clear.
because some studies have demonstrated a decreased incidence of BCC, but with results that were not statistically significant. Furthermore, the use of broad-spectrum sunscreen can reduce the photodamage and photoaging associated with chronic sun exposure, such as wrinkling and pigment changes.

Most sunscreens are considered to have an excellent safety profile, with many decades of research and use without adverse side effects. Rarely, an individual may develop an allergic reaction to the components of some sunscreens, with a local irritation in the areas to which the sunscreen was applied. There have also been reports of anaphylactic reactions to the use of some sunscreens, but this is rare. Furthermore, while sun exposure is necessary for the formation of biologically active vitamin D, there is no evidence to suggest that the use of sunscreen significantly suppresses the formation of vitamin D in the skin.

Although considered safe, some sunscreens have been shown to have estrogenizing effects in animal models when used in immature rats, but hormonal effects have not been demonstrated in humans. Recently, concern has been generated because of the systemic absorption of sunscreens that contain nanoparticle formulations of zinc oxide and titanium dioxide. Animal studies have shown that these molecules can lead to the generation of reactive oxygen species when absorbed into the blood stream, and therefore lead to potential toxicity. Although studies have shown that these particles remain on the outer surface of the skin and do not undergo cutaneous absorption, it is thought that aerosol formulations that contain these nanoparticles may be inhaled and lead to systemic absorption. Nevertheless, sunscreen is widely agreed to be beneficial and contribute to prevention of skin cancer and photoaging. The U.S. Food and Drug Administration ruled that sunscreen should be exempt from sales tax in an effort to promote the use of sunscreen as a public health measure.

Surgery

Since the earliest days of medicine, surgery has been employed to treat cancer. Medical advances such as the introduction of general anesthesia, antibiotics, and blood transfusions have fostered the development of safe and effective cancer operations. Surgical therapy has evolved as the understanding of the nature of cancer has grown. Today, surgery is often used as part of a multidisciplinary approach with chemotherapy, targeted therapy, and/or radiation. Surgery has a role not just in the first line treatment of cancer, but also in its diagnosis, staging, and palliation. The earliest description of cancer was found in an Egyptian papyrus from approximately 3000 B.C.E. It describes eight patients with breast tumors, one of whom was treated with a “fire drill.” The writings of Hippocrates discuss malignant tumors, which he called karkinos, and caution that removal of even small cancers hastened the death of the patient. Roman physician Galen (2nd century C.E.) named tumors oncos, Greek for “mass” or “swelling,” and recommended widely excising them and cauterizing the base to kill the “roots of the tumor.”

The 18th century saw a number of surgeons rise to prominence while treating cancer. John Hunter, a famed surgeon of the time, believed that surgery could be curative if the cancer was localized. He remarked that “if the tumor is moveable . . . there is no impropriety in removing it.” However, surgery during this time period was risky, and often resulted in the afflicted individual’s demise. The accomplished Scottish surgeon Alexander Monro
reported a case series of 60 patients undergoing surgery for breast cancer, only two of whom survived for two years.

The development of safe anesthesia in the 1840s and the widespread adoption of antiseptic techniques developed by Joseph Lister in 1867 ushered in a new era, where surgery could be more extensive without resulting in the death of the patient. The first major cancer operation under general anesthesia is believed to have taken place in 1846, when John Collins Warren removed a patient’s cancerous salivary glands. The “century of the surgeon” marked a time when improved survival statistics and the paucity of effective systemic treatments made surgical removal the primary treatment for most cancers. During this time, many of the operations still used today were developed and refined.

The surgical philosophy at the time was exemplified in the treatment for breast cancer, perfected and widely taught by William Halstead at Johns Hopkins University in the late 19th century. He noted that patients’ cancers were more likely to recur if the tissues surrounding the breast were not excised as well. In his classic operation, known as the radical mastectomy, not only was the breast removed, but also the muscles and sometimes bones of the chest wall, as well as all the regional lymph nodes. He reported a five-year survival rate of 40 percent, which was considered excellent at the time. The resulting disfigurement, however, was significant, and it became clear that more extensive surgery did not prevent the disease from recurring in the rest of the body.

It is now understood that while many early cancers can be completely cured with surgery, the presence of circulating tumor cells in the blood and lymphatic system may also require the addition of other modalities, such as chemotherapy and radiation therapy to prevent recurrence and spread. In the case of breast cancer, as these other therapies have been developed and refined, the extent of surgery has decreased. Today, it is common for women with breast cancer to be treated with removal of the tumor and preservation of the breast, and the radical mastectomy has largely become an operation of historical interest.

Surgery for Diagnosis

Today, surgery still has a significant role in the management of cancer. Although less invasive methods such as needle biopsy are now favored for tissue diagnosis, surgical biopsy remains an important tool for tumors that are inaccessible by other means, or when needle biopsy is inconclusive. Cancers within the lung, for example, are frequently not amenable to needle biopsy. Surgical biopsy is also useful where larger pieces of tissue are required for analysis. The diagnosis of lymphoma and certain sarcomas can be exceedingly difficult to make histologically if the scaffolding in which the cells live cannot be examined as well. In some circumstances, cancer can only be diagnosed when the entire lesion is removed, and the interface between normal and malignant tissue can be examined for telltale evidence of invasion, as in follicular cancer of the thyroid gland. At times, the diagnosis of cancer requires removal of an entire organ, especially when it is located deep in the abdomen. Investigation of suspicious masses in the adrenal glands and kidneys often necessitates surgical removal of these organs with subsequent pathological examination, and cancers of the ovary and testicle are frequently diagnosed in the same way.

Surgery as First Line Therapy

Surgery remains the first line of treatment for most solid tumors. The goal of surgery is to remove the entire primary tumor with microscopically negative margins, although the amount of normal tissue that needs to be removed to ensure a negative margin varies by the type of cancer and the organ involved. Breast cancer can be considered safely removed if there are no malignant cells seen at the cut edge of the tissue, but sarcomas of the bone require a 2 to 3 centimeter margin of normal tissue, often necessitating the sacrifice of a limb. Sometimes, the involvement with cancer is too extensive, and negative margins are simply not possible. This is seen in certain abdominal malignancies, such as ovarian cancer, sarcomas and carcinoid tumors, and also in brain tumors like anaplastic astrocytomas or glioblastomas. In those situations, debulking of a tumor can help increase the efficacy of other modalities such as chemotherapy, and provide symptom relief for the patient.

Sometimes, surgery targets secondary cancerous growths in addition to the primary tumor. Once a cancer has spread to sites distant from its organ of origin, it is considered Stage 4 (metastatic). In certain types of cancer, it has been found that removal of the metastasis, especially if confined to a single
Surgery site, can produce long-term survival for patients with Stage 4 disease. Metastectomy, as the procedure is called, is most commonly used for colon cancer that has spread to the liver, and can be curative in selected cases. It is also performed for secondary tumors of the lung (most often from osteosarcoma of the bone) and of the brain (from the kidney, melanoma, and sarcomas).

Surgical excision can take the traditional form of cold steel (cutting with a knife), but can also involve other technologies. Radiofrequency ablation kills cancer cells by heating them with high frequency radio waves delivered through a probe inserted into the tumor. Liver and kidney tumors are sometimes treated in this fashion after being exposed with a traditional abdominal incision. Tumors can also be frozen with a cryoprobe, or dissolved with injected ethanol. Lasers are sometimes utilized in surgery for tumors of the brain, and also to burn away lesions in readily accessible sites such as the cervix, larynx, skin, penis, or anus.

As an adjunct to its role as the primary treatment of cancer, surgery can be used to glean information about the stage of the disease, or its extent of spread. Certain types of cancer (carcinomas) spread by traveling first to regional lymph nodes, and so sampling of these tissues has become a part of the surgical management of diseases like breast cancer and melanoma. For other cancers, sampling is not sufficient or feasible, and so removal of all the adjacent lymph nodes is necessary. This is called a lymphadenectomy, and is usually done during the primary surgery. Other types of surgical staging also exist. Abdominal exploration still remains the most reliable way to stage many abdominal malignancies, such as ovarian and pancreatic cancer, even though imaging modalities such as computed tomography (CT) scan and magnetic resonance imaging (MRI) have improved the ability to detect disease outside of the primary organ. Similarly, thoracic surgery is sometimes needed to confirm secondary spread of cancer to the lung and its lining.

**Minimally Invasive Surgery**

Although cancer surgery has traditionally been considered maximally invasive, with large incisions into body cavities, increasingly more is being done with modalities that minimize the insult to the body. Laparoscopic surgery, utilizing ports placed into multiple small incisions through which a camera and a variety of instruments can be introduced, was first pioneered in the 1980s and popularized for the removal of the gallbladder. Laparoscopic techniques have since been applied to many oncologic procedures, and now intestines, kidneys, adrenal glands, and many other organs have been laparoscopically removed for the treatment of cancer. Robotic surgery, in which the instruments and camera are controlled by the surgeon at a bedside console, takes this a step further, and has been embraced in areas of the body where laparoscopy is more technically challenging, such as prostate, rectal, and gynecologic pelvic surgery. Endoscopic surgery, in which a flexible camera is inserted into an orifice, has revolutionized the treatment of small tumors of the urinary, digestive, and respiratory tracts, allowing their removal without external incisions.

*Surgery remains the first line of treatment for solid tumors and can often target secondary cancerous growths in addition to the primary tumor. (National Cancer Institute)*
Surgery and Other Treatment Modalities
In addition to being the primary treatment for many cancers, surgery can be used to aid delivery of other modalities of treatment. The simplest example of this is the placement of indwelling intravenous catheters into the large veins close to the heart in order to allow safe infusion of chemotherapy agents. Sometimes, chemotherapy is not systemically given to the whole body, but rather directed at the affected organ or limb. This requires placement of specialized catheters directly into adjacent arteries or veins. For the treatment of liver tumors, an infusion pump is sometimes implanted into the abdomen to deliver chemotherapy into the arteries supplying the cancer. Chemotherapy can also be directly applied to tissues involved with cancer. Hyperthermic intraperitoneal chemotherapy is a technique in which the abdominal cavity is rinsed with a heated chemotherapy solution after all visible tumor is removed (debulking). It is used for certain advanced-stage tumors that have spread throughout the abdomen and may not be completely resectable, most commonly cancer of the appendix, ovarian cancer, and colorectal cancer. A similar technique is used in the thoracic cavity to treat mesotheliomas and other cancers affecting the lining of the lung.

The delivery of radiation therapy can also be facilitated by surgery. Brachytherapy is a form of radiotherapy in which radioactive “seeds” are introduced in or near the tumor. This is a commonly used modality in prostate and cervical cancer, in which the surgeon places the seeds directly into the involved organ with the aid of a special applicator. This is often done in lieu of removing the tumor. In other instances, the tumor is surgically removed, and one or more specialized catheters are placed in the cavity to allow subsequent delivery of the radioactive seeds. This is seen in breast cancer treatment, where radiation plays an important role in preventing recurrence after resection. In selected cases, radiation can also be directly applied to the cavity during surgery through a device temporarily introduced into the wound by the surgeon.

Reconstruction
During the treatment of cancer, the surgeon must always balance complete removal of the tumor with cosmetic and functional outcome. The ultimate goal is survival, but restoration of normal function and appearance and preservation of the quality of life of the patient is of paramount importance. In intestinal cancer surgery, bowel continuity is interrupted, and must be reconstituted to allow normal eating and elimination. Surgery for cancer of the bile ducts and pancreas results in interruption of the flow of digestive juices, and requires complex reconstruction to reestablish digestion. In surgery for breast cancer, careful placement of the incision and removing the minimum amount of tissue necessary for clear margins are used to ensure the best possible cosmetic result. Similar concerns apply for tumors of the skin, especially in the facial area. Sometimes, the operation needed to remove a cancer is so extensive that more elaborate procedures are needed to restore form and function. Cancer of the bladder may necessitate removal of that entire organ and creation of a new bladder from intestinal tissue. A diseased esophagus must be removed from the neck down to the abdomen, with a new conduit created from the patient’s stomach or intestine.

Plastic surgeons often play an important role in the treatment of cancer. Resection of large tumors involving skin, muscle, or bone can leave significant wounds that cannot be closed by conventional methods. Plastic surgery techniques of mobilizing flaps of tissue from adjacent and sometimes remote areas of the patient’s body are an indispensable tool in these situations. At times, plastic surgeons are called on to do more than close wounds; they must restore normal appearance after cancer surgery. Removal of cancers of the head and neck region can result in significant deformity and loss of function. Microvascular free flap techniques, in which portions of skin, muscle, or even bone are removed from a distant part of the body, such as the forearm, and transplanted to the facial area by connecting miniscule vessels with the aid of a microscope, have revolutionized reconstructive surgery in this area. Breast reconstruction is another advancement in which either the patient’s tissue or manmade implants are used to recreate the normal breast contour, improving quality of life in breast cancer survivors treated with mastectomy.

Palliation
Even when surgery is no longer curative, it can still have a role in improving a patient’s pain, function, and overall quality of life. Large tumors of the breast, skin, muscle, and bone that are ulcerated and painful
can be excised to treat distressing symptoms. Similarly, cancer of the colon and small intestine that have already become metastatic are removed if they cause bleeding or obstruction of the flow of bowel contents. Advanced kidney tumors are taken out to prevent pain and blood loss in the urine.

Palliative surgery goes beyond the removal of tissues involved with cancer, and can address many of the sequelae of advanced disease. Obstruction of the flow of intestinal contents can be seen in the late stages of a number of cancers, including ovarian cancer and malignancies of the stomach and bowel. This may require intestinal surgery to bypass the obstructing areas or drain the blockage through permanent openings created in the stomach or bowel. Obstructing cancers of the biliary tract can cause severe jaundice, itching, and recurrent infection, and a bypass procedure can be used to relieve these symptoms if less invasive methods fail. Transabdominal placement of feeding tubes into the stomach or small intestine often plays a role in the management of tumors causing blockage of the upper digestive tract, especially advanced tumors of the head and neck region and esophagus.

Another symptom of advanced cancer is the accumulation of malignant fluid in a patient’s body cavities. When this happens in the chest, the fluid collapses the lung and makes breathing very difficult. Surgeons can place a catheter into the chest cavity for intermittent drainage, or alternately perform an operation to obliterate the space around the lung, thus preventing reaccumulation of fluid. Cerebrospinal fluid accumulating around the brain because of obstruction by a tumor causes a rise in pressure inside the skull, resulting in headaches, nausea, and altered consciousness. It can even be life threatening. In these circumstances, a neurosurgeon can place a ventriculo-peritoneal shunt, which is a drainage tube within the skull that is then tunneled out under the patient’s skin to empty harmlessly into the abdominal cavity.

Surgeons and Cancer
From the dawn of surgery as a distinct specialty within medicine, surgeons have devoted themselves to the understanding and treatment of cancer. Many of the cancer operations that are still used today were developed in the late 19th century, and still carry the names of the surgeons who described and refined them. The German surgeon Theodore Billroth is considered one of the founding fathers of modern abdominal surgery, and pioneered the safe removal of the larynx, esophagus, and stomach for cancer. Other landmark surgeons include Jan von Mikulicz (abdominal cancers), Charles Mayo and Theodor Kocher (thyroid cancer), Frank Lahey (rectal cancer), George Crile, Roswell Park, and Hayes Martin (head and neck cancer), and John G. Clark and Ernst Wertheim (cervical cancer).

Today, surgeons continue to be innovators, developing new procedures for the treatment of malignancy. Sentinel lymph node biopsy is one such advancement. Up until the late 20th century, lymph node staging for breast cancer and melanoma (skin cancer) was achieved by routinely removing all of the adjacent nodes, resulting in permanent limb swelling in about 15 percent of patients. The work of Donald Morton (melanoma), David Krag, and Armando Giuliano (breast cancer) demonstrated that a gatekeeper or “sentinel” lymph node could be identified by injecting a blue dye or radiolabelled substance close to the tumor, allowing for successful staging with removal of far fewer nodes. After designing and carrying out the trials needed to prove that the new technique was safe and accurate, they were able to alter the surgical management of these diseases forever.

Practitioners of surgery have also contributed to scientific knowledge about the causes and development of cancer through work in the laboratory. The first environmental cause of cancer was described by British surgeon Percivall Pott in 1775, when he noted that cancer of the scrotum was a common disease among chimney sweeps, and he theorized that the ash and soot they were exposed to had carcinogenic properties. In the 1860s, German surgeon Karl Thiersch showed that cancers metastasize (spread) through circulating malignant cells, and not through a liquid, as was thought at the time. In England, Stephen Paget noted that while cancer cells could travel in the blood and lymphatics, they could only grow in certain organs. He gave the inspired analogy of metastatic cancer cells as “seeds (that) are carried in all directions, but they can only live and grow if they fall on congenial soil.”

Surgeons who specialize in cancer care are known as surgical oncologists, and have usually undertaken an extra two or three years of focused training beyond general surgery residency. The surgical subspecialties such as orthopedics,
The Future of Cancer Surgery

Advances in surgical techniques, medical technology, and the understanding of human physiology are enabling cancer operations unfathomable in the time of Halstead and Billroth. Cancers previously considered unresectable are now becoming targets of curative surgery. Minimally invasive techniques are applied to large cancer operations, and procedures previously considered highly risky, like removal and reconstruction of large blood vessels involved with cancer, are becoming more commonplace. This is a reflection not only of newer technology and improved outcomes because of better surgical care, but also of the development of more effective chemotherapy and radiation. Application of these therapies before surgery can shrink tumors and improve the chance of complete removal. Additionally, for complex surgical procedures such as those for the treatment of pancreatic cancer, outcomes are closely related to surgical and institutional volumes. This has spurred an initiative to direct those patients to high-volume “centers of excellence,” and is expected to continue to improve outcomes for these types of procedures.

At the same time that some cancers are treated with increasingly complex operations, others are requiring less surgery. A multimodality approach, in which local therapies such as surgery and radiation and systemic therapy like chemotherapy are utilized together, has been very successful in the management of many cancers. The extent of surgery for lymph node spread in breast cancer, for example, continues to decrease as these therapies are used more effectively together. As the understanding of the biology of cancer improves, so does the ability to predict which patients will benefit from more aggressive surgery, and which will not. Ultimately molecular analysis of an individual’s tumor will allow surgical and other therapies to be tailored to provide the best chance of cure.

Survivors of Cancer

The past 30 years have seen a dramatic increase in the survival rates of most types of cancer, and cancer in general, in the United States. This has resulted in an increased interest in survivors of cancer, the long-term effects of the illness and its treatment, and how survivors view themselves. The National Cancer Institute’s recent Surveillance, Epidemiology, and End Results (SEER) report indicates that the five-year survival for all cancers is now above 66 percent. Survival rates for several of the most common cancers among adults, such as breast, colorectal, and prostate cancer, are now at 89, 65, and 99 percent, respectively. By comparison, in 1985, the survival rates for breast (78 percent),
colorectal (58 percent), and prostate (75 percent) cancers were lower. The increasing survivability of most types of cancer has generated a new discourse on cancer, one that focuses on living with cancer, rather than dying from it, and has changed the orientation from victimization to survivorship.

**From Victim**

When long-term survival from cancer was rare, the notion of survivorship was unrealistic for most diagnosed with cancer. For many patients, their families, and friends, the diagnosis was considered a death sentence. Cancer patients often chose to hide their diagnoses from others for as long as possible out of fear of negative responses and possible discrimination. As Paul Little and colleagues note, “A few decades ago, cancer illness was a topic shrouded in social silence . . .” In fact, many could not or would not even use the word “cancer” when discussing the illness. Even with increasing survival rates, public perceptions have lagged behind the realities of medical progress.

Research by Gary Deimling and colleagues at the Cancer Survivor Research Program (CSRP) found that as recently as 15 years ago, the “victim” label was endorsed by nearly 30 percent of older adults in their study of older adults previously diagnosed with cancer. However, even as perceptions of victimization have faded over time, there continue to be negative psycho-social responses to cancer that persist. Some of these are related to the individual's sense of self and identity.

Cancer may also have an impact on the self and identity by placing strain on core roles, such as spousal and parental roles. This type of role strain is more likely, and may be especially problematic, if cancer has caused long-term disability. Research has documented the long-term impact of cancer on physical functioning. This may be the result from the effects of the disease itself, or the greater number of health problems/comorbidities and illness symptoms that survivors report that result from treatment. During or after treatment, cancer patients may also experience difficulty with or a loss of other valued roles and activities. These may include work, hobbies, and recreation and social activities. This loss of valued roles may be compounded for older adults who have faced other role losses that are traditionally associated with aging (e.g., retirement, or the death of a spouse). Sex-specific cancers such as breast or prostate cancer may impact aspects of the self through gender identity, especially if cancer or its treatment impact sexual performance/satisfaction or body image. To the degree that those diagnosed with cancer believe that their behaviors may have increased their susceptibility to the disease (e.g., smoking and lung cancer, diet and colon cancer), the resulting self-blame can have a negative impact on their self-esteem. Self-blame may be heightened by feelings of stigma they perceive in the reactions of others to their illness.

In addition to the potentially negative effects of cancer on the individual's sense of self, research on the psychosocial effects of cancer has documented that cancer-related worries persist among those who have survived cancer, even those who have survived for an extended period, and even after recurrence is unlikely. Importantly, cancer-related worries have been shown to be linked to broader mental health effects, such as depression and anxiety.

**Toward Survivorship**

Fortunately, the emphasis on the long-term difficulties and vulnerability of survivors is being replaced by a focus on survivorship. The concept of survivorship has its origins in the mid-1980s, in Fitzhugh Mullan's paper, “Seasons of Survival.” Organizations such as the American Cancer Society (ACS), National Coalition of Cancer Survivorship (NCCS), and the Office of Cancer Survivorship (OCS) of the National Cancer Institute (NCI) have helped to reinforce a survivor orientation. As defined by the OCS, a cancer survivor is “anyone who has survived even one day after diagnosis.” Research at the CSRP has reported that well over three-fourths of long-term survivors studied by that group have adopted this label when referring to their cancer experience. The emergence of the cancer survivor label to describe those who have been diagnosed with cancer provides another perspective on their illness, one that focuses on the more optimistic, and for most a more realistic outcome. Even for types of cancer that are not curable, many are highly treatable, altering perceptions that some forms of cancer are chronic.

The portrayal of survivorship in the media that has brought celebrity survivors into the public discussion of the illness (e.g., cyclist Lance Armstrong, and singer/songwriter Sheryl Crow) has served to further promote the adoption of the
survivorship orientation by the general public and those who have had cancer. This is a change toward a celebration of survival, rather than focusing on stigma and victimization. This allows those who have survived cancer to join the growing number of high-profile survivors, and to some degree see themselves as a celebrity. Research has shown that the positive orientation that survivorship engenders can have the added health benefit of reinforcing ongoing relationships with their primary care providers, promoting more careful symptom monitoring, and engendering a focus on better health maintenance.

Moreover, cancer may be viewed as an opportunity for personal growth and improved wellbeing, and can motivate reintegration of the self. Phrases such as “self-transformation” and “reformulation of identity” have been used to describe the cancer experience. Based on his research, Bradley Zebrack quotes a survivor who reflects on the integrative aspects of the experience by saying, “for a long time now, maybe four or five years, cancer has felt like it’s been part of a quilt . . . one of those patches is cancer.” As survivors are able to return to effective and enjoyable participation in previously valued roles and activities, a sense of identity continuity may return, which in turn can enhance overall quality of life. Further, the adoption of the survivor identity may have important implications in terms of the distress that continues to be experienced by many survivors, even long after the completion of treatment. Viewing oneself as a survivor may help to buffer an individual from a preoccupation with cancer-related worries, and as a result may play a role in reducing anxiety and depression.

Much of the above identifies the positive aspects of a survival/survivorship orientation among individuals who have had cancer. However, a darker side has also emerged with the growth of the survivorship orientation in public discourse. Some have suggested that the survivor label or identity ignores the inherent uncertainty of the cancer experience, and may be rejected by many because of realistic fears of recurrence, or another type of cancer. For others, cancer survival may come with a responsibility to present one’s self as a role model to other individuals with the disease, or to “survive well.” It may also generate a sense of obligation to share their survival experience with others. Not every survivor is ready or willing to accept these responsibilities.

Into the Future
The general public’s and survivors’ adoption of the orientation and language of survival/survivorship has broader implications for the quality of life after cancer. With the shift from cancer victimization toward a focus on cancer as a survivable, or even a transformative illness, those diagnosed with the disease are provided with a new way of viewing themselves and their future. This suggests that a shift in the discourse on cancer, focused on survival and survivorship, is important, complex, and pervasive. As Cynthia Mathieson notes, the major challenge now faced by those who survive cancer is “the work of living with cancer.”

Survivors of Cancer, Families of

Finding out that a family member or loved one has cancer brings forth questions without immediate answers. How serious is this? Will they survive? What will the treatment be like? How will we manage? Who will assume the responsibilities of the diagnosed individual? Will they die? Families of cancer survivors find themselves in new roles, beginning as support systems and caregivers, throughout a process that challenges and redefines relationships, resources, spirituality, and roles. Children, parents,
spouses, and others become caregivers who need to multitask to process feelings about the person, the relationship, and the future while questioning their mortality. Many survive their cancer diagnosis with early detection and treatment. Recurrence is possible, and the word *remission* becomes filled with reassurance, but not as much as another, “cured.” Caregivers find their roles, family reconfiguration, and the return to previous norms challenged when the surviving member returns to their previous roles. Can individuals involved discuss their shared experiences and feelings? Will they be surprised again? How can I be angry with someone who has recovered from so much? How will I recover? What is the new normal? Can things ever be the same? Should they return to the way they were before, PC (pre-cancer)?

**Diagnosis**

Cancer can affect a tiny baby or a family elder. Surviving cancer is a medical success, yet there can be layers of loss, from a person’s fertility to a sense of immortality grabbed and replaced with awareness of one’s vulnerability and eventual mortality. A cancer diagnosis can bring seemingly endless fear to the person impacted, as well as affected friends and family. A range of overlapping and contradictory expectations arises in regard to what will unfold. Details about the diagnosis and prognosis may seem confusing. One hopes for the best outcome, but fears the worst. Support of the person diagnosed competes with self-protection by the loved ones who hope for the best, but begin mourning when they learn the news.

**New Beginning**

Surviving cancer treatment is multifaceted for the person recovering, as well as family members who are adjusting to their new roles and feelings. The person who is returning home with a positive prognosis needs to regain their strength and health, and to keep track of their symptoms and side effects from ongoing or recently completed treatment. They are likely to have conflicting feelings of wanting to put cancer behind them while being fearful of a recurrence. Family members are likely to feel awkward in trying to be thoughtful while taking their cues regarding expectations and degrees of intimacy as the recovering individual tries to answer these same questions. Recovery from cancer can impact how a person rejoins the family. Can they pick up where they left off? Can the wish to have a child be fulfilled? What are the fertility options? How has one’s body been impacted by the cancer treatments? Will they be desirable to an existing or future partner with a body that may bear scars? Family plans may be changed because of physical changes, financial burdens, and limitations in the cancer survivor. These can be challenging to family members who may experience frustration and anger while also wishing to be supportive and grateful that their loved one survived.

**Surviving Cancer as a Family**

Cancer is a very personal experience, replete with unknowns. Will one survive, die, or have a recurrence? Such challenging questions are often too great to pose. Cancer survival within a family can range from a prognosis of low to high risk of recurrence, or a very immediate health decline, which will quickly result in death. Regardless of the bounty of individuals providing support, someone diagnosed with cancer can experience a sequential journey, much like Elisabeth Kübler-Ross’ Five Stages of Grief, while anticipating treatment, life expectancy, losses, and feelings of being utterly alone, even within a crowd. This can be very challenging for spouses and children, as well as other family members who want to help, to be comforted about their reactions to the diagnosis and their fears of losing their loved one. To whom can a child turn for comfort about the diagnosis and journey of their primary caregiver? How can a parent process their feelings while addressing the needs of a dying child? Internal battles, as well as external ones, can prevail as one tries to balance personal needs with efforts to support the family member.

While all feelings are real, the family unit can be best served by acknowledging the disruption, dissonance, grief, and fear they share, consoling each other while prioritizing their wishes to be of support, as needed, when the diagnosed individual is ready. Small children and others may find this especially challenging. Frustrations may arise for the others involved in this family crisis; it can also be reassuring to be perceived as the source of strength and center of the family unit. The journey may be especially challenging as family wholeness and balance is sought. It is tempting to act as if everything is fine and normal, as it was prior to the intrusion of
the diagnosis and treatment. However, everything is different for the survivor and many others within the family. The fears and doubts ignited are not easily extinguished or reduced.

**Family Supports**
Regardless of the volumes of information published or preparation offered by professionals, changes in family dynamics and functioning will gradually unfold as challenges and successes present themselves. Working with professionals and peer-support groups of others who have been through this journey or are also experiencing recovery, caregiving, or grief, at the same or another stage can be beneficial for everyone. Outsiders with distance and perspective would do well to encourage the survivor and family to seek support during this complicated journey post treatment and a prognosis absent guarantees. While it is common to feel that one should know how to act or feel, it is more likely one will not know what to do in such a life-altering situation. The family unit experienced a frightening challenge to their future, social roles, goals, and dreams. How secure should they be about the future? Will there be another recurrence? Will it be the same cancer and/or in a different place, or another? Like many others, these unknowns can become part of family functioning as life moves forward.

**Planning a Future as a Family**
It is not uncommon for someone post diagnosis and treatment to feel depression and anxiety following their frightening life challenge. However, one can emerge from this experience with a new attitude and optimism about life and goals. Many who have survived cancer find that they wish to help others, create positive changes in their life, and become supportive of others with cancer or in other ways that may have long been of interest, but on the back burner for a time when scheduling would be easier. Such a life-altering experience presents choices and rethinking what one really wants to do with the rest of their life. Such a sudden diagnosis often presents one with a previously unanticipated mortality, a very personal consideration about their life’s end and urgent decisions. Regardless of the official prognosis, complicated by a plethora of unknowns, planning a future can include a variety of elements. Every minute takes on a new meaning, for the patient as well as friends and family members who most likely take their cues from the patient. How do they feel physically and emotionally? Will life ever be the same? Should it?

**Confusion About Death**
The unknowns of cancer can change everything or nothing. Some already live with optimism, not taking a moment for granted. Others lose track of moments, months, and years, which blend together without a review of personal choices. When a family member is diagnosed, they may die soon, from another malady, or after a full life. Mourning often begins at the moment of diagnosis, and the person with cancer, as well as friends and family, may be confused about what to say, anticipate, and do. Depression may result in anyone involved, and it is not uncommon for the diagnosed individual to support their supporters by giving permission for all
feelings, inviting discussion, or providing directives of what they want regarding care and/or interactions, as well as final arrangements. Many with any serious or critical diagnosis will wish to be treated as normally as possible. Some may wish to write letters to and/or spend time with individuals of their past and/or present in order to share important (re)connections or say goodbye.

Survival of an individual within a family, or alone, may be long term (lifelong) or very brief. Death or disability may come in response to cancer. Families must be prepared for the inevitable and unknown outcome. It becomes most challenging hoping for the best while protecting oneself and making family plans as a loved one is recovering. Is it a betrayal to consider how one might parent a family alone while simultaneously hoping for and encouraging a spouse to heed the promising prognosis and focus on good and healing things? When should children be told? Are they truly ignorant of the changes within the family dynamics? Do they see physical changes and overhear details that they may comprehend, even in part? Death may not come predictably, but may later or after a recurrence. In fact, everyone will die, but the very diagnosis of cancer, whether late stage and incurable or an easily remedied and cured type, brings to mind one's mortality and that of loved ones.

**Family Roles in the Face of Cancer**

A variety of changes often occur when someone is stricken with any sort of serious illness and prolonged treatment. In the case of cancer, aggressive treatments may require support, family care, and a shift in family roles. Perhaps a child will need to bathe and attend to a parent's intimate physical needs of hygiene, dressing, side effects, and more. What changes does such a child experience in their normal life? Perhaps extracurricular activities of a school-age child will be sacrificed to become a caregiver. Perhaps the role changes will result in caregivers giving up employment or relationships, no longer able to afford their homes, resulting in much-needed personal social support. How does a family address the financial challenges when most within the United States are barely surviving on existing incomes, and now must make important choices when economics betray monthly overhead? The process of healing or dying can take an unknown period of time. How does one survive the journey? With whom can fears and plans be shared? Support groups and therapy can be of priceless benefit to all involved.

**Conclusion**

Perhaps dreams have come true, and the person diagnosed has survived cancer and treatment. They have returned to their previous lives as they were before, or are differently abled. Maybe there is a permanent physical change. Maybe there are emotional transformations that have made everyone in the family reconsider the future. Perhaps the survivor has reevaluated what they want from their life following the shocking first-hand knowledge that cancer might have ended a life seemingly out of the blue.

Families are systems, which seek equilibrium at some cost to what was for what will be. Survivors of cancer live among the caregivers who stood and acted in support, those who bore witness to the journey, took care of children, paid bills, maintained homes, spirits, and challenged their hopes and doubts to surround the healing party with optimism. Families become redefined in their journey from cancer to recovery or loss. It is the challenge of the survivors to balance grief with guilt and relief of the stress of attending to the journey of the family member. It is also a challenge to consider one's mortality and cancer risks.

Sweden

The northeastern European nation officially called the Kingdom of Sweden has roots tracing as far back as the Kalmar Union, which was a state that Queen Margaret I of Denmark formed in 1397, which included Swedish and other Scandinavian territories. Sweden was unified with Norway from 1814 to 1905, until Norway declared its sovereignty and left Sweden in its modern rendition, the Kingdom of Sweden. Before the 18th century, an incidence of cancer in Sweden was untreatable because of the lack of understanding on how to treat the disease.

In the 18th century, as surgeons across the continent became much more proficient in surgical operations involving amputations and tumor removals, the capabilities of Swedish physicians increased. As tumor removals became more technically plausible and less risky to execute, Swedish surgeons helped steadily improve the survival rate of cancer victims in the country. In contrast to the 17th-century European belief that cancer was incurable, many 18th-century surgeons in Sweden and the rest of the continent performed radical and innovative new surgeries on cancer patients in an effort to find new ways to combat the spread of the disease within the human body. For example, surgeons of the period devised a new method to treat colon cancer, by removing parts of the bowel and then rerouting portions of the abdomen.

Today, Sweden has the peak prevalence rate of cancer incidences in all of Scandinavian Europe, with 3,050 cancer incidences per 100,000 Swedish citizens. In spite of this, Sweden has some of the highest life-expectancy rates in the whole world, with the average male living to 76.5 years old, and the average female living to 81.5 years old; this is thought to be because Sweden has an excellent health care system that is well financed, and though there are not many official cancer hospitals in the country that are designated for the specific purpose of cancer care, citizens are often referred to nearby university hospitals for more focused treatments. The country has a nationwide cancer registry, established since 1958, which provides physicians with information regarding domestic trends in the disease.

The most prevalent forms of cancer in Sweden are bowel cancer, breast cancer, lung cancer, skin cancer, and malignant melanoma. Prostate, skin, and colon cancers are the most common forms of cancer incidences in males in Sweden; whereas breast, skin, and bowel cancers account for the most prevalent forms of cancer incidences in females. Within the past 15 years, the preventable diseases of skin cancer and malignant melanoma have increased in prevalence in both sexes, and account for almost 15 percent of all cancer cases in Sweden. The widespread usage of tanning beds by the Swedish population is the predominant reason for such a consistent increase in skin cancer cases in the nation. Over the past few years, incidences of lung cancer are down in females, whereas incidences of prostate cancer in males and breast cancer in females are rising, partially a result of better screening techniques.

Many famous Swedish citizens have experienced cancer. For example, Academy Award–winning actress Ingrid Bergman of Stockholm passed away from breast cancer in 1982. Anna Maria Lenngren, one of the most popular and well-known Swedish writers in the nation’s history, also died of breast cancer in 1817.

More recently, the Swedish journalist, radio host, and television anchor Jarl Martin Alfredius died in Stockholm in 2009 after succumbing to a year-long battle with prostate cancer. Sweden is known for having a very strong health care system, and is known for its quality of care and its many skilled cancer specialists who are particularly concentrated throughout the nation’s universities. For instance, Dr. Kjell Oberg lives in Uppsala, and is a foremost expert in endocrinology. He is a renowned professor at Uppsala University, for which he created the Endocrine Oncology Department where he now teaches. Also at Uppsala University is the well-known specialist Lars Pahlman, who is an expert in the field of colorectal cancer and surgery.

Switzerland

The statehood of the central European nation officially termed the Swiss Confederation traces back to 1291, when regional cantons banded together to establish a confederacy. However, the modern state of Switzerland is considered to have been established in 1848, when the nation drafted a federal constitution. Currently, Switzerland is home to a population of over 8 million citizens. Switzerland has a long history in the field of cancer treatment and research. Paracelsus, who lived from 1493 to 1541, was a Swiss doctor and chemist who is viewed as the first person to conduct methodical chemotherapy treatments on cancer patients. He compiled various chemical elements, and distributed them to cancer patients for treatment. Several years after Paracelsus's death in 1541, his students compiled his writings on chemotherapy in De Grandibus. This text contains the first reported incidences of industrial cancer, documenting incidences of lung cancer in local miners and ore smelters. Another person of note in Switzerland's history of cancer research is Theophilus Boneti, who lived from 1620 to 1689. Boneti documented nearly 50 autopsies that modern researchers believe were mortalities resulting from cancer of the breast, lung, and kidneys. Boneti is also remembered for his research regarding nonmalignant tumors.

Switzerland is also a nation where promising research is currently being conducted in the battle against cancer. Millions of Swiss francs are poured into domestic research programs every year, and donations have consistently increased annually. There are many institutions dedicated to cancer research. The Swiss Group for Clinical Cancer Research recently conducted over 40 different cancer studies in 2012 alone. The National Institute for Cancer Epidemiology Registration is a Swiss organization that monitors trends in the incidences of cancer within the nation, as well as annually observing the quality of cancer care in the country. Another notable organization is the Swiss Pediatric Oncology Group, which consists of a group of physicians, researchers, and scientists whose common goal it is to combat domestic childhood and adolescent cancer.

The Swiss experience some of the highest rates of breast, bowel, and lung cancer in the world. Nearly 40,000 new incidences of cancer are diagnosed in Switzerland every year, and there are over 15,000 cancer mortalities annually. Cancer researchers in the country currently estimate that one out of every three Swiss citizens will be diagnosed with cancer at some point in their life. Fortunately, the medical progression of early screening techniques has led researchers to believe that over 50 percent of all Swiss cancer patients can be cured of their cancer; moreover, thanks to excellent treatment facilities and highly trained specialists, even Swiss cancer patients who cannot be entirely cured of their disease can usually have it effectively contained for several years. The most prevalent incidences of cancer in Switzerland have been bowel, breast, lung, prostate, and skin cancer. Bowel, lung, and prostate cancers have been the most prominent in males; whereas bowel, breast, and lung cancers have been the most prevalent in females. In the last decade, certain cancers such as skin, cervical, and stomach cancer have seen a nationwide increase in incidence in Switzerland.

Many famous citizens of the Swiss Confederation have had cancer. The internationally acclaimed Swiss kickboxer Andy Hug died in 2000 as a result of complications arising from leukemia. Winfried Hitzfeld, who was the brother of the current manager of the national Swiss soccer team, recently passed away after succumbing to his battle with blood cancer in 2014. With some of the highest cancer incidences in Europe, Switzerland is home to numerous cancer treatment facilities and world-renowned cancer specialists. Many cancer patients travel from around the globe to receive advanced treatment techniques in Switzerland; George Harrison of the Beatles and Apple cofounder Steve Jobs...
are examples of individuals who came to Switzerland for its excellent cancer care.

Syria

Syria is an Arab country in middle eastern Asia. It is bordered by Lebanon and the Mediterranean Sea on the west, Israel on the southwest, Jordan on the south, Iraq on the east, and Turkey on the north. Syria was formed after the defeat of the Ottoman Turks during World War I. The country was under French rule after 1920, from which it gained full independence in 1946. Between 1958 and 1961, Syria united with Egypt to form the United Arab Republic. In 1970, Hafiz Al-Asad, a member of the socialist Ba’th Party, overthrew the government and brought political stability to the country. Following the death of President Al-Asad, his son Bashar Al-Asad became president in July 2000. The Syrian Civil War began in 2011, and is ongoing. The death toll among Syrian government forces, opposition forces, and civilians is estimated at 100,000. In 2014, the Syrian Opposition Coalition and Syrian regime initiated peace talks at the United Nations-sponsored Geneva II conference.

The population of Syria was 17.95 million in 2014, spread over an area of 185,180 square kilometers. In a 2006 survey, it was estimated that 90 percent of the population were Muslim, and 10 percent were Christian. The capital of Syria is Damascus. Arabic is the official and most widely spoken language in Syria. In 2011, it was estimated that the health expenditure was 3.7 percent of the gross domestic product (GDP), with approximately 1.5 physicians and 1.5 beds for every 1,000 people. Syria’s health system focuses on primary health care at the level of villages, districts, and provinces. Most private hospitals are located in big cities such as Damascus, Aleppo, Tartus, and Latakia. In 2002, the highest incidence of cancer in males was reported to be bladder and lung cancer, and in females was breast cancer, uterine cancer, and leukemia. The highest incidence was found to be in southern Syria, in Al Souida. In 2012, Rasha Deeb and Safiah Eid reported that the major reasons for developing cancer among the Syrian population were their daily habits or practices, such as the type of jobs they had, diet, and smoking.

In Syria, as in most of the Middle East, water pipe smoking is commonly practiced. This form of smoking has existed for many centuries, and involves the tobacco smoke passing through water before being inhaled. Called by different names (e.g., sheesha, hookah, narghile, or arghile), water pipe smoking is associated with various health risks, including cancer. The Syrian Society for Countering Cancer reported that 60 percent of males and 23 percent females smoked, with close to 98 percent of people affected by passive smoking. In an effort to address this issue, the Syrian government passed many laws regulating tobacco consumption. In 1996, it banned advertising of tobacco; and in 2006, it banned smoking in government offices and public transport. In 2009, President Bashar Al-Assad signed an anti-smoking law, enforced in 2010, which outlawed smoking cigarettes, cigars, and waterpipes in public spaces such as restaurants, hospitals, and cinemas.

The Damascus University Al Bairouni University Cancer Center, established in 2006, and located in Harasta, Damascus, is the largest specialized hospital for cancer in Syria. The hospital has five divisions, including radiotherapy, cancer medicine, tumor surgery, laboratories, and histopathology. It has nine specialized units dealing with breast, bone and nerve tissue, gynecological, gastrointestinal,
head and neck, leukemia, pediatric, pulmonary, and urinary tract cancers. The Al Biruni Hospital reports receiving 70 percent of all Syrian patients with tumors, with daily visits of 800 to 1,200 patients. The hospital contains 525 beds, with 21 tumor specialists, 29 surgeons, and 13 physicians in other specialties. In an article published in *The Lancet Oncology* in 2014, Dr. Paul Spiegel from the United Nations High Commissioner for Refugees (UNHCR) reported that Syrian refugees and war victims were denied cancer treatment and care because of a lack of funds.

Famous Syrians who died of cancer in recent times are actor Khaled Taja, who died at the age of 73 from lung cancer in Damascus. Taja was listed as one of the top 50 actors worldwide by *Time* magazine. Syrian actor Wafiq Al-Zaeeem passed away in 2014 after a long battle with liver cancer. Recent research emerging from Syria includes findings from Frial Nizamli, Monireh Anoosheh, and Mohammadi Essah, who used a qualitative study to understand the chemotherapy experiences of women with breast cancer. Dr. Maher Saifo, who is an assistant professor in the Department of Gastro Intestinal and Lung Service at the Damascus University Al Bairouni University Cancer Center, has published many articles about cancer in Syria. The Syrian Cancer Society, a charitable society addressing cancer in Syria, is a member of the International Union Against Cancer. The first association to support children with cancer in Syria, Battling to Smile Again (BASMA), was founded in 2006. Dr. Al Moustafa Ala-Eddin is the director of the Syrian Cancer Research Center, which is a part of the Syrian Society against Cancer. The Middle-Eastern Association for Cancer Research (MEACR) was also founded by Dr. Al Moustafa in 2009.

Taisho Pharmaceutical (Japan)

Taisho Pharmaceutical Co., Ltd. is a pharmaceutical company that is incorporated in Tokyo, Japan. The company was established in 1912 with the ultimate aim being the production of over-the-counter drugs. It was only in 1955 that the company diversified and invested in prescription drugs, research, and development. The success of the company through the years has since seen it listed at the Tokyo Stock Exchange, with principal ownership of the company being under the Uehara family.

The principal line of business for the company so far still remains over-the-counter medication, wherein it has been able to introduce and promote into the market brands such as Pabron, Lipovitan-D, and many others. In as far as successful operation in the industry is concerned, one of the most successful products that the company introduced to the industry was clarithromycin, a macrolide antibiotic. The branded drug was called Clarith and was introduced into the Japanese market in 1991. For distribution outside Japanese borders, the company licensed Abbott Laboratories to handle the distribution.

Taisho Pharmaceuticals faces competition in the industry from players such as Astellas Pharma Inc., Otsuka Pharmaceutical Inc., Chugai Pharmaceutical Company, Ltd., Mochida Pharmaceutical Co., Ltd., and Kissei Pharmaceutical Co. In 2011, the company made changes and transitioned into a holding company, Taisho Pharmaceutical Holdings Co., Ltd. This was done through a sole-share transfer.

The company has been at the forefront in pharmaceutical research in Japan for many years, and over the past few years, it has been working toward developing successful treatment alternatives for the aging population while, at the same time, making sure that these are available affordably. The country has a primarily active aging labor force, and unfortunately, it is also one of the countries in the world that has a very low birth rate.

Structural changes in the economy and the environment within which the company operates has since made it mandatory for the company to look into the possibility of changing the ultimate business sphere while, at the same time, working toward an increased and enhanced business foundation. It is as a result of this that the decision to turn the company into a holding company was made. With the intermediaries in Japan and overseas, it was necessary that this would happen sooner rather than later.

The mission of Taisho Pharmaceutical Holdings is to make sure that the population in the country and beyond is able to enjoy the benefits of the creation and availability of superior pharmaceuticals. At the same time, the company is also keen on
developing health products and health care information and services to help in enriching the lives of those within society.

Research and Development
The company focuses on three important areas to be able to meet the overall goals and missions: convenience, effects and safety. It is upon these three pillars that the structure of the company has been established along with their research and development philosophy.

Over time, the need to meet the demands of customers has become ever so important, and it is as a result of this that the company keeps studying consumer needs with respect to drugs in particular. Most of the time, consumers are looking for drugs that can be used safely, that are very effective, and that are convenient. It is upon these precepts that the company also runs the research and development section.

In as far as safety and effects are concerned, the company’s drugs have since been switched to over-the-counter drugs. In as far as convenience is concerned, Taisho Pharmaceuticals also has gone far in developing products that are convenient and able to meet the customers’ ease of use demands while, at the same time, still making sure that they are safe for use by consumers even without the presence of health care practitioners. There are three categories of over-the-counter drugs that have since been instituted by the company.

Research Center
The company’s research facility was structured near the Omiya Factory in 1974. It is here that the research and development divisions of the prescription drug section and the over-the-counter drugs are located. It is in the research facility that all the work regarding the development of prescription drugs is carried out. This includes all the work between the investigation stage and preclinical testing. The research facility also is equipped with some of the latest equipment.

Corporate Social Responsibility
The emphasis of the company lies in research in the fields of life sciences, the promotion of self-education, and the ability to contribute effectively to arts and sports as reputable members of Japanese society. There are several ways through which the company has been able to engage in social contributions to society.

Early in 1985, the Uehara Memorial Foundation was established in memory of the honorary chair of the company, Shokichi Uehara. This was in honor of his struggle to promote research in pharmaceuticals and other areas in life sciences with the ultimate aim of enriching the lives and welfare of consumers.

In line with their mission to promote life sciences, the company spends a lot of effort toward recognizing those who have made significant achievements in as far as excellent research is concerned. The company has provided scholarships to young researchers to encourage them to further their dreams either abroad or in Japan.

The company has also organized and hosted symposiums and seminars for professionals within the medical industry. The Taisho Toyama Pharmaceutical branch also has hosted annual symposiums where doctors give lectures to the professionals who are in attendance on some of the issues that are affecting the industry, most importantly, the current trends.

Taisho Pharmaceuticals is actively involved in environmental conservation, especially since the company started conducting business activities with the main aim of cutting down on emissions into the environment, in particular carbon dioxide. In line with this, Taisho Pharmaceuticals has been at the forefront in promoting energy-saving activities and addressing some of the necessary technical elements.

Taiwan

Taiwan, formerly known as Formosa, is composed of a main island (Taiwan) and several smaller islands in East Asia. Taiwan claims status as an independent nation, but this is contested by China. At east longitude between 120 and 122 degrees and north latitude between 22 and 25 degrees, with the Tropic of Cancer running through the central and southern areas, Taiwan is close to the People's Republic of China to the west, Japan to the east and northeast, and the Philippines to the south.

Taiwan has experienced multiple wars and has been occupied by different countries in different historical periods. In 1621, at the Age of Discovery, the Dutch landed in southern Taiwan (today's Tainan). They then expanded farther south and to the north. Through interracial marriages between the Dutch and the locals, their offspring spread out all over the island. In 1626, the Spaniards arrived in northern Taiwan. There were turf battles between the two powerful players of international sea trading. Decades later, Koxinga, a Chinese military leader loyal to the Ming dynasty, escaped from mainland China to Taiwan in 1661. He expelled the Dutch and Spaniards and used the Taiwan area as a base to try to overthrow the Manchu dynasty at the time. Eventually, the Manchu dynasty was able to defeat Koxinga's successors and took over the Taiwan area in 1684.

Two centuries later, the Manchus were defeated by Japan. The latter demanded possession of Taiwan and surrounding islands and signed in the Treaty of Shimonoseki in 1897. The Taiwan area then became a Japanese colony for half of a century to come. The Japanese culture had a profound impact on Taiwan's education, including medical training and research. In 1911, during Japanese colonial times, the Taipei Hospital of Taiwan Governor-General's Office had a radiotherapy unit for treating tumors that did not need surgical removal, such as early-stage cervical, vocal cord, nasopharyngeal, and so on. By doing so, patients were able to retain their original organs. This was particularly popular among the Asians due to cultural implications. Some overseas Chinese traveled to Taiwan to seek such treatment approaches.

During the 1960s, the Cancer Prevention Movement emerged. The most well-known prevention and early cancer detection method was the Papanicalauo smear, or Pap smear, promoted by Julia J. Tsuei, M.D. The Pap smear was first published by American Dr. Georgios Papanicalauo in 1943 but did not gain much attention. Through Dr. Tsuei's tireless efforts, adoption of the Pap smear is now widespread in the world. Dr. Tsuei also invented the now commonly used cervical cancer staging, which helps to detect cervical cancer early on. In fact, precancerous lesions are able to be cured nearly 100 percent of the time.

In early-day cancer research, incidence rates were measured by the number of beds of cancer patients. In 1958, Chun-Jen Shih, M.D., advocated a cancer registry by implementing his experience at the Montreal Neurological Institute of McGill University in Canada. The three major public hospitals—the Western medicine reemerge. He opened a clinic in Taiwan Fu (today's Tainan) and trained the Taiwanese as medical assistants. The clinic thrived to become the Sin-Lau Hospital (Sin-Lau means new building in Taiwanese). His son was the first superintendent of the new hospital. The hospital still exists and is a major hospital and medical research center. Dr. Maxwell started Western medical education in Taiwan. During the Japanese colonial times, Japanese-style Western medical education was implemented as well.

After World War II, American aid to Taiwan (to fight against Communist China) also infused Western medicine. Hence, medical development in Taiwan has become a prototype of blending American and Japanese experiences. Prior to 1970, like the rest of the world, for lack of effective drugs, treating tumors in Taiwan was done mostly through surgery. The common types of cancer at the time were solid tumor, such as liver, stomach, nasopharyngeal, cervical, and breast cancer.

Prior to the popularity of chemotherapy, radiotherapy was the main method for treating cancer. In 1911, during Japanese colonial times, the Taipei Hospital of Taiwan Governor-General's Office had a radiotherapy unit for treating tumors that did not need surgical removal, such as early-stage cervical, vocal cord, nasopharyngeal, and so on. By doing so, patients were able to retain their original organs. This was particularly popular among the Asians due to cultural implications. Some overseas Chinese traveled to Taiwan to seek such treatment approaches.
Tri-Service Hospital, the Taiwan University Hospital, and the Veterans General Hospital—joined his efforts. In 1979, the Bureau of Health (today's Ministry of Health and Welfare) started a central cancer registry. The registry has achieved the standards for Registry Certification of the North American Association of Central Cancer Registries (NAACCR). The World Health Organization's (WHO's) International Agency for Research on Cancer (IARC) also includes the Taiwanese registry in the World Cancer Report. The WHO's cancer prevention initiative of 2003 also has had a long-term impact on cancer registries and effective care.

In 1984, internationally known cancer researchers Jacqueline Whang-Pend, M.D., and Cheng-Wen Wu, M.D., Ph.D., jointly pioneered a tumor specialist system. Then in 1987, the Academia Sinica established a medical oncology specialist training project. Drs. Paul Carbone, John Bennett, and B. J. Kennedy, the first wave of board-certified internal tumor specialists in the United States, were invited to help start a Taiwanese board certification program. Through this project, internationally known tumor specialists came to Taiwan to deliver the training. Both the trainers and trainees were able to interact and communicate with other medical fields. The interdisciplinary collaboration thus benefits not only the trainees but also the whole medical system in Taiwan in the area of comprehensive cancer research and treatment.

The most accomplished cancer researcher in Taiwan is Chi-Huey Wong at the Academia Sinica. He is a member of the American Academy of Arts and Sciences, the U.S. National Academy of Sciences, and the U.S. National Research Council on Chemical Sciences and Technology. He is also a recipient of numerous prestigious awards in the field of biochemistry. Dr. Wong was born in Chia-Yi (southern Taiwan). After finishing his education in Taiwan, he studied at the Massachusetts Institute of Technology (MIT) and earned his doctorate in chemistry in 1982. He then followed his mentor, George M. Whitesides, from MIT to Harvard University as a postdoctoral fellow for another year. He started his research and teaching career at Texas A&M University. In 2003, he returned to Taiwan to lead the Genomics Research Center at the Academia Sinica. His research team currently focuses on the possible correlations between cancer and carbohydrates, glycoprotein, and small-molecule probes, with the hope to develop new vaccines for treating cancer.

In addition to innovative cancer detection, treatment, and research, health insurance coverage is essential for cancer patients. The health insurance programs in Taiwan were developed incrementally by occupations that included laborers health insurance (1950), public employees health insurance (1961), and farmers health insurance (1985). Eventually in 1990, the national health insurance was implemented. Each insured patient carries an Integrated Circuit (IC) card that records office visits and medical records within the network's clinics and hospitals. The national health insurance program is particularly beneficial to cancer patients. Treating cancer is a time-consuming process, which in turn incurs economic burdens to the patients and their families. A cancer patient's IC card carries a mark of "serious illness," which means a waiver of certain medical expenses within five years of incidence. This provision has won international recognition.

Tajikistan

Tajikistan is a central Asian country of 8.0 million people that became independent following the breakup of the Soviet Union in 1991. Classified by the World Bank as a low-income country, Tajikistan spends 6.8 percent of its GDP on health care. Tajikistan's health care system was neglected during the Soviet years, with inadequate facilities and shortages of staff and supplies. However, more recently the government of Tajikistan, with assistance from the Aga Khan Development Network and other funders, has committed to a number of health promotion, disease prevention, and disease management programs, including policies to reduce tobacco use, reduce obesity, promote physical activity, and reduce harmful alcohol use. Other efforts relevant to cancer control include training members of the health care system and the indigenous population with respect to raising awareness about cancer, the different cancers that exist in society, with an emphasis on the most prevalent types, and the avoidable causes.

The Aga Khan Development Network

The Aga Khan Development Network (AKDN) provides leadership and services to help improve the health care system in Tajikistan and improve the health of the population. Among the reforms undertaken by the AKDN are the training of community health promoters; development of a national nursing curriculum; creation of a fund to provide high-quality, affordable drugs; rehabilitation of hospitals; and training of hospital staff. This includes the provision of general medical services and support for primary health care services to the population within the country. One of the main benefits that the country enjoys from working with the Aga Khan in particular is that the institution brings into play a worldwide network of policies and strategies that are applicable in cancer care and management while at the same time working with the indigenous players within the country to make sure that they are able to come up with scenarios for handling cancer in Tajikistan uniquely and for better efficiency.

Through the worldwide support network, the Aga Khan Hospital has been able to collaborate with the government and other relevant players in the industry, such as government hospitals that are located in Gorno-Badakhshan Autonomous Oblast and are able not only to rationalize but also to rehabilitate and work on improving the facilities that are available in the country for dealing with cancer effectively. This is in line with the need to provide clinical practice and services that are suitable to nursing and relevant care for cancer patients. One of the other points of note is that all of these partnerships are held in close collaboration with the other relevant Aga Khan support members, such as the Aga Khan University and the Aga Khan Foundation.

There are health care programs in place that have been designed in such a way that they are able to reach and support the vulnerable groups and communities within Tajikistan when it comes to cancer support. Of particular mention in these groups are the remote communities and the rural communities, while at the same time, they also cater to the needs of the low-middle class, urban families, and groups that are not able to gain access to the medical services that they require.

At each level of care, the Tajikistan government is committed to making sure that there is more than enough awareness, evidence-based practices, and most importantly, continuous and accurate education of health care service providers, such as doctors, nurses, and their assistants. The government has been working with a number of professionals and volunteers to help champion its support for and the need to highlight the plight of cancer support societies along with the need for awareness of cancer.

Khorog General Hospital

The Khorog General Hospital is one of the main facilities in the country that is devoted to helping the society deal with cancer in the best way possible. This hospital has a 550-bed capacity, which is supposed to cater to the more than 40,000 residents that reside in Khorog. This already indicates that the facilities are simply not big enough to be able to handle the needs of a society that keeps expanding with time.

One of the other challenges in as far as the health sector in Tajikistan is concerned is that there is never enough financing for the health sector, especially with respect to resource-intensive cases such as cancer research. There have been a lot of questions with regard to the public health sector reforms.
and in particular in regard to the commitment of the government in as far as providing primary health care at the basic level. This, coupled with the fact that there are basically insufficient treatment protocols in place at the regional levels is just one of the main concerns that the government has had to deal with over time.

Palliative care standards are lacking in Tajikistan, and as a result, there are concerns as to the effectiveness of the management of the human resources with respect to cancer research and facilities. One of the main problems that keeps coming up is the fact that preventive medicine is still a pipe dream, especially for those who are not able to afford mainstream medication or those who are not able to gain immediate access to the services that are offered to those with the capacity to afford them without requiring any support from the government.

As has been the case in so many other places, cancer can be effectively managed only if it is detected early enough and if there are procedures in place to handle the situation. However, early screening in Tajikistan is still one of the main challenges that the government has to deal with because of the lack of facilities.

Cancer alone has led to a global mortality rate of 414.6 deaths for every 100,000 people, which in Tajikistan is 33.7 for every 100,000 people, and this loosely translates to 8.1 percent of the population. More than 30,000 lives are lost every year in Tajikistan, with cancer taking close to 3,000 people annually. At close to a 10 percent fatality rate, this is a situation that is spiraling out of control unless other parties step in to help avert a crisis.

Takeda Pharmaceutical (Japan)

Takeda Pharmaceutical Co. is a Japanese pharmaceutical corporation with, as of early 2014, 31,255 employees worldwide including subsidiaries. It was, in terms of sales as of 2011, the largest Japanese pharmaceutical corporation and the 14th-largest pharmaceutical corporation in the world. Takeda has the core therapeutic areas of cardiovascular and metabolic conditions, oncology, the central nervous system, immunology and respiratory conditions, general medicine, and vaccines.

In terms of turnover, Actos (marketed as Glustin in Europe) for the treatment of type 2 diabetes has for a long time been one of the main products. In 2011, it accounted for approximately 27 percent of the corporation’s total revenues. However, it lost its exclusivity in August 2012, and the current Takeda top seller Blopress (candesartan cilexetil) for hypertension treatment sold for ¥169.6 billion compared to ¥122.9 billion for Actos/Glustin in fiscal year (FY) 2012. Other products with large-volume sales include Takepron (Prevacid in the United States) for gastric and duodenal ulcers, Leuplin (Enantone in Europe) for prostate and breast cancer and for endometriosis, and Velcade for treating multiple myeloma.

Corporate Philosophy and Recent Strategic Initiatives
Takeda started out as a seller of traditional medicines in Osaka, Japan, in 1781. After the long period of Japanese seclusion policy until the late 1800s, Takeda started importing Western medicines. The company marketed its first multivitamin in 1952 and started overseas activities in 1962. In the early 2010s, Takeda regarded its corporate development as being in a transformation period. The overall corporate philosophy is titled Takedaism and lists its core values as: ethics (the highest ethical standards), challenge (discover new potential, and make the most of one’s ingenuity), progress (pursue
individual growth, and always push oneself further), teamwork (act as a team, and develop ties of mutual trust and respect), and steadfastness (seek what matters, and embrace a simple, steady approach). The corporation implemented a Vision 2020 plan in 2011 containing a new Takeda operating model to be achieved by 2020, divided into the core principles globalization, diversity, and innovation.

Takeda pursues what it calls a holistic approach when it comes to policies for corporate social responsibility (CSR). Takeda is concerned about both creating as well as sustaining corporate values and thus strives to operate cases conducted alone as well as cases called producer-type activities together with other companies.

Takeda has in recent years acquired several other companies. In 2008, Takeda acquired the Cambridge, Massachusetts, corporation Millennium Pharmaceuticals, and the subsidiary was later called Millennium: The Takeda Oncology Company. The subsidiary has got approximately 1,200 employees. Millennium developed the first version of Velcade, one of Takeda’s current core products, approved by the Federal Drug Administration in 2008. This pipeline product, also intended for the treatment for multiple myeloma, builds on the proteasome inhibition technique, which began with Velcade and is in the development phases, called MLN9708. It was the first oral proteasome inhibitor to enter clinical trials. In 2011, Takeda acquired the Swiss company Nycomed because it was conceived of as having a strong fit with Takeda’s overall growth strategy. At the time of Takeda’s acquisition, Nycomed had approximately 11,800 employees worldwide, and it was the 29th-largest pharmaceutical company worldwide based on global sales in 2010.

The company had its own commercial network throughout most countries in Europe. Its expansion has been remarkable when it comes to its presence within fast-growing, emerging markets, and operations in these markets accounted for about 40 percent of Nycomed’s total net turnover in fiscal 2010. In addition to these business aspects, the acquisition was envisioned as beneficial to Takeda’s efforts at achieving an internationalized corporate culture through the injection of diverse talents. Some other acquisitions and efforts at reorganizing include the 2005 acquisition of the San Diego-based company Syrrx, specializing in X-ray crystallography, and the 2008 acquisition of TAP Pharmaceutical Products. The latter was formed in 1977 as a joint venture between Takeda and Abbott Laboratories. Abbott, acquired in 2008, split the U.S. rights to the drug Lupron, whereas Takeda received rights to both the marketed drug Prevacid as well as TAP’s pipeline candidates. In 2012, Takeda acquired Philadelphia-based URL Pharma. The motive behind this acquisition is said to be obtaining the gout therapy drug Colcrys, and the non-Colcrys generic business was subsequently spun out to a subsidiary of Sun Pharmaceutical. Takeda also purchased the Brazilian pharmaceutical company Multilab in 2012.

Research and Development
Takeda’s expenditures for research and development (R&D) were 20.8 percent in FY 2012, when calculated as a percentage in relation to total sales. This was a slight increase from the previous year. There were 21 different R&D sites worldwide as of 2013, whereas the global research network hub is considered to be the Shonan Research Center, established in eastern Japan in 2011. It is a combination of functions previously held by the former Tsukuba Research Center and the Osaka Research Center. Takeda announced a new organizational framework regarding R&D in May 2013. Within this framework, a chief medical and scientific officer would lead the global R&D organization, and the oncology R&D function of Millennium Pharmaceuticals would be integrated into the global R&D organization. This move was...
considered to be in line with Takeda's commitment to enhance R&D operational excellence worldwide. Takeda also has efforts aimed at accelerating innovation in drug discovery. One such effort is to attempt a diversification of methods for identifying novel targets by way of harnessing the basic technologies that they acquire through partnerships.

One recent controversy involving Takeda concerns the 2011 release by the U.S. Federal Drug Administration warning that using Actos for more than a year may be associated with an increased risk of bladder cancer. The first Actos-related bladder cancer suits were filed the same year.

Tamoxifen

Breast cancer represents the most common malignancy for women in the United States, with 70 percent of these breast cancers being estrogen receptor positive. For this reason, many therapies focus on hormonal ablation, antagonism of estrogen receptor signaling, and inhibition of estrogen synthesis. The drug tamoxifen treats hormone receptor-positive breast cancer after an individual undergoes surgery for complete removal of the breast cancer. This medication lowers the chance of cancer returning later, reduces the risk of a new cancer in the other breast, and prolongs survival after the initial episode of cancer. Tamoxifen falls into the category of a nonsteroidal antiestrogen drug (called selective estrogen receptor modulators [SERMs]) that thwarts the effects of estrogens in tissues. The exact mechanism of action remains unknown, but it is thought to connect with and blockade estrogen receptors on the surface of cells, precluding estrogens from binding and stimulating the cell. The Food and Drug Administration (FDA) reviewed the first formulation of tamoxifen in December 1977. The original multiple uses of tamoxifen ranged from preventing breast cancer in high-risk women (up to 50 percent in individuals 35 years and older); lowering the risk of acquiring invasive breast cancer in women with ductal cancer in situ (DCIS); preventing cancer from returning after aggressive treatment with surgery, radiation, and chemotherapy; and dealing with advanced breast cancer.

Examples of chemopreventives that have exhibited anti-promotional activity include tamoxifen (an antiestrogen), retinoids, and carotenoids, which are also inhibitors of proliferation.

Historical Background
Researchers described the initial notion of SERMs action first in the late 1980s and later on perfected and defined it as a balance of receptors and co-regulators. A cooperative group of physicians in the United States formed to carry out clinical trials on individuals with breast and colorectal cancer. This trial became known as the National Surgical Adjuvant Breast and Bowel Project (NSABP). From April 1992 to 1998, the NSABP group studied 13,388 women and discovered that women with a high risk of breast cancer could significantly reduce the risk of developing the condition by taking tamoxifen.

A second key breast cancer prevention trial started in 1998, titled Phase III Randomized Study of Tamoxifen and Raloxifene (STAR), and compared
Raloxifene to tamoxifen in preventing breast cancer in postmenopausal women. V. G. Vogel and colleagues published results showing that raloxifene and tamoxifen equally reduce the chance of developing invasive breast cancer, but raloxifene demonstrates a reduced risk of side effects and a higher risk of noninvasive breast cancer. In 2010, Vogel and colleagues published a longer-term follow-up of the STAR study. The results demonstrated that both raloxifene and tamoxifen represent good choices for prevention of breast cancer for postmenopausal women.

Since the earlier trials, aromatase inhibitors came into being to treat postmenopausal patients, but tamoxifen continues to be an inexpensive, lifesaving drug for premenopausal patients. Breast cancer returns, so patients need to continue adjuvant tamoxifen for five years to reduce recurrence by 50 percent. The effect of tamoxifen continues long after the first five years, but the issue of resistance contributes to breast cancer returning. C. Davies and colleagues recently showed that continuing tamoxifen to more than 10 years further reduces recurrence and mortality.

How Does the Drug Work?
As a unique form of a hormone drug, tamoxifen attaches to estrogen receptors in the body, where it prevents the action of estrogen. The drug is referred to as antiestrogen or a SERM. It works efficiently in breast cancers that need estrogen to grow because, with tamoxifen present to block the receptors, the cancer cells cannot get estrogen, and then the cancer stops growing and dies. Of course, tamoxifen works only for breast cancers that are estrogen-receptor positive. Remarkably, while the drug produces antiestrogen activity in the breast, it operates like an estrogen in the bones and the endometrium, or surface of the uterus. Biochemically, tamoxifen produces its cytotoxic influence primarily through cytostasis, a process associated with the accretion of cells in the G0/G1 phase of the cell cycle. Apoptotic activity also can be triggered by tamoxifen and involves cleavage of caspase 9, caspase 7, caspase 3, and poly-ADP-ribose polymerase (PARP). Downregulation of antiapoptotic proteins Bcl-2 and Bcl-XL and upregulation of proapoptotic proteins Bax and Bak appear to also occur.

Researchers explained the importance of the enzyme pathway of CYP 2D6 for tamoxifen. Tamoxifen activation transpires through two pathways to the final active form of endoxifen, a product 10- to 100-fold more efficient in obstructing estrogen receptors than tamoxifen. The primary channel ensues first through N-desmethyI tamoxifen (NDM) via CYP 3A and subsequently endoxifen through CYP 2D6. The lesser pathway encompasses 4-hydroxytamoxifen through CYP 2D6, CYP 2B6, CYP 2C9, and CYP 2C19, and consequently to endoxifen through CYP 3A. The meaning of CYP 2D6 genotypes for tamoxifen therapy to treat disease and monitor relapse-free survival for breast cancer remains an ongoing debate due to studies demonstrating both benefits and no value. R. Ter Heine and colleagues developed population pharmacokinetic models showing that not only CYP 2D6 but also CYP 3A enzyme activity affects the change of tamoxifen to the metabolite endoxifen in breast cancer patients.

According to researchers, if pharmacogenomics testing for tamoxifen became routinely available, patients with poor metabolizing of the drug could be switched to a different medication (like aromatase inhibitors) after the onset of treatment. In the scenario with premenopausal patients who are extensive metabolizers and receiving tamoxifen, therapeutic drug monitoring for endoxifen steady state could be used to predict outcomes.

S. Darakhshan, A. Bidmeshkipour, K. Mansouri, H. M. Saeid, and A. Ghanbari carried out studies in vitro on the effect of tamoxifen and the antiallergic tranilast drugs on CXCL12 and CXCR4. CXCL12 and CXCR4 enzymes both increase survival and proliferation of malignant cells. This preliminary work demonstrated that tranilast elevated the anti metastatic effect of tamoxifen. The research showed that the synergistic action of tranilast fails to be estrogen dependent. The data further suggests that CXCL12 and CXCR4 are key targets for drug therapy.

How Effectively Does Tamoxifen Work?
Tamoxifen effectively lowers the risk of the breast cancer recurrence, especially in women with one breast already removed. Researchers found a two-stage treatment with two different drugs may be a superior treatment in postmenopausal women. First, tamoxifen is given, followed by an aromatase inhibitor (e.g., anastrozole, exemestane, or letrozole).

Research shows that age influences the effectiveness of tamoxifen. Females less than 40 years old exhibit the least response to the drug, ages 40 to 50 years show some response, and women over
Tamoxifen

50 years profit the most from tamoxifen. As a matter of fact, early-stage breast cancer patients over age 50 years treated with the drug before surgery may reduce the tumor size so much that a lumpectomy can be performed instead of a mastectomy. In addition to preventing breast cancer recurrence, tamoxifen exhibits beneficial estrogenic effects. Tamoxifen reduces serum cholesterol and safeguards against bone loss and cardiovascular disease.

Prognostic Biomarkers for Tamoxifen Resistance
Recent research by T. Gao and colleagues explored the prognostic capability of the gene CCNA2 in estrogen receptor positive (ER+) breast cancer. CCNA1, or CyclinA2, present in almost all tissues in the human body, plays a key role in the control of the cell cycle. Previous research demonstrates the overexpression of the gene CCNA2 in literally dozens of cancer types, indicating its possible role in cancer transformation and progression. Gao and colleagues showed the predictive power of CCNAs in survival of ER+ breast cancer and closely associated with tamoxifen resistance. Their research suggests that CCNA2 is a biomarker for the prognosis of ER+ breast cancer and the monitoring of tamoxifen efficacy. Multicenter, randomized, controlled clinical trials still will be needed before this finding can be used in the clinical arena.

Possible Side Effects
Discussion with the health care provider must occur prior to prescribing tamoxifen to determine the risks and benefits of the treatment. The benefits need to outweigh the risks. The provider also needs to cover all the possible side effects that may occur with the medication so that the patient truly can make an informed decision about whether to take the medication. Common side effects consist of hot flashes and sweating, which occurs in about 45 percent of women on the drug; premenopausal women can experience irregular periods or stopping of their periods (periods start again after treatment ends); vaginal dryness, discharge, or itching transpires in 10 percent of women; fatigue occurs in 25 percent of women; light-headedness; eye problems such as cataracts and eyesight changes can occur; and diminished sex drive has been reported.

In about 10 in 100 people, occasional adverse effects occur. Fluid can build up in the ankles or fingers, causing swelling or weight gain. The sensation of feeling or being sick can take place at the initiation of treatment with tamoxifen but usually subsides after a few days to weeks. Tamoxifen can alter components of the blood (e.g., thrombocytopenia, leukopenia, or neutropenia). About 10 percent of individuals exhibit a change in their mood that produces sadness or depression. Hair thinning ensues in some individuals but generally triggers only slight, nonnoticeable hair loss. Individuals on tamoxifen may complain of bone pain or pain in the area of the tumor. Headache and leg cramps ensue in some individuals. Walking or stretching the muscles helps relieve leg cramps.

Rare side effects transpire in less than one in 100 people. Serious or life-threatening, but less likely, side effects include blood clots within the blood vessels of the eyes, damage to the retina of the eye, blood clots in the legs or lungs, stroke, ovarian cysts, liver abnormalities (hepatitis), liver cancer, and cancer of the lining of the uterus. Because ovarian cysts and cancer of the lining of the uterus possibly arise, patients are advised to undergo annual pelvic examinations yearly or more often.

Negative Interactions With Other Drugs
Tamoxifen possesses the ability to interact with other drugs that cause a lowering of the effectiveness of the tamoxifen, altering the efficacy of the other drug or producing a negative consequence in the human body.

Practitioners use selective serotonin reuptake inhibitors (SSRIs) to reduce the side effects of menopause, but unfortunately, this drug group blocks the CYP2D6 enzyme that activates tamoxifen to the more active endoxifen, leading to an increase in mortality. The effectiveness of tamoxifen can be reduced by as much as 40 percent. The drug fluoxetine, used for depression, also acts on the CYP2D6 enzyme and produces a decrease in efficacy of tamoxifen. This problem can be remedied easily by switching to venlafaxine, a selective norepinephrine reuptake inhibitor (SNRI). A Canadian study showed that venlafaxine decreased the mortality in breast cancer.

J. P. Kitzmiller, D. K. Groen, M. A. Phelps, and W. Sadee describe the inhibition of CYP2D6 by many different drugs. The drugs known to inhibit CYP2D6 and decrease the effectiveness of tamoxifen include the following:
C. B. Givens, D. K. Groen, M. A. Phelps, and W. Sadee carried out a systematic review of the literature on warfarin and tamoxifen. Patients concomitantly receiving both warfarin and tamoxifen demonstrate a higher risk of bleeding episodes. The exact mechanism of the interaction of the two drugs remains unknown, but one theory purports that tamoxifen inhibits the CYP2C9 enzyme involved in the metabolism of the S-isomer of warfarin. The combined use of the two drugs remains contraindicated, but if given together, highly vigilant and careful monitoring must be enforced. Recently, H. Ruhl and colleagues studied tamoxifen-induced activated protein C (APC) resistance. Researchers measured blood levels of APC before adjuvant treatment with tamoxifen for breast cancer on 25 women and monthly after treatment initiation. The study showed for the first time acquired APC resistance with tamoxifen use. Scientists believe the acquired APC resistance might explain the elevated thrombotic risk with tamoxifen treatment. Further research is needed to evaluate this effect.

A. Patel, E. B. Schwarz, and the Society of Family Planning published guidelines on contraceptive practices among breast cancer survivors using tamoxifen. Women of childbearing age, being treated for cancer, are advised to stay away from mixed hormonal contraceptive methods (containing estrogen and progestin) as these further elevate the risk of venous thromboembolism. Of course, the recommended contraceptive for individuals taking tamoxifen is the levonorgestrel-containing intrauterine system (IUS) because it reduces endometrial proliferation (a side effect of tamoxifen).

Recently, the FDA approved paroxetine (brand names: Brisdelle and Noven) in a dosage of 7.5 milligrams (mg) for menopausal hot flashes despite the fact that this drug interacts negatively with tamoxifen. Paroxetine strongly inhibits the cytochrome P-450 CYP2D6 enzyme. According to R. J. Orleans and colleagues, this enzyme converts tamoxifen to endoxifen, an important metabolite for the pharmacological activity of tamoxifen. Research shows that the concomitant administration of paroxetine (10 mg per day) in females using tamoxifen can reduce the plasma concentrations of endoxifen to 64 percent, but the risk of breast cancer relapse and death remains unknown.

Researchers studied the influence of Chinese herbal products (CHP) and tamoxifen intake on endometrial cancer risk among female breast cancer subjects. Y. T. Tsai, J. N. Lai, and C. T. Wu used a population-based study of 20,466 subjects to look at this interaction. Half of the subjects in this population-based study used one of two CHPs (Jia-Wei-Xiao-Yao-San or Shu-Jing-Huo-Xue-Tang), the most commonly used CHPs in China. The researchers found that, among the tamoxifen therapy group, CHP consumption decreased the risk of developing endometrial cancer.

Contraindications
A few other conditions produce negative reactions with tamoxifen. Since tamoxifen intensifies the risk of blood clots in the leg or arm, the lungs, or brain, individuals with a history of blood clots, heart attacks, or stroke may not take tamoxifen. Because this drug may cause harm to the fetus, tamoxifen must not be taken during pregnancy or breastfeeding.

Neutral Interactions With Other Drugs
Because tamoxifen provokes intolerable hot flashes in some women, W. L. Yeh, H. Y. Lin, H. M. Wu, and D. R. Chen studied the interaction of risperidone with tamoxifen to find drugs that could be used when women take tamoxifen. Risperidone failed to inhibit tamoxifen's cytotoxic impacts in vitro and in vivo. As risperidone does not interfere with the efficacy of tamoxifen, it warrants further research.

Resistance to Tamoxifen
Long-term adjuvant therapy with tamoxifen significantly improved breast cancer survival over the last 40 years. However, acquired resistance to tamoxifen
occurs in 40 percent of breast cancer patients and 25 percent of patients die from their disease. P. Fan and V. C. Craig describe laboratory studies in vivo that demonstrated three phases of acquired SERM exist. Cancers with phase I resistance undergo stimulation by both SERMs and estrogen; phase II resistance gets triggered by SERMs, but estrogen inhibits it by apoptosis. Phase III suggests that short-duration, low-dose estrogen may purge phase II-resistant breast cancer cells. This novel information provides a new direction to trial estrogen therapy after long-term anti-hormone therapy.

**Alternative Drugs**

Studies show that the drug raloxifene, originally approved for osteoporosis, acts similarly to tamoxifen as an antiestrogen drug in breast tissue, but it causes less cancer of the uterus and blood clots than tamoxifen. S. Zervoudis and colleagues summarized the comparison of tamoxifen and raloxifene by stating that postmenopausal women can decide on tamoxifen, the most effective drug, accepting its toxicities, or can chose raloxifene with slightly less efficacy but more tolerable side effects.

P. Y. Maximov, T. M. Lee, and V. C. Jordan reviewed the newer SERMs for breast cancer treatment. Research on arzoxifene demonstrated it to be effective in treating metastatic breast cancer and in reducing risk of invasive breast cancer with favorable response to bone health. The drug produces the same side effects as tamoxifen for venous thrombotic events, endometrial cancer, and hyperplasia, as well as hot flashes in 56 percent of research subjects.

Aromatase inhibitors (AI) recently became the gold standard as the primary therapy for females with hormone receptor-positive breast cancer in place of tamoxifen. They also may be employed sequentially with tamoxifen for postmenopausal women. These inhibitors focus on the estrogen biosynthetic pathway and take away the growth-promoting influence of estrogen from the cancer cells. The AIs lower the body’s estrogen by barring an enzyme called aromatase from changing androgen into estrogen. The AIs really provide a major benefit for disease-free survival of breast cancer. The AIs reduces estrogen-like effects such as endometrial cancer and thromboembolic disorders that are problematic in patients taking tamoxifen. A downside of AIs consists of osteopenia, osteoporosis, bone loss, and the risk of fractures. Bone loss can be managed with the use of bisphosphonates or other interventions (e.g., calcium, exercise, or vitamin D). The third-generation AIs currently on the market include anastrozole, letrozole, and exemestane.

**Conclusion**

Tamoxifen started out as a failed contraceptive, but progressed to be used to deal with all stages of breast cancer and to be employed as a chemoprevention agent for women at high risk for breast cancer, and proved to exert advantageous effects on bone density and serum lipids in postmenopausal women. Plus, the effects of tamoxifen continue for a decade after the drug is stopped. At the same time, the negative effects of thromboembolic disorders and uterine cancer ought to be kept in mind because tamoxifen must be given over a long time to treat and prevent breast cancer.

Tanzania

The United Republic of Tanzania, which was formerly known as German East Africa and then as Tanganyika, is situated in eastern Africa. It is bordered on the north by Uganda and Kenya, on the east by the Indian Ocean, on the south by Mozambique, Malawi, and Zambia, and on the west by Rwanda, Burundi, and the Democratic Republic of the Congo. It is the seventh-most populous country in Africa and 35th-most populous country in the world, with a population of more than 36 million. Kiswahili is the de facto national language, and there are 126 living indigenous languages still spoken by respective ethnic groups in Tanzania; the most widely spoken ethnic languages include Bena, Gogo, Haya, Hehe, Makonde, Nyukyusa, and Sukuma. Each ethnic group has its own rich traditions of ethnomedicine. For example, a traditional healer who uses medicinal plants for treating ailments is known as mganga in Kiswahili, and medicinal plants are called miti shamba.

Traditional medicine and associated beliefs continue to play a significant role, particularly in rural areas of Tanzania. Traditional medicine is typically less expensive and more readily accessible than the public health system. Many Tanzanians continue to believe that traditional healers are more powerful and holistic than Western practitioners. Accordingly, when someone dies of cancer in a rural village, it is not uncommon, even today, for local...
inhabitants to assert a superstitious explanation, such as that of witchcraft or a malevolent curse.

There are many traditional medicinal preparations still commonly used in Tanzania. Most of these incorporate use of local plant materials, many of which have shown medicinal properties in laboratory studies. For example, extracts from several medicinal plants used in Tanzania, such as *Garcinia senescens*, demonstrate cytotoxic specificity and may be a future source of antitumor compounds. Research suggests that use of certain plants may actually help protect against cancer by reducing oxidative stress and stimulating enzymes and other processes that help the body fight carcinogens. For example, an extract from *Salvia nilotica* demonstrated considerable antioxidant activity, as did extracts from root and stem bark of *Allanblackia ulugurensis*, and extracts from leaf, stem bark, and roots of *Combretum schumannii*.

Medicinal plants are used in Tanzania traditionally to treat many health problems associated with cancers and associated conditions. For example, the Zigua of the Bagamoyo District traditionally drink a root decoction of *Anchomanes diff formis*, which they call *cheho*, for joint pain. A leaf decoction of *Aloe lateritia*, which the Chagga call *mrature*, the Nyakyusa call *ibugubugu*, the Pare call *kithapa*, and is called *mlalangao* in Kiswahili, is traditionally drunk for treating hepatitis. The Digo take a leaf decoction of *Aloe rabaiensis*, which they call *jolanji*, for traditionally treating an enlarged spleen.

There are serious deficiencies of modern pharmaceutical supplies, as opposed to traditional preparations, and medical services in Tanzania. Tanzania has a relative shortage of medical doctors, with about 300, and in 2009, there were 640 licensed pharmacists. Due, in part, to the shortage of medical services and supplies, health problems are endemic in Tanzania. On the other hand, modern cancer treatments, such as chemotherapy and radiotherapy, are generally available in the public health system in Tanzania. Nevertheless, the 10 leading causes of mortality in Tanzania, in rank order, are complicated malaria, uncomplicated malaria, human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS), tuberculosis, anemia, sickling disease, pneumonia, poisoning, diarrhea, and cardiac failure. The average number of cancer cases annually are 87.2 per 100,000 of the population.

Cancers account for a substantial amount of disability and suffering among impacted populations. According to the International Agency for Research on Cancer, in 2012 the five most common types of cancer for men in Tanzania were prostate cancer (estimated age-standardized incidence rate of 34.6 per 100,000 population), Kaposi’s sarcoma (22.8 per 100,000), and cancers of the esophagus (12.9 per 100,000), lip and oral cavity (6.8 per 100,000) and larynx (4.3 per 100,000). For women, the most common cancers were cancers of the cervix and uterus (estimated age-standardized incidence rate of 54.1 per 100,000 population, breast (19.4 per 100,000), Kaposi’s sarcoma (9.9. per 100,000), and esophageal (6.1 per 100,000) and colorectal cancer (5.8 per 100,000).
Modern pharmacological supplies, as opposed to traditional preparations, are generally, if available at all, in short supply in Tanzania. Both prescription and over-the-counter products often are unavailable. Consequently, health problems are endemic and limit development. For example, an estimated 1.6 million people live with HIV in Tanzania, which ranks the country eighth-highest in Africa and ninth-highest in the world. Debate continues on the relative risks in Africa for respective cancer types for those infected with HIV. The mortality rate for tuberculosis in 2008 was 13 per 100,000 of the population and that for malaria in 2006 was 98 per 100,000, while that for cancers in 2009 was 150 per 100,000. Furthermore, according to the WHO’s Global Health Observatory Data Repository, in 2008, the age-standardized estimates of deaths from all cancers was 79 per of the 100,000 of the population for males and 74 per 100,000 for females. As a consequence, life expectancy is only 44.88 years, which ranks Tanzania 38th in Africa and 209th in the world. There is a clear and urgent need for improved cancer awareness, early detection programs, and health services infrastructure in Tanzania.

**Taxation**

Taxation of specific cancer-causing products or practices is, in the United States, on one level, a compromise between two values critical to the national self-image: the preservation of freedom of choice of the individual and concern for the health of the individual and of the public. If the issue were only about these two values, it might be a stalemate. But the reality is that purchases of cancer-causing products are an individual choice with an impact beyond the individual. Products that cause cancer in the consumer, like cigarettes, alcohol, or indoor tanning, nevertheless pass on parts of the cost of that cancer to the public, whether in the form of Medicare and Medicaid, public funds for cancer research, or simply by raising everyone else’s insurance premiums. Health-related behavior simply exacts a cost that is not contained to the individual, which is an important reality of public health policy that we as a country are not yet adept at acknowledging or discussing but which is reflected in cancer-related taxes and to a lesser degree in other taxes or tax proposals constructed with public health in mind.

Furthermore, not every purchase of carcinogens will have its carcinogenic effects limited to the individual purchaser. This is certainly true of cigarettes, given how much we know about the dangers of secondhand smoke. It is also true of gasoline, which contributes to carcinogenesis through its effect on
the environment and thence on the public at large, not simply on the individual driver.

As part of the Patient Protection and Affordable Care Act, effective July 1, 2010, the federal government imposed a 10 percent sales tax on indoor tanning. The tax offsets the public costs of health care for those who develop skin cancer as a result of this luxury service. Tanning beds use ultraviolet (UV) radiation, a combination of primarily UVA radiation and a smaller amount of UVB, in order to tan the skin. UV radiation exposure is a cause of cataracts, immune system problems, skin aging, and perhaps most importantly, skin cancer. UVA specifically, which makes up 90 to 100 percent of the radiation used by tanning beds, is the primary cause of melanoma, skin cancer that forms in the melanocytes and causes 75 percent of skin cancer-related deaths. The average tanning session is 10 minutes, providing the equivalent of 30 minutes of natural sunlight, but devoted tanners may go two or three times as long on a near-daily basis. Each session costs $15 to $30 in different parts of the country. Regular tanners are 4.5 times more likely to develop melanoma, 2.5 times more likely to develop squamous cell carcinoma, and 1.5 times more likely to develop basal cell carcinoma, compared to people who do not use tanning salons.

Like most taxes, the indoor tanning tax was met with controversy. Tea Party congressman Ted Yoho of Florida decried the tax as “racist,” because it targeted a service used almost exclusively by light-skinned people. Expected to generate $2.7 billion over 10 years—compared to the $18 billion that will be spent on treating skin cancer in that same period—it was enacted to offset costs of health care reform, but tanning salon owners complained they were unfairly targeted. Interestingly, Botox injections and elective (not reconstructive) plastic surgery was originally going to be taxed instead, but lobbying from the medical industry forced the change. While a tax on plastic surgery would have raised revenue, it would not have accomplished the additional goal of disincentivizing an activity that elevates cancer risk and results in significant public health costs.

Once the indoor tanning tax was proposed in Congress, the arguments in its favor were easy to make due to the relative success of cigarette tax. The Centers for Disease Control (CDC) says that, for every 10 percent price increase, cigarette consumption drops 3 to 4 percent in adults and 6 to 8 percent in young people. The doubled decrease among young people is likely due to increasing the cost for first-time or new smokers who are not yet addicted and thus find it easier to quit, whereas adult smokers include many longtime smokers who are not only physically addicted but have developed emotional and psychological attachments to smoking and their identity as smokers.

While the indoor tanning tax is an ad valorem tax—a tax proportional to the sale price of the service, as 10 percent of the price—most taxes on cancer-causing products or services are per-unit excise taxes, meaning that the amount of tax is a constant in dollars and cents and one that is levied in addition to any percentage-based sales tax that may also apply as part of a general sales tax for the jurisdiction. Excise taxes are often used as motivators or disincentives, such as taxes on gambling or prostitution—in this context, they are sometimes called a sin tax, usually pejoratively, though it is hard to stretch that term to encompass tanning. In the United States, excise taxes are levied both by the federal government and by most state governments as well as some local governments. For instance, the city of Anchorage, Alaska, has a $1.30 per pack excise tax on cigarettes, which is in addition to the federal and state taxes.

Excise tax on tobacco was first levied during the Civil War, after a failed attempt decades earlier by then-Secretary of the Treasury Alexander Hamilton. These first tobacco taxes were simple revenue generators with no motivating component, and for a brief period of time, tobacco tax was the government’s largest source of income. (The financing of government was a very different thing in the 19th century than it is today.) From 1921 to 1969, every state along with the District of Columbia adopted a tobacco excise tax—nearly always specifically on cigarettes—for a variety of reasons. Cigarette taxes, though they are always greeted with complaint, are a good way to increase revenue because they are an optional activity that no one will argue is necessary and so, in theory, present less cause for complaint than a general sales or income tax.

The federal tax on cigarettes increased from 39 cents per pack to $1.01 per pack in 2009, as part of the Children’s Health Insurance Program Reauthorization Act. This provided some of the revenue to fund the State Children’s Health Insurance Program (SCHIP), which provides aid to impoverished children and expanded its coverage in this reauthorization to include working and lower middle-class...
families at three times the federal poverty level, as well as children from eligible families in New York and New Jersey who are above that income threshold, in addition to expanding coverage to include dental and mental health benefits and services for immigrant children.

The arguments over the SCHIP cigarette tax increase illustrate the economic and ethical complexities of cigarette taxation.

Economists, for instance, pointed out that increasing the federal cigarette tax is likely to decrease state cigarette tax revenue. Cigarette price increases, whether from taxes or other factors, decrease consumption, as mentioned. That decreased consumption means fewer cigarette sales for the states to collect their individual taxes on. Cigarette taxes are also considered a regressive tax, de facto if not by design, in that half of cigarette smokers are in low-income households, who are thus disproportionately affected.

However, both of those facts have ethical and health-impact dimensions that are more complicated than simple sales figures. If a high federal cigarette tax reduces cigarette smoking, for instance, how can this be anything but good? This reduces cancer, reduces heart and lung disease, reduces the carcinogenic effects of secondhand smoke, and reduces the public health toll and expense of smoking. Further, the working class is the group least able to absorb the economic impact of an increase in cigarette cost and so the most likely to be dissuaded from smoking. They also possess the worst health coverage and are more likely to be at risk of cancer for reasons related to their workplace or carcinogens in their residential environment. Reducing cancer risks for the poor by making it more difficult for them to smoke may not be ethically clear-cut but neither is it as purely exploitative as a regressive tax sounds.

Studies consistently support the link between cigarette tax increases and cigarette smoking decreases. The federal government and 49 states also tax several categories of noncigarette tobacco products. The federal government, for instance, has specific excise taxes for snuff, chewing tobacco, pipe tobacco, roll-your-own loose tobacco, large cigars, and small cigars.

In addition to the federal cigarette tax and taxes levied by local or county governments (notably New York City and Chicago), state excise taxes vary widely and usually do not include the state or local sales tax:

- Alabama: $0.0425
- Alaska: $2.00
- Arizona: $2.00
- Arkansas: $1.15
- California: $0.87
- Colorado: $0.84
- Connecticut: $3.40
- Delaware: $1.60
- District of Columbia: $2.50
- Florida: $1.339
- Georgia: $0.37
- Hawai‘i: $3.20
- Idaho: $0.57
- Illinois: $1.98
- Indiana: $0.995
- Iowa: $1.36
- Kansas: $0.79
- Kentucky: $0.60
- Louisiana: $0.36
- Maine: $2.00
- Maryland: $2.00
- Massachusetts: $3.51
- Michigan: $2.00
- Minnesota: $2.83
- Mississippi: $0.68
- Missouri: $0.17
- Montana: $1.70
- Nebraska: $0.64
- Nevada: $0.80
- New Hampshire: $1.68
- New Jersey: $2.70
- New Mexico: $1.66
- New York: $4.35
- North Carolina: $0.45
- North Dakota: $0.44
- Ohio: $1.25
- Oklahoma: $1.03
- Oregon: $1.31
- Pennsylvania: $1.60
- Rhode Island: $3.50
- South Carolina: $0.57
- South Dakota: $1.53
- Tennessee: $0.62
- Texas: $1.41
- Utah: $1.70
- Vermont: $2.62
- Virginia: $0.30
The United States is not the only country that taxes cigarettes and other tobacco products. The World Health Organization Framework Convention on Tobacco Control was adopted by the 56th World Health Assembly in 2003 and is legally binding in 179 countries. It calls for signatories to act to "protect present and future generations from the devastating health, social, environmental and economic consequences of tobacco consumption and exposure to tobacco smoke," such as by limiting production and consumption through regulations on sales, production, and advertising and by taxing tobacco products. It is the most significant international public health agreement that does not deal with a contagious disease, malnutrition, or clean water access. It limits tobacco industry lobbying, calls for taxation as a demand reduction strategy, creates an obligation to protect the public from secondhand smoke, bans tobacco advertising, and requires a health warning on tobacco products that occupies at least 30 percent of the visible surface area of the packaging.

The United States, however, is one of the few United Nations members that is not a party to the WHO framework convention on tobacco control. President Bush elected not to send it to the Senate for consideration. Not only is the country not bound by the treaty, but it actually has sought to change various of its provisions—succeeding in removing from the treaty a ban on free tobacco samples and redefining its use of the term *minor* for purposes of restricting sales to such in order to protect the interests of American tobacco producers and their export revenues. The United States also attempted to oppose the requirement that warning labels be written in the language of the country where the tobacco product is sold.

One of the reasons for demand reduction of tobacco products, as mentioned, is the danger of secondhand smoke, also called environmental tobacco smoke or passive smoking. Secondhand smoke is the smoke released into the air from the burning of tobacco products, which lingers in the air for hours afterward and is inhaled by nonsmokers and smokers alike. There is no established safe level of exposure to secondhand smoke, which in the short term impacts blood platelets and the linings of blood vessels in ways that increase the risk of heart attacks.

Cumulative exposure to secondhand smoke, in the long term, increases both heart disease and lung and breast cancer risk as well as respiratory infections, asthma, ear infections and even hearing loss, dementia in patients over 50, and atopic dermatitis. In children and pregnant women, secondhand smoke increases the chance of brain tumors and damages carotid arteries and can result in low birth weight. Children are also at elevated risk for asthma and ear infections from secondhand smoke. There is increasing evidence that secondhand smoke is a factor in Sudden Infant Death Syndrome, tooth decay in young children, bronchitis and pneumonia in prepubescents, and the development of Crohn's disease in young children.

Alcohol is taxed at the state level with an excise tax applicable to off-premise sales (i.e., not drinks served in bars or restaurants) of distilled spirits of at least 40 percent alcohol by volume, which includes all whiskeys, brandies, rums, vodkas, and so on. That tax rate varies considerably by state:

- Alabama: $18.23
- Alaska: $12.80
- Arizona: $2.00
- Arkansas: $6.57
- California: $3.30
- Colorado: $2.28
- Connecticut: $5.40
- District of Columbia: $5.37
- Delaware: $3.75
- Florida: $6.50
- Georgia: $3.79
- Hawai‘i: $5.98
- Idaho: $10.92
- Illinois: $8.55
- Indiana: $2.68
- Iowa: $12.43
- Kansas: $2.50
- Kentucky: $6.76
- Louisiana: $2.50
- Maine: $5.80
- Maryland: $4.41
- Massachusetts: $4.05
- Michigan: $11.91
- Minnesota: $8.71
- Mississippi: $7.41
- Missouri: $2.00
- Montana: $9.34
- Nebraska: $3.75
- New Hampshire: $0 (Beer taxed at $0.30)
- New Jersey: $5.50
- New Mexico: $6.06
- New York: $6.44
- Nevada: $3.60
- North Carolina: $12.36
- North Dakota: $4.66
- Ohio: $9.32
- Oklahoma: $5.56
- Oregon: $22.73
- Pennsylvania: $7.21
- Rhode Island: $3.75
- South Carolina: $5.42
- South Dakota: $4.68
- Tennessee: $4.46
- Texas: $2.40
- Utah: $12.19
- Vermont: $5.86
- Virginia: $19.19
- Washington: $35.22
- West Virginia: $1.87
- Wisconsin: $3.25
- Wyoming: $0

In many states, different rates or rate modifiers apply according to the size of the container, place of production, alcohol content, and whether the alcohol is sold on board an airline.

Fuel exhaust is one source of atmospheric carcinogens. Diesel exhaust in particular is tied positively to lung cancer and likely implicated in bladder cancer as well. Emissions standards are one way to reduce the danger, but many countries use a fuel tax as a way to make the use of carcinogenic fuels more expensive and encourage the private sector to find other means while, at the same time, recovering revenues that offset the public health costs of these carcinogens. France, for instance, recently adopted a new tax to make diesel fuel more expensive than gasoline for this reason (unlike the United States, the majority of France's passenger cars are diesel). Gas taxes often are criticized as impacting the cost of other goods and so, theoretically, introducing a drag on the economy. On the other hand, in many sectors, goods are only transported as far as they are because of a long history of transportation fuel prices that have been kept artificially low compared to those of Europe; for instance, considerably more fuel per calorie of food is spent in bringing food to market now than in the 1940s, more than 10 times as much. Decentralized distribution would make this unnecessary, with the incidental benefit of reducing the scale of some of the country's food contamination crises.

The federal government imposes a $0.184 per gallon tax on gasoline and $0.244 per gallon on diesel. Aviation gasoline is taxed separately at $0.194 per gallon, while jet fuel is taxed at $0.219 per gallon or $0.044/gallon when used for commercial flights. State taxes vary, with gasoline listed first:

- Alabama: $0.393, $0.463
- Alaska: $0.308, $0.371
- Arizona: $0.374, $0.514
- Arkansas: $0.402, $0.472
- California: $0.713, $0.74
- Colorado: $0.404, $0.449
- Connecticut: $0.677, $0.793
- Delaware: $0.414, $0.464
- District of Columbia: $0.419, $0.479
- Florida: $0.544, $0.568
- Georgia: $0.459, $0.553
- Hawai’i: $0.665, $0.745
- Idaho: $0.434, $0.494
- Illinois: $0.575, $0.693
- Indiana: $0.592, $0.757
- Iowa: $0.404, $0.479
- Kansas: $0.434, $0.514
- Louisiana: $0.384, $0.444
- Maine: $0.484, $0.556
- Maryland: $0.454, $0.522
- Massachusetts: $0.449, $0.509
- Michigan: $0.598, $0.642
- Minnesota: $0.47, $0.53
- Mississippi: $0.368, $0.424
- Missouri: $0.357, $0.417
- Montana: $0.462, $0.529
- Nebraska: $0.457, $0.511
- Nevada: $0.516, $0.53
- New Hampshire: $0.38, $0.44
- New Jersey: $0.329, $0.419
- New Mexico: $0.373, $0.473

Fuel exhaust is one source of atmospheric carcinogens. Diesel exhaust in particular is tied positively to lung cancer and likely implicated in bladder cancer as well. Emissions standards are one way to reduce the danger, but many countries use a fuel tax as a way to make the use of carcinogenic fuels more expensive and encourage the private sector to find other means while, at the same time, recovering revenues that offset the public health costs of these carcinogens. Technology, Imaging

Imaging modalities are central to the treatment of cancer given as they play integral roles in its early detection, diagnosis, and treatment. The different techniques available are applicable to different tumor types and locations, often providing unique benefits and disadvantages. Tools such as computed tomography (CT) scans and single-photon emission computed tomography (SPECT) can aid in the detection of tumors, while ultrasound and other techniques can guide treatment. Familiarity with present state and future advances in the imaging field is crucial to understanding the options for cancer detection and treatment.

Cancer Imaging for Diagnosis and Detection

Radiography is one of the oldest available imaging techniques, using X-rays and measuring the absorption of these light waves by different components of the body. Soft tissues tend to absorb very little of the radiation, while bones tend to absorb more. This difference can be used to distinguish between different organs and tissues to create a 2-D representation of the internal body structure. These images can be used by themselves to detect tumors, as in the case of cancer of the lungs or bones. X-ray imaging can also be used with injected contrast agents, which absorb X-rays, to visualize structures such as blood vessels. This may be indicative of the presence of a tumor in regions such as the breast, as in a contrast-enhanced mammogram.

While radiography usually provides 2-D images, computed axial tomography (CAT) uses multiple X-ray scans that penetrate at different depths to
create a 3-D representation of the body in the form of multiple slices. The multi-slice technique achieves higher resolution by using a system capable of scanning several parallel sections simultaneously. In both cases, computer algorithms reconstruct the 3-D structure based on the multiple X-ray images. This technique provides a noninvasive means of cancer detection in environments such as the colon.

Ultrasound has a very different mode of operation, relying on high-frequency (above 20 kHz) sound waves that are emitted into the body and reflected back by the internal structures. The reflected waves that are collected can then be used to construct an image of those internal structures. For example, transvaginal ultrasonography can be used to detect endometrial cancer.

One of the most powerful and expensive imaging techniques is magnetic resonance imaging (MRI), which uses a strong, oscillating magnetic field to align the nuclear spins of hydrogen atoms and measure the resulting patterns to create a high-resolution, 3-D image. MRI can be used to locate, visualize, and stage cancers in various soft tissues, including the brain. However, use of MRI is restricted by the effects that the magnetic field would have on implants and prostheses.

Finally, nuclear imaging works by using small amount of radioactively labeled chemical tracers that localize to specific tissues of the body, including tumors. Positron emission tomography (PET) creates a 2-D image of a region of the body based on the changing distribution of a radioactively labeled molecule, such as a sugar. This technique can serve to detect a tumor in a tissue, such as the brain, because the cancerous cells will have high metabolic demands and take up a large amount of the labeled sugar. SPECT, while yielding a lower resolution than PET scanning, creates a 3-D image by reconstruction from multiple images taken from different angles. This can be utilized in conjunction
with labeled antibodies that bind specifically to cancerous cells in order to visualize tumors.

**Cancer Imaging in Treatment**
The usefulness of the above imaging techniques is not limited to diagnosis and detection; these methods frequently play roles in guiding the treatment of various cancers. Procedures such as biopsies, resections, and tumor ablations all can be facilitated through the use of imaging techniques that reveal the locations of tumors, their severity, and even real-time changes in their conditions.

Biopsies of cancer cells provide histological information critical to staging a tumor and informing a plan of treatment. Extraction of a biopsy from a tissue deep in the body requires accurate knowledge of the location of the tissue of interest and the ability to insert the needle directly into the region of interest. Needle placement can be guided by modalities such as radiography, CT, and ultrasound as these techniques can distinguish between a tumor and its background. Surgical removal of a tumor is an important means of cancer treatment. Similar to a biopsy, it requires spatial information for planning and conducting the surgical removal. This is particularly important in delicate regions like the brain, where the surgeon must be guided to remove the tumor with minimal damage to the surrounding noncancerous tissue. In addition, it is important to ensure that every cancer has been removed. MRI can fulfill this role by providing the surgeon with high-resolution views of the structure of the brain and target tumor.

Ablation offers another, minimally invasive means for the elimination of cancer from the body. This involves the use of energy sources outside the body, such as ultrasound, to destroy the targeted diseased tissues. In techniques such as image-guided focused ultrasound (FUS) ablation, the ultrasound beams that destroy tissue are accurately directed toward the cancer through spatial information derived from MRI or ultrasound imaging.

**Future of Cancer Imaging**
Although the above techniques are well-established in their current uses, it is important to look to the future of the field for improvements in diagnosis and treatment. These advancements come in the form of new uses of imaging modalities as well as in integrative approaches that combine two or more of these techniques. In addition, novel computational approaches to extract maximal information from the derived images is currently a strong area of focus.

There is much relevant information to be derived from novel uses of existing imaging technologies. For examples, diffusion tensor imaging (DTI) uses nuclear magnetic resonance (NMR) to determine restrictions in the diffusion patterns of water in a tissue. Such restrictions are indicative of changes in the tissue structure and can be used for the detection of cancer in tissues such as the prostate and breast. Another promising advancement lies in the use of nanoparticles (molecules with at least one dimension below $10^{-9}$ meters) that selectively localize to cancerous tissues where they can be detected by MRI, PET, SPECT, and ultrasound. This provides greater resolution and improved detection capabilities for traditional imaging modalities.

The combination of existing techniques can improve biopsy and surgical treatment by providing both a detailed structural overview of the region for reference along with a dynamic representation of the same areas during the procedure. For example, the combination of MRI and ultrasound imaging can provide an accurate structural map for locating a tumor using the former technique as a general guide for biopsy, while the latter can help the surgeon as he or she guides the needle directly to the site. In addition, there are a number of emerging imaging modalities based on biophotonics such as optical coherence tomography (OCT), light scattering, multi-photon, Raman spectroscopy, and infrared spectroscopy; however these tools have not yet progressed to widespread clinical use.

In short, cancer imaging informs detection, diagnosis, and treatment through multiple modalities. The current techniques and recent advances in the field provide important tools for dealing with cancer and will continue to do so in the future.

Technology, New Therapies

Cancer therapies have been continuously researched since the 19th century, and because cancer refers to a type of disease rather than a single illness, there will likely never be a silver-bullet cure for cancer but rather many treatments, some of them even cures or preventatives, for many types of cancer. Further, it has become commonplace, even standard, to employ multiple modalities in treating the same cancer: frequently surgery, if possible and advisable, combined with chemotherapy and radiation therapy.

Each of those modalities, in turn, may have side effects that necessitate their own treatment, such as the nausea induced by chemotherapy. As a result, there are numerous areas in which researchers continue to explore new cancer therapies. In 2014, the Pharmaceutical Research and Manufacturers of America (PhRMA) listed 771 new drugs in development, either in clinical trials or awaiting Food and Drug Administration (FDA) approval in addition to the drug discovery underway in labs throughout the scientific community, research into new combinations of existing chemotherapy treatments, new combinations of modalities, experimental forms of radiation therapy, and work on biologics and non-pharmaceutical treatments.

Among the experimental drugs or drug approaches in development, Human Alpha-lactalbumin Made LEthal to Tumor cells (HAMLET) has an interesting potential as a chemotherapy drug. HAMLET is a protein compound derived from human breast milk and in tests has induced cell death in several pathogens, including pneumococcus bacteria and human lung carcinoma cells. It also has demonstrated that it is useful in helping antibiotics kill off antibiotic-resistant bacteria (MRSA), which is of interest in the treatment of immunocompromised cancer patients, who are often left vulnerable to infection after radiation treatments or chemotherapy and spend a good deal of time in hospitals, which are rife with MRSA. Studies are applying the use of HAMLET to cancers of the lung, throat, kidney, colon, prostate, and ovaries, as well as leukemia, glioblastomas, and melanoma.

One rich area of research is the use of bacteria as cancer drugs because anaerobic Clostridia bacteria offer the potential to attack the interior of tumors, after which they die harmlessly in the oxygen-rich system of the body. There are several approaches that are possible here. C. novyi has been extensively researched as a cancer therapy for solid tumors, the interior cells of which are resistant to radiotherapy and chemotherapy. A genetically modified form of C. novyi, C. novyi-NT, infects and lyases hypoxic tumor cells but is ineffective against the cancer cells of the tumor surface.

An obvious solution to this is to use C. novyi-NT in combination with chemo- or radiotherapy, each addressing the other’s weaknesses. Radioactive monoclonal antibodies (mabs) also may be used with C. novyi-NT, with the benefit of sparing a greater amount of healthy tissue than traditional radiotherapy. C. novyi-NT also could be modified further to produce prodrug-converting enzymes to deliver to the tumor site or liposomes carrying anticancer drugs in order to increase the dose of chemotherapy experienced by the tumor cells without increasing the absolute dose and its damage to healthy cells. Alternately, the tumor can be pretreated with drugs like dolastatin, which widen the hypoxic core so that the C. novyi-NT can kill a greater percentage of the tumor. Techniques using

multiple administrations of *C. novyi*-NT also have been suggested, especially if this proves to be as effective as chemotherapy, with fewer of chemo’s debilitating side effects.

A relatively new form of cancer therapy is gene therapy, which was proposed in 1972 but saw little success until the 2000s. Originally conceived of as a treatment for hereditary diseases, gene therapy in the 2000s and 2010s has shown a great deal of promise as a cancer treatment. There are several forms of gene therapy used to treat cancer, all of which package DNA that encodes a specific protein into a vector—such as a virus—which is then introduced to the body or the target site. The DNA is delivered to a mutated gene, which it then replaces, causing the new DNA to release the protein that has been encoded. This has been used to successfully treat leukemias and myelomas in clinical trials.

Viruses can be used in other ways. In 2004, University of Texas researchers programmed a cold virus to attack cancer cells, and an engineered version of the herpes virus later made it into phase III clinical trials for the treatment of melanoma. Such viruses are called oncolytic viruses and kill cancer cells by infecting them and destroying them through lysis, the viral breakdown of a cell. In 2014, almost a dozen different groups of viruses were undergoing clinical trials as cancer treatments.

Cancer cells also can be killed by heat, and there are several methods by which heat can be applied to cancer cells. Photodynamic therapy is one method in which photosensitive agents are delivered to the tumor and exposed to light; they absorb and turn into heat in order to burn the tumor cells away. There is also renewed interest in whole-body hyperthermia therapy, long used to treat severe or recurrent cancer and, in recent years, becoming more popular as an adjuvant therapy. In whole-body hyperthermia, the patient’s whole body is heated until the body temperature reaches a certain threshold. There is no widespread agreement about that threshold, with researchers in Japan and Russia targeting 109 to 111 degrees F, and researchers in the West targeting somewhere between 104 and 107 degrees.

These few degrees make significant differences, both in technique and, many would argue, in the risk of toxicity to healthy cells. That said, the reason hyperthermia works is that tumor cells, though they excel at propagating throughout the body, are nevertheless not as efficient as healthy tissue in other respects, and in particular their inefficient vascular structure makes it difficult for them to shed excess heat. Healthy tissue is much more adept at it, and so while both sets of tissue are exposed to a temperature that is dangerous to them, the cancer cells consistently lose the battle first. Nevertheless, hyperthermia recipients must be closely monitored; damage from overheating can be severe and can lead to organ damage, exactly as with a very high fever.

As an alternative to whole-body hyperthermia, local hyperthermia can be conducted through magnetic hyperthermia, in which magnetic nanoparticles are injected that generate heat when the body is exposed to an alternating magnetic field. This poses fewer risks than whole-body hyperthermia. Similarly, nanoparticles made of gold or carbon can be injected and heated through exposure to radio waves.

The rapid cell division of cancer cells can be disrupted with Tumor Treating Fields (TTFs), electromagnetic devices marked by Novocure and approved by the FDA in 2011. The first systematic review of TTF’s effectiveness, in 2013, found that it was as effective as standard chemotherapy, with different side effects—primarily skin rashes caused by the electrodes, as opposed to the nausea, hair loss, and sometimes myelosuppression of chemotherapy.

Further Readings
After World War II, America saw a surge in smoking. Returning GIs brought back with them smoking habits many did not have before their service; the new medium of television invited major tobacco companies to sponsor programs; women, many joining the workforce or wanting to make a statement for gender equality, began the habit; workplaces were foggy with smoke; doctors and nurses smoked; celebrities advertised cigarettes in splashy magazine and newspaper layouts.

The tobacco industry estimated just under half of adult Americans smoked. Although scratch medical research had indicated that prolonged use of tobacco caused lethargy, physical and mental, and could create peculiar side effects if it was stopped entirely, few public health advocates acknowledged more serious health impacts from cigarettes. In the 1950s, however, research began to suggest causal links between tobacco use and a variety of lung ailments, including bronchitis, emphysema, and heart disease. In 1957, Leroy Burney, then surgeon general, issued a largely ignored memo that first publicly linked smoking to lung cancer.

Seven years later, his successor, Dr. Luther Terry, would issue a far bolder, far broader indictment of smoking, calling it a public hazard and linking it definitively to a host of terminal diseases, most prominently lung cancer. That landmark report, the product not of zealous crusading or some antitobacco agenda (Terry himself was a smoker until a few months before the release of the report, when he switched to a pipe and even then never smoked publicly) but rather of Terry’s own determination to alert the American public of a critical health threat, now stands among the most important public health documents of the 20th century.

The son of a country doctor who worked with families across three counties in rural southern Alabama, Luther Leonidas Terry, born September 15, 1911, in the town of Red Level (population 612), grew up watching his father helping patients one on one and learned the responsibility of doctors when their patients were healthy and that prevention was far more practical than treatment. There was never a doubt he would be a doctor. Earning his bachelor’s in science from Birmingham–Southern College in 1931, he completed his M.D. four years later at Tulane University in New Orleans. After a number of medical appointments at prestigious facilities and university professorships specializing in the cardiovascular system, Terry decided research facilities and university classrooms were too divorced from the real work of helping people maintain their health. In 1943, he joined the United States Public Health Service—and over the next decade, he headed up the service’s medical offices in Baltimore, Maryland. He was a model bureaucrat—the offices ran efficiently and issued specific warnings and guidelines, largely concerning healthy heart habits, that were distinguished by their unbiased, matter-of-fact tone and their use of up-to-date medical data.

President John Kennedy (a cigar smoker, although seldom in front of cameras as he feared contributing to Irish caricatures) tapped Terry to be the nation’s ninth surgeon general, the chief of the National Health Service, the government’s official mouthpiece responsible for directing significant medical data to the public to prevent and treat diseases. There was little doubt where Terry would begin. Smoking was rapidly attracting more and more attention within the international medical community as a likely cause of lung cancer and bronchitis as well as general pulmonary-cardio distress. But the tobacco industry had long fended off such research as inconclusive and biased. Terry decided it was well within the purview of his office to study the reliability of the data and to reach a sound and unbiased conclusion.

Terry, determined to reach out to the widest range of the medical community, selected a 10-person, blue-ribbon committee; Terry personally vetted hundreds of doctors, cardiovascular researchers, public health officials, and pharmaceutical company representatives. To ensure the committee’s reliability, Terry even gave the tobacco industry representatives the power to veto any appointment to the committee. More than half of the final committee smoked. The committee worked diligently under Terry’s guidance for more than 14 months. The committee did no original research or fund specific data gathering—rather it became a kind of clearinghouse, investigating the reliability of data (more than 7,000 research documents) that had been published over more than 30 years. When the report was ready to be issued, close to 400 pages, Terry knew the report would be a bombshell. He timed the press conference to announce the results
of the report carefully—a Saturday, January 11, 1964—a day when the alarming news could not impact Wall Street, with its heavy tobacco industry presence, and would dominate Sunday morning newspapers and Sunday morning news programs on television.

The report, although massive in size, made a very clear and specific point: Unquestionably, smoking caused lung cancer. The death rate from lung cancer was astronomically higher among smokers than nonsmokers. In addition, data indicated irrefutably that smoking caused chronic bronchitis, emphysema, and heart disease. The report made no recommendations for action—Terry was determined to put the facts in front of the American people, certain the data would be sufficient to convince them. The tobacco industry representatives were quick to dismiss the report as it offered no original research. Although there had been public pronouncements before concerning the risks of smoking, *Smoking and Health: Report of the Advisory Committee of the Surgeon General of the Public Health Service* used a far more emphatic tone, describing smoking a public health hazard. In addition, Terry himself was perceived as no fiery antismoking lunatic fringer—his demeanor was calm, he was soft-spoken, he came across as reliable, and his data were carefully weighed, his conclusions sound and logical.

Terry spent the rest of his tenure as surgeon general (he served until 1965) tirelessly promoting the dangers of smoking. Before Terry came into office, Gallup surveys indicated less than 40 percent of Americans believed in a causal link between smoking and cancer; in 1968, nearly 80 percent believed it. In the year following the report’s release, estimates suggested nearly 20 million Americans quit smoking. Largely through Terry’s efforts, cigarette packaging was required to indicate that the product was a health risk. Terry, who accepted a teaching appointment at the University of Pennsylvania, would remain a public advocate for smoking bans, specifically the effects of secondhand smoke in the workplace, until his death, from a heart attack, March 29, 1985.

Testicular Cancer

Testicular cancer (TC) forms in one or both testicles, often in young men. The American Cancer Society estimates that about 8,430 new cases of TC will be diagnosed in the United States in 2015, and about 380 men are expected to die of TC in that time. Half of these cases occur between the ages of 20 and 34. Because TC is rare, highly curable, and can be discovered at an early stage, most men have only a one in 5,000 lifetime risk of dying from the disease.

TC is typically detected by the male, an intimate partner, or a medical practitioner as a painless lump on, or swelling of, the testicle. Most cases are diagnosed following a physical examination, an ultrasound of the testicle, blood tests for tumor markers, or pathology reports following an orchiectomy. If left untreated, TC can spread along a predictable path through abdominal lymph nodes upward toward the lungs and outward to the liver, brain, and elsewhere. Treatment decisions for TC include orchiectomy in most cases, and radiation, chemotherapy, or surgery to remove abdominal lymph nodes if the cancer has spread beyond the testicle. Treatment can cause infertility, diminished sex drive, and additional concerns.

While TC rates have been increasing around the world for several decades, researchers are unsure of the causes. Few risk factors for the disease are currently known. However, psychosocial challenges during TC survivorship, barriers to early detection, and racial and ethnic disparities in TC outcomes are well documented.

Psychosocial Concerns

Because TC is highly treatable and the most common form of cancer in young men, most TC survivors live the majority of their lives facing a number of related psychosocial concerns. At the time of diagnosis, young men are already undergoing a number of normative life transitions that are less of a concern for older adults and younger children (e.g., finishing school, forming intimate relationships, beginning a career, starting a family, achieving independence, establishing an identity, and planning for the future). Young males also must work to initiate and maintain social relationships with family, friends, and peer support systems that are often less established than at other stages of life.

A TC diagnosis delays and sometimes prevents the achievement of these plans and milestones, and it often disrupts the initiation and maintenance of close relationships. Many TC survivors hesitate to disclose their illness to other men because they are afraid to be perceived as different, less masculine, and more vulnerable and incomplete. However, TC survivors have said that the use of humorous slogans, often on clothing and accessories (e.g., “Don’t be a punk, check your junk”), can serve as effective icebreakers in promoting a sense of normalcy and raising TC awareness among friend and peer groups.

Many single men experience lasting concerns about forming intimate relationships due to changes in physical appearance and function, fear of recurrence and death, and diminished finances. Although partnered TC survivors sometimes report that their cancer diagnosis helped to increase their relational closeness, both partners often experience uncertainty about possible infertility and an altered sexual relationship. Additionally, conflicts about primary caregiving roles and duties are common between newly formed romantic partners and the young man’s mother. Although psychosocial services and support programs are available specifically to address the unique concerns of a young adult with cancer, many TC survivors are unaware that these programs exist.

Barriers to Early TC Detection

Successfully persuading males that they are at risk for TC and that they should perform monthly testicular self-examinations (TSE) are challenges currently facing scholars and practitioners. Perhaps as a result of TC’s perceived limited susceptibility and severity,
males know little about TC and do not engage in regular TSE. Males’ uncertainty regarding their ability to reliably perform TSE is one of the most prevalent barriers to conduct effective screening. Beneficial conversations about TC and TSE often do not take place within male relationships due to normative expectations of masculinity, which also discourage men from engaging in TSE, seeking health information, and using health care services to address symptoms. Men may perceive such conversations and behaviors to violate stereotypical expectations of masculinity such as strength and stoicism.

Males are more likely to perform TSE if they are properly educated about TC risk and believe that TSEs are an easy and effective means of detecting abnormalities. Because this disease strikes primarily in young men, high schools and universities are often the targets of interventions intended to increase knowledge and foster positive attitudes toward TC prevention. A recent TC communication campaign called Check Yo Nutz increased college males’ intent to conduct TSE, search for TC information, and schedule appointments with their doctors. The campaign featured unique and humorous messages about TC and TSE disseminated through a wide range of communication channels, including on-campus events, printed shower cards, and a smartphone video game application called Nut Warz.

However, few TC mass media campaigns have been implemented and evaluated on a wider scale in the United States. Entertainment—education programs like MTV’s The Tom Green Cancer Special, which aired in the United States in 2000 and documented the comedian’s TC diagnosis and surgery provide opportunities to create TC awareness and normalize among at-risk males.

Racial and Ethnic Disparities

Males within racial and ethnic minority groups in the United States demonstrate even less knowledge and risk of TC compared to whites. Minority males’ tendency to maintain lower socioeconomic status, education level, income, health literacy, and access to health care often leads to delayed medical visits, which results in higher TC stages at diagnosis and higher rates of mortality.

Although TC is rarer in the black community than it is among whites, black men experience significantly lower five- and 10-year survival rates than whites with similar tumor types, and they have significantly higher stages of cancer progression upon diagnosis. Black men display the lowest TC education among all American racial and ethnic groups, and they are most likely to endorse traditional attitudes regarding health and masculinity. Many researchers agree that more effective health education and promotion programs for young minority men are needed at the interpersonal, organizational, and mass media levels to counter these disparities.

Textile Dyes

The art and practice of dyeing clothing to meet individuals’ preferences and tastes is a long-standing tradition across many human cultures. In fact, historical evidence suggests that Neanderthal man was the first to use dye some 180,000 years ago. For the vast majority of human history, dyes were derived from organic materials—namely plants, minerals, animals, and insects. However, since the first discovery of synthetic dye in 1856, the art and practice of using dye has changed dramatically. This has included the overwhelming practice of using synthetic dyes for a number of reasons. This entry
explores this development, the concerns and scientific evidence connecting synthetic dyes to cancer incidence, the conflicts of interest in textile manufacturing, and how regulations are crucial toward improving both the human and environmental risks posed by such chemicals and introduces a few potential solutions and improvements to the current state of textile production.

**Development of the Synthetic Dye Industry**

For most of human history, the production of dyes to color clothing and goods was a highly labor- and land-intensive production. Much organic material had to be used and cultivated to produce a relatively small amount of dye. However, in the mid-19th century, this began to change with the discovery of the first synthetic dye, mauveine. This discovery enabled dyes to be produced on a much larger scale and also began to expose textile workers to new chemicals and chemical intermediates formed in the clothing manufacturing process at considerable levels. Regulations and testing for chemical toxicity at this time were largely nonexistent, and it was not until many textile workers years later began to suffer from bladder cancer at alarming rates did manufacturers and health policy pundits in society begin to take notice and question the safety of certain textile dyes, especially those such as fuchsine, auramine, benzidine, and 2-naphthylamine.

Once this information began to spread throughout the textile industry and slowly into the medical community, responsible textile manufacturers ceased use of such carcinogenic dyes and replaced them with safer alternatives. However, regulatory testing and safety for chemical dyes in general continued to be lacking well into the mid to late 20th century. Recognizing this shortcoming, the colorant and textile industry of western Europe began to step up and is credited for being the first organization to systematically examine and test textile dyes for safety and toxicology on a large scale. This eventually led to the formation of the Ecological and Toxicological Association of Dyes and Organic Pigment Manufacturers (ETADOPM) in 1974, which developed safety data sheets on chemicals typically used in the textile manufacturing process. These safety data sheets have since spread worldwide and have become commonplace in the textile industry. However, unfortunately, this has not meant that the process of dyeing clothing and consumer goods is now an entirely safe one because a number of issues still extant in the industry globally.

**Synthetic Dyes, Health Risks, and the Cancer Connection**

Over the last 40 years since the genesis of the ETADOPM organization, testing of textile dyes has become much more stringent and regulated across much of the globe, especially in Western countries. Unfortunately, this has not meant that all dyes used in textile manufacturing are necessarily safe nor are the regulations and safety findings always enforced, especially in developing countries. It is conceivable and perhaps not coincidental then why so many major clothiers wishing to avoid stringent regulations largely have outsourced their manufacturing operations to such locales. Subsequently, this has created a perilous situation in such countries due to the increased chemical exposure, which threatens the health and welfare of individuals (such as textile workers exposed to large amounts of chemicals and dyes in the manufacturing process), communities, and the environment at large.

Due to the plethora of scientific studies and epidemiological data going back decades now, it is not so much the issue that there is much debate as to whether certain textile dyes or chemical intermediates may be risky for both consumers and textile workers alike. Rather it is the case of what to do about manufacturing plants trying to illegally cut costs at the expense of their workers’ health and the environment and how to protect consumers and textile workers from exposures in the meantime that may threaten their health.

While safety data sheets have suggested that, on average, many problematic dyes (such as disperse dyes) may have low potential for acute toxic effects, these averages have seemed to run counter to the consistent reports by many dermatologists and consumers. Moreover, dyes used in the manufacturing process that are not left in the end clothing product but are part of the dyeing process (such as those termed reactive dyes) have been implicated in many allergic and dermatological reactions for textile workers.

Specifically related to genotoxicity and mutagenicity, certain textile dyes have been identified as especially concerning, such as certain classes of azo dyes. While many subtypes used in years past have been generally outlawed or phased out of usage due
Textile Dyes

to health concerns, this class of dyes is still used prolifically on a global scale, accounting for some 50 percent of the some 1 million tons of dyes produced annually, especially in developing countries in the textile manufacturing process. It is important to realize that both the dye itself or the metabolites of dyes can be carcinogenic. Thus, even though an initial dye itself may be considered safe in the manufacturing process, subsequent wearing, washing, and treating the dye in the garment later on can cause the dye to transform into dangerous metabolites that have the potential to be absorbed through the skin or the air or contaminate the water supply.

In the case of the azo dyes, this has been studied extensively. Interestingly, just slight chemical differences in the dyes can make dramatic impacts on their relative risk to humans and animals alike. For instance, the class of azo dyes called 4-aminoazo dyes were noted in studies in the 1980s to all be carcinogenic, whereas the 2-aminoazo dyes were not. This is explained by their different capacities to create different reactive metabolites through their differing degrees of solubility with solvents. Studies conducted in the 1970s and 1980s further illustrated that textile workers were often developing health problems and bladder cancer in particular due to the reactive metabolites of these types of dyes, not the original dyes themselves.

While some of these subcategories of chemicals have been substituted for and abandoned by manufacturers over time, this is not the case in many instances, especially in developing countries. Moreover, other problematic chemicals used in the manufacturing or the fabric finishing process still continue to be used with known health or cancer risks such as: azo dyes (class III A1 and A2 in particular), dioxin, heavy metals such as copper, chrome, zinc, nonylphenol ethoxylates (NPEs), and formaldehyde.

Other Dyes Used in Textile Manufacturing and Their Relative Health Risks

While azo dyes represent the largest class of textile dyes, other dyes have been used and also examined for potential toxicity and safety over the last number of decades. The second-most important class of dyes used in the textile industry has traditionally been the anthraquinone class (although they have diminished in importance in recent years). Interestingly, they have shown a similar pattern when compared to the azo dyes as they relate to health and carcinogenic risk. For example, those that are classified as solvent or disperse dyes containing amino- or methylamino-groups have the potential to metabolize into mutagenic or carcinogenic compounds.

Industry Conflicts of Interest and Problematic Regulatory Testing

All of these issues are compounded by the fact that, while manufacturers today are much more attentive and aware of health risks of chemicals as compared to decades ago, oftentimes the testing of chemicals is not always done thoroughly enough before a new dye is introduced into the commercial marketplace. Then, as the case is often with many pharmaceutical drugs, ill effects are often discovered after the fact once it has been introduced into general usage. This was the case with the dye Amaranth, which was introduced, then discovered to be carcinogenic, and then subsequently withdrawn.

Other times, companies, in pursuit of cutting costs, greater profits, and quicker turnaround times in garment manufacturing, have continued to use already banned dyes and chemicals. Greenpeace International recently commissioned a study to investigate many popular clothing manufacturers’ use of known hormone-disrupting and potentially cancer-causing compounds called NPEs. Independent labs found two-thirds of clothing items testing positive for these compounds. While these compounds are banned in the European Union (EU) and parts of North America, many international clothiers, as noted earlier, outsource to developing countries where regulatory testing and regulations are more lax.

Needless to say, this situation creates an especially concerning situation for residents and textile workers in these countries who are unwittingly being exposed to potential dangerous levels of such chemicals. Furthermore, these chemicals also often are being released into water supplies through either illegal dumping of wastewater or via ill-suited water treatment plants in such locales unable to filter out such chemicals. Thus, aquatic life and those dependent on using local waters for recreation, drinking, or bathing are being endangered due to such practices.

Studies such as those funded by Greenpeace, furthermore, have illustrated the plethora of dangerous and hazardous chemicals being released into wastewater and water treatment supplies, such as
Thailand

Thailand is a country located in the Indochina peninsula in southeast Asia and is made up of four areas: the north, northeast, south, and central regions. It was once deeply rooted in its indigenous medical practices, which stem both from the Buddhist belief system as well as those of indigenous tribes: the Mon and Khmer. In addition to these medical practices, Western medicine has become increasingly popular and advanced over the last 60 years.

By the 1900s, there was a large influx of migration of peoples from regions in southern China—what we know today as the Thai people. With this migration came new beliefs about medical practices. Western medicine was adopted, and many renounced the effectiveness of traditional, indigenous medical practices. Eventually, traditional medicine found its way back into validity in Thailand. Currently, there are two main strains of traditional medicine. The first is called Traditional Thai Medicine (TTM), which refers to traditional practices that are regulated by the Ministry of Public Health. The second is called Traditional Medicine of Thailand, which adopts its practices from ancient texts and is practiced throughout the country, although it is not systematized by the Ministry of Public Health, which oversees and regulates medicine and health care practices throughout Thailand.

While Thailand has been largely untouched from much Western influence, as it was not colonized like other parts of southeast Asia, Western medicine became more prevalent throughout the 1900s, and medical practices were largely advanced and refined by the 1970s. Western medical treatments for cancer are widely used and available throughout Thailand, with the rise of cancer treatment clinics, medical journals, and studies.

Cancer has been an increasing problem in Thailand over the last 15 years. People are most commonly subject to cholangiocarcinoma, a type of cancer that affects the liver and parts of the gastrointestinal tract.

Cholangiocarcinoma is also referred to as bile duct cancer, and it is caused by the consumption of raw fish from various regions in northeast Thailand. The fish oftentimes are infested with either a parasite or a liver fluke, which in turn affects the human host, leading to recurring incidents of infectious disease, which ultimately lead to cancer. Bile duct cancer typically has a poor prognosis and is rare in Western countries.

In a 2001 study conducted by the Japanese Journal of Clinical Oncology, it was reported that cancer was the leading cause of death overall in Thailand. In 2001, liver cancer or cholangiocarcinoma was

perfluorinated chemicals (PFCs) and alkylphenols. Solutions do exist thankfully, however, to change such situations through combined efforts of better regulation, forcing greater accountability on textile manufacturers and parent companies, and through the substitution of more natural dyes as well as well-tested synthetic substitutes such as the 2-aminoazo dyes instead of the 4-aminoazos.

Part of the challenge here has been companies who have been reticent to comply or be proactive in adopting more stringent guidelines when it comes to chemical use and proven health risks, which include many major clothing manufacturers popular with many consumers globally including Adidas, Abercrombie & Fitch, Calvin Klein, Nike, Ralph Lauren, and others. Moving such initiatives along continues to be an ongoing struggle of pitting health and environmental advocacy groups and concerned consumers against manufacturing plants and parent clothing manufacturers, with governments often stuck in the middle of it all in many countries.

Further Readings
the leading cause of cancer-related deaths in both men and women. Thailand's incidence of liver cancer is much higher than any other region in the world due to liver flukes that correlate with the consumption of raw seafood. Because of increases of this disease in recent years, Thai political officials have been canvassing to promote dietary and health education to limit the consumption of raw and potentially infested foods.

Dr. Tanasanvimon is an oncologist at King Chulalongkorn Memorial Hospital in Bangkok. Even with Thailand's advances in Western medicine, specifically in the field of cancer, there are still few well-known oncologists. Dr. Tanasanvimon specializes in the study of cholangiocarcinoma and other gastrointestinal cancers. Because cholangiocarcinoma is the leading cause of cancer-related deaths in Thailand, Dr. Tanasanvimon has dedicated much of his research and practice to the branch.

Much of Dr. Tanasanvimon's research has substantiated claims that cholangiocarcinoma is caused by nitrate contamination and parasitical infestation of local seafood. Dr. Tanasanvimon recently received a grant in 2013 to continue his research, which he hopes will provide himself and other oncologists the ability to narrow treatment options and provide for earlier prognosis. In addition to his research, he perpetuates the political message of the importance of a healthy diet.

In addition to breakthroughs promoting dietary education, there also is a national dialogue of the benefits of screening for both cervical and breast cancers in women. While incidents of breast and cervical cancer among Thai and Asian women in general is lower than in other ethnic groups, the screening practice of these cancers is relatively low. The lack of self-screening among Asian women corresponds to the social attitudes and beliefs about the subject in those regions.

While the risk for these types of cancers seems to be a lower concern for Thai women, the mortality rate for these cancers is higher than would be expected as most women do not regularly practice self-screening.

Religious beliefs also play a large role in health care and health practices in Thailand. Buddhism is the official religion and has influence over a great deal of people's lives, specifically regarding alternative medical treatment.

Buddhist mind power healing is an avenue that the people of Thailand may consider exploring, especially if they already actively practice Buddhism. Most people who turn to this method operate on the belief that the disease was caused by some wrongdoing or bad will on their part in an earlier time during their lives.

This practice, though not uncommon, is typically reserved for those in the later stages of cancer who are seeking an alternative treatment after already undergoing traditional, Western methods like chemotherapy and radiation.

Wat Kampramong is another holistic approach rooted in TTM. Wat Kampramong was created by a Buddhist monk and largely targets cancer patients in later stages of the disease, much like Buddhist mind power healing. Wat Kampramong does not employ any Western strategies, and instead, the treatment consists of various mixtures of herbs and teas. While there is no empirical evidence to support the effectiveness of Wat Kampramong, many patients have described a feeling of overall well-being after they have taken part in the treatment.

Thymoma, Childhood

The majority of the reports that describe the benefits of thymectomy involving juvenile myasthenia gravis (MG) were inferred from adult cases, whereas those relating to pediatric cases are minimal. This situation has thus prompted research groups to investigate the outcome of thymectomy in children diagnosed with thymoma. Recent studies have shown that pediatric thymoma patients within the age range of one to 15 years old at disease onset can present with various stages of thymoma, ranging from stage II to IV.

Furthermore, the use of the Osserman classification scheme has facilitated in the staging of pediatric cases of thymoma. Research investigations also have shown that screening for antibody titers for anti-acetylcholine receptor assists in the design of a personalized treatment scheme for a child diagnosed with thymoma.

MG pertains to a neuromuscular disorder characterized by dysfunctional transmission of signals due to damage in the postsynaptic endplates of nerve cells. The damage is mainly due to the responses of the immune system, thus resulting in variable degrees of muscle weakness and rapid fatigue in an individual. The extent of muscle types involved in MG varies among patients and also can change during the course of the disease. Mild MG often involves the muscles of the eyes, whereas more severe forms present generalized muscle weakness that is usually coupled with respiratory failure and bulbar symptoms.

In the Western parts of the world, almost 20 percent of patients diagnosed with immune-mediated MG develop their first symptoms prior to age 15. Although MG extensively varies in terms of its epidemiology and progress, the pathophysiology of its juvenile-onset stage is similar to that of adult-onset cases. Researchers have thus suggested that the treatment regimen for MG, regardless of age of onset, should be similar because of its identical pathophysiological characteristics. Furthermore, antibody titers for the acetylcholine receptor are commonly detected in approximately 85 percent of patients presenting generalized MG. On the other hand, only 50 percent of patients with mild MG, and thus showing only ocular involvement, test positive for the acetylcholine receptor.

In the case of patients who test negative for acetylcholine receptors, antibodies against muscle-specific kinase can be screened, which has been observed in approximately 30 percent of patients who test negative for this receptor protein. Previous studies also have suggested that the thymus plays an important role in the generation of an immune response, which in turn induces the production of antibodies against the acetylcholine receptor in MG patients. The relationship between MG and thymic hyperplasia also has been confirmed in thymoma, although this disorder rarely occurs in children.

Since the 1940s, thymectomy has been utilized as the treatment scheme for MG. The choice of thymectomy as the effective approach for MG treatment is based mainly on the reported improvement in the condition of MG patients after the procedure. The evidence-based findings from a significantly high number of reports support this treatment scheme, despite the absence of randomized controlled trials. Retrospective studies of MG have shown that, when thymectomy was conducted during childhood, the improvement was observed in 68 percent of the pediatric patients. In addition, half of this subpopulation was taken off their medications for MG after thymectomy. However, caution should also be exercised in this retrospective study because the pediatric MG patients presented heterogeneous symptoms, which in turn reflects potential variations in their responses to thymectomy. Studies have shown that the specific age of the pediatric patient also can influence the outcome of thymectomy; therefore, one cannot immediately generalize the outcomes of pediatric MG patients. Other factors that also could directly or indirectly influence pediatric patient outcome
after thymectomy include the specific surgical technique employed, the administration of immune therapies that are simultaneously administered with the surgical procedure, and the time interval between the thymectomy and the follow-up visit to the attending physician.

It is also important to consider that the majority of the pediatric MG patients is acetylcholine receptor antibody-negative, whereas some of these patients are muscle-specific kinase antibody-positive. Other cases might have unrecognized congenital-type myasthenic syndromes, which are often unresponsive to surgical techniques such as thymectomy due to their particular genotypic constitution. Several studies have thus examined the effect of thymectomy on juvenile MG. Most hospitals offer thymectomy as a standard treatment scheme for pediatric juvenile MG patients who are acetylcholine antibody-positive based on their generalized symptoms and their uncontrolled condition using medications alone. These studies have shown that pediatric patients with juvenile MG have higher rates of remission (38 percent) regardless of the presence or absence of treatment using medications. On the other hand, pediatric patients who did not undergo thymectomy had significantly lower remission rates (7 percent), irrespective of the administration of medications.

The severity of MG is determined by the Osserman classification scheme, which has been used extensively in juvenile MG studies for years. This classification system commonly is applied to clinical studies that focus on the effects of thymectomy on pediatric patients with juvenile MG. Examples of classification groups using the Osserman system after thymectomy include in remission, condition improved, disease unchanged, condition worsened, or dead. Other clinicians also include modifications in the medications received by the patient. A more detailed scheme for classifying MG was developed by the Myasthenia Gravis Foundation of America; however, this system has not been validated in pediatric patients.

Factors that significantly contribute to patient outcomes in using thymectomy include the selection of acetylcholine receptor antibody-positive pediatric patients, a relatively short interval between onset of MG and surgery, the use of the transternal technique in surgery that facilitates in the visualization as well as the excision of the thymus, and the administration of immune-modulating agents after thymectomy. Previous studies have shown that, when thymectomy is conducted early on, the patient often achieves a higher chance of achieving remission. An earlier study involving 85 pediatric MG patients showed that 61 percent of the patients who underwent surgical removal of their thymus within a year of disease onset were observed to be in remission at three-year follow-up. On the other hand, 24 percent of the patients who did not undergo thymectomy within a year were in remission by the third year of follow-up. The effects of thymectomy gradually occur, and thus, the entire general outcome might not be evident until at least one year after the surgical procedure.

Thymoma and Thymic Carcinoma

Thymic carcinoma is a rare tumor involving the mediastinum and is generally considered as an orphan disease based on its relatively low prevalence. The current histological classification of thymic carcinomas consists of three categories, namely thymomas, thymic carcinomas, and lastly, neuroendocrine thymic tumors. The earliest research reports on thymic tumors were based mainly on
Thymoma and Thymic Carcinoma

single-institution cases that were diagnosed and treated in the past few decades. These long-term studies were conducted due to the rarity in the occurrence of thymic carcinoma, and thus, several years of collection of case reports were required to create a study population of acceptable size. In the past decade, the interest in thymic carcinoma has increased, which resulted in the establishment of a thymic working group that closely looked into various clinical aspects of this particular malignancy. The European Society of Thoracic Surgeons (ESTS) is an organization consisting of general thoracic surgeons from various countries who are dedicated in establishing a platform for studies on the clinical aspects of thymic carcinoma.

Thymic tumors are relatively rare tumors that occur in adults and involve the anterior mediastinal compartment. These tumors are highly heterogeneous, thus resulting in its further classification into subgroups based on histological features, namely, thymomas, thymic carcinomas, as well as neuroendocrine thymic tumors. Thymic malignancies have long been considered as orphan diseases. However, there has been a recent increase in interest in these malignancies, thus resulting in the creation of internationally based thymic interest groups in various countries around the world.

In the United States, the incidence of thymic tumors is 0.15 cases for every 100,000 person-years. Thymic carcinomas are the most common anterior mediastinal tumor that occurs in adults; however, these tumors also can develop at any age. A significant peak in incidence during the age range of 30 to 40 years has been reported for thymomas associated with myasthenia gravis, whereas the age range of 60 to 70 years of age was associated with the highest incidence of thymomas that were not associated with myasthenia gravis.

The incidence of thymic carcinoma is similar among males and females. Approximately 30 percent of patients diagnosed with thymoma are asymptomatic, whereas 60 to 70 percent of patients with thymic carcinoma and neuroendocrine thymic tumors show symptoms upon presentation. The most common symptoms recorded in any type of thymic tumor are often local, which include chest pain, difficulty or shortness of breath, and cough. In the case of invasive thymic carcinomas, the most common presentations include superior vena cava syndrome, paralysis of the hemidiaphragm with involvement of the phrenic nerve, and hoarseness of voice, possibly due to recurrent infiltration of the laryngeal nerve. Thymic carcinomas that have reached pleural spreading often present symptoms of pleural effusion coupled with chest pain.

Thymic malignancies often are associated with paraneoplastic or parathymic diseases. The most prevalent paraneoplastic disease among thymoma patients is myasthenia gravis, which has been observed in almost 50 percent of patients. In paraneoplastic syndromes not associated with myasthenia gravis, pure red cell aplasia or hypogammaglobulinemia is often observed, usually occurring in 5 percent of thymic carcinoma patients. These particular carcinomas are rarely associated with myasthenia gravis, and its prevalence ranges from 0 to 30 percent, often depending on the series being examined. Thymic carcinomas have very rarely been observed in cases of polymyositis, dermatomyositis, and erythrocytosis. Neuroendocrine thymic tumors often are associated with approximately 30 percent of endocrinopathies, which include Cushing’s syndrome and multiple endocrine neoplasia type 1. Wermer syndrome associated with parathyroid tumors, pancreatic islets cells, as well as the pituitary gland have also been associated with neuroendocrine thymic tumors. There also are cases in which the excessive production of growth hormone-releasing hormone associated with ectopic acromegaly have been associated

A basaloid type thymic carcinoma. Thymic carcinomas are the most common anterior mediastinal tumor that occurs in adults; however, in general it is a rare tumor. (Wikimedia Commons)
Thyroid Cancer

with neuroendocrine thymic tumors. Other rare syndromes linked to neuroendocrine thymic malignancies consist of prolactin secretion, multiple endocrine neoplasia type 2, peripheral neuropathy, myasthenia gravis, Eaton-Lambert syndrome, and carcinoid syndrome.

Thymoma patients generally have a twofold higher risk of developing second malignancies. Thymic tumors are generally diagnosed after clinical examination, radiographic imaging, and collection of a biopsy specimen for histological analysis. Clinical examination of the patient facilitates in the identification of symptoms of parathyroid syndromes. The use of computer tomography (CT) imaging also has been considered as an imaging standard for the initial assessment of patients with thymic malignancies. CT imaging is also the preferred procedure during follow-up monitoring of thymic carcinoma patients. On the other hand, magnetic resonance imaging (MRI) is apparently of little use in the diagnosis of thymic carcinomas, except in cases involving possible infiltration of the large vascular tissues and the heart. Positron emission tomography (PET) scanning also has been employed for the differentiation between thymic hyperplasia and thymoma, as well as low- and high-risk thymomas, and thymoma versus thymic carcinoma.

The cytohistological assessment of a biopsy specimen often is required for the diagnosis of thymic carcinoma. However, this has been less frequently employed in the previous decade. The significant improvement in imaging technologies has, since then, improved the diagnostic capability of histological assessment; and therefore, the utilization of this technique has increased in the past several years. A consensus, however, has been reached that assessment of a biopsy specimen would be required only in cases wherein the results of CT scanning are vague or seem to be unable to fully classify the tissue of interest or when the target tumor has been determined to be unresectable prior to initiation of chemotherapy or chemoradiotherapy.

Unfortunately, there is currently no established classification system for thymic carcinomas. The governing body mandated to define specific malignancies, Union of Internationale Contre le Cancer, in collaboration with the American Joint Commission on Cancer, has proposed a preliminary classification scheme. However, no official system has so far been identified. The most frequently used classification system for thymic carcinomas is the Masaoka staging system, which was first presented in 1981. Minor modifications to the classification system were incorporated in 1994. The Masaoka staging system uses four stages of disease progression, although the N factor is often of little value to the scheme. The new tumor, node, metastases (TNM) system is anticipated to be released in 2017, through the collaborative efforts of the International Thymic Malignancies Interest Groups together with the International Association for the Study of Lung Cancer.

Thyroid Cancer

The term thyroid cancer refers to cancer that originates in the thyroid gland, the butterfly-shaped gland located in the neck responsible for hormones that regulate major systems of the body (including the cardiac, digestive and reproductive systems). Thyroid cancer is the fastest-increasing cancer in adults in the United States and is rising throughout the world. Two main risks that increase the chances of thyroid cancer are genetic predisposition and exposure to radiation (environmental or medical). Most thyroid cancer responds well to treatment if caught early and treated effectively.
Risk, Prevalence, and Outcomes
Though thyroid cancer can develop without any specific identified cause, there are known risk factors. Nuclear accidents are known causes of thyroid cancer due to exposure to radiation and radioactive iodine (which can be prevented with potassium iodine). Exposure to external radiation through medical treatment is known to increase the risk of developing thyroid cancer.

Thyroid cancer is more common in areas where diets are low in iodine. Individuals with thyroid disorders or a family history of thyroid disorders or cancer are also at higher risk of thyroid cancer, and genetic mutations have been identified that may lead to development of thyroid cancer over the life span. The risk of thyroid cancer increases with age, and females are more likely to develop thyroid cancer than males. Children are much less likely to develop thyroid cancer and tend to have very good outcomes.

Thyroid cancer is typically slow growing and responds well to treatment, and long-term prognosis for patients undergoing treatment is positive. Studies of thyroid cancer patients over many years have shown that the vast majority, estimated between 90 and 100 percent, survive at least 10 years after diagnosis. Individuals under the age of 45 and those with small tumors and limited or no metastases usually have the best chance of a cure, though those over 45 also have a positive prognosis, though with a higher risk of recurrence.

Types of Thyroid Cancer
Thyroid cancer can be either differentiated (having relatively normal cell structures), including papillary and follicular thyroid cancer, or undifferentiated (having abnormal cells lacking typical cell structure), including medullary and anaplastic thyroid cancer.

Papillary cancer is the most common form of thyroid cancer in both adults and children, accounting for more than 85 percent of new cancer diagnoses. This form of cancer begins in the follicular cells and grows slowly. The risk of papillary cancer increases with exposure to external radiation (most commonly from medical treatment), although some researchers believe that carcinogens may affect the thyroid and increase the chance of thyroid cancer. Genetic mutations also have been linked to thyroid cancer of all types. The prognosis for papillary cancer, when diagnosed early, is very positive with a strong possibility of a cure.

Individuals with papillary thyroid cancer may have metastases (cancer that has spread to other parts of the body) to the lymph nodes, lungs, and bones, though thyroid cancer can spread to other areas of the body.

Follicular cancer is much rarer than papillary cancer but remains the second-most common form of thyroid cancer. Most people respond well to treatment and have positive outcomes. Follicular cancer is more aggressive than papillary and often invades the vascular system, which can lead to metastases in the lungs and bones. Even so, most individuals with this form of thyroid cancer do well with appropriate treatment. The majority of individuals diagnosed in early stages can be cured, and those in later stages have a positive prognosis, although reoccurrence is possible.

Medullary thyroid cancer, an undifferentiated thyroid cancer, is an uncommon, slow-growing cancer, which typically can be controlled if caught and treated before it metastases (spreads) to the rest of the body. Medullary cancer may run in families, passed from parent to child through changes in the genes. Outcomes for medullary thyroid cancer are dependent on how extensive the cancer has spread and how well the individual responds to treatment.

Anaplastic thyroid cancer is the rarest form of thyroid cancer but has the poorest outcome. Anaplastic thyroid cancer tends to occur most commonly in those over 60, and cancer cells grow and spread quickly. This type of cancer is hard to control and does not respond easily to treatment.

Symptoms and Detection
Thyroid cancer usually is diagnosed when a nodule, or mass, is found on the thyroid. Most nodules are benign, with between 10 and 30 percent being cancerous. Most cases of thyroid cancer are found during a standard doctor’s appointment, when a mass is felt or seen in the throat or neck. Thyroid cancer is usually painless, though in more advanced cases, nonspecific symptoms also may be present, including difficulty swallowing, difficulty breathing, or shortness of breath and persistent hoarseness.

If a mass is found during a physical exam, typically it is followed by tests including a neck ultrasound and needle aspiration. Blood work often is
used to identify issues in thyroid functioning. Other tests that may be done include chest X-rays, computed tomography (CT) scans, and thyroid scans to check for the extent of the cancer and to determine if it has spread to other parts of the body.

Treatment
Once identified, thyroid cancer is treated through surgical removal of the thyroid. Radioactive iodine often is used a few weeks after surgery to destroy any remaining thyroid tissue. The thyroid gland absorbs iodine, and a dose of radioactive iodine will destroy thyroid tissues. Other forms of treatment may be used, especially if thyroid cancer has metastasized throughout the body.

Conclusion
Thyroid cancer is a primary cancer of the thyroid, which can occur in any age group, but is very rare in children and adolescents and occurs more frequently in older individuals. Most forms of thyroid cancer are identified during routine health visits after a nodule has been identified and biopsied (most nodules are benign). Treatment for thyroid cancer is typically surgery followed by radioactive iodine, and long-term prognosis for those with thyroid cancer is generally positive, with favorable outcomes in most cases, including the possibility of a cure, especially for those under 45 years old, in early stages, and with the most common two forms (papillary and follicular). Thyroid cancer is rarely found in children.

Further Readings
Thyroid Cancer, Childhood

for the large majority of thyroid cancers, or undifferentiated (having abnormal cells lacking typical cell structure), including medullary and anaplastic thyroid cancer. These four main types of thyroid cancer are described by the appearance of the cells using a microscope.

Papillary cancer is the most common form of thyroid cancer in both adults in children, accounting for more than 85 percent of new cancer diagnoses in adults and children. This form of cancer begins in the follicular cells and grows slowly. The risk of papillary cancer increases with exposure to external radiation (most commonly from medical radiation), although some researchers believe that carcinogens may affect the thyroid and increase the chance of thyroid cancer. Genetic mutations also have also been linked to thyroid cancer of all types. The prognosis for papillary cancer, when diagnosed early, is very positive, with a strong possibility of a cure. Many children with papillary thyroid cancer will have metastases (cancer that has spread to other parts of the body), most commonly to the lymph nodes of the neck. Between 10 and 20 percent of these will have metastases that have spread elsewhere, most commonly to the lung. In spite of this, children typically respond well to treatment with a high possibility of a cure with appropriate treatment.

Follicular cancer is much less common, even rarer in children, and is a slow-growing cancer in the follicles. Diagnosed early, children respond well to treatment, with positive outcomes, although more aggressive treatment may be required due to the fact that follicular cancer is more aggressive and often invades the vascular system, which can lead to metastases in the lungs and bones as well as other areas of the body. Even so, children with this form of thyroid cancer do well with appropriate treatment, most with a cure, though recurrences is possible.

Medullary thyroid cancer is an uncommon, slow-growing cancer, which typically can be controlled if caught and treated before it spreads to the rest of the body. Medullary cancer may run in families, passed from parent to child through changes in the genes. Medullary cancer typically requires more aggressive treatment and has a higher risk of recurrence, though most children with this form of cancer respond well to treatment.

Anaplastic thyroid cancer, which is not found in children, is a very uncommon, aggressive, and highly lethal form of thyroid cancer.

Symptoms and Detection
Thyroid cancer is usually diagnosed when a nodule, or mass, is found on the thyroid. Most nodules are benign, but between 10 and 30 percent of all nodules are cancerous. Most cases of thyroid cancer are found during a standard doctor’s appointment, when a mass is felt or seen in the throat or neck. Thyroid cancer is usually painless, though in more advanced cases, symptoms may be present including difficulty swallowing, difficulty breathing, or shortness of breath and persistent hoarseness.

If a mass if found during a physical exam, typically it is followed by tests including a neck ultrasound and needle aspiration. Blood work is often used to identify issues in thyroid functioning. Other tests that may be done include chest X-rays, computed tomography (CT) scans and thyroid scans to check for the extent of the cancer and to determine if it has spread beyond the thyroid.

Treatment
Treatment for thyroid cancer in children is the same as that in adults. Once identified, thyroid cancer usually is treated through surgical removal of the thyroid. Radioactive iodine often is used a few weeks after surgery to destroy any remaining thyroid tissue. The thyroid gland absorbs iodine, and a dose of radioactive iodine will destroy thyroid cells, including cancer cells.

Thyroid cancer usually responds readily to therapy, with positive outcomes for the majority of those diagnosed. Thyroid cancer can reoccur, and those diagnosed and treated for thyroid cancer must be monitored throughout their lives.

After thyroid removal, patients must go on levothyroxine (thyroid hormone replacement therapy) in order to maintain their health. Levothyroxine also suppresses thyroid stimulating hormone (TSH), which helps in preventing recurrance of cancer. Children typically receive a dose of levothyroxine, which is measured to keep TSH in the lower normal range in order for optimal health and growth.

Conclusion
Thyroid cancer is a rare cancer in children, occurring slightly more frequently in adolescents, especially females, that responds well to treatment with a high possibility of a cure. Treatment of thyroid cancers typically involves surgery followed by radioactive iodine and then hormone replacement.
Individuals with a history of thyroid cancer need frequent monitoring throughout their lifetime as thyroid cancer can reoccur and usually presents few symptoms. Some cases of thyroid cancer can be prevented by protective measures during radiation exposure and proper dietary iodine levels.

Tobacco in History

The smoking of tobacco first took place as early as 5000 B.C.E. and grew over time from its roots in the Americas to a worldwide phenomenon. Struggles over the cultivation and sale of tobacco have shaped and colored many other significant events throughout history, including wars, slavery, territorial disputes, and trade battles. Across time and place, tobacco has been used in multiple cultures for religious purposes and pleasure. The sale and marketing of tobacco has been and remains a major source of global revenue. Although German scientists identified a link between tobacco smoking and health as early as the 1920s, this practice continues in much of the world, causing a variety of health problems. As the link between tobacco and a variety of health concerns, including cancer, has grown, efforts to reduce its availability or ban it outright have grown.

Background
Tobacco was first cultivated as a crop in South America approximately 7,000 years ago. Tobacco often was used as part of shamanistic religious rituals, with it being burned as other civilizations burned incense during religious rituals. Over time, the use of tobacco expanded to include smoking the substance, either by itself or in combination with various hallucinogenic drugs. Tobacco also was seen as having certain medicinal benefits and was sometimes used in an attempt to ameliorate a variety of conditions, such as earaches, toothaches, and as a cure for the common cold.

European explorers first were introduced to tobacco by the indigenous Americans, and its use soon became popular with them. Tobacco use was introduced to Europe around 1600 C.E. and met with widespread opposition from political and religious leaders. This opposition led to a variety of measures intended to curtail its use, from large taxes being assessed upon the sale of tobacco to outright bans of the substance. Despite these efforts, however, tobacco use had become widespread by the mid-17th century. In London alone, more than 7,000 tobacco shops were doing business, and a variety of other outlets for its sale existed across the European continent. Snuff and pipe tobacco were the most popular ways of using tobacco, although other ways of consuming the product were also known.

John Rolfe, an early settler in the English community of Jamestown in Virginia, is credited as being the first European to cultivate tobacco as a cash crop. Strong demand in Europe soon led to tobacco being planted widely in Virginia and other American colonies. The tendency of tobacco to rapidly deplete the soil in which it is planted, however, led to a push from many tobacco farmers for further westward expansion as fresh soil was needed for tobacco cultivation.

As a labor-intensive crop, tobacco also presented planters with labor issues as it was difficult to secure the number of workers needed while still permitting its cultivation to be profitable. Indentured servants were used first, and then slaves were imported from Africa. Tobacco generated large tax revenues for the British government, sometimes in excess of £300,000 pound per year. The American Revolution greatly affected the tobacco market as the British significantly interrupted the export of tobacco to Europe. This caused many farmers to
turn to crops other than tobacco for the duration of the war.

**Growth Era**

In the years following the American Revolution, changing tobacco usage patterns affected tobacco farming. Certain European markets for American tobacco, such as Great Britain and France, never recovered from the blockades produced as a result of the war, and consumers there turned to other sources, such as Turkey and Africa, for tobacco. Domestic use of tobacco in the United States, however, grew markedly, and chewing tobacco became increasingly popular with this market. Overall, smokers began to switch from pipes to cigars, which slightly altered the types of tobacco planted. Cigarettes, which had been around since the early 19th century, saw an exponential increase in demand after 1881, when a machine that could manufacture them was created, greatly reducing their cost. The ability to produce cigarettes inexpensively and in large quantities led to the rapid growth of cigarette manufacturing companies. The American Tobacco Company, for example, had annual sales of approximately $25 million in 1890, a figure that had grown to exceed $300 million a decade later.

This growth in cigarette sales, combined with the development of color lithography, permitted tobacco advertising to grow exponentially during the 20th century. Advertising agencies engaged by the tobacco companies created slogans and advertising campaigns for specific cigarettes, with specific brands attempting to appeal to certain segments of the market. During the first decades of the 20th century, most advertisements were print based, and newspapers and glossy magazines were filled with these. Beginning during the 1930s, tobacco companies also began sponsoring specific radio shows, and certain celebrities became affiliated with certain brands of cigarettes, such as Jack Benny with Lucky Strike and Bing Crosby with Chesterfield. The use of endorsements from famous men and women was seen as a way of appealing to the public’s desire to affiliate with those seen as glamorous and successful. As television became popular after World War II, cigarette advertisements became common on that medium, with various brands seeking to create images that supported use of their cigarettes.

**Awareness of Health Concerns**

As early as the 1920s, German scientists became aware that certain health conditions, including lung cancer, heart disease, and emphysema, were strongly linked with tobacco use. On the basis of these studies, the National Socialist (Nazi) government of Adolf Hitler took a strong antitobacco stance. During this era, the Germans banned smoking on trams, buses, and trains, and organized antitobacco lectures for the public. The Nazis also placed severe restrictions upon advertisements for tobacco products and limited smoking in restaurants and other public spaces. Although forward thinking, Germany’s defeat in World War II, and its relative isolation beforehand, limited the spread of
this campaign to other nations. In the postwar era, German consumption of tobacco increased greatly.

Beginning in 1950, British physician Richard Doll began publishing a series of studies that strongly linked tobacco smoking to lung cancer. Unlike the earlier German studies, this research was influential in the United States and elsewhere. The popular American magazine *Readers Digest* ran an article disclosing this link to the general public in 1952. The health risks associated with tobacco smoking were highlighted in the widely disseminated British Doctors Study, which compiled more than 20 years of research linking tobacco smoking to cancer. In 1964, the United States surgeon general issued a report on smoking and health that greatly increased American public awareness of the health risks of tobacco. The Federal Communications Commission (FCC) began requiring television and radio broadcasters to air antismoking messages in response to cigarette commercials, and in 1971, the United States Congress banned tobacco advertising from the airwaves. During the next three decades, cigarette advertising was limited to newspapers, magazines, and billboards.

Although litigants had tried to sue the tobacco companies for health problems that had arisen as a result of their smoking cigarettes manufactured by these entities, these lawsuits were largely unsuccessful through the 1980s. During the 1990s, however, a series of lawsuits were brought by state's attorney generals in an attempt to defray the medical costs state and local governments had been forced to bear as a result of their residents smoking cigarettes. These lawsuits resulted in what is known as the Tobacco Master Settlement Agreement, entered into among the attorney generals of 46 states and R. J. Reynolds Tobacco Company, Brown & Williamson, Lorrillard Tobacco Company, and Philip Morris Companies. In exchange for an exemption from tort liability from private lawsuits, the tobacco companies agreed to pay out more than $200 billion over a 25-year period and to curtail or cease most advertising of their products. The Tobacco Master Settlement Agreement has created a fund that sponsors antismoking campaigns and smoking cessation programs.

Globally, tobacco is used daily by more than 3 billion people, including 49 percent of men and 11 percent of women. In the United States, rates of smoking have declined over the past five decades, from a high of approximately 40 percent of the population in 1965 to fewer than 20 percent of the adult population today. This decline has been especially significant among affluent, well-educated men. Tobacco use remains relatively high among lower-income groups, and among younger smokers, the percentage of women smoking is now nearly identical to the rate of men. Continued governmental efforts exist to curtail tobacco use, and the Federal Drug Administration (FDA) recently has been permitted to regulate tobacco sales.

**Tobacco Smoking**

According to reports by the United States surgeon general, cigarette smoking is a major cause of cancer mortality in the United States. Nearly one in five deaths in the United States can be attributed to tobacco use. Tobacco smoking is also the most preventable cause of death in this country because it is a choice to smoke.

**Centers for Disease Control and Prevention Statistics**

According to the Centers for Disease Control and Prevention (CDC) report, about 42 million, or
18 percent, of all adults were cigarette smokers in 2012. More cigarette smokers were in younger age groups in 2012, although these figures might be influenced by early deaths in older smokers. There has been a new trend in smoking among high school students. About 14 percent of high school students were smoking cigarettes in 2012, and an additional 13 percent of high school students were smoking cigars. The cigars have changed in appearance, looking more like cigarettes. They cost less and come in flavors, which make them more appealing to a younger population. Adolescents are smoking several a day and inhaling the smoke like they would cigarettes.

Tobacco smoking has a high mortality rate and is responsible for the deaths of about half of all Americans who keep smoking. In the United States, about 480,000 people die annually from illnesses related to tobacco use. Smoking cigarettes kills more Americans than alcohol, car accidents, suicide, acquired immune deficiency syndrome (AIDS), homicide, and illegal drugs combined. It is also linked to many forms of cancer and is responsible for about 30 percent of all cancer deaths. Smoking increases the risk of developing cancers such as lung, larynx, oral cavity, nose and sinuses, throat, esophagus, stomach, pancreas, cervix, kidney, bladder, ovary, colorectal, and acute myeloid leukemia. Lung cancer is one of the hardest cancers to treat and is the leading cause of cancer death. Tobacco smoking is responsible for about 87 percent of lung cancer deaths in men and 70 percent in women. Religious groups that promote or require nonsmoking in its members have much lower rates of lung cancer and other smoking-related cancers than other religious organizations. Sadly, as high as these figures are, cancer accounts for less than half of the deaths related to tobacco smoking each year.

Tobacco smoking also causes other health problems, some of which are deadly, including heart disease, aneurysms, bronchitis, emphysema, and stroke. It also can negatively affect female reproductive health and the health of an unborn fetus. Tobacco smoking has been associated with increased risk of miscarriage, premature birth, stillbirth, low birth weight, birth defects, and sudden infant death syndrome. Smoking can make pneumonia, asthma, and other respiratory conditions worse and can exacerbate other health problems, including gum disease, cataracts, bone thinning, hip fractures, and peptic ulcers. Smoking can cause or worsen poor blood flow in the arms and legs.

The smoke from cigarettes that is inhaled by nonsmokers, or secondhand smoke, also can have harmful health effects on those exposed to it. Adults and children can acquire health problems just from breathing in the secondhand smoke. Smoking affects longevity and quality of life. Tobacco smoking shortens the lives of smokers. Male smokers' lives are shortened by 13.2 years and female smokers' lives by 14.5 years. Tobacco smokers are more likely to die between the ages of 35 and 69. When individuals stop smoking before the age of 40, they reduce the risk of tobacco smoking-related fatalities by 90 percent.

In addition to tobacco smoking-related deaths, other less-fatal health issues can arise, including chronic bronchitis, emphysema, heart attacks, strokes, and cancer. Some studies also have linked tobacco smoking with sexual impotence in male smokers. Smoking-related illnesses limit a person's daily activities due to shortness of breath or trouble breathing, which can reduce the individual's energy or ability to engage in activities. When someone quits smoking, especially at a younger age, tobacco smoking-related disability risks are greatly reduced.

Misconceptions of Tobacco Smoking

All types of tobacco smoking are dangerous and addictive. While it is important to cut down on the number of cigarettes smoked, it still poses a risk. Some research indicates that smoking even one to four cigarettes a day still increases the risk of serious health problems, including heart disease and the likelihood of dying at a younger age. Light and low-tar cigarettes also pose serious health risks. Many individuals do not understand this and assume that these types of cigarettes are safer for them to smoke. As a result, the United States Food and Drug Administration banned the use of the words light, mild, and low as descriptors for cigarettes. This ban, however, has not been extended to the cigarette-like cigars.

Some individuals erroneously believe that hand-rolled cigarettes are a cheaper and healthier way to smoke, but they are no safer than commercial brands. The opposite seems to be true. Longtime hand-rolled cigarette smokers have been shown to have an increased risk of developing cancers of the larynx, esophagus, mouth, and pharynx when
compared with smokers of commercially made cigarettes. Cigarettes advertised as all natural are marketed as having no chemicals or additives and are rolled with 100 percent cotton filters. These products do not have a basis for health claims and contain agents that can cause cancer. There are also toxins that come from the burning of the tobacco, including tar and carbon monoxide. This is also true of herbal cigarettes that do not contain tobacco.

Menthol cigarettes are no safer and might present an increased risk. The added menthol tends to produce a pleasant sensation in the throat when the smoke is inhaled. This decreases the dry feeling in the throat often present in smokers. As a result, smokers tend to inhale more deeply and hold the smoke longer. Menthol cigarettes account for about one-third of all cigarettes sold in the United States, and they tend to be a popular option with child and adolescent tobacco smokers. The menthol tends to make cigarettes seem smoother and less harsh, making them easier to smoke for first use and harder to quit.

Chemicals in Tobacco Smoke

Tobacco smoke is harmful to both smokers and nonsmokers, causing various forms of cancer and other health issues previously listed. When smokers quit, they reduce the health risks caused by exposure to tobacco smoke because they are no longer ingesting harmful chemicals. Tobacco smoke contains chemicals that can negatively impact the health of smokers and nonsmokers who breathe in secondhand smoke, including hydrogen cyanide, carbon monoxide, ammonia, arsenic, formaldehyde, and cadmium. There are 250 known harmful chemicals in tobacco smoke, and at least 69 are currently believed to be cancer-causing agents.

Nicotine is a substance that is present naturally in the tobacco plant and is considered the primary source of addiction to tobacco products. The nicotine enters the lungs as smokers inhale and is quickly absorbed into the bloodstream, where it travels to the brain. This process occurs in just a few seconds, releasing brain chemicals in response. Tobacco smokers who inhale deeply are at greater risk than those who smoke a higher nicotine content and do not inhale as deeply. The way the person smokes the tobacco is more important than the content of the nicotine in the tobacco for determining how much nicotine gets into the body. The nicotine is absorbed in the lungs and the lining of the mouth, and inhaling deeply through frequent puffs presents the greatest absorption of nicotine.

Secondhand Smoke

Secondhand smoke is a combination of smoke exhaled by a smoker and smoke given off by the burning tobacco product. Secondhand smoke causes lung cancer in nonsmoking adults as they inhale the smoke of others. It is also implicated in an increased risk of heart disease and can cause low birth weight in pregnant women who inhale secondhand smoke. Children who are exposed to secondhand tobacco smoke face an increased risk of sudden infant death syndrome (SIDS), ear infections, colds, pneumonia, bronchitis, and more severe asthma. It can also slow the growth of the child’s lungs, causing him or her to have respiratory issues.

Tobacco Facts

Cigarette smoking is responsible for approximately 480,000 deaths each year in the United States, including approximately 49,000 deaths related to breathing in secondhand smoke. Lung cancer is the leading cause of cancer death among both men and women in the United States, and 90 percent of lung cancer deaths among men and approximately 80 percent of lung cancer deaths among women are due to smoking. Smokers also have an increased risk of heart disease and heart attacks. They are as much as six times more likely to develop these problems, and the risk increases with the number of cigarettes smoked. Smoking also causes most cases of chronic lung disease.

There has been an overall decline in tobacco smoking between 2005 and 2011 for adults between the ages of 18 and 24 years. While the decline is significant, there are still many people who are smoking. In an effort to further reduce tobacco smoking, policy makers have considered increasing the price of tobacco products, implementing smoke-free laws in workplaces and public places, increasing antitobacco campaigns in the media, increasing incentives to help quitting, and enforcing restrictions on tobacco advertising.

Although comprehensive tobacco control programs have been effective in decreasing tobacco use in the United States, they do not receive as much funding as they need. The Centers for Disease Control and Prevention (CDC) recently recommended what it believed to be appropriate annual funding levels for each state’s comprehensive tobacco control program. Unfortunately, only two states chose to budget in tobacco control programs at
Tobacco-Related Exposures

Exposure to tobacco is strongly linked to cancer. Such exposure can occur through ingestion of tobacco related products such as cigarettes, cigars, and smokeless tobacco. Exposure also can occur through secondhand smoke or through exposure to tobacco plants in the environment, such as the workplace. Despite the fact that death from tobacco related exposure is highly preventable, tobacco exposure causes thousands of deaths from various diseases and cancers each year.

Epidemiology

Approximately half of those who continue to smoke will die of a smoking-related illness, disease, or cancer. Cigarette smoke is responsible for approximately one out of every five deaths in the United States. The overall mortality in the United States is approximately three times higher among smokers than nonsmokers. The primary causes of the increased mortality rate among smokers are cancers and diseases related to smoking, such as respiratory and vascular diseases. It is estimated that 159,260 deaths from lung cancer will occur in 2014. Men who smoke are 23 times more likely to develop lung cancer than nonsmoking men. Women who smoke are 13 times more likely to develop lung cancer than nonsmoking women. Smoking also is related to cancers of the lip, oral cavity, pharynx, esophagus, pancreas, larynx, cervix, bladder, liver, stomach, ovaries, colon, and kidneys. Exposure to tobacco through cigarette smoke is also the cause of many diseases, such as chronic obstructive pulmonary disease and heart disease. A smoker who experiences cardiac arrest is at a greater risk of death than a nonsmoker who experiences cardiac arrest. Smokers are also at an increased risk of strokes and aneurysms than nonsmokers. Worldwide, exposure to tobacco results in 6 million premature deaths annually.

Further Readings

Some chemicals found in tobacco smoke include cyanide, benzene, formaldehyde, methanol, acetylene, ammonia, tar, carbon monoxide, and nitrogen oxide. Nonsmokers also may be exposed to these chemicals through secondhand smoke. More than 7,000 cases of lung cancer and more than 33,000 cases of heart disease occur each year in the United States as a result of secondhand smoke.

The life expectancy of smokers is about 10 years shorter than it is for nonsmokers. The use of smokeless tobacco is linked to an increase in the risk of death from an irregular heartbeat. Secondhand smoke is responsible for about 42,000 deaths in the United States each year.

Middle-aged individuals who smoke are four times more likely to die from coronary heart disease than those who do not smoke. In both men and women, smoking also increases the risk of dying from emphysema, bronchitis, cancer of the trachea, lung, and bronchus. Women who smoke often have lower bone density and are therefore at greater risk of broken bones and hip fractures. Smoking weakens blood flow and is linked to the development of an abnormal heartbeat.

Many childhood diseases are related to tobacco exposure in the womb, often resulting from smoking or exposure to secondhand smoke during pregnancy. Smoking during pregnancy increases the risk of the child developing lung cancer, heart disease, emphysema, asthma, and allergies. Smoking during pregnancy is related to an increased risk of low birth weight, premature births, and infant deaths. Approximately 5 percent of infant deaths are caused by smoking during pregnancy. Infants who are born to parents who smoke have an increased risk of heart defects, cleft lip or palate, and other birth defects. Infants also can be exposed to tobacco related carcinogens through breast milk in mothers who smoke or use tobacco products. Secondhand smoke damages cells in the same way smoking does. Secondhand smoke exposure is dangerous for pregnant women, and it has been linked to an increase rate of miscarriages.

Smoking and Other Forms of Tobacco Consumption

Tobacco products such as cigarettes, cigars, and smokeless tobacco have been linked to lung, head, and neck cancers. The more an individual uses tobacco products, the greater the cancer risk.

Smoking cigarettes is one of the leading causes of cancer, including lung cancer. It is estimated that 221,200 new cases of lung cancer will occur in 2015. Smoking increases the risk of developing lung cancer by more than 25 times. Smoking is responsible for about 87 percent of lung cancer deaths in men and 70 percent of lung cancer deaths in women. Smoking increases the risk of developing cancer by damaging the lungs, weakening the immune system, and causing changes in the genes. Tobacco use is responsible for approximately 30 percent of all cancer deaths.

Those who quit smoking have a greater chance of recovering from cancer than those who do not quit. Individuals who have cancer and who continue to smoke may not respond well to treatment and increase their risk of developing secondary cancer.

Cigars, as well as cigarettes, contain many carcinogens, and cigar smoking is related to cancers of the lung, mouth, throat, larynx, esophagus, and pancreas. Like cigarettes and cigars, smokeless tobacco products contain carcinogens. The use of smokeless tobacco increases the risk of developing cancers of the mouth, throat, pancreas, and esophagus.

Snuff is ground tobacco packaged in pouches or cans and is placed between the lower lip and gum. Nicotine in snuff is absorbed through tissues in the mouth. Snus is a common form of finely ground, moist snuff. The use of snus is related to an increased risk of pancreatic cancer. Snus users often develop lesions in the mouth, where the product is placed. All forms of snuff and smokeless tobacco contain carcinogens.

Cancers related to smokeless tobacco include cancers of the mouth, tongue, cheek, gum, throat, esophagus, stomach, and pancreas. In addition to various forms of cancer, smokeless tobacco also is linked to an increase in risk of heart disease, heart attacks, stroke, high blood pressure, tooth loss, tooth decay, cavities, bad breath, tooth abrasions, bone loss around the teeth, receding gums, leukoplakia, and an increased addiction to nicotine.

Secondhand Smoke

Secondhand smoke exposure can occur in the home or the workplace, and such exposure increases the risk of lung cancer by 20 to 30 percent. Even for nonsmokers and those who have never smoked, exposure to secondhand smoke can cause lung cancer. Nonsmokers who are exposed to secondhand
smoke inhale the same carcinogenic substances as those who smoke. Secondhand smoke is responsible for about 3,400 lung cancer-related deaths each year in the United States. Exposure to secondhand smoke can damage cells, even if the period of exposure was brief. The longer a person is exposed to secondhand smoke, the greater the risk of developing lung cancer. Secondhand smoke is also responsible for about 42,000 deaths each year in the United States as a result of heart disease. Secondhand smoke results in exposure to nicotine and toxic chemicals. Asthma is commonly developed by children who are exposed to secondhand smoke.

**Workplace Exposure to Tobacco**

Green tobacco sickness (GTS) is a form of acute nicotine poisoning resulting from absorption of nicotine through the skin as a result of picking tobacco and working in tobacco fields. GTS is a unique occupational hazard for farmworkers. Symptoms of GTS include nausea, vomiting, headaches, and dizziness. Some studies indicate that more than 40 percent of farmworkers reported having suffered from GTS at least once during the harvesting season. Even for farmworkers who do not smoke cigarettes, those who work in tobacco fields have levels of nicotine in their bodies equivalent to levels in regular smokers. The dizziness and nausea associated with GTS can become so severe that workers often vomit in the tobacco fields. Working with wet tobacco or wearing wet clothing while working increases the risk of GTS. GTS is highly preventable and could be avoided if farmworkers were provided with the proper protective clothing. Children and adolescents are at a greater risk of GTS than adults.

**Symptoms**

Smoking is the number one risk factor for developing lung cancer. There are many symptoms of lung cancer, including: coughing, shortness of breath, hoarseness, trouble breathing, wheezing, chest pain, fatigue, weight loss, and coughing up blood. Swollen or enlarged lymph nodes between the lungs also sometimes occur as symptoms of lung cancer. Often, symptoms do not occur until the cancer is advanced, and not all those who have lung cancer will exhibit all of these symptoms.

Exposure to tobacco products increases the risk of heart disease. Symptoms of heart disease include chest pain, shortness of breath, pain or numbness in the arms and legs, fatigue, and irregular heartbeat.

Laryngeal cancer also is commonly related to tobacco products. Symptoms of laryngeal cancer include a sore throat, constant coughing, trouble breathing, trouble or pain when swallowing, ear pain, weight loss, or a lump in the neck.

Likewise, esophageal cancer can be caused by tobacco or cigarettes. Symptoms of esophageal cancer include difficulty swallowing, weight loss, chest pain, fatigue, pressure or burning in the chest, coughing or hoarseness, frequent choking, indigestion, or heartburn. However, the early stages of both laryngeal cancer and esophageal cancer may cause no signs or symptoms.

Tobacco use has also been associated with recurrence and death from gastric cancer, even after initial surgeries to remove the cancer.
Prevention
In the United States, smoking is responsible for approximately 90 percent of lung cancer deaths in males and approximately 80 percent of lung cancer deaths in females. Quitting smoking is the most effective way to prevent lung cancer and other forms of cancer related to tobacco exposure. Despite the dangers related to tobacco use, more than 20 percent of men and 15 percent of women smoke cigarettes in the United States. Quitting smoking before the age of 40 has been shown to reduce the risk of death from a tobacco exposure by approximately 90 percent. In addition to quitting smoking, secondhand smoke also should be avoided.

Regular medical checkups and cancer screenings can help detect early signs of cancer related to tobacco exposure. Early detection of cancer can increase the possibility of remission.

Treatment
Treatment for tobacco-related cancer depends on the stage at which the cancer is first identified. Treatment options include surgery, radiation therapy, chemotherapy, various drugs, or a combination of these treatments.

Depending on the type and stage of the cancer, surgical removal of the cancer is sometimes a possible treatment. Additionally, certain drugs can be used to shrink lymph nodes and kill cancer cells. Radiation therapy uses radiation to kill cancer cells and prevent cancer from spreading.

It is important to quit smoking during treatment as exposure to tobacco can interfere with the success of the treatment. Secondhand smoke and smokeless tobacco products also should be avoided. It is important for both patients and clinicians to play a role in reducing the burden of tobacco-related cancers by engaging with tobacco cessation treatment.

Togo

The Republic of Togo is situated in western Africa. It is the 33rd most populous country in Africa and 108th globally, with a population of more than 5.6 million. French is the statutory national language, and there are 39 living languages spoken in Togo by respective ethnic groups. The most widely spoken include Ewe, Kabiye, Moba, Moore, and Nawdm. Each ethnic group has its own traditions of ethnomedicine. For example, a traditional healer who uses medicinal plants for treating cancers and other ailments is called agbawola in Ewe, lintou in Kasem, and tip-tiim in Moore.

Many in Togo typically would rely upon traditional medicines more than modern pharmaceuticals for dealing with health concerns. This is due to the fact that traditional medicines are generally more accessible and less expensive as well as that many have greater familiarity with and trust in traditional practices. Accordingly, there are many traditional medicinal preparations used in Togo. Most of these incorporate use of local plant materials, many of which have been shown to have medicinal properties in laboratory studies.

For example, an extract from Cymbopogon citratus demonstrated cytotoxic activity. Research also suggests that use of certain plants may help protect against cancer by reducing oxidative stress and stimulating enzymes and other processes that help the
body fight carcinogens. For example, an extract from leaves of *Annona senegalensis*, as well as extracts from *Momordica charantia*, *Parinari curatellifolia*, and *Entada africana* demonstrated antioxidant activities.

Medicinal plants are used widely in Togo to treat cancers and associated conditions. For example, breast cancer traditionally is treated by rubbing the breast with grated twigs of *Cissus quadrangularis*, which the Kabre call *kodia*.

There are serious deficiencies of modern pharmaceutical supplies, as opposed to traditional preparations, and in modern medical services for cancer and similar conditions. According to the World Health Organization's Health System Response and Capacity, as of 2010, there was no general availability of either chemotherapy or radiotherapy in the public health system in Togo. Togo is a signatory to the Single Convention on Narcotic Drugs, Convention on Psychotropic Substances, and UN Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances; consequently, laws exist to control narcotic and psychotropic substances and precursors. Annual consumption of controlled substances is regulated to curtail abuse. Accordingly, annual consumption of morphine is 0.071 milligram per capita (mg/capita), fentanyl 0.000011 mg/capita, pethidine 0.036 mg/capita, and phenobarbital 82.1 mg/capita. These factors make providing palliative care for cancers and other conditions very difficult.

The average number of cancer cases annually are 101.5 per 100,000 population. In a review of more than 5,000 cancer cases in Togo from 1984 to 2008, the average annual frequency was 210 cases. These had a male-to-female sex ratio of 0.9; average age of occurrence was 46.9 for males and 43.8 for females, with an overall average age of occurring at 45.3. The most frequent cancers for men were prostate cancer at 12.9 percent, non-melanoma skin cancer at 10.4 percent, and gastric cancer at 10.3 percent.

With respect to prostate cancer in 2002, the estimated age-standardized rate of new cases annually was 19.3 per 100,000 population, and estimated age-standardized number of deaths annually was 16.0 per 100,000; by 2011, prostate cancer reached 0.60 percent of total deaths, which accounted for an age-standardized death rate of 19.96 per 100,000, which ranks Togo 48th globally. In west Africa, the region to which Togo belongs, it is estimated that about 23.3 percent of women in the general population harbor the human papillomavirus (HPV) at any given time and that 51.4 percent of invasive cervical cancers are attributable to HPV 16 or 18. The most common cancers in children were Burkitt lymphoma at 27.9 percent and retinoblastoma at 8.5 percent of the cases; average age of occurrence of childhood cancers was 8.1 years with a sex ratio of 1.5 (218 cases in boys, 146 in girls). Histologically, carcinomas accounted for 68.1 percent of cases, sarcomas for 11.2 percent, and non-Hodgkin's lymphomas for 12.6 percent.

Despite the abundance of traditional and modern medical products and services, health problems are endemic in Togo. The 10 leading causes of death, in rank order, are malaria, human immunodeficiency virus (HIV) and autoimmune deficiency syndrome (AIDS), anemia, cerebrovascular disease, pneumonia, septicemia, hypertension, cardiac diseases, meningitis, and diarrhea. For example, there are an estimated 110,000 people living with HIV in Togo, which ranks it 30th highest in Africa and 47th globally. Debate continues on the relative risks in Africa for respective cancer types for those infected with HIV. Furthermore, according to the World Health Organization's Global Health Observatory Data Repository, in 2008, the age-standardized estimates of deaths from all cancers was 86 per 100,000 for males and 91 per 100,000 for females. As a consequence, life expectancy is 53.05 years, which ranks Togo 90th in Africa and 189th globally. There is a clear and urgent need for improved cancer awareness, early detection programs, and health services infrastructure in Togo.

Town Plans

Town planning, more commonly referred to as urban planning or simply planning, is the professional discipline tasked with making civic improvements. During the past decade, the dialogue between the urban planning and public health sectors became increasingly intersected as research revealed the links between disease and place.

Many of these links were discovered with the help of new information technology, particularly geographic information systems (GIS), which uses geography as the common foundation. Allowing large and multiple datasets to be visualized, it has facilitated health data, including cancer, to more readily be examined within the context of the natural and built environments. These data and spatial layers, combined with socioeconomic data, provided new knowledge about housing, industry, and other planning issues affecting health status.

As a result, the planning and public health industries are converging around issues of population health. Additionally, planning tools are helping health practitioners examine cancer rates beyond the aggregate or merely in terms of race, gender, age, and income. With GIS software, they are now able to identify clusters of certain types of cancer and identify potential causes, such as industrial waste, air pollutants, housing proximity to cancer-causing agents, and so on. Industry, housing patterns, transit networks, and the location of public-good facilities (e.g., schools, hospitals, grocery stores, etc.) are all part of town planning. Understanding placement and proximity to carcinogens helps inform planning decisions and reduce risk of cancer as an unintended consequence of development.

The Historical Link Between Public Health and Town Planning

Planning dates to the beginning of civilization. In its most fundamental form, it is the attempt to create orderly human settlements while meeting the needs of the residents. This includes maintaining population health. For example, once it was discovered that corpses spread disease, cemeteries were relocated farther from water sources and housing. Function, more than form and aesthetics, were primary.

When new manufacturing processes led to the Industrial Revolution, cities grew quickly and exponentially. The lack of modern transportation forced workers to live within close proximity of factories, slaughterhouses, and other generators of pollution and carcinogens. The housing was often substandard and lacked sources of fresh air. Furthermore, these workers often lived long distances from open spaces and fresh air. In the late 1880s, social reformers, such as Jane Addams and Jens Jensen, worked to address the social and health needs of the ever-growing urban working class. Jensen, a landscape architect, helped design Chicago’s parks and fought for a park system that allowed workers to escape overcrowded, polluted areas without having to travel to the country. Although rarely credited in the history of town planning, he played a significant role in the field by arguing that people need to be connected to nature in order to be healthy. This was the same ideal behind the Garden City Movement, which was a 19th century town planning scheme aimed at using nature to buffer citizens from urban center industry.

By 1900, industrialization and rapid urban growth had compounded the problems of cities. Unsafe working conditions, overcrowded housing (often without fresh air access), sanitation, and other health risks led social reformers to push public health initiatives and the passage of housing statutes. This, in turn, led architects to become more involved with social needs through design. Shortly thereafter, planning emerged as an autonomous profession, and many of the early planners aimed to address all major urban components at
once. They were often reformers who held the belief that social and physical planning could not, and should not, be separated from one another. Eventually, social and physical planning separated as town planning increasingly became about design and the creation of purely functional places or beautiful spaces.

**Public Health and Planning**

Public health practitioners regularly utilize GIS to map data to understand patterns of disease, whereas planners use it for a variety of reasons. Some of these have direct and indirect impact on public health, such as location of health facilities, zoning between residential areas and industry, and maintenance of contaminated land and natural resources. While the technology is new, the use of mapping in health is not.

Epidemiology, the cornerstone of public health, is the medical specialty that studies patterns, causes, and effect of health and disease conditions in defined populations. In the mid-1800s, Dr. John Snow (considered the father of epidemiology) led the way in linking health to town infrastructure. During the 1854 London cholera outbreak, 500 people died within 10 days. Using simple mapping techniques, he identified water pumps as the source of the outbreak. This led to the construction of improved sanitation facilities throughout the world. Today, epidemiologists work with a variety of diseases, including cancer. With diagnosis data sets, they now use mapping technology to identify clusters of certain types of cancer. When overlaid upon planning maps, they can more readily identify causes of the disease or even the cause of a particular type of cancer. A classic case is that of breast cancer in Cape Cod, Massachusetts. Cancer data (1982–1990) showed an incidence rate up to 130 times higher than in other areas of the state, leading researcher to seek causation. Using other geographic data, they discovered the disease was linked to pesticides used in cranberry bogs, including former bogs that were now housing and industry sites.

**Planning and Cancer**

Cancer can be a direct or indirect consequence of planning decisions that shape places and how people function within them. A recent Centers for Disease Control (CDC)—funded study of 3 million malignant tumors in 16 states linked poverty with higher mortality cancers. This study claims to be the most comprehensive assessment of the relationship between cancer, socioeconomic status, and place. People living in census tracts with higher poverty rates were found to have a prevalence of rarer cancers with high mortality rates. Likewise, lower-income people are more likely to die of cancer. The researchers hypothesize that the disparities may be due to behavioral and economic factors, such as substance abuse and access to medical care or healthy foods. Access is increasingly a planning issue to guide private resources to better meet the needs of lower-income communities. It is also these types of data that have driven the environmental justice and social justice movements. These movements help raise the voice of those most likely to suffer negative consequences of development decisions.

While zoning was an early, effective tool for separating housing from industrial pollution, other advances and urban shifts have resulted in other public health concerns. For example, along with suburban development came industrial decentralization. Many of these former industrial sites provided the space for office buildings and large public housing developments.

Like the Cape Cod example, workers and residents on some of these sites have higher rates of certain types of cancer as well as other illnesses. As public health informs the planning industry, new statutes and practices are put into place. Among these are federally mandated environmental impact assessments, a formal process aimed at not just protecting the environment but mitigating environmental damage that could be detrimental to health. Health impact assessment is also an emerging methodology to deal specifically with potential population health effects. In fact, the CDC and American Planning Association partnered to develop a free Web-based training.

Economically driven, the private sector lacks the motivation to plan comprehensively; however, public-sector planning attempts to achieve this through master planning. The process is largely ideological as politics and private capital are often the drivers of decisions. Planners help guide and inform the decisions and regularly deal with natural resource management, transportation, utilities, industry, housing, and the location of health resources, from hospitals to healthy foods.
Toxic Mold

Mold is a type of fungus, distinct from yeasts in that molds are multicellular while yeasts are unicellular, and distinct from mushrooms in that molds are microbes, while mushrooms are the fruiting bodies of large funguses. All funguses are distinct from plants, belonging to a separate kingdom. Many molds are involved in the biodegradation of natural materials, and mold spores (the means by which they reproduce), molds themselves, and compounds produced by molds all may have adverse health effects on humans who come into contact with them or inhale them. Molds also have been the source of significant medical advances, though—penicillin, one of the first antibiotic drugs, is derived from penicillium mold, and molds of the Aspergillus species are used in the production of soy sauce, sake, Katsuobushi, and miso and help to preserve foods against bacterial spoilage. The powdery white mold Penicillium nalgiovense provides a similar service to Italian dry salami, and Geotrichum candidum provides the natural bloomy rind of Camembert cheese. More recently, cholesterol-lowering statins and immunosuppressant drugs have been derived from molds; cyclosporine, for instance, is used to prevent and treat graft-versus-host disease in bone marrow transplants of cancer patients receiving radiation treatments. It was derived from a fungus found in Norwegian soil. Other fungal derivatives are used as cytotoxins, antibiotics, antimalarials, diabetes treatments, and even as treatments for fungal infections.

Molds are present virtually everywhere. When they are able to grow unchecked, like in parts of buildings out of reach of cleaning (inside walls or under floorboards), the dense concentration of mold spores can be a serious health problem. Toxic mold refers to molds that produce mycotoxins, but otherwise harmless molds can still cause allergic reactions, irritation, respiratory problems, headaches, migraines, coughing, and sleep disorders when people regularly inhale too many of their spores. Outdoor molds are a contributor to seasonal allergies for many people, and indoor molds may be found in dark or humid areas of the house, especially those with poor ventilation.

Mycotoxins are secondary metabolites produced by molds. Many mycotoxins are produced by more than one kind of mold, and similarly, many molds produce more than one kind of mycotoxin. The evolutionary explanation for mycotoxins is not clear because they do not seem to be involved in the mold’s growth or development. Mycotoxin levels generally only become high enough to matter when the conditions are right for the mold to thrive and form colonies. While most houses, especially in

Even within the planning field, the debate continues about whether the ultimate goal of planning is to create beautiful cities or generate better quality of life for residents and visitors. Inside this debate, planners are becoming increasingly specialized, and health planning is emerging as a new category. Today, much of the town planning conversation around health aims at increasing physical activity (e.g., bike lanes, increasing walkability, and improving park utilization) and improving living conditions in low-income communities (e.g., access to community facilities, healthy food options, and crime reduction). With more emphasis on the intersection between planning and public health, planners are increasingly challenged with creating attractive physical spaces that also meet the economic and social needs of people. Generating positive health impacts and mitigating negative health consequences and health disparities has now become part of the complicated work of designing places.

Further Readings
humid climates, likely have some amount of mold growing somewhere in them, and that may include a mold producing a mycotoxin, in most cases, the mycotoxin levels will not be sufficient to have health effects, either in the short term or cumulatively. When a plumbing leak leads to a buildup of stagnant water between the walls, on the other hand, and black mold thrives, an entire household can suddenly develop respiratory problems.

Mycotoxins are superbly resilient and not only resist decomposition but often survive being ingested, so when toxic molds infect crops and produce mycotoxins, those toxins not only remain in the crops throughout their processing into food, but if they are then turned into animal feed, they can remain in the meat or dairy products that result as well. Some mycotoxins further survive cooking or freezing. There is a great deal still to learn about molds, mycotoxins, and the mechanisms by which they interact with other organisms and so impact human health. Ergotism was once a serious recurring food supply problem for many civilizations, for instance. These alkaloids were produced by molds that were found among the various grass species used as cereal grains, including wheat and its ancestors. The alkaloids survived threshing, grinding, and baking, resulting in a supply of tainted bread that either turned its victims’ limbs gangrenous or induced convulsions. In the modern world, ergotism virtually has been eliminated as a human health concern (it still impacts livestock feed), but aflatoxin infestations have caused several recent food crises, including the 2013 aflatoxin contamination that impacted countries in Europe and the Americas.

Aflatoxin disease can cause acute hepatic necrosis and cirrhosis of the liver or liver cancer, but chronic aflatoxin exposure at subclinical levels also has dangerous effects. Children so exposed may experience delayed puberty, stunted growth, and hormonal imbalances or low production of certain hormones. Adults and children alike face an increased risk of liver cancer, though a diet with sufficient consumption of members of the apiaceae family—celery, carrots, parsley, cumin, cilantro, dill, fennel, and asafoetida, among other herbs—significantly reduces this risk, which may in fact have played a role in the adoption of those herbs and vegetables in the diets of ancient aflatoxin-vulnerable populations.

Groups of mycotoxins include ochratoxins, which are produced by some Aspergillus and Penicillium species, and can sometimes be found in red wine, cereals, coffee, and dried fruit. It accumulates in the meat of animals, is toxic to the kidneys, and is a suspected human carcinogen. Fumonisins are produced by Fusarium molds and found mainly in corn and wheat.

They are toxic to the liver and kidneys and believed to increase risk of cancer of the esophagus. Studies have found that poorer populations with less varied diets have a greater incidence of esophageal cancer the more dependent that diet is on corn. Patulin is produced by a number of molds and often found in rotting apples. Because it is a suspected carcinogen—there is not sufficient epidemiological data to investigate, and this suspicion is grounded on comparisons to other mycotoxins—the Food and Drug Administration (FDA) has set a limit on the acceptable levels of patulin in apple cider. This may have been premature because subsequent tests of patulin as an antibiotic against the common cold, while unsuccessful in that effort, found no ill effects from patulin consumption.

One of the best-known toxic molds is *Stachybotrys chartarum*, a black mold that can be found in soil or grain (it can infest silos) but is best known for its insidious presence in damp or water-damaged buildings. *S. chartarum* thrives in cellulose-rich building materials like damp wallpaper and is a frequent problem in homes that are recovering from flooding, whether from natural sources or plumbing accidents. Some studies have suggested that *S. chartarum* is a major factor in sick building syndrome, but more work is required. *S. chartarum* is toxic to both people and pets, producing satratoxin-H, a mycotoxin that can cause nosebleeds, bleeding in the lungs, headaches, chronic fatigue, rash with ulcerations, and hyperthermia. It is lethal in large quantities, such as when used as a chemical weapon, and symptoms can result either from ingestion or inhalation or simply from physical contact with the mold.

Transportation

The causes of all types of cancer are not fully understood, but researchers know that pathogens, age, genetics, behavior, and environmental contaminants are factors in the development of the disease. The role of transportation in relation to cancer is complex. In order to understand the correlation, transportation as a cause and transportation as an intervention must be examined. Beyond direct exposure to air pollutants and chemicals, the link also must be examined within the context of lifestyle choices, socioeconomics, modernization, public policy, and urban planning trends. All of these impact transportation options, choices, and exposure to risk. A mode of transportation should not be viewed as a direct cause or intervention. Rather, each mode has direct and indirect health consequences that can help combat or contribute to the development of cancer.

Modes of Transportation and Associated Risks

Different modes of transportation serve different lifestyles, needs, and geographic areas. For example, the transit needs of an older person living in a rural area are different than those of a young, urban professional. The most traditional modes of transportation include automobiles, public transit (e.g., buses and trains), cycling, and walking. Each has associated merits and risks for health outcomes, including cancer, injuries, fitness levels, and exposure to environmental hazards.

The direct exposure to cancer risks is the simplest correlation to understand. These risks include exposure to air pollution (e.g., toxic outputs from fossil fuels), carcinogens at street level, and ultraviolet radiation. Although there is no evidence that exposure to gasoline causes cancer, long-term exposure to high levels of benzene (a component of gasoline) has been linked to an increased risk of leukemia (a form of cancer). Furthermore, researchers have identified a link between lung cancer and diesel exhaust, a major component of air pollution. Another direct cause is increased sun exposure while engaging in active transportation modes, such as walking or cycling.

The indirect causation is more complicated and difficult to identify or fully understand. However, this link between transportation and cancer is largely related to sedentary lifestyle, obesity, and higher stress levels. Each of these increases a person’s risk for developing certain types of cancer, particularly colon and breast cancer. Higher stress levels are known to impair immune response, contributing to the development and progression of some types of cancer. There is a direct correlation between physical activity, healthier body weight, and lower stress rates. Combined, these can help the body combat the onset of disease. Many people use active transportation to save money while also building exercise into their daily routines for both physical and mental fitness. Alternatively, active transportation increases exposure to environmental risks. Thus, modes of active transportation can decrease some cancer risks while increasing others.

Other forms of transportation are passive and may be contributing factors to sedentary lifestyles, obesity, and even increased stress. In the Western world, people most often utilize automobiles for their daily transportation needs. Many believe that car culture and urban sprawl are direct causes of obesity, but scholarly research examining these has not been conclusive. While the rise of car ownership, obesity, and cancer rates have steadily
increased since the 1950s, so too has American life expectancy. In fact, some research suggests that people with weight problems (thus at higher cancer risk) are more apt to live in areas requiring frequent utilization of a car. Therefore, car ownership may not be the direct cause of health problems but a contributing factor for people who do not actively engage in healthy lifestyle choices.

The conversation about health and cities often centers on walkable cities being healthier than auto-oriented suburbs. While this is true for some populations and places, it is an oversimplification for understanding the relationship between health and the built environment, especially for conditions that increase cancer risk. Data shows that many inner city areas, with high rates of public transit utilization, also have high rates of obesity and disease. Whereas cars are blamed for suburban health problems, food deserts (i.e., areas lacking of access to fresh fruit and vegetables) is noted as the primary cause of poor health outcomes for low-income people. This too is an oversimplification for understanding health disparities.

Distance decay theory suggests that the farther people are from what they need, the less likely they are to access that resource. Regardless of socioeconomic status or residential location, transportation provides access to resources. This includes health care, healthy food, and jobs. Certainly, car ownership provides more flexibility, and while it may increase the risk of a sedentary lifestyle, it also reduces transit burden. Personal finances, transit availability, residential location choice, and even health status are key factors in closing the spatial gap between person and resources. It is within this framework that transportation becomes a social determinant of health. For example, people with high transit burdens are more likely to consume convenience food, such as fast food and high-calorie processed foods. They are also less likely to seek preventive care, such as cancer screenings.

The Role of Policy Makers, Planners, and Architects

Until recently, transit policy has rarely incorporated health effects into decision making. This is changing as researchers are taking a more comprehensive approach to understanding the social and health impacts of the built environment. This approach helps decision makers understand the complexities of communities and transportation networks. Viewed as an intricate web of systems,
policy makers and planners more readily can see opportunities for improving access and ultimately population health.

At the macro level, transportation planning plays a key role in the implementation of greenhouse mitigation strategies. Better design can reduce the number of vehicle hours driven (or at least curtail an increase of vehicle hours). In turn, this may result in large-scale health benefits through the reduction of air pollution and protection of the Earth’s ozone layer, the atmospheric protection against ultraviolet radiation that causes skin cancer. At the micro-level, planners and architects can design streets and spaces to encourage walking and cycling.

Transportation planning and transit options are part of larger land use and urban planning decisions. They are also largely dependent upon the commitment of public funds. Although controversial, public monies are used to subsidize the operations of public transit systems. This keeps this option affordable for low-income households while also helping to promote ridership regardless of socioeconomic status. In fact, due to better planning, promotion, and increased gasoline and parking costs, public transit ridership has steadily increased in the past decade, and public transit utilization rates have reached the same utilization rates as in the 1950s, when car ownership rates began increasing.

Public transit systems reduce carbon emissions, and higher utilization rates encourage improved routing to serve a variety of population needs better. Some systems have integrated active transportation by installing bike racks on buses and in train stations. Some cities have constructed bike commuter stations with showers and lockers. Initially, the intent was to reduce traffic congestion; these programs also have become part of the larger public health initiative. Other transportation interventions with health benefits include interstate sound-pollution barriers, creation of bike lanes, bike share programs, and street-level beautification. In addition to transit systems, planners and architects are also creating urban design strategies as part of the larger public health initiative to reduce obesity and disease. Popular ideas include developing transit-oriented designs in which people live near public transit hubs (thus reducing dependency on cars), improving urban neighborhoods to increase walkability, and creating bike transit networks, so cyclists can navigate city streets more safely.

Even with increased awareness of health consequences associated with the built environment and transportation options, there is still much to be learned. Large transit projects can take years to plan, fund, and implement, and this process rarely incorporates health implications in evaluation of design and policies. To encourage health as a component of decision making, the U.S. Centers for Disease Control has endorsed Health Impact Assessment (HIA). This new method uses a variety of data sources and analysis but has yet to be adopted widely for transportation planning. As more researchers and practitioners become aware of health consequences associated with the built environment, health will increasingly be considered within the framework of transportation options and systems. Although not likely to reduce cancer rates, better options can be included in a series of crucial health interventions.

Trichopoulos, Dimitrios

Dimitrios Trichopoulos was one of the great living academicians of the century. He was a professor of cancer prevention and professor of epidemiology at Harvard University, chair professor of epidemiology at the Medical University of Karolinska in
Stockholm, and member of the Academy of Athens. Born in Athens in 1938, Trichopoulos studied medicine at the University of Athens and specialized in internal medicine, microbiology, public health, and epidemiology at the Universities of Athens, London, Harvard, and Oxford. Since 1989, he served as a professor and the director of the Department of Hygiene and Epidemiology, Harvard School of Public Health (HSPH). Since 1992, he also served as a professor of cancer prevention and the director of the Center for Cancer Prevention, Harvard University. Trichopoulos died on December 1, 2014.

Having grown up in Athens, Greece, his education began there in 1963; he received his doctorate in medicine at the University of Athens Medical School. In 1968, he graduated with a master’s in science from HSPH. He furthered his education in his native Athens, and in 1971 he became a professor at the University of Athens Medical School.

In his native Greece, Trichopoulos served as chair of the Interuniversity Center, the State Council of Occupational Diseases, the State Population Committee, and other committees; as rapporteur of the State Health Planning Committee; and as a member of more than 40 state committees.

His ability was recognized internationally, and he served in various capacities and organizations. He served as a temporary advisor and consultant to the World Health Organization (WHO) on several topics, including the epidemiology of various diseases and conditions, health statistics, health services research, and cancer etiology and prevention. He also served as a faculty member in several graduate or postgraduate courses of the International Agency for Research of Cancer (IARC), the European School of Oncology, and several other universities.

At the international level, he also served as a member of the Panel of Social Medicine and Epidemiology of the European Community (EC) and of the EC Working Group of Epidemiology and Biostatistics, and as an organizer of several EC projects, including those dealing with cancer control, passive smoking, and teaching and epidemiology.

Outside Greece, but not at an international level, Trichopoulos served in the United States in several organizations and institutions at varying leadership levels. Among the many positions he held in the United States are chair of the Tobacco Related Diseases Epidemiology Program (University of California), member of the Environmental Epidemiology Group of the American Health Foundation, and a key member of the Department of Energy review group that studies the use of electromagnetic fields.

Trichopoulos made many breakthroughs in the area of cancer and in particular malignant tumors, which is what he investigated. As he noted, malignant tumors are what scare most people. Although cardiovascular diseases contribute to about half of human deaths, the majority of these are myocardial infarctions, and about 20 percent are malignant tumors (this statistic might have changed due to advancement in technology and the innovation of more effective cardiovascular treatment—today, cancer is the biggest killer). Having realized the threat of cancer, Trichopoulos set out as a youth to investigate this killer. In what could be regarded as his contributions, Trichopoulos made several discoveries, among them viral etiology of liver cancer; probably the most popular of his discoveries—that passive smoking causes lung cancer; and a focus on breast cancer, on which he developed a theory that is gradually becoming more widely accepted, in which the roots of cancer can be traced at a very early stage. Based on this discovery, Trichopoulos proposed that we cannot deal with cancer successfully simply with various preventive measures in adulthood.

Through his work, Trichopoulos has authored or coauthored more than 1,000 scientific publications, including research papers, commentaries, monographs, books, reviews, and reports. Through his work, the role of passive smoking in the causation of lung cancer and chronic obstructive lung disease has been brought to the fore. Other discoveries courtesy of his research include the quantification of the association between psychological stress and coronary heart disease and the identification of several dietary issues, the elucidation of the etiology of hepatocellular carcinoma, and other important risk factors in the etiology of a number of cancers and other diseases. Prior to his death, it is believed he was working on a major hypothesis that he developed concerning the etiology of breast cancer.

The recognition of his research work in the field of cancer has been recognized at several levels through awards. Trichopoulos was a recipient of the International Cancer Medal. Trichopoulos, a Vincent L. Gregory professor of cancer prevention at HSPH, was awarded the Medal of Honor from the IARC, which is part of the WHO. The medal was due to Trichopoulos’s research and contributions to
cancer etiology. Trichopoulos accepted the award at a ceremony in 2007 at the IARC headquarters in Lyon, France.

Other honors awarded to Trichopoulos include: Cutter Lecturer at HSPH (1982), Eleanor Roosevelt Fellowship, Member of the Delta Omega Honorary Public Health Society, United States, Ipsen Lecturer at the Institute of Social Medicine of Aarhus University (1987), European or International Scientific Societies, Chair of the EC Health Group and the EC AIDS Group during the Greek Presidency (1988) of the European Community, Distinguished Lecturer in the Japan Cancer Research Center (1992), Honorary Doctor of Medicine at the University of Uppsala (1994), Officer with the Palmes Academiques in France, and a member of medicine academies in France and Belgium, among other places.

Trophoblastic Tumor, Gestational

Gestational trophoblastic tumors (GTT), also known as the gestational trophoblastic disease or gestational trophoblastic neoplasms, are cancers seen rarely in women, where abnormal cellular proliferation is observed in the tissues formed after conception. These tumors start inside the uterus of the woman from the trophoblast layer, a layer of cells normally surrounding the embryo. Trophoblast cells, under normal circumstances, grow and surround a fertilized egg in the uterus and help in connecting the fertilized egg to the uterine wall and in the formation of the placenta. GTT does not develop from uterine cells; instead, these tumors start in the cells that would normally develop into the placenta during pregnancy. In GTTs, the development of the embryo may or may not take place. Often, the development of the embryo is flawed, resulting in the termination of the pregnancy. GTT is extremely rare in Europe and North America. The incidence of GTT is highest in southeast Asia, with one in 200 to one on 300 live births.

Gestational trophoblastic tumors are classified into two types: the hydatidiform mole and choriocarcinoma. Hydatidiform mole (also referred to as the molar pregnancy) is the most common type of GTT and involves the development of grapelike cysts once the sperm and the egg cells have fused. Hydatidiform moles do not metastasize outside of the uterus and account for almost 80 percent of GTT cases. Hydatidiform moles further can be classified as complete or partial. A complete hydatidiform mole results when a sperm fertilizes an abnormal egg lacking mother’s DNA or a nucleus and has a higher risk of becoming cancerous. A partial hydatidiform mole begins when two sperms fertilize a normal egg, resulting in two sets of DNA from the father. There is no system of staging for hydatidiform moles. Hydatidiform moles can be treated by surgery to remove the tumor. The levels of hormone β-hCG (beta human chorionic gonadotropin) are checked weekly after tumor removal to evaluate the status of the patient. In cases where the levels of β-hCG do not go back to normal levels, it indicates an incomplete removal of the mole or, in rare cases, if the mole has become cancerous.
A choriocarcinoma may initiate as a hydatidiform mole or from the tissue remaining in the uterus after an abortion or delivery of a baby. Choriocarcinomas can spread to other parts of the body. Approximately 15 percent of women with hydatidiform moles develop choriocarcinoma and GTT. Choriocarcinomas can be classified into four stages, that is, stage I through stage IV. Stage I refers to the period when the tumor is localized to the uterus. Stage II involves the spread of tumor to the ovarian tissue, the fallopian tubes, and other parts of the female reproductive system. Stage III GTTs spread beyond the reproductive system into the lungs, and in stage IV, the tumor generally has spread farther in the body. An extremely rare gestational trophoblastic tumor can initiate in the uterus at the site of placenta attachment and is called as the placental-site trophoblastic disease.

### Symptoms

GTT may remain undiagnosed in the early stages as the symptoms resemble early stages of a normal pregnancy. Generally, the symptoms associated with GTT are vaginal bleeding during or after pregnancy, a larger than expected uterus during pregnancy, severe nausea or vomiting during pregnancy, high blood pressure and headaches early in the pregnancy, pain in pelvic area, abdominal swelling, and unexplained weight loss.

### Risk Factors and Diagnosis

A history of oral contraceptive use has been associated with the increased risk of hydatidiform moles. Women with a prior history of spontaneous abortion are also at a two- to threefold higher risk of mole development. Genetic factors such as a missense NLRP7 gene mutation on chromosome 19q are also associated with an increased risk of development of moles. Hydatidiform mole is a single most important risk factor for the development of choriocarcinomas, and maternal ABO blood group also has been linked to an increased risk of development of GTT.

In their initial stages, GTTs are difficult to locate as they show the symptoms associated with normal pregnancies. The identification of tumors can be done by ultrasound tests, which have been shown consistently to be safe, sensitive, and reliable. Ultrasound tests alone are not sufficient for diagnosis and are always used in combination with the levels of the hormone β-hCG, which is present during normal pregnancy.

### Treatment Options

Low-risk GTTs may be treated using chemotherapy using either a single drug or a combination of drugs until the levels of the hormone β-hCG return back to normal. High-risk metastatic GTTs may be treated by a combination chemotherapy and radiation therapy, depending on the site of metastasis. As β-hCG is a highly sensitive biomarker for GTT, 90 percent of GTTs are curable due to early diagnosis and management of the tumors. Prognosis and treatment depend on the factors such as general patient health and if the tumor is metastatic.

### Tunisia

Cancer in the north African nation of Tunisia is one of the country’s leading causes of mortality and morbidity, with roughly 12,000 new cases of cancer reported annually among its 11 million inhabitants. The incidence of cancer is increasing...
due to population growth in the country, population aging, industrialization, increasing Westernization of diet and lifestyle, and the pervasiveness of tobacco smoking. The increase in diagnoses also may, in part, be due to the result of more sophisticated diagnosis practices among oncologists as well as awareness among patients. The most common cancers in the nation for men are lung and prostate cancer, while the most common for women is breast cancer, with 1,500 new cases reported each year and incidence ranging from 27 to 30 of 100,000; further, breast cancer causes high morbidity and mortality among Tunisian women.

Gynecological malignancies include cervix uteri, corpus uteri, and ovary. Urological malignancies include bladder, kidney, prostate, and testis; however, incidence of testicular cancer is low. Other types of cancers, such as colorectal cancer and hematological malignancies, including leukemia, Hodgkin’s lymphoma, non-Hodgkin’s lymphoma, and multiple myeloma have seen increasing incidence. Colorectal cancer is ranked the fifth overall cancer for Tunisian males and third among Tunisian women. The incidence rates remain relatively low, which may be due to the Mediterranean diet, characterized by high intake of fruits and vegetables. Risk factors for colorectal cancer tend to be correlated with economic development and Westernization, most notably Western dietary norms.

Health Care During and Since Transitions in Governance
The health care infrastructure in Tunisia is one of the best across the African continent. During French colonial rule (1881–1956), Tunisian medical practitioners were trained in European techniques, and health care in the French protectorate came to be well regarded abroad. In the decades since independence, the health care sector continued to be one of the best across the African continent, with a mix of public and private institutions, the latter of which grew in scope and number in the past few decades. In addition, international partnerships and collaborations with cancer specialists and members of the pan-Mediterranean, pan-Arab World and international organizations such as the Arab Medical Association of Cancer, l’Association Internationale des Registres du Cancer, la Société Internationale de Chirurgie Hépato-Pancréato-Biliaire, la Fédération Pan-Arabe de Chirurgie, la Fondation Française de Carcinologie Digestive, and la Société Française de Cancérologie have enhanced expertise and practice in this most northern African nation.

In the past four years, given political and governmental unrest during and since the so-called Arab Spring, which many attest began on December 10, 2010, in the provincial Tunisian town of Sidi Bouzid, the Tunisian health care system has not seen the development and modernization for which it was previously known. Before the citizen uprisings of 2010 and 2011, the Tunisian government appropriated robust funds to the nation’s Ministry of Public Health, which in turn, expended roughly half its annual expenditure on tertiary care with the remaining half split between primary and secondary care. Recovery has been evident, however. For example, in 2013, the Minister of Health, Dr. Abdellatif Mekki, approved a collaboration with the International Atomic Energy Agency (IAEA) Programme of Action for Cancer Therapy (PACT) to conduct a national cancer control assessment, imPACT mission. Further, despite resource concerns during and since the 2010 to 2011 unrest, Tunisia still achieves a considerable level of development despite needs of modernizing health care infrastructure and given that the epidemiological profile of Tunisia is changing with increases in noncommunicable diseases such as cardiovascular diseases, diabetes, and cancer.

Cancer-Specific Health Care Infrastructure
Along with the growing health care infrastructure more generally, the cancer-specific health care infrastructure is developing. Given the National Strategy on Cancer Control, which will cover a five-year period, Tunisia has made major advances in cancer control. National organizations include l’Association Tunisienne de Lutte Contre le Cancer, located in the capital city of Tunis. Broader organizations include Societe Tunisienne des Sciences Medicales. Note-worthy clinics with specialization in oncology and radiotherapy include Institute Pasteur de Tunis; le Service de Radiothérapie, l’Hôpital Universitaire Farhat Hached at l’Université de Sousse, in Sousse, Tunisia; l’Institut Salah Azaiez in Tunis; Laboratoire d’Immuno-oncologie Moléculaire; and Faculté de Médecine de Monastir, in Monastir, Tunisia.

Population-based cancer registries in Tunisia and those of neighboring nations Morocco, Algeria, Libya, and Egypt have increased in number
from one to nine and cover at least 13 percent of the total regional population. One of the first population-based cancer registries in Tunisia, reporting on incidences of cancer in the central region of Tunisia, was established in 1987 in partnership with the International Agency of Research on Cancer (IARC) in Lyon, France, and located in the Pathology Department of l'Hôpital Universitaire Farhat Hached at l'Université de Sousse. This and other cancer registries in the region and in the country, such as the Cancer Registry of Tunis at the National Cancer Center of l’Institut Salah Azaiz, the main cancer treatment center in the nation, and the Cancer Registry of Sfax, housed at the pathology department of l’Hôpital Universitaire Habib Bourgiba at l’Université Habib Bourgiba in Sfax, which registers cases in the southern region of the country, have provided important information on cancer patterns over the previous years.

The quality of the data provided by the cancer registries is considered to maintain quality levels from acceptable to good, according to available indicators. The pattern of risk shown by north African cancer registries is exceptional in that the total cancer burden in the region ranges from one-third to one-half of what is observed in western Europe. The pattern of consistency between north Africa and western Europe diverges entirely from that of sub-Saharan central and southern African countries, where infection-related cancers are predominant.

Tobacco use continues to be an important risk factor for lung cancer. A World Health Organization study reported that 58 percent of adult men and 7 percent of women in Tunisia use tobacco. Risk for nasopharyngeal carcinoma in Tunisia and its north African neighbors is high; rates are 5.4 in men and 1.9 in women, which is 10 times higher than that in its European neighbors to the north of the Mediterranean. Standard treatment in Tunisia of locally advanced undifferentiated carcinoma of the nasopharyngeal type is chemotherapy followed by loco-regional radiotherapy.

Researchers have reported striking geographic variations in the incidence of inflammatory breast cancer (IBC). There is a higher occurrence of IBC in north African countries, most notably in Morocco, Algeria, Tunisia, and Egypt, where IBC incidence ranges from 10 to 15 percent. It should be noted, however, that cancer registries may have a variance of conceptual definitions used to diagnose IBC.

Nevertheless, IBC incidences have been rising throughout Africa; that is the case in Tunisia as well as in its neighboring north African nations. Research from centers including le Faculté de Médecine de Monastir, in Monastir, Tunisia, reports IBC, an inadequately understood and particularly aggressive form of breast cancer, makes up a larger proportion of breast cancer cases in north Africa than in the United States. Across north Africa, there is a high frequency of IBC diagnosed at relatively late stage as well as cancers that are either estrogen receptor negative (ER−) or triple negative (ER−, progesterone negative, and human epidermal growth factor receptor-2 negative), which tend to occur at younger ages.

Research in Tunisia, most notably from research practitioners at le Faculté de Médecine de Monastir, in Monastir, has found that there exists inadequate knowledge of breast cancer and screening methods as well as low levels of practice of breast cancer screening methods of among women in the region of Monastir. Further, the Tunisian l’Office Nationale de Famille et de la Population (National Office of Family and Population) has instructed pilot public health initiatives focusing on breast cancer mass screening using mammography in particular villages, such as Ariana, which is on the outskirts of Tunis. While improving, there remains an urgent need for updating public health education to raise women’s awareness and adherence to breast self-examination programs in Tunisia.

Turkey

Turkey Republic, which was founded in 1923, is at the crossroads of Europe and Asia but mostly located on Asia with the population of 75.6 million. The country was headed by the Ottoman empire till 1923, and health services were not for the public but for the court and army. In the 19th century, the Ottoman empire made some progress in health, such as opening a medicine school and preparing laws, regulations, and rules regarding health services. Relations with Western countries in that period definitely affected those improvements in health services.

As of the establishment of the Turkey Republic, health services became a primary responsibility, which is still conducted by the Ministry of Health. Constitution and provision of health care centers, generation of health policies, and production and implementation of national health strategies were the main duties of the Health Ministry. The private sector and blue-collar public sector workers were provided health insurance by 1946, when Sosyal Sigortalari Kurumu (SSK; social insurance organization) was established. Following SSK, other social security organizations were founded in 1950 (Government Employees’ Retirement Fund [GERF], or Emekli sandığı) and in 1971 (Social Insurance Agency for Merchants, Artisans and the Self-Employed, or Bag–Kur). The Ministry of Health also focused on preventive public health programs to control communicable diseases such as tuberculosis, malaria, and leprosy.

Despite the economic recession, the health care system and health policies have progressed quickly in Turkey. After employing liberal policies for both economic and social life in the 1980s, healthy lifestyles, quality health service delivery, and environmental health came into prominence. The Ministry of Health focused on general health insurance and family practitioner schemes in 1990s but failed to carry out those reforms. After elections in 2002, the new government took office with many reforms, including health. The Health Transformation Program was introduced, and accordingly, all health insurance facilities were consolidated under the management of the Ministry of Health. So, the government became the major provider of health services. Projects regarding family practitioner schemes and preventive and primary health care were put into practice, respectively. National programs were planned with respect to noncommunicable diseases, such as cardiovascular diseases, diabetes, respiratory diseases, and cancer, in addition to enhancing primary health care.

Cancer has become one of the prominent public health problems as well as in other countries all over the world. Following cardiovascular diseases, cancer is the second-highest cause of death in Turkey. Although efforts related to cancer have not been conducted in an extensive and coordinated way, there have been positive strides to improve
cancer care, increase awareness, and provide infrastructure and equipment.

As a part of the Health Transformation Program, early diagnosis, screening, and training centers (KETEM) were established in 81 provinces across the country in 2012. Considering statistics regarding cancer screening, in comparison to 2012, it can be seen clearly that rates of breast (9 percent) and cervical cancer (23 percent) screening have been on the rise through 2013 by force of KETEM. The aim of the center is to extend cancer screening to all cancer groups by the end of 2015.

According to the Health Statistics Yearbook (2012) published by the Ministry of Health, cancer deaths in Turkey increased from 12 to 20 percent between 2002 and 2009. The most frequent types of cancer diagnosed among males are lung, trachea, and bronchial cancer (84.9 percent) and breast cancer (45.1 percent) among females.

The latest scientific studies and drug developments in the field of cancer disease has indicated some reasonable progress related to producing local medications. In addition to this, home production of 33 cancer medications for Turkish patients is seen as a research and development success by the Ministry of Health. Also, there is continuing study on cancer in the Black Sea region regarding the potential impact of the accident at the Chernobyl nuclear plant in 1986.

Cancer incidence and mortality rates being on rise prompted the government to develop powerful public health strategies. The National Cancer Control Program has been developed by the Ministry of Health with support of international institutes and agencies such as the World Health Organization (WHO), International Association for Cancer Registry (IACR), International Union Against Cancer (UICC), National Cancer Institute (NIC), and Middle East Cancer Consortium (MECC) in 2012.

**National Cancer Control Program**

The rising burden of cancer and its negative impact on the health status of communities and on financial expenditures have led to an extensive strategy for all phases of the disease. The National Cancer Control Program developed by the Ministry of Health in 2012 has been trying to enhance the registration system and reduce the incidence of preventable cancers. In a report from the Ministry of Health regarding application of the membership of IARC, other specific aims of the program are as follows:

- To reduce the consumption of tobacco as well as prevention of new smokers and passive smoking due to being one of the main risk factors for cancer.
- To control the lifestyle factors such as obesity and inactivity.
- To focus on environmental and occupational factors so as to reduce the frequency of cancers.
- To establish a delivery chain structure for the diagnosis, treatment, and scientific research for cancer.
- To establish a national organization structure for cancer.
- To extend palliative care services countrywide.

Decreasing the incidence of noncommunicable diseases and risk factors are some of the main targets of the Health of Ministry’s 2013 to 2017 strategic planning. Expanding the capacity related to technology, education, and infrastructure to enhance the National Cancer Program outcomes shows that the program is an ongoing process. Raising awareness of early diagnosis of cancer among the public by using famous role models and improving cancer screening...
programs are also accepted as essential duties to be fulfilled between 2013 and 2017.

Turkish Society of Haematology

As one of the oldest societies in Turkey, the Turkish Society of Hematology (TSH) was founded in 1967 by Sedat Tavat, Arif Ismet Çetingil, F. Reimann, Seref Inceman, Orhan N. Ulutin, Ayhan Çavdar, Burhan Say, Nail Tartaroglu, and Mustafa Karaca, and by 2014, the society has reached more than 700 members. The society is run by seven members of the board of directors and scientific subcommittees that operate under them.

The scientific subcommittees consist of Hemophilia, Homeostasis–Thrombosis, Laboratory Standards, Red Blood Cell Disorders and Hemoglobin, Multiple Myeloma, Infectious Diseases and Supportive Therapies, Bone Marrow Failure, Hemapheresis, Blood Banking and Transfusion, Acute Leukemia, Molecular Hematology and Cytogenetic, Chronic Myelocytic Leukemia and Chronic Myeloproliferative Disorders, Lymphoma, Hematopathology, Stem Cell Transplantation, Stem Cell Biology, and Research Scientific Subcommittees.

The objectives of the society are to increase the level of hematology education and standardize it throughout the country; to create a network for hematology workers for cooperation, collaboration, and communication; and to develop and support research in the field of hematology. In the scope of these objectives, TSH organizes conferences and educational events, publishes a journal, provides grants and scholarships, and promotes national and international cooperation in the field of hematology.

In the scope of educational activities, TSH organizes a number of events including courses, seminars, workshops, conferences, and training programs both at the national and international level. The Annual Hematology Congress is the main national conference, and since its foundation in 1967, TSH has hosted 40 conferences as of 2014. This annual congress addresses new research and developments in the field and brings hematology workers together. The society also organizes the National Bone Marrow Transplantation and Stem Cell Therapies Congress every two years since 1996. This event aims to highlight recent developments in bone marrow transplantation and stem cell therapies. The society also organizes an international event called the International Congress on Lymphoma–Leukemia–Myeloma, which aims to create a platform for the international exchange of knowledge, practices, and ideas in the field.

Another major activity of the society is the Turkish School of Hematology. The school was launched in 2008 with the purpose of filling the gaps in hematology education in Turkey. The duration of the school is three years, and 12 courses are offered during this period. The school also aims to be a bridge for the European Hematology Association (EHA) passport accreditation; thus, the content of the courses are in line with the EHA curriculum and CV passport. The courses are held on weekends in different parts of the country, the first being held in Edirne in 2008. Apart from medical knowledge and skills, the school aims to inform the participants about other EHA & European Society of Hematology (ESH) courses and conferences and encourage them to participate.

The society also organizes various training programs that target different populations for different purposes. The HEKHEP training program aims to train medical doctors on basic and up-to-date
principles of hematology in the cities where hematologists do not exist. Another program called HALKHEP aims to inform patients and their relatives about new developments in hematology to support them during their treatment processes. TSH also organizes training programs for those who work in the pharmaceutical industry.

TSH also initiates public campaigns to raise awareness about blood diseases and provides information about prevention, early diagnosis, and treatment of blood diseases. For instance, in 2013, TSH started a public campaign called Blood Is You to create awareness about various blood diseases. Another campaign was implemented to raise awareness about chronic myeloid leukemia in 2011. The society also has broadcast a national TV video to inform the public about the reasons for and consequences of anemia. Apart from the training programs and campaigns, TSH tries to educate the public through both printed material and the digital press. On the society's Web site, there is an online library that provides information and education for hematology workers, patients, and their relatives. Moreover, TSH has more than 50 educational books published, including handbooks, atlases, and dictionaries.

The society has its own peer-reviewed periodical journal called the Turkish Journal of Hematology, which is a continuation of the New Istanbul Contribution of Clinical Science, established by Professor E. Frank in 1951. The journal is published quarterly in English and indexed in SCI, PubMed Central, EMBASE, SCOPUS, CINAHL, Index Copernicus, GALE, EBSCO, DOAJ, and the Turkish Medicine Index. The Turkish Journal of Hematology aims to publish high-quality research papers on clinical hematology as well as educational materials, reviews, editorial notes, and case reports.

TSH provides a number of grants and awards to junior, basic, and clinical researchers to support hematological research. These funding programs include the hematology fellow international training grant (HAUD), research project awards, international congress grants, TSH annual congress awards, the international scientific publication award (UYDO), fellowship grants, and THD-industrial sponsored grants.

Finally, TSH is an internationally recognized society, and it operates under the Europe–Africa branch of the International Society of Hematology (ISH). Since 2004, TSH is accredited with continuing medical education (CME) accreditation points for participating in scientific and educational programs. TSH also carries out educational and training events with other societies, such as the European Group for Blood and Marrow Transplantation (EBMT) and the International Society on Thrombosis and Homeostasis.

Turkmenistan

The Republic of Turkmenistan is located on the western part of the Caspian Sea. It is bordered by Iran to the south and southwest, Afghanistan to the southeast, Kazakhstan to the northwest, and Uzbekistan in the north. In 2014, the population was estimated to be more than 5.1 million with a median age of 26.6. Turkmenistan occupies 488,100 square kilometers (188.456 square miles). More than 70 percent of Turkmenistan is covered by subtropical desert called Karakum or Garagum (meaning black sand in Turkmen), which holds the world’s fourth-largest natural gas resources in the world.

Present-day Turkmenistan has been conquered by Persian empires, the Greek Kingdom of Macedon by Alexander the Great, Muslims, Turkic tribes, and Russians. Turkmenistan is a relatively young country, with a rich history and culture that dates back to the 8th century, when Turkic (Oghuz) tribes moved from Mongolia to central Asia. The current Turkmenistan region Mary (historically called Merv) was on the crossroads of the historic Silk Road. Around the 10th century, Oghuz tribes accepted Islam and started to be called Turkmen.
Some Turkmens migrated westward into present-day Iran, Azerbaijan, and Turkey, spreading Turkic culture and living as part of the Seljuk empire. Later around 13th century, Turkmens forced to move southward formed new tribes when Mongols invaded most of their lands. In the late 19th century, the Russian empire occupied Turkmenistan. In 1924, it was part of Soviet Union. On October 27, 1991, upon the dissolution of the Soviet Union, Turkmenistan declared its independence after a national referendum to leave the Soviet Union.

Due to limited funding after independence in 1991, the health system was in poor condition with limited hospital beds and medical facilities, poorly trained medical personnel, and a low ratio of doctors to patients. There are major health factors such as poor diet, polluted drinking water, and contaminated soil, especially in the northeastern, rural areas. In addition, there is a significant income inequality between urban and rural communities in terms of accessing quality health care and medical centers.

Turkmenistan has several environmental issues, from contamination of the soil and groundwater to decreasing water levels in rivers (e.g., Amu Darya) and lakes (e.g., Sarygamymsh Koli). Drinking water sources are improving, especially in urban settings (2011 estimates); for instance, 89.1 percent of the population in urban settings can access improved-quality waters. On the other hand, 46.3 percent of the population in rural settings do not have access to quality drinking water.

According to United Nations Human Development Index, Turkmenistan is ranked 145th in the world. There are different estimates for life expectancy. According to the World Health Organization (WHO) 2011 data, life expectancy is 63.4 (59.8 for males and 67.1 for females), coming in 142nd on the World Life Expectancy ranking. The Central Intelligence Agency (CIA) World Factbook reports 69.47 years (66.48 for males and 72.61 females), ranking Turkmenistan 155th in the world. On the other hand, the State Statistics Committee of Turkmenistan, in 2011, reported the average life expectancy as 70.6 years (67.7 for males and 73.5 for females), which indicates an increase since 1990 (66.4 years) as well as decreasing infant mortality.

According to the CIA World Factbook, Turkmenistan spends 2.7 percent of gross domestic product (2011) on health, ranking 183rd in the world; there are 2.44 physicians for 1,000 people (2007) and 4.1 beds per 1,000 population (2011).

As part of the World Health Organization (WHO) Europe Region, the government of Turkmenistan hosted the WHO European Ministerial Conference on the Prevention and Control of Non-communicable Diseases (NCDs) for Health 2020 on December 3 and 4, 2013, in Ashgabat.

In comparison to other eastern European countries, cancer mortality rates are lower in Turkmenistan. However, cancer is one of the most common causes of death in Turkmenistan as well as cardiovascular and respiratory diseases. Common cancer types among men are stomach, lung, esophagus, liver, and colon; among women, they are breast, esophagus, cervical, stomach, and colon or rectum cancer. There is a high mortality rate for liver and lung cancers. The overall ratio of mortality to incidence is 72 percent among the Turkmen population.

Esophageal cancer is the eighth-most common cancer in the world, and according to GLOBOCAN 2012, Turkmenistan is listed among the highest incidences of esophageal cancer in the world.

According to the WHO April 2011 data, there are 341 or 0.90 percent of total deaths due to breast cancer in Turkmenistan, which ranks Turkmenistan 87th in the world for breast cancer. In the last two decades, while female populations increased by approximately one-third, there is a twofold increase (108 percent) in breast cancer (from 195 to 406) cases. The International Agency for Research on Cancer (IARC) predicts higher cases of breast cancer in Turkmenistan as demographics and life change with higher caloric intake, less physical activity, and limited access to mammogram screening.

According to the Human Papillomavirus (HPV) Center fact sheet, cervical cancer ranks as the fourth-most common cancer among women, with the fifth-most common cancer incidence among females 15 to 44 years old in Turkmenistan. It is estimated that 129 females die annually from cervical cancer out of 324 diagnosed cancer cases. In addition, WHO 2011 data lists 451 deaths or 1.19 percent of stomach cancer-related deaths, which ranks Turkmenistan 33rd in the world with lung cancers deaths at 377 or 1.00 percent of total lung cancer-related deaths, which ranks Turkmenistan 100th in the world.
Even though there are limited data and statistics available in the field of health and medicine through the Turkmen government, there is a significant effort to rebuild the country, increasing resources in health and medicine and increasing involvement in international organizations and projects. With a median human development index of 102nd out of 186 countries in the world, Turkmenistan has been welcoming the scientific research and conferences in the field of medicine and health education. The Ministry of Education and the Ministry of Health and Medical Industry collaborate on the implementation of a number of health programs (e.g., immunization, human immunodeficiency virus [HIV] prevention, and prenatal care). Since 1996, the Ministries of Education and Health have developed textbooks and integrated health education into the kindergarten through grade 12 curriculum.

Uganda

The Republic of Uganda is located in eastern Africa. It is bordered on the north by South Sudan, on the east by Kenya, on the south by Rwanda and Tanzania, and on the west by the Democratic Republic of the Congo. It is the 11th-most-populous country in Africa and 44th most populous in the world, with a population of over 26.4 million. Although English is the official national language, most Ugandans learn a local language before English. Ganda is the de facto national language, while Kiswahili is the statutory national working language; there are also 41 living indigenous languages still spoken by respective ethnic groups in Uganda. The most widely spoken ethnic languages include Chiga, Konzo, Lango, Masaaba, Nyankore, Soga, and Teso. Each ethnic group has its own rich traditions of ethnomedicine. For example, in Kiswahili, a traditional healer who uses medicinal plants for treating ailments is known as mganga, and medicinal plants are called miti shamba.

There are many traditional medicinal preparations used in Uganda. Most of these incorporate myriad local plant materials, many of which have shown medicinal properties in laboratory studies. For example, extracts from Podocarpus sensu demonstrate significant anti-tumor activity. Research suggests that the use of certain plants may help protect against cancer by reducing oxidative stress and stimulating enzymes and other processes that help the body fight carcinogens. For example, an extract from Nymphaea lotus, locally referred to as lora, demonstrates substantial antioxidant potential. This quality is also found in extracts of Kigelia africana (which the Gbe-Gen call nyakpokpo, the Luganda call mussa, the Tem call abilu, and the Vhe call niagpe) as well as in extracts of Hallea rubrostipulata and Zanthoxylum chalybeum.

Medicinal plants are used in Uganda to treat many health problems associated with cancers. For example, the So of northeast Uganda traditionally drink a root decoction of Ackanthera spp. to treat “white urine.” The So also apply the leaves of Rhoicissus tridentata, which they call robol-e, as a plaster to treat wounds.

Unlike traditional preparations, there are serious deficiencies of modern pharmaceutical supplies in Uganda. Uganda is a signatory to the Single Convention on Narcotic Drugs, the Convention on Psychotropic Substances, and the UN Convention against the Illicit Traffic in Narcotic Drugs and Psychotropic Substances; consequently, laws exist to control narcotic and psychotropic substances and precursors. The annual consumption of controlled substances is highly regulated to curtail abuse. Accordingly, the annual consumption of morphine is 0.7416 mg/capita, and the consumption of pethidine is 0.2090 mg/capita. In 2010, the annual prevalence of opiate use by the population aged
15 to 64 years was 0.05 percent, one of the lowest rates in the world. This creates a serious lack of access to basic palliative care that makes cancer experiences in Uganda very different from those elsewhere in the world.

Due, in part, to the shortage of medical services and supplies, health problems are endemic in Uganda. The 10 leading causes of mortality, in rank order, are malaria, HIV/AIDS, anemia, pneumonia, tuberculosis, septicemia, diarrhea, respiratory infections, injuries, and perinatal conditions. The average number of cancer cases annually in Uganda is 171.9 per 100,000 population.

There are also serious deficiencies in modern medical services for cancer and similar conditions in Uganda. According to the World Health Organization’s “Health System Response and Capacity,” as of 2010 there was no general availability of either chemotherapy or radiotherapy in the public health system in Uganda.

Cancers account for a substantial amount of disability and suffering among impacted populations. According to the World Health Organization’s “Disease and Injury Country Estimates” for 2004, the ten most prevalent cancers in Uganda were esophageal cancer, at 193 per 100,000 population; prostate cancer at 163 per 100,000 population; cervical and uterine cancers at 121 per 100,000 population; lymphomas at 98 per 100,000 population; stomach cancer at 85 per 100,000 population; breast cancer at 80 per 100,000 population; liver cancer at 77 per 100,000 population; colon and rectal cancers at 76 per 100,000 population; mouth and oropharynx cancer at 60 per 100,000 population; and trachea, bronchial, and lung cancers at 53 per 100,000 population.

Modern medical services and supplies, as opposed to traditional preparations, are generally in short supply in Uganda, if available at all. Both prescription and over-the-counter products are often unavailable. Consequently, health problems are endemic and limit development. For example, an estimated 600,000 people live with HIV in Uganda, ranking the country 11th highest in Africa and 16th highest globally. The mortality rate for HIV/AIDS is 209 per 100,000 population. Debate continues on the relative risks in Africa for respective cancer types for those infected with HIV. The mortality rate for tuberculosis is 27 per 100,000 population, and for malaria it is 145 per 100,000 population, while for cancers it is 138 per 100,000 population. Furthermore, according to the World Health Organization’s “Global Health Observatory Data Repository,” in 2008 the age-standardized estimates of deaths from all cancers was 127 per 100,000 population for males and 140 per 100,000 population for females. As a consequence, life expectancy is only 50.43 years, which ranks the Uganda 23rd in Africa and 194th in the world. There is a clear and urgent need for improved cancer awareness, early detection programs, and health services infrastructure in Uganda.

Ukraine

The eastern European nation officially termed Ukraine has experienced many variations in its statehood over the past several centuries. This has led to confusion even among contemporary historians regarding the nation's proper history, but what is known is that the roots of the modern state of Ukraine can be traced back to the ninth-century federation of tribes called the Kyivan Rus. The region underwent many political variations in the ensuing millennia. In 1922, Ukraine became the Ukrainian Soviet Socialist Republic and was incorporated into the Soviet Union until the nation declared its independence in 1991 after the Union's dissolution, and thus arrived at its modern rendition.

With regard to Ukraine's battle against cancer, the infamous disaster that occurred in April 1986 at Chernobyl's nuclear power plant has had repercussions on the rate of cancer incidences in the country, especially in adolescents. Improperly trained staff members and mistakes in the facility's design led to a nuclear meltdown at the facility that caused nuclear fallout to be expelled high into the atmosphere. The fallout drifted over portions of Ukraine, Belarus, and Russia, and in the years following the disaster, a tangible increase in the incidences of thyroid cancer diagnosed in children from regions near Chernobyl has led specialists to believe that fallout from the nuclear accident is likely to blame. Specifically, scientists believe that the radioactive isotope I-131 that was present in the nuclear fallout from the disaster is the main reason for the noticeable increase in thyroid cancers in the region's youth. Thyroid cancer rates in the area continue to be closely monitored by domestic and international scientists.

In the past 25 years, Ukraine has initiated an overhaul of its medical system by striving to give the nation's medical students the best possible cancer-education resources. Prospective cancer specialists can go to one of 19 state-run medical universities for their education, and, if they graduate, they can follow up their training at one of three post-graduate training academies. Incidences of cancer have been consistently trending upwards in Ukraine in recent years, so the Ukrainian Ministry of Health has been going to great lengths to ensure that the country will have an adequate amount of highly trained cancer specialists to combat the disease in forthcoming decades. On average, there are currently only four cancer specialists in the country for every 100,000 Ukrainian citizens.

The most prevalent forms of cancer in Ukraine are lung cancer, breast cancer, skin cancer, prostate cancer, and stomach cancer. Lung, skin, and prostate cancers make up nearly half of all cancer incidences in males in the nation, while breast, skin, and uterine cancers are the most prevalent cancer incidences in females. Within the past 10 years, certain cancers such as skin cancer, stomach cancer, uterine cancer, lung cancer, and thyroid cancer have seen a nationwide increase in prevalency, while incidences of gallbladder cancer have steadily been declining. Certain parts of Ukraine experience more cases of specific cancers than other parts of the country; there are higher incidences of thyroid cancer in the youth of the region that was affected by the Chernobyl nuclear disaster in 1986 than in the rest of the nation.

As in all nations, many citizens of Ukraine have had cancer throughout the country's history. The Kiev-born and world-renowned tennis athlete Elena Baltacha passed away after a two-month battle with liver cancer. The Ukrainian Vladimir Shevchenko, who famously filmed the immediate aftermath of the Chernobyl nuclear disaster, died in 1987 from complications resulting from cancer induced by the accident's radiation fallout. Volodymyr Sabodan, who was the primate of the Ukrainian Orthodox Church, passed away in July 2014 at a hospital in Kiev after his own battle with cancer.

Ukraine is home to 27 cancer specialist centers. The nation is also home to numerous medical academies and university hospitals that function in similar capacities. Ukrainian cancer specialists are well
Ultraviolet A Radiation

Exposure to ultraviolet (UV) radiation is a major risk factor for the development of many skin cancers. Sunlight is the main source of UV rays, but tanning lamps and beds also produce UV rays. People who get a lot of UV exposure from these sources are at greater risk for skin cancer. UV rays are only a small portion of the sun's rays, but they produce the main harmful effects of the sun as they damage the DNA of skin cells. When the sun's UV ray damage affects the DNA of the genes that control skin cell growth, the body is vulnerable to the development of skin cancer.

Not all UV rays are the same. There are three main types of UV rays, ultraviolet A (UVA) rays, ultraviolet B (UVB) rays, and ultraviolet C (UVC) rays. UVA rays are responsible for aging skin cells and damaging skin cell DNA. UVA rays have been linked to long-term forms of skin damage, including wrinkles. These rays also have a part in the development of some skin cancers. Most of the tanning beds on the market give off large amounts of UVA radiation, which is one reason these beds pose a skin cancer risk. UVB rays are the rays mainly responsible for sunburns and produce direct damage to skin cell DNA. UVB rays are often implicated as a causal agent in most forms of skin cancer. UVC rays are absorbed by the Earth's ozone layer and do not reach the Earth's surface. As such, these rays do not normally play a large part in the process of skin cancer development. Most of the UV rays that come in contact with humans are UVA, with a smaller amount of UVB. While both UVA and UVB rays damage skin and cause skin cancer, UVB rays are thought to be the more potent of the two, and more heavily involved in causing at least some skin cancers. Fortunately, some UVB rays are also absorbed by the Earth's ozone layer. Other UVB
rays, however, are not absorbed and are able to pass through and affect humans. Overall, there are no safe UV rays. They are all harmful. The amount of UV exposure a person gets depends on the strength of the rays, the length of time the skin is exposed, and whether the skin is protected with clothing or sunscreen.

**Effects of UV Rays**
Sun is often thought of as the main causal agent in skin cancers, and it is classified as a human carcinogen. If people get too much sun, they increase their risk of skin cancer. Yet, there are other effects of UV exposure. Sunburn and tanning are the short-term results of too much exposure to UV rays, and they are the overt signs of skin damage. Long-term exposure can cause early skin aging, wrinkles, loss of skin elasticity, and dark patches known as age spots. Long-term exposure can also cause precancerous skin changes, including dry, scaly, rough patches called actinic keratosis.

The sun's UV rays can also increase a person's risk of cataracts and other eye problems. UV rays can also suppress the skin's immune system. Darker-skinned people are generally less likely to get skin cancer than light-skinned people, but they can still get cataracts and immune suppression. UV rays from the sun are not the only harmful source. UV radiation is also transmitted from tanning beds, classifying it as a source of human carcinogen. Other sources of UV radiation include mercury vapor lighting; halogen, fluorescent, and incandescent lighting; and some types of lasers. Additionally, certain oral and topical medicines, such as antibiotics, birth control pills, and benzoyl peroxide products, as well as some cosmetics, may increase skin and eye sensitivity to UV rays in all skin types.

**The UV Index**
The amount of UV light reaching the ground in any given place depends on a number of factors, including the time of day, time of year, elevation, and cloud cover. The UV Index was designed by the National Weather Service and the Environmental Protection Agency (EPA) to provide an indicator of the strength of UV rays on any given day in any given area. The scale runs from 1 to 11+, with a higher number indicating greater risk of UV ray exposure. The greater risk of exposure also increases the chance sunburn and skin damage that could potentially lead to skin cancer. Local changes in cloud cover and other factors may change the actual UV levels experienced.

**UVA**
All radiation is a form of energy, most of which is invisible to the human eye. UV radiation is only one form of radiation, and it is measured on a scientific scale called the electromagnetic (EM) spectrum. UV radiation is only one type of EM energy. Radio waves that transmit sound from a radio station's tower or between cell phones; visible light that is emitted from the lights in a home; and X-rays like those used in hospital X-ray machines are all forms of EM energy. Like all forms of light on the EM spectrum, UV radiation is classified by wavelength. Wavelength describes the distance between the peaks in a series of waves. Of the three types of UV rays, UVA rays have the longest wavelengths, and UVC rays have the shortest wavelengths; UVB rays fall in between the two. The longer wavelength of UVA rays is able to penetrate the middle layer, or dermis, of human skin.

UVA is the most commonly encountered type of UV light. Most humans are exposed to large amounts of UVA throughout their lifetime. UVA rays account for up to 95 percent of the UV radiation reaching the earth's surface. Atmospheric ozone absorbs very little of this part of the UV spectrum. UVA is needed by humans for synthesis of vitamin D; however, overexposure to UVA has been associated with toughening of the skin, suppression of the immune system, and cataract formation. UVA light is often called black light. Most phototherapy and tanning booths use UVA lamps.

Although they are not as intense as UVB rays, UVA rays are 30 to 50 times more prevalent. They are present with relatively equal intensity during all daylight hours throughout the year, and they can penetrate clouds and glass. UVA, which penetrates the skin more deeply than UVB, has long been implicated in skin aging and wrinkling. UVA exposure has an initial pigment-darkening effect (tanning) followed by erythema if the exposure is excessive. Initially, scientists believed UVA did not cause significant damage in areas of the epidermis where most skin cancers occur. Recent studies, however, show that UVA damages skin cells called keratinocytes in the basal layer of the epidermis, where most skin cancers occur. UVA radiation contributes to and may even initiate the development of skin cancers.
UVA is the dominant tanning ray. Tanning in any form, whether outdoors or in a salon, causes cumulative damage over time. A tan results from injury to the skin’s DNA; the skin darkens in an imperfect attempt to prevent further DNA damage. These imperfections, or mutations, can lead to skin cancer. Tanning booths primarily emit UVA. The intense sunlamps used in tanning salons emit doses of UVA as much as 12 times that of the sun. Not surprisingly, people who use tanning salons are 2.5 times more likely to develop squamous cell carcinoma, and 1.5 times more likely to develop basal cell carcinoma. According to recent research, exposure to tanning beds in youth increases melanoma risk by 75 percent.

**Factors Influencing UVA Levels**
The level of UV radiation reaching the earth’s surface can vary. The amount of UV rays the ozone layer absorbs varies depending on the time of year and other natural events. The sun’s angle changes with the seasons, which affects the intensity of the UV rays. The UV rays tend to be more intense in the summer months. Time of day is also a consideration. The sun is highest in the sky around noon. The sun’s rays pass directly through the atmosphere from the shortest distance, causing levels to be at their highest. In the early morning and late afternoon the sun’s rays are slanted, and the intensity is reduced. The sun is most directly overhead around the equator, which makes the sun’s rays strongest in this area. The rays do not have to travel as far through the atmosphere.

Ozone also is naturally thinner in the tropics compared to the mid and high latitudes, so there is less ozone to absorb the UV radiation as it passes through the atmosphere. At higher latitudes, the sun is lower in the sky, so UV rays must travel a greater distance through ozone-rich portions of the atmosphere and, in turn, expose those latitudes to less UV radiation. In addition to location, the ozone layer has been affected by environmental concerns. The ozone layer is thinner than it used to be due to ozone-depleting chemicals used in industry and consumer products. These chemicals are being phased out, but the ozone layer is not predicted to return to pre-1980 levels until mid- to late century. This allows the UV rays to reach the earth with less filtering.

Higher altitude levels also increase the intensity of UV radiation because there is less atmosphere to absorb the damaging rays. The risk to skin and eyes increases in high-altitude locations. Cloud cover also reduces the UV radiation that reaches the earth’s surface. Thinner cloud cover, even on colder days, can still allow UV radiation in strong enough doses to burn skin. Surfaces like snow, sand, pavement, and water reflect much of the UV radiation that reaches them. Because of this reflection, UV intensity can be deceptively high even in shaded areas.

The photochemical effects of UV radiation can be exacerbated by chemical agents including birth control pills, tetracycline, sulphathiazole, cyclamates, antidepressants, coal tar distillates found in antidandruff shampoos, lime oil, and some cosmetics. Protection from UV is provided by clothing, polycarbonate, glass, acrylics, and plastic diffusers used in office lighting. Sun-blocking lotions offer limited protection against UV exposure. Accidental overexposure might not be detected because the
UV radiation is invisible and does not produce an immediate reaction. Yet, this radiation can injure individuals. Labeling on UV sources usually consists of a caution or warning label on the product or the bulb packaging cover, or a warning sign on the entryway.

Ultraviolet B Radiation

Exposure to ultraviolet (UV) radiation is a major risk factor for development of many skin cancers. Sunlight is the main source of UV rays, but tanning lamps and beds also produce UV rays. People who receive a lot of UV exposure from these sources are at greater risk for skin cancer. UV rays are only a small portion of the sun’s rays, but they produce the main harmful effects of the sun because they damage the DNA of skin cells. When the sun’s UV ray damage affects the DNA of the genes that control skin cell growth, the body is vulnerable to the development of skin cancer.

Not all UV rays are the same. There are three main types of UV rays, ultraviolet A rays (UVA), ultraviolet B rays (UVB), and ultraviolet C rays (UVC). UVA rays are responsible for aging skin cells and damaging skin cell DNA. UVA rays have been linked to long-term forms of skin damage, including wrinkles. These rays also have a part in the development of some skin cancers. Most of the tanning beds on the market give off large amounts of UVA, which is one reason these beds pose a skin cancer risk. UVB rays are the rays mainly responsible for sunburns, and produce direct damage to skin cell DNA. UVB rays are often implicated as a causal agent in most forms of skin cancer. UVC rays are absorbed by the Earth’s ozone layer, and are not based in sunlight. As such, these rays do not normally play a large part in the process of skin cancer development. Most of the UV rays that come in contact with humans are UVA, with a smaller amount of UVB. While both UVA and UVB rays damage skin and cause skin cancer, UVB rays are thought to be the more potent of the two, and are more heavily involved in causing at least some skin cancers. Fortunately, some UVB rays are also absorbed by the Earth’s ozone layer. Other UVB rays, however, are not absorbed, and are able to pass through and affect humans. Overall, there are no safe UV rays. They are all harmful, and the longer someone is exposed, the greater the risk. It is also important to look at the strength of the rays, and whether the skin is protected with clothing or sunscreen.

Effects of UV Rays
Sun is often thought of as the main causal agent in skin cancers, and is classified as a human carcinogen. The more sun that an individual receives, the more they increase their risk of skin cancer. Yet, there are other effects of UV exposure. Sunburn and tanning are the obvious short-term signs of too much UV ray exposure. Long-term exposure can cause early skin aging, wrinkles, loss of skin elasticity, and dark patches known as age spots. Long-term exposure can also cause precancerous skin changes, including dry scaly rough patches called actinic keratosis.
The sun's UV rays can increase a person's risk of cataracts and other eye problems. These rays are also responsible for problems with the function of the skin's immune system. People with lighter skin are at higher risk for developing skin cancer than people with darker skin, but people with darker skin are still at risk for developing cataracts and a suppressed immune system. UV rays from the sun are not the only harmful source. UV radiation is also transmitted from tanning beds, classifying them as a human carcinogen. Other sources of UV radiation include mercury vapor lighting; halogen, fluorescent, and incandescent lighting; and some types of lasers. Additionally, some medicines can increase susceptibility to UV rays and their harmful effects, including certain prescription and over-the-counter oral and topical medicines, and some types of cosmetics. These products can increase sensitivity for all skin types.

**UV Index**

The amount of UV light reaching the ground in any given place depends on a number of factors, including the time of day, time of year, elevation, and cloud cover. The UV Index was designed by the National Weather Service and the Environmental Protection Agency (EPA) to provide an indicator of the strength of UV rays on any given day in any given area. The scale runs from 1 to 11+, with a higher number indicating greater risk of UV ray exposure. The greater risk of exposure also increases the chance sunburn and skin damage that could potentially lead to skin cancer. Local changes in cloud cover and other factors may change the actual UV levels experienced.

**UVB**

UVB radiation is the chief cause of skin reddening and sunburn, which tends to damage the skin's more superficial epidermal layers. It plays a key role in the development of skin cancer, and a contributory role in tanning and photoaging. The intensity of UVB radiation varies by season, location, and time of day. The more intense amounts of UVB radiation occur in the United States between 10:00 A.M. and 4:00 P.M. from April through October. However, UVB rays can burn and damage skin throughout the year. Locations with higher altitudes are at greater risk, and snow and ice increase this risk because they reflect the sun's rays and bounce back up to 80 percent of the rays so that they hit the skin twice. UVB rays are not as able to cause damage through glass. UVB rays have a short wavelength that reaches the outer layer of the skin (the epidermis). UVB radiation that reaches the Earth's surface has the potential to create serious health effects, and can negatively impact the environment. Levels of UVB radiation are not as constant as UVA, but are more intense and capable of doing damage.

UVB radiation is typically the most destructive form of UV radiation because it has enough energy to cause photochemical damage to cellular DNA, yet not enough to be completely absorbed by the atmosphere. Some UVB radiation is needed to help synthesize vitamin D. Even with this benefit, harmful effects can occur, including erythema (sunburn), cataracts, and development of skin cancer. Individuals working outdoors are at the greatest risk of UVB effects, and should take precautions to minimize this risk. Most solar UVB radiation is blocked from reaching the surface by the ozone layer of the atmosphere. Thus, there are concerns that reductions in atmospheric ozone could increase the prevalence of skin cancer.

**Sun Exposure and UVB Radiation**

Since the invention of modern day sunscreens, a sunscreen's efficacy has been measured by its sun protection factor (SPF). SPF is not the amount of protection that a product provides. The SPF number provides a guideline for how long it will take for UVB rays to redden skin when using that level of SPF sunscreen, compared to how long skin would take to redden without the product. For example, someone using a sunscreen with an SPF of 30 will take 30 times longer to redden than without the sunscreen. An SPF 15 sunscreen screens 93 percent of the sun's UVB rays; SPF 30 protects against 97 percent; and SPF 50, 98 percent. The Skin Cancer Foundation maintains that SPFs of 15 or higher are necessary for adequate protection.

UVB radiation has some health benefits in addition to the risks. Exposure to UVB radiation helps the skin produce vitamin D3, which plays an important role, along with calcium, in bone and muscle health. The amount of UVB exposure necessary for this development and other potential health benefits depends on different factors, including the amount of vitamin D that the person takes in in other ways, darkness of skin color, sunscreen
Exposure to ultraviolet (UV) radiation is a major risk factor for development of many types of skin cancer. One of the most common sources of UV rays is sunlight, but tanning lamps and beds also use, clothing, geographical location of home (latitude and altitude), time of day, and time of year. At this time, the FDA has not cleared or approved any indoor tanning device for producing vitamin D using UVB radiation.

UV radiation is also present in lasers and UV lamps. Some topical medications used for certain diseases that are unresponsive to other forms of medical therapy can increase UV sensitivity. This process is called phototherapy. Phototherapy provides UV exposure, administered by a trained health care professional, under the supervision of a dermatologist. Studies suggest that phototherapy can help treat unresponsive and severe cases of several diseases, including rickets, psoriasis, eczema, vitiligo, and lupus. Phototherapy occurs by exposing a patient to a specific closely monitored dose of UV radiation administered at regular intervals on a set schedule. In some cases, effective therapy requires that a patient’s skin is first treated with a prescription drug, ointment, or bath that increases its UV sensitivity.

Factors Influencing UV Radiation Levels
The level of UV radiation reaching the Earth’s surface can vary. The amount of UV rays that the ozone layer absorbs varies depending on the time of year and other natural events. The sun’s angle changes with the seasons, which affects the intensity of UV rays. UV rays tend to be more intense in the summer months. Time of day is also a consideration. The sun is highest in the sky around noon. The sun’s rays pass directly through the atmosphere from the shortest distance, causing levels to be at their highest. During early morning and late afternoon, the sun’s rays are slanted, and the intensity is reduced. The sun is most directly overhead around the equator, which makes the sun's rays strongest in this area. The rays do not have to travel as far through the atmosphere.

Ozone also is naturally thinner in the tropics compared to the mid- and high-latitudes, so there is less ozone to absorb the UV radiation as it passes through the atmosphere. At higher latitudes, the sun is lower in the sky, so UV rays must travel a greater distance through ozone-rich portions of the atmosphere and, in turn, expose those latitudes to less UV radiation. In addition to location, the ozone layer has been affected by environmental concerns. The ozone layer is thinner than it used to be because of ozone-depleting chemicals used in industry and consumer products. These chemicals are being phased out, but the ozone layer is not predicted to heal to pre-1980 levels until mid- to late-century. This allows the UV rays to reach the Earth with less filtering.

Short exposure to UVB radiation generates vitamin D, but can also lead to sunburn, depending on an individual’s skin type. Fortunately, the ozone layer in the atmosphere shields some UVB radiation, but not all of it. UVB radiation is a potent danger if individuals do not take measures to minimize or prevent the possible damage. Since the benefits of sunlight cannot be separated from its damaging effects, it is important to understand the risks of overexposure, and take simple precautions to protect oneself.

Factors Influencing UV Radiation Levels
The level of UV radiation reaching the Earth’s surface can vary. The amount of UV rays that the ozone layer absorbs varies depending on the time of year and other natural events. The sun’s angle changes with the seasons, which affects the intensity of UV rays. UV rays tend to be more intense in the summer months. Time of day is also a consideration. The sun is highest in the sky around noon. The sun’s rays pass directly through the atmosphere from the shortest distance, causing levels to be at their highest. During early morning and late afternoon, the sun’s rays are slanted, and the intensity is reduced. The sun is most directly overhead around the equator, which makes the sun's rays strongest in this area. The rays do not have to travel as far through the atmosphere.

Ozone also is naturally thinner in the tropics compared to the mid- and high-latitudes, so there is less ozone to absorb the UV radiation as it passes through the atmosphere. At higher latitudes, the sun is lower in the sky, so UV rays must travel a greater distance through ozone-rich portions of the atmosphere and, in turn, expose those latitudes to less UV radiation. In addition to location, the ozone layer has been affected by environmental concerns. The ozone layer is thinner than it used to be because of ozone-depleting chemicals used in industry and consumer products. These chemicals are being phased out, but the ozone layer is not predicted to heal to pre-1980 levels until mid- to late-century. This allows the UV rays to reach the Earth with less filtering.

Ultraviolet C Radiation
Exposure to ultraviolet (UV) radiation is a major risk factor for development of many types of skin cancer. One of the most common sources of UV rays is sunlight, but tanning lamps and beds also
produce UV rays. People who are exposed to the UV rays from these sources face higher risks of developing skin cancer. UV rays make up a small amount of the sun's rays, but they produce the main harmful effects of the sun because they damage the DNA of skin cells. When the sun's UV ray damage affects the DNA of the genes that control skin cell growth, the body is vulnerable to the development of skin cancer.

Not all UV rays are the same. There are three main types of UV rays: ultraviolet A rays (UVA), ultraviolet B rays (UVB), and ultraviolet C rays (UVC). UVA rays are responsible for aging skin cells and damaging skin cell DNA. UVA rays have been linked to long-term forms of skin damage, including wrinkles. These rays also have a part in the development of some skin cancers. Most of the tanning beds on the markets give off large amounts of UVA, which is one reason why these beds pose a skin cancer risk. UVB rays are mainly responsible for sunburns, and produce direct damage to skin cell DNA. UVB rays are often implicated as a causal agent in most forms of skin cancer. UVC rays are absorbed by the Earth's ozone layer, and are not based in sunlight. As such, these rays do not normally play a large part in the process of skin cancer development. Most of the UV rays that come into contact with humans are UVA, with a smaller amount of UVB. While both UVA and UVB rays damage skin and cause skin cancer, UVB rays are thought to be the more potent of the two, and are more heavily involved in causing at least some skin cancers. Fortunately, some UVB rays are also absorbed by the Earth's ozone layer. Other UVB rays, however, are not absorbed, and are able to pass through and affect humans. Overall, there are no safe UV rays. They are all harmful. The extent of harmful UV exposure normally depends on the strength of the rays, how much time the exposure to the skin occurs, and what type of protection is on the skin, including clothing or sunscreen.

**Ultraviolet C Radiation**

UVC is very rarely observed in its natural state because it is absorbed completely by the carbon dioxide and ozone in the atmosphere. This is a good thing because UVC rays are very dangerous, and even short exposure to any quantity of UVC is very harmful to the eyes and causes severe sunburn. In essence, the shorter the wavelength, the more potentially dangerous the ultraviolet radiation. UVC radiation is extremely dangerous for humans; some forms are produced on the Earth's surface by such processes as arc welding. It is part of the far regions of ultraviolet radiation, with wavelengths between 200 and 290 nanometers, or wavelength range, all of which is filtered out by the ozone layer and does not reach the Earth's surface. UVA and UVB have larger wavelength ranges, and are thus able to permeate the atmosphere and affect skin by exposure to sunlight. The shorter wavelengths produce ozone in air (oxygen). Differences in size of wavelength can produce differences in what occurs with them. For example, the wavelengths at the bottom of the spectrum radio have radio waves with photons containing low energies. This causes wavelengths with long peaks that are farther apart. The photons of microwaves have higher energies, followed by infrared waves, UV rays, and X-rays. At the top of the spectrum, gamma rays have photons with very high energies and short wavelengths, with peaks that are close together. The shorter gamma ray wavelengths present the greater danger with exposure to humans.

UVC light tends to be utilized through manufactured means, rather than impacting humans in its natural state. When humans are exposed to UVC radiation, it is absorbed in the outer dead layers of the epidermis. UVC overexposure creates the potential for corneal burns, which is also called welders' flash, and snow blindness. This results in a severe sunburn to the face. While UVC injury usually clears up in a day or two, it can be extremely painful. UVC wavelengths are not produced by the ultraviolet radiation sources utilized by the indoor tanning industry.

UVC radiation has properties that have the ability to kill bacteria. The shorter-wavelength, higher-energy UV radiation associated with the UVC category is very strongly absorbed by most organic materials. This makes it a good candidate for use in treatment of certain diseases. UVC is used in germicidal lamps in medical facilities. Light in the UVC wavelength can be used for disinfecting water, sterilizing surfaces, destroying harmful microorganisms in food products and in the air, and is also used in ultraviolet phototherapy. UVC radiation, in the range of 255 to 275 nanometers, renders harmful microorganisms such as bacteria and viruses ineffective by destroying the genetic information
in DNA. The microorganisms are unable to reproduce, which leads to the death of the microbes. The germicidal nature of UV is well suited to treat parasites that are extremely resistant to chemical disinfectants, such as Cryptosporidium or Giardia.

UVC radiation is aggressive enough that individual photons may produce chemical bond breakage and ionization of some atoms and molecules. The preferential absorption of particular energy photons by materials, both organic and inorganic, is evident throughout the electromagnetic spectrum, from microwaves through infrared and visible light, ultraviolet, X-rays, and gamma rays. The absorption at particular wavelengths may be associated with resonance-type effects in which the gaps between certain energy states in an atom or molecule are nearly matched by the energies of the incoming photons. Atomic or molecular excitation may occur as a result of the absorption, or an electron may be ejected from an atom when the incoming photon energy exceeds the binding energy of the electron in the atom. There is a pattern to photon absorption by particular atoms or molecules that could begin small at a given energy, increase with increasing energy, and then decrease again at yet higher energies, so it is not surprising that some higher-energy UV radiation may be more strongly absorbed than lower-energy UV.

UVC radiation has not been implicated as a cause of human skin cancer or other types of human cancer, although some experiments with mice have demonstrated a causative link between squamous cell cancer and UVC irradiation. The dead skin on most of the human body is sufficient to absorb UVC radiation almost completely. In areas of reduced dead-skin thickness and intense radiation, however, UVC radiation might reach live skin tissue, and could produce erythema and possibly other undocumented effects. This would be true especially in an abraded area of skin, or in the region of a significant flesh wound.

Since UVC radiation is greatly diminished by atmospheric gases, no significant irradiation of human beings on Earth results from natural sources. With increasing germicidal uses of man-made UVC radiation, especially in hospital settings where there is a strong concern about the spread of harmful bacteria, it is likely that more human exposures will occur, and future studies may show some links with disease that have not been identified as yet. UVC radiation can damage the superficial tissues of the eye, and care must be taken to avoid excessive exposures of the eye to this form of radiation. While eye exposures to UVC may cause extreme discomfort, the symptoms usually subside within a rather short time, and no evidence of any lasting malignant effects has been discovered at this point.

**Ultraviolet Germicidal Irradiation**

Shortwave UVC radiation is also called ionizing radiation because it has enough energy to quickly destroy important molecular bonds, such as those found in deoxyribonucleic acid (DNA), the molecular blueprint of all living cells. By creating random breaks in DNA, UV radiation can introduce mutations, and in most microorganisms, this causes cell death. Ultraviolet germicidal irradiation (UVGI) is one of the most adaptable and effective ways of sterilizing an object without causing damage and without generating harmful byproducts. Because of its versatility and safety, UVGI has been used to sterilize air, drinking water, aquariums, ponds, laboratory equipment, medical instruments, food, and beverages. The UVGI process uses short-wavelength UVC in a contained area to kill microorganisms such as viruses, bacteria, and molds, some of which can cause human disease and are called pathogens. The pathogenic microorganisms normally resistant to other forms of sterilization, including chemical forms, are destroyed using UVGI. UVGI is also effective when the use of heat sterilization is not feasible. Each microorganism has a different level of sensitivity to UVC radiation. Some microorganisms require only a small amount of UVGI to break apart its DNA and prevent reproduction, whereas others require more.

**Arc Welding**

Another place where radiation in the UVC range can be found is in welding. It is present in the arc of a welding torch. This has given rise to the term “welder’s eye,” referring to optical damage caused by UVC light. UVA and UVB light can cause similar skin and eye damage, but much higher levels and much longer exposure times are required. The short distance between the arc and the welder’s skin may not be sufficient to absorb most of the UVB and UVC radiation, allowing it to remain at a higher concentration for human exposure. As a result, arc welders may be at significantly increased risk of
developing actinic skin and ocular damage, including malignancy, particularly if they have inadequate protection. Additionally, thermal burns from hot metal can occur when welding, contributing to this risk. Welders can be advised regarding appropriate clothing and be encouraged to choose sunscreens that include UVC protection. Workers welding aluminum risk the highest exposures to artificial UV, and should take extra precautions. The lack of quality studies on UVC exposure means there is uncertainty about the risk of skin cancers from arc welding operations, and further investigations are needed.

While UVC radiation is not as prevalent on the Earth's surface as UVA and UVB radiation, the shorter wavelength creates the potential for more severe harm when contact is made. Most of the UVC radiation is created synthetically, rather than occurring naturally from the sun. This does not make it any less potent. There are benefits to UVC radiation because it has been shown to be helpful in eradicating certain types of germs that are resistant to other antibacterial measures. Jobs that expose individuals to UVC radiation should provide safety measures that will effectively prevent employees from risk to exposure and painful consequences. Arc welders must learn about and use recommended safety equipment in order to reduce their risk.

Exposure to ultraviolet (UV) radiation is a major risk factor for development of many types of skin cancer. One of the most common sources of UV rays is sunlight, but tanning lamps and beds also produce UV rays. People who are exposed to the UV rays from these sources face higher risks of developing skin cancer. UV rays make up a small amount of the sun's rays, but they produce the main harmful effects of the sun because they damage the DNA of skin cells. When the sun's UV ray damage affects the DNA of the genes that control skin cell growth, the body is vulnerable to the development of skin cancer.

Not all UV rays are the same. There are three main types of UV rays, ultraviolet A rays (UVA), ultraviolet B rays (UVB), and ultraviolet C rays (UVC). UVA rays are responsible for aging skin cells and damaging skin cell DNA. UVA rays have been linked to long-term forms of skin damage, including wrinkles. These rays also have a part in the development of some skin cancers.

Most of the tanning beds on the markets give off large amounts of UVA, which is one reason why these beds pose a skin cancer risk. UVB rays are the rays mainly responsible for sunburns, and produce direct damage to skin cell DNA. UVB rays are often implicated as a causal agent in most forms of skin cancer. UVC rays are absorbed by the Earth's ozone layer, and are not based in sunlight. As such, these rays do not normally play a large part in the process of skin cancer development. Most of the UV rays that come in contact with humans are UVA, with a smaller amount of UVB. While both UVA and UVB rays damage skin and cause skin cancer, UVB rays are thought to be the stronger and more dangerous of the two types of rays, and are more heavily involved in causing at least some skin cancers. Fortunately, some UVB rays are also absorbed by the Earth's ozone layer. Other UVB rays, however, are not absorbed, and are able to pass through and affect humans. Overall, there are no safe UV rays. They are all harmful. The extent of harmful UV exposure normally depends on the strength of the rays, how much time the exposure to the skin occurs, and what type of protection is on the skin, including clothing or sunscreen.
Ultraviolet Radiation

All radiation is a form of energy, most of which is invisible to the human eye. UV radiation is only one form of radiation, and it is measured on a scientific scale called the electromagnetic spectrum (EM). UV radiation is only one type of EM energy. Radio waves that transmit sound from a radio station’s tower or between cell phones; visible light that is emitted from the lights in a home; and X-rays like those used in hospital X-ray machines are all forms of EM energy. Like all forms of light on the EM spectrum, UV radiation is classified by wavelength. Wavelength describes the distance between the peaks in a series of waves. UVA rays have the longer wavelengths, and UVC rays have the shortest wavelengths. UVB rays fall in between the two. The longer wavelength of the UVA rays is able to penetrate the middle layer, or dermis, of human skin.

Differences in size of wavelength can produce differences in what occurs with them. For example, the wavelengths at the bottom of the spectrum have radio waves with photons containing low energies. This causes wavelengths with long peaks that are farther apart. The photons of microwaves have higher energies, followed by infrared waves, UV rays, and X-rays. At the top of the spectrum, gamma rays have photons with very high energies and short wavelengths, with peaks that are close together. The shorter gamma ray wavelengths present the greater danger with exposure to humans. Both UVA and UVB, however, are able to penetrate the atmosphere, and play an important role in conditions such as premature skin aging, eye damage (including cataracts), and skin cancers. They also suppress the immune system, reducing an individual’s ability to fight off these and other maladies.

Effects of UV Rays

Sun is often thought of as the main causal agent in skin cancers, and is classified as a human carcinogen. If an individual receives too much sun, they increase their risk of skin cancer. Yet, there are other effects of UV exposure. Sunburn and tanning are the most evident short-term results of too much exposure to UV rays, and are the most obvious signs that the skin has been affected by this exposure. Longer exposure can cause more severe skin aging before its time, wrinkles, dry scaly skin, and age spots. Long-term exposure can also present precancerous skin changes, including dry scaly rough patches called actinic keratosis.

The sun’s UV rays can also increase a person’s risk of cataracts and other eye problems. These rays are responsible for problems with the function of the skin’s immune system. People with lighter skin are at higher risk for developing skin cancer than people with darker skin, but people with darker skin are still at risk for developing cataracts and a suppressed immune system. UV rays from the sun are not the only harmful source. UV radiation is also transmitted from tanning beds, classifying them as a human carcinogen. Other sources of UV radiation include mercury vapor lighting; halogen, fluorescent, and incandescent lighting; and some types of lasers. Additionally, some medicines can increase susceptibility to the UV rays and their harmful effects, including certain prescription and over-the-counter oral and topical medicines, and some types of cosmetics. These products can increase sensitivity for all skin types.

UV Index

The amount of UV light reaching the ground in any given place depends on a number of factors,
Ultraviolet Radiation Related Exposures

including the time of day, time of year, elevation, and cloud cover. The UV Index was designed by the National Weather Service and the Environmental Protection Agency (EPA) to provide an indicator of the strength of UV rays on any given day in any given area. The scale runs from 1 to 11-plus, with a higher number indicated greater risk of UV ray exposure. The greater risk of exposure also increases the chance sunburn and skin damage that could potentially lead to skin cancer. Local changes in cloud cover and other factors may change the actual UV levels experienced.

Exposure
Exposure to UV rays is linked to a number of harmful health conditions, including skin cancer. More than 1 million cases of nonmelanoma skin cancer are diagnosed in the United States each year. Most incidences of skin cancer appear in middle age or later, after the age of 50. Although it appears later, skin damage from the sun begins much earlier in life. Protection from overexposure to the sun's harmful rays should begin in childhood in order to prevent skin cancer later in life. This is difficult because children and adolescents do not see the consequences and might not heed warnings as a result.

Exposure to UV radiation can also cause photoaging, or premature aging of the skin. This is different from the chronological aging that is celebrated every year on someone's birthday. Sunbathers show photoaging earlier in life, often before they are 30 years old. Symptoms of the photoaging process include freckling, fine wrinkling, and dilation of capillaries. The photoaged skin frequently develops irregular pigmentation called liver spots in later years. Both photoaging and chronological aging cause wrinkling and loss of skin elasticity. However, these changes occur much earlier when skin has been overexposed to the sun.

Cataracts are classified as an eye disorder, and are characterized by a change in the structure of the crystalline lens that causes blurred vision. Cataracts are a leading cause of blindness around the world. One of the main risk factors associated with developing cataracts is excessive UV radiation exposure. Research indicates that individuals who spend more time in the sun may develop cataracts earlier than others. In an effort to decrease this risk, the American Academy of Ophthalmology now recommends wearing UV sunglasses and a wide brimmed hat to lessen exposure to ultraviolet rays. Additionally, corneal sunburn, growths on the outer surface of the eye, retinal-tissue damage, and other eye diseases are also known or are suspected to be related to long-term exposure to UV rays.

The skin is part of the body's natural defense system. Some research indicates that the UV radiation absorbed through the skin can negatively alter immune system functions, especially through invasion of skin cells. When UV radiation impedes the immune response of the system, it hampers an individual's ability to fight certain diseases, including skin cancer. Some health professionals have proposed that the overexposure of UV radiation also has the ability to interfere with the desired results of immunizations given through the skin. UV radiation has been a topic of concern for both the U.S. Departments of Health and Human Services as a proven human carcinogen. UV radiation is considered the main cause of nonmelanoma skin cancers (NMSC), including basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). UV radiation has also been linked to melanoma, the most virulent and deadly form of skin cancer, by many professionals. They point to increased risk for people who have fairer skin tones.

Sunscreen Ingredients
Since both UVA and UVB are harmful, individuals need protection from both kinds of rays. Sun protection products are beginning to offer additional UVC radiation protection. Modern-day sunscreens are measured by sun protection factor (SPF) levels, which provide an individual with information on its effectiveness in protecting from harmful sun rays. SPF is not the amount of protection a product provides. The SPF number indicates how long it will take for UVB rays to redden skin when using a sunscreen, compared to how long skin would take to redden without the product. Someone using an SPF of 45 will be protected from reddening in the sun 45 times longer than if they did not use protection. An SPF 15 sunscreen screens 93 percent of the sun's UVB rays; SPF 30 protects against 97 percent; and SPF 50, 98 percent. The Skin Cancer Foundation maintains that SPFs of 15 or higher are necessary for adequate protection.

The photochemical effects of UV radiation can be exacerbated by chemical agents. Protection from UV is provided by clothing, polycarbonate,
glasses, acrylics, and plastic diffusers used in office lighting. Sun-blocking lotions offer limited protection against UV exposure. Accidental overexposure might not be detected because the UV radiation is invisible, and does not produce an immediate reaction. Yet, this radiation can injure individuals.

Further Readings

Union for International Cancer Control

The Union for International Cancer Control (UICC), formerly named the International Union Against Cancer (IUAC), is the largest cancer-fighting organization in the world. It focuses on helping the global health community in its battle against cancer. The member organization includes approximately 815 organizations from 155 countries, from cancer societies and research institutes to government and international health organizations, patient groups, and corporate partners.

IUAC was established in 1933 when cancer researchers founded the organization to enhance the global sharing of knowledge and expertise. IUAC changed its name to UICC in 2014. Based in Geneva, Switzerland, UICC fosters the fight against cancer on a global scale. Its member organizations govern the organization, which has an executive body made up of 17 board of directors members. UICC’s longstanding partners include the National Cancer Institute, Centers for Disease Control and Prevention, World Cancer Research Fund Society, American Cancer Society, Swiss Cancer League, Norwegian Cancer Society, and World Health Organization (WHO).

UICC primarily focus on three interlinked pursuits: advocacy, convening member meetings, and running building projects. The organization has stated that its specific purpose is to bring together the international cancer community to reduce the burden of cancer on an international scale. Other goals include promoting greater equity in cancer research and care and fostering the inclusion of cancer control issues in the agendas of world health and development organizations.

UICC is the administrator of the International Cancer Fellowship program, and its official publication is the International Journal of Cancer. In terms of advocacy efforts, UICC oversees various advocacy efforts and education initiatives designed to have the greatest impact on reducing the cancer burden. Its advocacy efforts include providing support to increase resources to fight cancer with a special focus on developing countries, which are most at risk of cancer overwhelming their health systems and hindering economic growth.

Advocacy campaigns include efforts such as improving access to cancer medicines via the WHO Model List of Essential Medicines, increasing the availability of radiotherapy for cancer control in low- and middle-income countries, and setting cancer prevention and control priorities for global health and development projects. These advocacy efforts typically include communication programs to disseminate important information about cancer; sharing data on cancer prevention and control concerning specific countries, and developing UICC authored or coauthored position papers, factsheets, and other written contributions.

UICC helps coordinate global cancer programs, such as the Global Education and Training Initiative, to help meet the growing global shortage in the health care workforce. The organization’s Global Access to Pain Relief Initiative is a joint program with the American Cancer Society to ensure
the universal availability of essential cancer pain medicines by 2020. The Cervical Cancer Initiative focuses on reducing the development of cervical cancer in women, as well as death from the disease.

UICC’s Childhood Cancer (ChiCa) program is dedicated to increasing the number of children who survive cancer in low- and middle-income countries by providing guidance on developing prompt, essential treatment initiatives in these countries, with an emphasis on accessibility and affordability. The Global Initiative for Cancer Registry Development program is a multi-organizational effort led by UICC and the International Agency for Research on Cancer. The program focuses on increasing cancer registry efforts in countries to help effectively use available resources in areas such as cancer prevention, treatment, rehabilitation, and palliative care, as well as to set research agendas.

UICC also holds a general assembly every two years in collaboration with the World Cancer Congress. The assembly serves to bring together UICC members from around the world to foster discourse, advocacy, and cancer education. UICC and member organizations typically supply printed information, including news releases on topics discussed. For example, the 2012 meeting included releases concerning how lifestyle changes could prevent 50 percent of common cancer, including issues surrounding smoking and obesity, as well as how to protect against the main viruses associated with cancer.

UICC is also a cosponsor of World Cancer Day, which in 2014 focused on reducing the stigmas associated with cancer and dispelling myths about the disease. The four myths addressed were (1) people do not need to talk about cancer, (2) signs or symptoms for cancer do not exist, (3) nothing can be done about cancer, and (4) the belief held by some people, primarily in developing countries, that they do not have the right to cancer care.

Another convening program supported by UICC is the World’s Cancer Leaders’ Summit. Designed to bring key decision makers together, the summit is a high-level policy meeting that fosters debate on emerging cancer issues designed. A goal is to ensure that various cancer organizations around the world mount positive responses to support government initiatives. These meetings also feature time allotted for both organizations and individuals to make public commitments on various cancer control programs and projects.

The UICC Global Roundtable Series features roundtables focusing on key cancer issues in cities around the world. The roundtables typically bring together civil organizations, governments, and representatives from the private sector. The series fosters discussion of pressing issues such as the cancer information dilemma, understanding and curing prostate cancer, and the development of personalized cancer medicine.

In 2013, UICC joined forces with IBM to develop the largest and most comprehensive clinical dataset on cancer patients in the world. The effort focuses primarily on building cancer registries in developing countries. The initiative began in sub-Saharan Africa, where an 85 percent–plus increase in the area’s cancer burden is expected to take place by 2030. The effort is anticipated to extend to Southeast Asia and Latin America. The plan is to improve cancer registry data to show population-based trends that can help countries shape and adapt their cancer strategies.

United Arab Emirates

The country of the United Arab Emirates (UAE) lies on the southeast end of the Arabian Peninsula on the Persian Gulf. The country formed in December 1971,
with the combination of seven principalities or emirates. A hereditary emir governs each emirate, and the seven emirs comprise the Federal Supreme Council, which is the highest executive body in the UAE. The emirs select a president from their group. The conduct of national business occurs in Abu Dhabi, the capital city of UAE. Islam is the official religion, and Arabic is the official language. Since 1971, incredible financial and industrial progress with the exportation of oil occurred in the UAE, causing a change from the old-style seminomadic existence to a contemporary urbanized and technology-propelled lifestyle. Cancer is the second-largest cause of death globally, but it is the third-largest cause of death in the Emirates. In the beginning of the 1900s, the UAE demonstrated a very low incidence of cancer compared to developed countries, but since the 1970s, the country has gone through upheaval in the economic, social, and demographic platforms, leading to increased prosperity. These alterations resulted in significant increases in all chronic noncommunicable disease, including cancer. Deaths from cancer climbed to 10 percent of all deaths in 2010.

No national or regional population-based cancer registry currently exists in the UAE. With no cancer registry, the UAE produces no comprehensive information on the incidence of cancer. Despite this limitation, the Minister of Health gathered some data for the UAE to enter in the Globocan database and Gulf Cooperation Council-wide cancer registry report. The number of cancer deaths in the UAE for both sexes is 54.9 per 100,000 person years; whereas in the United States, the number of cancer death for both sexes remains at 104.1 per 100,000 person years. Despite the lower rates at this time, the rate of all cancers is anticipated to double by 2020. Researchers expect that aging and an elevated exposure to risk factors in a more Westernized society will trigger the increase in cancer rates.

Breast cancer is the most regularly occurring cancer in females in the UAE, and is the most prevalent cancer in both genders; whereas lung cancer remains the most commonplace cancer among males, but scarcely occurs in females (mirrored by the smoking rate: males 23 percent, and females 0.5 percent). Not only is breast cancer the most frequent cancer in females, the malignancy appears a decade earlier in UAE women than females in Western countries, with the majority of patients premenopausal. Because of social traditions, many females in the UAE fail to attend regular medical examinations until symptoms from advanced stages of the disease appear. The tumors appear with more aggressive histology and biology. The majority of tumors demonstrate vascular and lymphatic invasion. Gene (P53 and Her-2 neu) over-expression remains relatively high in breast cancer cases in the UAE. Elobaid and colleagues conducted a cross-sectional survey of women (≥ 40 years) in one city in the UAE. The study found that many women lacked information about breast cancer screening, with 44.8 percent never receiving a clinical breast exam, and 44.1 percent never undergoing a mammography. Contact with a health care practitioner represented the most important pathway for alerting women to the value of periodic breast screening.

Colorectal cancer is the second most frequent cancer in both genders, followed by leukemia and non-Hodgkin lymphoma. Pediatric cancers account for approximately 9.5 percent of all cancer events, with an average of 9.2 cases per 100,000 children in the UAE. Lymphoma occurs as the most frequent childhood malignancy, and accounts for nearly 60 percent of all childhood cancers. Prostate cancer is the second-most-common cancer among national males in the UAE.

The UAE hosted the 5th Pan Arab Human Genetics Conference jointly with the 2013 Golden Helix Symposium. The meeting revolved around nine sessions, consisting of cancer genomics and epigenetics, genomic and epigenetic studies, genomics of blood and metabolic disorders, cytogenetic diagnosis and molecular profiling, next-generation sequencing, consanguinity and hereditary diseases, clinical genomics, clinical applications of pharmacogenomics, and genomics in public health. Scientists discovered that cancer in the Arab world shows an increased homozygosity from consanguinity. Elevated homozygosity from consanguinity links to a high risk of cancer. One study reported on breast cancer in women accounting for 42 percent of all tumors. The study showed that triple-negative breast cancer (e.g., any breast cancer failing to express genes for estrogen receptor, progesterone receptor, and Her2/neu) remains more common in this area.

The UAE attended the Afro Middle East Asian Symposium in 2014 to present its current oncology situation and needs. The Middle East countries or Gulf countries represent only 1.2 percent of the
United Kingdom

The northwestern European nation currently termed the United Kingdom of Great Britain and Northern Ireland became a modern state in 1707, when the Treaty of Union was ratified by the various kingdoms of England, such as Scotland and Wales. Consequently, this treaty made the United Kingdom a single sovereign state. Nearly a century later, the United Kingdom ratified an Act of Union in 1800 that further added the Kingdom of Ireland to the United Kingdom.

In many western European countries in the 18th and 19th centuries, cancer was perceived to be a predominately female disease due to the high prevalence of breast and uterine cancers, and during this time period this belief was particularly dominant in the United Kingdom. At the time, many English social commentators believed that men could only contract cancer by emasculating themselves through eating excessive amounts of food and not exercising often enough. Even experts of the era, like Walter Hayle Walshe who was the author of a leading textbook on cancer in 1846, maintained that women were as much as three times more likely to experience an incidence of cancer than males were.

When incidences of cancer in males rose during this period, gender as a causing factor of the disease became refutable, and other avenues of causation were explored; some of the other sources that had begun to be explored as cancer-causing agents included physical trauma, sexual intercourse, masturbation, occupation, residence, unpleasant emotional states, and nutrition. In the early 19th century, doctors were extremely hesitant to perform surgery on cancerous tumors because it was believed that this would not treat the underlying constitutional cause of the cancer. Also, surgical techniques were still relatively crude at this time, and operations on tumors were considered more risky than beneficial. Patients deemed terminally ill were copiously prescribed opiates and were advised to shun any form of physical exertion.

Toward the end of the 19th century, physicians began to move away from the notion of gender, morality, or one's constitution as the causes of cancer; instead, as surgeons became more technically skilled and knowledgeable, cancer began to be understood as a disease that was localized in specific organs and tissues and that was caused by the degeneration of cells, and thus surgery became the most viable and dominant treatment option during the 1860s and onwards. Surgeons such as William De Morgan and Charles Moore became vocal leaders in the shift towards this modern understanding of the disease.

When the United Kingdom entered the 20th century, this new understanding of cancer helped lead its...
citizens to a strong social awareness of the dire need to combat the disease effectively. Over the past 100 years, numerous domestic research institutions have been created to contribute to the global effort to find a reliable cure. The United Kingdom Association of Cancer Registries was initiated in 1992 to provide a single and reliable source for important cancer information within the country. As a part of the global World Cancer Research Fund, the World Cancer Research Fund UK was begun in 1990 as a charity entirely focused on the domestic prevention of cancer. In 2013, Cancer Research UK discerned 80 novel genetic variations that increase the risk of certain cancers.

Currently, the most prevalent forms of cancer in the United Kingdom are bowel cancer, breast cancer, lung cancer, and prostate cancer. Bowel, lung, and prostate cancers make up over half of all cancer incidences in males in the United Kingdom, while bowel, breast, and lung cancers account for over half of all cancer incidences in females there. Within the past 10 years, certain cancers such as malignant melanoma, thyroid cancer, uterine cancer, liver cancer, and kidney cancer have seen a nationwide increase in prevalence, while incidences of bladder cancer have steadily but consistently dropped. Certain parts of the United Kingdom experience more cases of specific cancers than other parts of the country, such as the high incidence of lung cancer in Scotland due to higher levels of smoking there than the rest of the nation.

Unfortunately, many citizens of the United Kingdom have had cancer. The world-renowned musician and songwriter George Harrison (1943–2001) of the Beatles died from lung cancer that had spread to his brain; the popular broadcaster and journalist Alistair Cooke (1908–2004) also died from lung cancer that had spread to his bones. Moreover, the critically acclaimed British actor Sir Alec Guinness (1914–2000) passed away due to liver cancer. There are currently many gifted cancer specialists operating in the United Kingdom at world-class facilities. For instance, Dr. Nick Plowman is the Senior Clinical Oncologist at St. Bartholomew’s Hospital and the Hospital for Sick Children at Great Ormond Street; he is extremely well renowned in the field of cancer treatment for his seminal expertise in radiation therapies. Another renowned specialist is Dr. Nihal Shah, who is the Consultant Clinical Oncologist at the Mount Vernon Cancer Centre in London. He is a foremost expert in the treatment of breast, head, lung, and neck cancers, and Dr. Nihal also specializes in treating patients with unknown primary cancers.

Further Readings
United States

The United States is a former British colony that declared its independence from Great Britain in 1776 and was recognized as the new nation of the United States of America following the Treaty of Paris in 1783. During the late 18th, 19th, and 20th centuries, 37 new states were added to the original 13 colonies as the nation expanded across the North American continent and acquired a number of overseas possessions.

Two of the most traumatic experiences in the nation’s history were the Civil War (1861–1865), in which a northern Union of states defeated a secessionist Confederacy of 11 southern slave states, and the Great Depression of the 1930s, an economic downturn during which about a quarter of the labor force lost its jobs. Even with the challenge presented by the recession that started in 2008, the United States remains the world’s most powerful nation state. The economy has achieved relatively steady growth, low unemployment and inflation, and rapid advances in technology in global comparisons.

As one of the most developed countries in the world, the United States faces a tremendous cancer burden. The United States is one of the most populous nations with a 2013 population of over 318.9 million, and in 2013, there was an estimated 1,665,540 new cancer cases diagnosed and 585,720 cancer deaths in the United States. Cancer remains the second most common cause of death in the United States (after heart disease), accounting for nearly one of every four deaths. For every 100,000 people there are 250 physicians and 980 nurses, for all areas of specialization.

As a world leader in health care, the United States has many organizations on the forefront to fight cancer. The American Society of Clinical Oncology (ASCO) is one such organization. In their landmark report on the state of cancer care in America, they recognized that the demand for cancer prevention, screening, and treatment services is growing rapidly. The ASCO reports that by 2030, the number of new cancer cases in the United States will increase by 45 percent, and cancer will become the nation’s leading cause of death, largely as a result of the aging of the nation’s population. At the same time, the number of cancer survivors, which totaled 13.7 million in 2012, will continue to grow. Many of these individuals will require significant, ongoing care. After reviewing the current need for cancer care in America, the ASCO report examined and identified many future challenges to the U.S. cancer care system, and specifically addressed the need to increase the number of oncology workers and the racial and ethnic diversity of those workers.

Another issue identified, a problem similar to what other developing nations face, is access to quality health care for the poor or otherwise disenfranchised. In the United States, access to quality cancer care remains uneven, which is often reflected in various health disparities. Millions of people with cancer lack access to quality medical care, and rates of access to care are disproportionately lower for African Americans and Latinos. About 30 percent of Americans reported foregoing medical care due to cost in 2013, and those without a regular source of care are less likely to receive cancer screening. The Patient Protection and Affordable Care Act (ACA) is expected to provide millions more Americans with health insurance coverage in the coming years. However, the ACA alone may not solve disparities in cancer care as it places significant emphasis on expanding Medicaid coverage, which has been associated with poor outcomes for patients with cancer. The ACA is not a universal coverage plan, and in the first quarter of 2015, one year after implementation of the ACA, 11.9 percent of adult Americans (age 18 and older) were uninsured. Soaring costs have created an urgent need to improve the value of patient care. While costs are rising throughout the health care system, the trend is especially pronounced in cancer care as annual costs have risen from $104 billion in 2006 and are expected to reach more than $173 billion in 2020. This increase is a result of many factors, including the cost of many new cancer therapies. Access to high-quality cancer care will be sustained and expanded only if we address these rising costs, including the use of unnecessary or ineffective tests and treatments.

Cancer Scientists

Historically, many prominent cancer scientists have come from the United States or have received their training and education in the United States. John Collins Warren (1778–1856), one of the most renowned surgeons of the 19th century, wrote *Surgical Observations on Tumors, With Cases and Operations* (1837). Others were Nobel Prize winners for cancer research: Peyton Rous (1879–1970)
was awarded the Nobel Prize for Physiology or Medicine in 1966 for his work with sarcomas and how they could be transmitted; Ernest Orlando Lawrence (1901–1958) won the 1939 prize for Physics for his invention of the cyclotron, the first particle accelerator to achieve high energies, and was later involved in the use of neutron beams in treating cancer; and Salvador Luria (1912–1991), who won the Nobel Prize for Physiology or Medicine in 1969 for his work concerning the genetic structure of viruses, was later appointed director of the Center for Cancer Research at MIT.

In 2006, five Johns Hopkins Cancer Researchers, Bert Vogelstein, M.D., Kenneth Kinzler, Ph.D., James Herman, M.D., Stephen Baylin, M.D., and David Sidransky, M.D., were named doctors of the decade as their research has influenced modern scientific thought in oncology based on the number of citations their work has received. Vogelstein and Kinzler, both leading experts in molecular genetics, had over 50,000 citations. In 2014, Owen Witte, M.D., a prominent stem cell researcher, established a targeted therapy for chronic myeloid leukemia.

Cancer research is advancing in several areas, beginning with more targeted therapies. And as more is learned about the molecular biology of cancer, researchers will have more targets for their new drugs. Some of these areas include immunotherapy, in which drugs aimed at specific immune checkpoints are being developed to help the immune system better kill cancer cells; cancer genetics, in which scientists identify gene mutations that cause some patients to respond better to certain drugs; nanotechnology, which is a new technology for producing materials that form extremely tiny particles used in imaging to locate tumors; robotic surgery, which is used to remove tumors with less surgical trauma; expression profiling and proteomics, in which expression profiling identifies what proteins are present in cells, their behavior, and their aggression levels, which can help scientists predict the drugs a tumor will respond to; and proteomic methods, which is measuring the amount and type of protein in the blood that can be used for cancer screening.

Research and Advocacy Organizations
The United States is not only the leader in cancer research and treatment, the nation leads the world in patient-centered self-help and political advocacy groups. One grassroots political advocacy organization is the National Breast Cancer Coalition (NBCC), a nonprofit organization founded in 1991 with the goal of ending breast cancer, not just treating it. In 2010, the NBCC set a deadline of knowing how to end breast cancer by 2020, and it launched a plan to achieve this. Breast Cancer Deadline 2020 is their call to action for all stakeholders to focus efforts on knowing how to end the disease by the end of the decade. The Accelerating the End of Breast Cancer Act, S. 865 and H.R. 1830, defines an important role the federal government must play in this effort. The legislation complements and enhances the strategic work being done by NBCC to end breast cancer. Earlier grassroots advocacy work resulted in the Department of Defense Breast Cancer Research Program (DOD BCRP), which was created in 1992 to “eradicate breast cancer by funding innovative, high-impact
research through a partnership of scientists and consumers.” The DOD BCRP is widely viewed as an innovative, unique, and efficient medical research model, which has proven to be accountable to the public and has produced extraordinary results. NBCC seeks continued funding for this successful program.

Other important organizations include the American Association for Cancer Research, the American Cancer Society, the American College of Radiology, the American College of Surgeons, the American Society for Therapeutic Radiology and Oncology, the American Society of Clinical Oncology, the Arthur G. James Cancer Hospital Research Institute, the Black Women's Health Imperative, Campaign for Tobacco-Free Kids, the Cancer Treatment Centers of America, the Candlelighters Childhood Cancer Family Alliance, the C-Change: Collaborating to Conquer Cancer, the Centers for Disease Control and Prevention, the College of American Pathologists, the Fred Hutchinson Cancer Research Center, FORCE: Facing Our Risk of Cancer Empowered, the Gerald P. Murphy Cancer Center, the Kellogg Cancer Care Center, the LIVESTRONG Foundation, the Massey Cancer Center, the MD Anderson Cancer Center, the National Cancer Institute, the Oncology Nursing Society, the Smilow Cancer Center at Yale Hospital, the St. Jude Children’s Research Hospital, and the Susan G. Komen Breast Cancer Foundation. There are many others.

University of Alabama at Birmingham Comprehensive Cancer Center

The University of Alabama at Birmingham Comprehensive Cancer Center (UAB CCC) is one of the nation's leading cancer research and treatment centers. Established in 1971, it was the first National Cancer Institute (NCI)--designated center in the region. It is the only NCI-endorsed full-service cancer center in Louisiana, Mississippi, Alabama, Georgia, South Carolina, and Arkansas. The center treats approximately 5,000 new cancer patients annually. It has more than 330 scientists on its staff, comprised of researchers and physicians. In addition to treatment for cancer, the center also conducts research. The mission of the UAB CCC is to provide the highest quality of life for people diagnosed with cancer while advancing the world's understanding of cancer, and translating this knowledge into prevention, detection, treatment, and survivorship. The vision is to eliminate cancer as a major public health problem.

To achieve the mission and vision, the center has comprehensive research activities in the areas of immunotherapy, drug discovery and development, and gene therapy. Scientists in the center have been sourced from various professions to ensure that every aspect of cancer is involved in the treatment and research. These include the areas of immunotherapy, surgery, radiotherapy, chemotherapy, and nutrition. In each of these areas, the scientists have made considerable advances. Currently, scientists in the center are devising new antibiotic treatments for cancers of all sorts.

One of the strengths of the center is in the area of translational research. This strength is coupled with active programs of research and patient care in the
areas of ovarian, breast, pancreatic, and brain cancers. Patient care in UAB CCC is delivered in multidisciplinary clinics that also foster accrual to clinical trials with novel treatments. These novel treatment techniques use genetically engineered monoclonal antibodies, alone or in combination with radioactive isotopes, chemotherapy, or immunotoxins to specifically target a broad array of cancers. The team of researchers in the center is also developing a series of cancer vaccine trials using genetically engineered vaccine reagents. The UAB CCC has developed a number of therapeutic vaccine strategies. To develop an overall vaccine strategy, researchers at UAB CCC are exploring a broad array of approaches to induce an immune response to molecules prevalent in tumor cells.

To promote cancer awareness, one of the core elements in the mission of the center, the Deep South Network for Cancer Control, was formed. The Deep South Network for Cancer Control is a program of UAB that seeks to enhance outreach and collaboration, with the objectives of training, gathering cancer related data, and providing education to the 22 counties in Alabama and the Mississippi Delta. Toward this end, the UAB CCC has held hundreds of community events on the importance of cancer prevention, awareness, and cancer screening. To ensure that professional cancer information is available through the outreach program, the center uses trained volunteers as community health advisors to educate community members.

The ultimate goal of the Deep South Network is to build a community-based infrastructure that will aid in eliminating cancer health disparities in underserved African American communities. To fast track this initiative, the center has formed collaboration with local communities that has resulted in network collaborations with more than 300 community partners, including small businesses, industries, schools, faith-based groups, and other organizations to implement cancer prevention and wellness programs. Other organizations, including nonprofit organizations, state agencies, and media partners, have come onboard to help the Deep South Network in disseminating information to local communities.

The UAB CCC strives for excellence in its dual roles as a regional cancer referral center and a cutting-edge research entity. This is realized through having the information established in the research work translated to treatment and patient care. However, the first step toward realizing this is clinical trials. UAB CCC members actively participate in efforts to improve cancer therapy, diagnosis, and prevention through original research protocols and the NCI’s high-priority trials and multicenter research collaborations, including national cooperative group studies. This multifaceted approach towards research and clinical trials maintains the center’s connections with the national cancer research community while fostering the development of translational research linked to the UAB’s scientific resources.

Treatment of cancer patients at the UAB CCC is done through the practice of comprehensive cancer treatment. This practice requires that patients be treated not just by one doctor, but by a team of highly specialized professionals who work together to determine the best course of action for each patient. Through this practice, cancer patients seeking treatment at the UAB CCC can expect a visit by up to three specialists on the first day.

One of the outstanding treatments at the UAB CCC is mesothelioma cancer treatment. The diagnosis for this diseases is one of the most challenging because of its symptoms that include chest pain, cough, and fatigue—symptoms that are similar to other diseases. To provide treatment, it requires appropriate diagnosis, and the comprehensive cancer treatment practiced at the UAB CCC serves to increase the probability of a correct diagnosis. At the UAB CCC, patients suffering from the disease are treated at the Lung Health Center, which focuses on diagnosis, treatment, research, and innovations related to lung diseases. Treatment of mesothelioma at the UAB CCC consists of a combination of surgery, chemotherapy, and radiation. If a patient decides to take part in the clinical trial for novel treatment techniques, then they are treated using new treatments not yet available to the public.

In addition to mesothelioma treatment, the Cancer Vaccine Development program of the UAB CCC has been charged by the NCI with development of a series of vaccine trials using properly and professionally engineered vaccine reagents. So far, the center has successfully developed four therapeutic vaccine strategies: a vaccine that can control the development of tumors in those who have metastatic breast cancer that has been known to respond well to hormonal treatments and adjustments, a genetically engineered vaccine virus (smallpox) to eradicate colon cancer, a naked deoxyribonucleic acid (DNA) gene therapy vaccine for colon cancer,
and studies to test immunization to the carcinoembryonic antigen (CEA) for several different cancer sites, including the colon and breast.

Further Readings

University of California, Davis, Comprehensive Cancer Center

The UC Davis Cancer Center is designated as a National Cancer Institute (NCI) Comprehensive Care Center. The specialized team of doctors works to develop treatment plans for each cancer patient. The center is recognized nationally as a leader in research, treatment, and education. It is one of the largest and most comprehensive available on the West Coast.

The pediatric oncology section at the center is a member of the Children's Oncology Group (COG), a federally funded cooperative for the treatment of pediatric cancers. The center offers more than 40 pediatric cancer clinical trials at any given time and is one of only two Sacramento COG programs. The center provides diagnosis and management of all types of pediatric cancers and blood disorders. Specialists in neuro-oncology, radiation oncology, otolaryngology, ophthalmology, and urology are also available. Resources for patients and their families may include social support services, temporary housing, and case management.

Plastic surgery is also a key program available at the center. Plastic surgeons have been dedicated to patient care since 1975. They are trained as clinicians and educators and bring the highest standards of professional care. Services in plastic surgery include: facial aesthetic surgery; aesthetic surgery of the trunk and extremities; reconstructive surgery of the breast, trunk, and extremities; hand surgery; and skin care.

The Department of Radiation Oncology is nationally recognized for pioneering state-of-the-art technology and treatment methods for cancer patients. The ultimate goal of the department is the relief of symptoms and the eradication of cancer. The department includes research programs that advance technology through clinical trials and laboratory research. The department focuses on treating cancer patients using state-of-the-art technology and clinical trials...
on research in cancer stem cells, DNA repair, low-dose radiation, and new imaging technologies. The department also has residency programs in radiation oncology and medical physics. They are committed to expert patient-centered care, research, and quality teaching.

The UC Davis Stem Cell Transplant Program performed its first bone marrow transplant in 1993. The program currently serves adults and children and is the region’s only National Marrow Donor Transplant Program giving patients access to potential donors worldwide.

The Surgical Oncology Program provides highly skilled, board-certified, nationally recognized surgeons. The program assures that each patient’s surgical care is planned by a team of cancer specialists (i.e., radiation oncologists, medical oncologists, surgical oncologists, plastic surgeons, etc.); is comprehensive from diagnosis through treatment; is based on the most current knowledge of cancer disease and surgical applications; is appropriate after fully considering the risks and benefits; and is continued with regular follow-up. UC Davis Medical Center also offers robotic-assisted surgery in several specialties (i.e., gastrointestinal surgery, cardiothoracic surgery, gynecologic oncology, otolaryngology, and urology). The da Vinci robotic surgical system represents the latest in minimally invasive surgery while offering a broader visualization of the operative field and precision control of surgical instruments not available in traditional laparoscopic surgery. Benefits associated with the da Vinci system can include significantly less pain, less blood loss, less risk of infection, less scarring, shorter hospital stays, and shorter recovery times.

UC Davis Cancer Center offers research programs with researchers who are experts in a variety of fields and are interested in a related group of cancers. The Molecular Oncology Program seeks to unravel cancer’s molecular secrets to better diagnose and treat cancers. Seventy percent of cancer patients whose cancer involves treatment-resistant malignant cells can benefit from molecular oncology research.

In all cancers combined, the death rate is 25 percent higher for African Americans than for whites. White women have the highest rate for breast cancer, but African American women are more likely to die from breast cancer. Hispanic women have the highest cervical cancer rate. African American men have the highest rate for prostate cancer in the United States and are more than twice as likely as white men to die from this disease. Pacific Islanders and Asian Americans have the highest rate for liver and stomach cancer and are twice as likely to die from these diseases as whites. Alaska Natives and American Indians have higher rates and deaths for kidney cancer than any other racial or ethnic group.

UC Davis Cancer Center cites these disparities as the primary reason for the creation of the Cancer Disparities Research Program, which is dedicated to understanding why cancer affects people differently and how to eliminate disparities among ethnic and racial groups. The NCI defines cancer health disparities as adverse differences in the incidence, prevalence, mortality, and survivorship of cancer. These differences do not necessarily fall in racial or ethnic lines but can include: age, disability, education, gender, income, and geographic location.

The Comparative Oncology Program has an interest in comparative medicine approaches. Comparative oncology can include research in canine cancer, as it does at UC Davis. The effort to understand comparative oncology is critical as there is increasing difficulty in new successful drug treatment for cancer, and only five percent of new drugs investigated ever end up receiving approval from the Food and Drug Administration.

The Prostate Cancer Research Program at UC Davis is ranked third in the nation with regard to research grants. The program also ranks among the top three institutions receiving NIH funding over the previous three years.

The Cancer Therapeutics Research Program focuses on innovative methods for identifying new systems to treat cancer. As an example, the first chemotherapy agent was derived from mustard gas when somebody noticed those exposed to it were low on white blood cells. Researchers used this finding to treat lymphoma, a cancer of the white blood cells. The aim of the Cancer Therapeutics Research Program is to discover new drugs, take them through the necessary trials, and then get them into the clinic.

The Biomedical Technology Research Program researches innovative engineering technologies to solve cancer problems. For example, when a surgeon removes a tumor, a biopsy of healthy
tissue is removed from the edge of the tumor to be reviewed under a microscope to ensure that the entire tumor has been removed. If pathology is found, the surgeon removes more tissue, and the process is repeated until no further malignancy is evident. UC Davis researchers have been engaged in the development of a light tool that would assist the surgeon so that healthy tissue can be distinguished from malignant tissue during surgery, without the need for repeated checking with a microscope.

Further Readings

University of California, Los Angeles, Jonsson Comprehensive Cancer Center

The Jonsson Comprehensive Cancer Center (JCCC) began in 1974 as a cancer center started by scientists at the University of California, Los Angeles (UCLA). In 1976, the National Cancer Institute (NCI) designated it as a comprehensive cancer center. The UCLA Medical Center, in particular, has been ranked by U.S. News and World Report as the best medical center in the western United States and one of the best three hospitals in the country. As of 2013, it was ranked 11th nationally among cancer centers. JCCC received the comprehensive designation because it offers a wide range of services in terms of treatment, research, and support of patients in treatment and their families. Issues with regard to survivorship and prevention are also under the JCCC umbrella of services.

JCCC works closely with the UCLA School of Medicine. As such, JCCC lists more than 100 UCLA physicians who are considered to be among the best doctors in America. Interdisciplinary treatment of patients at JCCC also provides patients with care from more than 350 physicians and scientists from areas that include immunology, genetics, geriatrics, nursing, and dentistry. Services provided to patients include early detection, treatment, psychological care, guidance with nutrition and general wellness, as well as survivorship.

JCCC is located in California and has clinics in Westwood, Santa Monica, Alhambra, Irvine, Pasadena, Porter Ranch, Santa Clarita, and Simi Valley. Although clinics are located in California, through partnerships with other programs, JCCC is able to offer clinical trials throughout the United States. These partnerships were made possible by Dennis Slamon, M.D., who launched Translational Oncology Research International (TORI). TORI provides opportunities for UCLA physicians and scientists to partner with other researchers, health care providers, and research institutions to provide clinical trials of experimental medications and treatments. TORI also offers cancer patients the opportunity to search for experimental trials of medications and treatments on their specific cancer diagnosis, thus linking a more diverse population of cancer patients to cancer research. Patients can search and find clinical trials specifically through the JCCC Web site or by calling the Clinical Trials Hotline at (888) 798-0719. The TORI network has brought together more than 25 oncology practices, 130 physicians, and 5,000 patients throughout the United States in the fight against cancer.

The JCCC Web site offers a vast amount of information to patients, caregivers (including family and
friends), and health care practitioners. Information and support can be found based on specific cancer diagnosis and organ system affected. Survivorship support and opportunities for survivors to organize and fund-raise are included on the Web site. Further, patients and family and friends can find physicians at UCLA based on a search of their gender, language, and specialty.

Survivorship, in particular, is a focus of JCCC. Some of the programs survivors can participate in through JCCC include the UCLA–Livestrong Center of Excellence; Simm/Mann–UCLA Center for Integrative Oncology; Athena Breast Health Network; and UCLA Family Cancer Registry. For survivors who want to give back, the Jonsson Cancer Center Foundation provides a place for survivors to participate in cancer fund-raising events.

As the Jonsson Comprehensive Cancer Center Foundation is the primary sponsor of JCCC, it is active in fund-raising to continue research on and treatment of cancer. The foundation can be accessed through the UCLA Fights Cancer page on Facebook, Twitter, or YouTube. The JCCC Foundation, along with grants from other research organizations, supports a wide variety of research at JCCC and UCLA.

Research at JCCC focuses on eight program areas. These include cancer and stem cell biology; cancer molecular imaging; gene regulation; genitourinary oncology; healthy and at-risk populations; patients and survivors; signal transduction and therapeutics; and tumor immunology. Another program on nanotechnology is under development. The program areas were created to encourage interdisciplinary research across disciplines. Other research programs, called shared resources, focus on the prevention, diagnosis, and treatment of cancer and include: biostatistics, analytical support, and evaluation; embryonic stem cell/transgenic mice; flow cytometry; genomics; informatics; molecular screening; small animal imaging; and a translational pathology core laboratory.

Breast and ovarian cancer research at JCCC serves as an example of the cutting-edge research conducted there. JCCC received grant support from the Noreen Fraser Foundation. Both breast and ovarian cancers are not specific types of cancer but instead different forms of cancer that only have in common the organ where they can be found. Through the breast cancer research at JCCC, they have developed a medication presently called PD 0332991, which can be used to inhibit cdk-4/6 and thus stop the growing of estrogen receptor positive (ER+) breast cancer cells. The results to date are stronger when the new medication is combined with tamoxifen. A phase III trial is in the planning process for the new drug.

With regard to ovarian cancer, UCLA researchers have accumulated 41 human ovarian cancer cell lines and 225 clinical ovarian tumor samples. Through analyses of these specimens, they have found that there are specific subtypes of the cancers with unique signaling pathways that cause tumor growth. Further, they have identified one pathway, called IGF-1, and have developed a product to block IGF-1 signaling of cancer tumor growth. The drug is in initial testing but demonstrates the type of research conducted at UCLA–JCCC.

Other research conducted at JCCC focuses on health disparities. The Division of Cancer Prevention and Control Research (DCPCR) is a program at JCCC that supports research on cancer in specific populations. The program also works with community partners to provide cancer education to low-income and ethnic minority populations.

**Conclusion**

UCLA’s JCCC is an organization that focuses on cancer prevention, treatment, research, and survivorship. It has been designated a comprehensive cancer center by the NCI, and although it has several locations in California, it provides access to research or clinical trials throughout the United States.

University of California, San Francisco, Helen Diller Family Comprehensive Cancer Center

Over 1 million Americans receive the diagnosis of cancer each year, with one in four dying from the disease. In the face of these statistics, cancer centers work to expand comprehension of cancer, make new therapies available, enhance quality of life, and bring new optimism to patients. The University of California at San Francisco’s (UCSF) Helen Diller Comprehensive Cancer Center follows this tradition. The UCSF Helen Diller Comprehensive Cancer Center opened in 1999. It is one out of 1,500 cancer centers in the United States designated by the National Cancer Institute (NCI), meaning that it receives core funding from the NCI. Despite its late designation as an NCI facility, this cancer institution moved to one of the top positions in California based on grant funding. The center underwent a name change in 2007, to the UCSF Helen Diller Comprehensive Cancer Center. The new name acknowledges Helen Diller, a long-term Bay Area resident, who motivated her neighbors and others to move beyond themselves to address the needs of their communities.

The UCSF Cancer Center provides a distinct program, with its concentration on biomedical research and graduate health-science education. The program places faculty and researchers in five principal campuses and multiple satellite locations. The UCSF located the newest campus and largest research university expansion to Mission Bay in San Francisco. The UCSF Cancer Center continues to expand, with construction that will house cancer programs on the prostate, kidney, and brain. The UCSF plans a new cancer hospital at this location in the future. The Helen Diller Family Comprehensive Cancer Center utilizes four San Francisco medical centers for care of cancer patients. The hospitals include UCSF Medical Center at Mount Zion, UCSF Medical Center at Parnassus, San Francisco General Hospital, and the San Francisco Veterans Affairs Medical Center.

About half of the UCSF Cancer Center’s multidisciplinary programs focus on disease, and the other half comprise leading programs in genetics, immunity, signaling, tobacco control, and society diversity and disparity. Three NCI Specialized Program of Research Excellence (SPORE) grants for breast, prostate, and brain tumor research remain housed under the UCSF Comprehensive Cancer Center. The National Cancer Institute allows the cancer center to employ the title of “comprehensive” because the program treats every form of cancer. The UCSF’s long tradition of prominence in cancer research includes the distinguished work of Nobel Prize winners J. Michael Bishop and Harold Varmus, who uncovered cancer-causing oncogenes. These individuals laid the groundwork for investigating genetic errors that cause cancer. Their pioneering work provided the background for breakthroughs occurring in cancer research today.

As one of the leading research institutions in cancer, the UCSF Cancer Center offers over 1,000 research trials at any one time. The NCI revolutionized its clinical research program in an effort to keep ahead of advances in the science of cancer. The NCI created the National Clinical Trials Network (NCTN) and the NCI Community Oncology Research Program (NCORP). The NCTN’s novel infrastructure permits investigators to start clinical trials more rapidly, complete results faster, and recommend patient studies at over 3,000 clinical trial locations. The mission of the UCSF Helen Diller Comprehensive Cancer Center’s clinical program delivers thorough care through multidisciplinary teamwork to provide innovative cancer therapies via clinical research, and to educate prospective physicians to treat cancer patients. The mutual approach to research and managing patient treatment remains a trademark of the cancer center’s program, procuring the involvement of surgeons, medical oncologists, radiation oncologists,
pediatric oncologists, radiologist, and pathologists. Working in conjunction with prominent UCSF scientists in disciplines varying from molecular biology and biochemistry to epidemiology, biostatistics, and public policy analysis, UCSF clinic specialists remain dedicated to transforming scientific visions into lifesaving experiences for cancer patients around the world.

The UCSF program sits at 6th place in receiving grants among all NCI grantee institutions, but it ranked first out of the 10 NCI-designated centers in California. Significant aspects of the center’s clinical program include premier bone marrow transplantation procedures; highly advanced radiation therapies (e.g., high-dose brachytherapy, conformal radiotherapy, and radio-immunotherapy); specialized therapy for AIDS-related malignancies; translational studies for managing cancers of prostate, breast, head and neck, colon, liver, lung, melanoma, and other solid tumors; and leadership in treating pediatric malignancies. The UCSF Cancer Center received one of the 53 community grants under NCORP. The cancer center sponsors the pioneers for investigating genetic, cellular, and immune-system triggers and responses to cancer. The UCSF possesses the nation’s largest brain tumor program, with state-of-the-art research and therapy for children and adults.

Carlo Maley, a scientist at UCSF Cancer Center, uncovered the reason for aspirin lowering the risk of some cancers in 2013. Aspirin and other non-steroidal anti-inflammatory drugs slow the accumulation of DNA mutations in abnormal cells. The aspirin exerts cancer-prevention by lowering mutation rates in cells. Maley and colleagues analyzed biopsies of tissue samples from patients with a precancerous condition called Barrett’s esophagus. The researchers studied the subjects with Barrett’s esophagus (both on and off aspirin) for 19 years. By looking at biopsies taken when subjects took aspirin, the investigators found that patients accumulated new mutations 10 times more slowly. Maley hypothesized that aspirin’s lowering of the mutation rate is probably because of the effect of reducing inflammation. The next area of research will focus on inflammation that leads to cancer in precancerous tissue. Maley and colleagues’ research represents just one of many molecular level studies in progress at the SCSF Cancer Center.

In prevention research at the SCSF Cancer Center, Sutton and colleagues set out to brainstorm alternative ways to look at prevention of breast cancer. The group proposed looking at the environment because it is a poorly utilized pathway to the prevention of breast cancer. A project called the California Breast Cancer Prevention Initiative became the focus for prevention research. This initiative set an agenda to investigate the environment, discrepancies, and prevention for exposures to chemicals, physical agents, and socially constructed situations. The outcome to this large task remains how to modify the world to attain a less carcinogenic milieu. The UCSF Helen Diller Comprehensive Cancer Center provides a two-prong approach to cancer by sustaining infrastructure for both biomedical research and clinical care for cancer patients. The cancer center maintains robust operations for both programs in the fight against cancer.

Further Readings

University of Chicago Medicine Comprehensive Cancer Center

The University of Chicago Medicine Comprehensive Cancer Center (known by the acronym UCCCC) is a cancer research program headquartered in New Lenox, Illinois. Founded in 1973, the
program is comprised of 210 scientists and physicians who serve over 1,000 patients annually in over 200 varying comprehensive clinical trials.

The University of Chicago’s program is one of two cancer research programs in Illinois (including the Robert H. Lurie Comprehensive Cancer Center at Northwestern University) to be designated a comprehensive care program by the National Cancer Institute (NCI). The center’s new facility at New Lenox’s Silver Cross Hospital opened in 2012.

History and Facilities
The program was established as the University of Chicago Cancer Research Center in 1973 following the institution’s designation as a “Clinical Cancer Center” by the NCI. The name was changed in 2010 after the program received the NCI’s “Comprehensive Care Center” designation.

The center’s 2010 NCI “comprehensive” designation was awarded after the center expanded efforts in its cancer prevention and control research, as well as for its numerous clinical trials concentrating prevention and early detection and implementation of cancer awareness programs for the Chicago metropolitan area’s underserved communities.

The center conducts research at 13 disparate facilities in and around Chicago, the majority of which are housed at Silver Cross Hospital in the New Lenox, fifty miles south of downtown Chicago. The 560,000-square-foot facility is home to 289 beds in addition to state-of-the-art chemotherapy and radiation therapy. The facility was completed with a construction cost of $21.6 million.

The UCCCC’s numerous facilities include the Biostatistics Core Facility, dedicated to observational studies on patient data; the Human Immuno logical Monitoring-cGMP Facility that primarily investigates immune responses to cancer; and the Integrated Small Animal Imaging Research Resource, which specializes in clinical research trials involving tissue and organ and other animal-borne specimens.

Other major UCCCC facilities include the Image Computing, Analysis, and Repository Facility, which provides researchers with the latest in medical image viewing and processing technology, and the Human Tissue Resource Center, which specializes in the procurement, storage, distribution, and analysis of human biospecimens.

Landmark Programs and Researchers
The UCCCC has been the site of numerous landmark accomplishments and discoveries in cancer research since its inception. In 1972, Dr. Janet Rowley spearheaded the center’s work identifying genetic anomalies in leukemia patients. The discovery would eventually become a staple in modern medicine’s understanding of the link between genetics and cancer. Rowley received the Presidential Medal of Freedom in 2009 for her long career of groundbreaking cancer research.

A 1988 study based at the UCCCC led to the discovery of the mechanism that blocks the effects of estrogen in the spread of certain types of breast cancers. This discovery ultimately led to widespread use of the drug tamoxifen, regarded as one of the most effective cancer treatments available today.

Another one of UCCCC’s prominent researchers was Dr. Elwood Jensen, whose 35 years of research at the center culminated with the development of tests that could predict whether patients with certain types of breast cancer would benefit from hormonal therapy treatments.

Programs
The UCCCC research division is divided into six integrated programs, each specifically dedicated to a particular facet of the disease.

The Molecular Mechanisms of Cancer group focuses on how genetic and cell-signaling alterations impact the development of cancer. Doctors and students who comprise UCCCC’s Hematopoiesis and Hematological Malignancies concentrate on the molecular origin of hematological diseases, while those in the Immunology and Cancer program attempt to understand the relationship between immune systems and malignant tumors, in hopes of one day transforming their knowledge into clinical applications.

The center’s Pharmacogenomics and Experimental Therapeutics program works to develop new cancer treatment therapies while evaluating the interaction between chemotherapy and radiation. The UCCCC is also home to a research group dedicated to making improvements in Advanced Imaging and computer-aided cancer treatments and diagnosis, while the Cancer Prevention and Control program concentrates on potential behavioral, epidemiological, and population-based genetic research surrounding cancer in its many forms.
The UCCCC is also home to one of 11 of the NCI’s Specialized Programs of Research Excellence (SPORE) in Breast Cancer programs. In addition to investigating the global issues and trends related to the disparities of cancer types among varying ethnic and racial groups, UCCCC’s SPORE program also concentrates on genetic and imaging-based cancer prevention methods.

Community Support Initiatives
The UCCCC’s Cancer Resource Center, a partnership between the center and the American Cancer Society (ACS), stands as the facility’s flagship for community programs. Housed in the Duchossois Center for Advanced Medicine at the University of Chicago, the center offers patients and their families one-on-one counseling as well as seminars on information surrounding breakthroughs in the center’s research trials. In addition to their numerous cancer support groups, the UCCCC Cancer Resource Center also holds a regular schedule of networking seminars to allow interaction between families and patients who share a similar diagnosis.

The UCCCC’s Office of Community Engagement and Cancer Disparities (OCECD) spearheads the center’s efforts in engaging with its metro-Chicago community. The UCCCC has fostered a variety of outreach programs designed to increase the visibility of cancer treatment and prevention and to empower citizens to take necessary precautions such as screening to preempt and prevent the spread of the disease. The UCCCC’s Mentored Education Now Taking on Research (MENTOR) program encourages area undergraduate and graduate students to engage in research regarding health problems among specific populations, while the center’s Cancer Transitions program, operated in conjunction with the LIVESTRONG organization, helps to improve the emotional health and quality of life of patients who have recently completed their cancer treatment.

The UCCCC OCECD also hosts a rotating annual calendar of community-based and faith-based events aimed at cancer advocacy and outreach, including movie screenings, celebrity breakfasts, luncheons, walk-a-thons, and corporate-sponsored family wellness nights.

Publications
The UCCCC’s latest projects, staff developments, landmark trials, and role as a nationally renowned center for cancer research are profiled in its quarterly magazine Pathways to Discovery. The center also hosts a blog featuring staff and patient perspectives on emerging trends and treatments as well as information regarding the center’s latest philanthropic and fundraising events.

Further Readings

University of Colorado Cancer Center

The University of Colorado Cancer Center was founded in 1988 and is headquartered at the University of Colorado Anschutz Medical Campus in Aurora, CO. The CU Cancer Center is the only National Cancer Institute (NCI)-designated comprehensive cancer center in Colorado and the
Rocky Mountain region. The center is a consortium of researchers and physicians from three state universities and six institutions in the Colorado area. The mission of the CU Cancer Center is to discover, develop, and deliver breakthroughs in diagnosis, treatment, and prevention to improve cancer care locally, nationally, and globally.

The CU Cancer Center is part of the University of Colorado Hospital (UCH), the primary adult teaching hospital and the location where most of the CU Cancer Center clinical care is delivered and research is conducted. Each year, over 63,000 patients visit the center, and thousands more visit the UCH community satellite office; in 2013, UCH admitted 2,750 new adult patients for cancer treatment. In addition to the multitude of noteworthy achievements announced each year by the CU Cancer Center, U.S. News & World Report consistently ranks the CU Cancer Center among the top 25 cancer centers in the United States.

**Founding and NCI Designation**

Founded in 1988, the CU Cancer Center began under the leadership of Dr. Paul Bunn. Initially, the center began with the development of a statewide consortium cancer center, which included seven participating institutions. The CU Cancer Center grew under Dr. Bunn’s direction, and he served as its director until 2009. In July 2010, the CU Cancer Center welcomed its second director, Dr. Dan Theodorescu. In addition to Dr. Theodorescu, Dr. Andrew Thorburn serves as the deputy director, and Dr. S. Gail Eckhardt is the senior associate director; these individuals comprise the leadership of the institution.

The CU Cancer Center is one of 68 cancer centers with a consortium designation from the National Cancer Institute (NCI), and the only NCI-designated cancer center in Colorado. These institutions are dedicated to research and the development of innovative approaches to the prevention, diagnosis, and treatment of all types of cancer. All NCI-designated cancer centers engage in research that spans laboratory science, clinical research, and population-based research. In addition to research, the CU Cancer Center also has a clinical program that provides patients with cutting-edge treatments and access to experimental clinical trials. In order to become a NCI-designated cancer center, institutions must demonstrate that they possess advanced research facilities, faculty, and a clear track record of proven success in treating cancer patients. The CU Cancer Center received its first five-year NCI cancer center support grant in 1987 and the comprehensive NCI designation in 1997. In 2005, the CU Cancer Center was awarded a formal consortium designation that included three of the state universities and six cancer care and research institutions located in Colorado.

**Members of the CU Cancer Center Consortium**

Initially, the CU Cancer Center included full and associate members from the University of Colorado School of Medicine, National Jewish Health, University of Colorado Hospital, Denver Health, Denver Veterans Affairs Medical Center, and Children’s Hospital Colorado. Later, the Children’s Hospital Colorado merged with the University of Colorado School of Medicine, and researchers at both organizations became faculty at the CU Cancer Center. In 2005, when the CU Cancer Center received its formal NCI consortium designation, researchers from the University of Colorado Boulder, Colorado State University (including the Flint animal cancer center), and Kaiser Permanente Colorado also joined the cancer center to complete the current configuration of the consortium. All members of the consortium have access to shared resources from the CU Cancer Center, which are used by members from all of the associated sites. These resources include: clinical trials, flow cytometry, functional genomics, genomics, human tumor model-based databank, molecular pathology, pharmacology, protein production/tissue culture, research informatics, structural biology, and tissue biobanking and processing.

**Research and Special Departments**

As of 2013, the CU Cancer Center received $98 million in direct annual cancer research funding; received $24 million in direct annual NCI research funding; and had invested approximately $102 million in institutional cancer research since 2005. The CU Cancer Center has six research programs: in cancer cell biology; cancer prevention and control; developmental therapeutics; hormone-related malignancies; lung, head, and neck cancer; and molecular oncology. In 2013, the research programs at the CU Cancer Center produced 636 publications, of which 38% were collaborations with other institutions. The center has a strong
program of clinical trials; approximately 21% of patients diagnosed there were enrolled in treatment trials in 2013. The CU Cancer Center is also associated with the treatment of pediatric cancers and blood disorders; however, the majority of this treatment takes place through the center’s partner, the Center for Cancer and Blood Disorders at Children’s Hospital Colorado. This facility ranks as one of the top pediatric cancer centers in the United States.

As a regional leader in cancer care, the center provides multidisciplinary care within each subspecialty of oncology. The University of Colorado Hospital and Cancer Center treats patients suffering from all types of cancer; however, the center specializes in the following areas: breast cancer, lung cancer, gastrointestinal cancers, cutaneous oncology, neuro-oncology, head and neck cancer including thyroid cancer, gynecological cancers, developmental therapeutics urological cancers, radiation oncology, hematologic malignancies, and bone marrow transplants. The center is the coordinating center for the Lung Cancer Mutations Consortium, which is funded by a $5.3 million American Reinvestment and Recovery Act Grand Opportunities grant. Additionally, the CU Cancer Center serves as the home to three cancer survivorship clinics for the Rocky Mountain region: the TACTIC clinic for adult survivors of childhood cancer, the THRIVE clinic for transitioning adult cancer patients back to primary care, and the young adult survivors of cancer. CU Cancer Center is also one of the LIVESTRONG Survivorship Centers of Excellence.

As part of the University of Colorado Hospital (UCH), the CU Cancer Center provides training to students, residents, and fellows in the practice of medical oncology, hematology, radiation oncology, and many other medical subdisciplines. The center provides students with the opportunity to participate in several training tracks, which include: clinical investigation, disease-oriented basic science research, and bone marrow transplantation research. In addition to training at UCH, students also receive training at other members of the CU Cancer Center Consortium, including the Denver Veterans Affairs Hospital, the Children’s Hospital of Colorado, Denver Health, and National Jewish Health.

Accomplishments
The CU Cancer Center is home to many accomplishments and breakthroughs in the field of oncology. Each year the CU Cancer Center has some of the highest five-year cancer survival rates of any hospital and medical facility in the Rocky Mountain region. The center is especially noteworthy for the survival rates of patients who suffer from late-stage cancers. For instance, the center is home to one of the world’s best lung cancer research and treatment centers; one-year survival rates of patients suffering from stage-four lung cancer are more than two times the national average.

The Colorado Colorectal Screening Program has become a national model for individuals who meet specific financial and risk criteria to receive the necessary colorectal screening and follow-up treatment at no cost to the patient. The program is coordinated by the center and has more than 65 community partners throughout the state that offer endoscopy and colonoscopies to individuals who qualify for the screening program. The center is also noteworthy for its Phase I cancer clinical trials program. This program offers patients who are treated at the CU Cancer Center access to the largest number of cancer clinical trials as well as cutting-edge cancer treatments and care.

The Cancer Clinical Trials Office (CCTO) at the center coordinates clinical trials by ensuring the clinical investigators have the resources necessary to conduct successful clinical trials. The CCTO ensures that clinical trials can be translated from research into everyday basic knowledge for both patients and providers. Finally, the center’s shared resource, Structural Biology, houses the CU Cancer Center’s Nuclear Magnetic Resonance (NMR) Spectroscopy and X-ray facilities, which are considered to be some of the best in the world. The Structural Biology Shared Resource is one of only two NCI-designated centers with X-ray Crystallography, NMR, high-field NMR, and synchrotron.

Further Readings
The University of Hawai‘i’s (UH) Cancer Center strives to be a world leader in eliminating cancer through improved patient care, education, and research. The university’s scientists and physicians focus on cancers that are of key impact to Hawai‘i while contributing to the global body of knowledge regarding cancer treatment and therapies. The UH Cancer Center collaborates internationally, from clinical trials conducted in the United States to partnership programs in Guam, Micronesia, and other parts of the Pacific. The university actively recruits new talent to develop new strategies for discovery, to drive findings into clinical practice, and to deliver optimal outcomes in patient treatment and recovery.

Hawai‘i is a geographically and demographically diverse state. It has the highest percentage of individuals with mixed-race ethnicity in the United States. Two of every 10 citizens of Hawai‘i describe themselves as mixed-race. Hawai‘i residents have the longest life span of any of the United States; yet, each year, more than 6,000 Hawai‘ians are diagnosed with cancer and another 2,000 die from cancer-related disease.

The UH Cancer Center, designated by the National Cancer Institute (NCI), is a consortium cancer center. The UH Cancer Center collaborates with The Queen’s Medical Center, Hawai‘i Pacific Health, Kuakini Medical Center, and UH Manoa’s John A. Burns School of Medicine. The common goal is the elimination of cancer through science. The consortium represents basic, translational, and clinical cancer research efforts to benefit all citizens of Hawai‘i and the Pacific Rim. The consortium’s vision is to substantially reduce the burden of cancer through the support of clinical and translational research. The consortium’s mission is to facilitate, support, and assure that high-impact patient research is efficient and safe and substantially reduces the burden of cancer.

The UH Cancer Center houses the central administrative and organizational structure of the Hawai‘i Cancer Consortium. It is the central authority that focuses and organizes the efforts of and resources for efficient accomplishment of the consortium’s goals. The Kuakini Medical Center’s Oncology Services uses a multidisciplinary approach to address the individual needs of each cancer patient. Services include prevention, early detection, treatment, medical care, education, and support. The Oncology Services members also participate in community activities and events while providing information, education, and free screenings. The Queen’s Medical Center offers comprehensive, multidisciplinary cancer treatment and research. It was designed to reduce the need to travel to the mainland for quality cancer care. It offers advanced technology in a patient-centered, comfortable setting. The John A. Burns School of Medicine seeks health solutions for Hawai‘i and the Pacific Rim’s multicultural society and the world. The school is the most culturally diverse in the United States, and its vision is A.L.O.H.A. (Attain Lasting Optimal Health for All).

The UH Cancer Center conducts research on prevention, treatment, and causes of cancer. Areas of focus include new therapeutic approaches, community-based interventions, quality of life for survivors, prevention, and epidemiology. The Cancer Biology Program seeks to discover mechanisms that drive cancer development and progression, then to translate those discoveries into better diagnostics and interventions. Program objectives include: providing better knowledge concerning the development and progression of cancer; developing new diagnostics and therapies; and initiating new clinical trials in Hawai‘i.

The Cancer Epidemiology Program seeks to understand the reasons underlying ethnic/racial differences in cancer incidence and mortality rates. The program studies the role of lifestyle (diet, obesity, exercise, etc.), genetics, and infectious agents to identify risk factors that can lead to successful interventions. The program places special research emphasis on the role of dietary nutrition and external factors (i.e., infectious agents, inherited factors,
etc.) related to the incidence of breast, prostate, colorectal, cervical, ovarian, and lung cancers.

The Cancer Prevention and Control Program aims to reduce cancer risk, incidence, morbidity, and mortality. Early screening and detection, elimination of tobacco use, increased physical activity, reduced unprotected exposure to sunlight and artificial light, and improved dietary consumption are all critical to reducing the incidence of cancer. Goals for the Cancer Prevention and Control Program include (1) advancing understanding of behavioral, psychosocial, biological, environmental, and social factors associated with cancer risk, incidence, morbidity, mortality, and survival; (2) testing interventions that reduce cancer risk, increase early detection, and improve survival rates; and (3) increasing knowledge on how to disseminate research so that it benefits multicultural, multiethnic, and underserved populations.

The Clinical and Translational Research Program seeks to translate discoveries into clinical applications, in order to generate innovative and high-impact research interventions. The program aims to identify interventions (i.e., agents, devices, and diagnostic tests) that, when applied, are more helpful than harmful, especially with regard to liver and breast cancer, which disproportionately impact Hawai’i’s population. The program also provides Hawai’i residents with access to clinical trials that are the most promising and contribute Hawai’i’s multiethnic population to nationally conducted trials. Participants get state-of-the-art care without having to leave the state.

The Natural Products and Experimental Therapeutics Program leads translational drug discovery and development research with an emphasis on identifying natural product-based therapeutics. There is a vast chemical diversity in the natural products unique to Hawai’i’s agriculture and environment. The program’s goals include (1) investigation of anticancer targets and pathways; (2) exploration and development of natural products and synthetics that modulate cancer pathways; and (3) design, pursuit, and analysis of natural products in innovative clinical trials.

Further Readings
collaborations since, but the UMCCC building remains a state-of-the-art treatment and research center.

Currently, over 350 University of Michigan faculty members as well as 27 clinics provide patient care. Of the 27 clinics, 17 are considered multidisciplinary in their approach to cancer treatment. UMCCC also has been rated by U.S. News and World Report as 34th on its list of the best hospitals for cancer treatment and is the only hospital in the state of Michigan to rank in the top 50.

Accreditations and certifications further demonstrate UMCCC’s commitment to excellent patient care. First, UMCCC has been accredited by the Joint Commission. The Joint Commission accreditation is voluntary and represents an organization’s demonstration of safe and comprehensive treatment of patients diagnosed with cancer (i.e., fully informing patients of all risks and options of treatments). UMCCC has also received a three-year certification from the Quality Oncology Practice Initiative for providing quality cancer treatment. UMCCC has even been designated as a Blue Distinction Center for Complex and Rare Cancers by the national Blue Cross and Blue Shield Association.

UMCCC is also a member of the Michigan Cancer Consortium, Big Ten Cancer Research Consortium, National Comprehensive Cancer Network, and Commission on Cancer of the American College of Surgeons. These associations represent collaborations among UMCCC members and other research and oncology care institutions. Through such collaborations, UMCCC and its partners can provide the newest information and treatments to patients.

Research
UMCCC’s focus with regard to cancer research is to seek to improve understanding of the genetic markers and triggers of cancer; researchers strive to understand cancer at its molecular level. UMCCC is one of the few centers in North America dedicated to cancer stem cell research. To that end, UMCCC has 22 research programs, which include six basic (or laboratory) science programs, 14 clinical trial research programs, and two programs devoted to the development and testing of prevention and control strategies. The Basic Science programs include: Cancer Cell Biology, Cancer Genetics, Experimental Therapeutics, Molecular Imaging, Radiation Sciences, and a Tumor Immunology and Host Response Program.

UMCCC research has also received three Specialized Programs of Research Excellence (SPORE) grants from the NCI. Another SPORE grant in sarcoma was awarded to UMCCC through its participation in the Sarcoma Alliance for Research through Collaboration (SARC). SPORE grants represent prestigious awards, which are only awarded to top institutions.

Patients benefit from the clinical research and trials at UMCCC and its partners. Some of the clinical research programs include: Breast Oncology, Childhood Cancers, Endocrine Oncology, Prostate Cancer, Neuro-Oncology, and Thoracic Oncology. Finally, the two prevention and control programs are the Biomedical and Socio-Behavioral Prevention programs. Patients can search through the UMCCC Web site for opportunities to participate in over 285 cancer research clinical trials.
**Patient Care**

According to the UMCCC Web site, in 2012 there were 93,319 outpatient visits to the clinic, 51,884 infusion treatments, 4,184 radiation consults, and 2,854 cancer patients admitted to hospitals. Of the cancer diagnosed and treated at UMCCC, the top five are: melanoma, breast cancer, prostate cancer, blood cancers, and lung cancer.

Although UMCCC is a leader in the treatment and diagnosis of common and rare forms of cancer, the institution also is a leader in the support of patients and families. UMCCC provides multiple levels of support for patients and families through prevention, detection, treatment, and survivorship. The Patient and Family Support Services Program (PFSS) at UMCCC, for example, offers more than 30 programs for patients and their family members. Social workers, psychology professionals, nutritionists, and other professionals trained in cancer treatment work with patients and families through PFSS to support patients and families through art therapy, financial management of cancer treatment, nutrition, and other programs. The U-M Cancer AnswerLine is another example of patient and family support; patients and family members can call and reach an oncology registered nurse to answer questions. Patients and family cannot receive diagnoses or recommendations for treatment through the AnswerLine but can receive information about their current treatments and concerns. UMCCC also provides genetic counseling to patients to determine if they are at risk of developing cancer so that they can enact behaviors, such as improved diet and exercise, to minimize the risk.

Other amenities and services offered to patients and families include the Overnight Accommodations program; the Guest Assistance Program; the Practical Assistance Center; and the Voices of Art Gallery, which features patients' and family members' artwork.

Patient support continues through survivorship programs at UMCCC. UMCCC maintains two clinics focused on the survivorship of those afflicted with breast or prostate cancer. Patients are referred to these clinics after treatment for breast or prostate cancer. At the clinics they receive another comprehensive health exam as well as opportunities to talk with health care practitioners about their real life concerns. Some topics discussed include the management of continued side effects from their treatments as well as their sexual health. Other survivorship programs at UMCCC include continued help with management of financial issues, occupational therapy, support groups, a blog for conversations related to cancer, and providing other online resources that patients and families can access.

**Outreach**

UMCCC provides extensive outreach to the community. One opportunity offered by UMCCC is the Physician Liaison Program, in which a UMCCC physician liaison will visit a health care practitioner's practice and offer support and information about new treatments and clinical trials. UMCCC also offers a Speaker's Bureau, Community Outreach Events, Minority Outreach Initiative with culturally targeted community events, free cancer displays and materials for health fairs, etc., and free cancer screenings. Finally, survivorship outreach is provided by UMCCC in the form of a yearly community event that celebrates National Cancer Survivors' Day.

**Training of Health Care Professionals**

UMCCC, through its partnership with the University of Michigan Medical School, offers an education in medicine through 20 clinical and nine basic science departments. Approximately 170 physicians graduate each year, and U-M Medical School alumni include Nobel Prize winners, leaders of Fortune 500 companies, as well as leaders at educational and research institutions.

**Conclusion**

UMCCC was one of the first cancer centers focused on the use of multidisciplinary teams in the fight against and research of cancer. The center has won several accolades for its dedication to providing quality care to patients, and research at UMCCC is focused on understanding cancer at the molecular level so as to improve knowledge about the genetic markers and triggers of cancer.

University of Minnesota Masonic Cancer Center

The University of Minnesota Masonic Cancer Center serves as that institution’s premier institute for cancer research. As part of the University of Minnesota, the center seeks to create a collaborative research environment that concentrates on the causes, prevention, detection, and treatment of cancer. The University of Minnesota Masonic Cancer Center also works to apply this knowledge in ways that will improve the quality of life for patients and survivors and to share its discoveries with others, including students, scientists, researchers, medical professionals, and the community. Designated a comprehensive cancer center by the National Cancer Institute, the University of Minnesota Masonic Cancer Center collaborates with other individuals and institutions to make ongoing and significant advances in cancer research, treatment, and education.

Background
Founded in 1851, the University of Minnesota is a publicly funded research institution located in Minneapolis and Saint Paul, Minnesota. Organized into 19 different colleges and schools, the University of Minnesota has several units that engage in stem cell research. The College of Science and Engineering was organized in 1935 as the Institute of Technology and comprises the university’s departments of mathematics, engineering, and the physical sciences. The University of Minnesota Medical School is located in Minneapolis and Duluth and is one of two medical schools in Minnesota (the other being affiliated with the Mayo Clinic in Rochester). Dr. Robert A. Good of the University of Minnesota Medical School conducted the first bone marrow transplant between individuals who were not identical twins and is considered one of the founders of the field of immunology. The University of Minnesota College of Biological Sciences is located in Minneapolis and was the alma mater of Dr. Edward B. Lewis, who won the 1995 Nobel Prize in Physiology or Medicine. Lewis was a founder of the field of developmental genetics and was primarily responsible for discovering the Drosophila bithorax complex.

The University of Minnesota Masonic Cancer Center was founded in 1991. Representing a long tradition of Masonic support for cancer research within Minnesota, the center changed its name to honor the Masons in 2008, after a $65 million donation. The Masonic Cancer Center is part of the university’s Academic Health Center. The Academic Health Center includes the University of Minnesota’s Medical School, School of Dentistry, School of Nursing, College of Pharmacy, School of Public Health, and College of Veterinary Medicine.

Focused upon building a collaborative environment, the university’s Stem Cell Institute, the Center for Immunology, and the Center for Magnetic Resonance Imaging serve as some of the Masonic Cancer Center’s main research partners. The Masonic Cancer Center’s clinical research and treatment work is done in conjunction with the University of Minnesota Physicians, the University of Minnesota Medical Center, Fairview Hospital, and the University of Minnesota Amplatz Children’s Hospital.

Cancer Research and Treatment
Research at the University of Minnesota Masonic Cancer Center is organized to address several
themes identified as holding the most promise. These themes include the following:

- Prevention and etiology
- Carcinogenesis and chemoprevention
- Genetic mechanisms of cancer
- Tumor microenvironment
- Immunology
- Cell signaling
- Transplant biology and therapy

Teams working on each of these themes bring together scientists from different disciplines to discover processes and procedures that might affect cancer.

Scientists who work at the Masonic Cancer Center are making discoveries that are leading to better ways to treat and prevent cancer. Dr. Stephen Hecht and colleagues, working in the area of carcinogenesis and chemoprevention, are looking to identify chemical and molecular mechanisms of carcinogenesis, specifically in regard to tobacco, and to use this knowledge to develop and evaluate practical methods for cancer prevention. These practical methods have included examining the chemical and molecular mechanisms of carcinogenesis and how chemoprevention can be used to address these.

Other researchers, such as Dr. Anja Bielinsky and Dr. Peter Bitterman, are working to better define and understand the genetic changes that occur during cancer development. These include specific changes that drive tumor initiation and progression and those that influence a patient’s cancer susceptibility. Dr. Carol Lange and her colleagues, who examine cell signaling, are looking to improve their understanding of the spectrum of altered signaling pathways and their components that contribute to cancer initiation, promotion, and disease progression. Lange’s research group is engaged in the step-wide translation of this knowledge into strategies that will facilitate the prevention, early detection, diagnosis, and treatment of cancer.

Dr. Yoji Shimizu and other immunologists at the Masonic Cancer Center are seeking to define the basic mechanisms that control adaptive immunity. Gaining this understanding will assist researchers in developing immunotherapies that can overcome the significant barriers associated with generating a durable immune response against tumor-associated antigens. Researchers investigating prevention and etiology, such as Dr. Anne Joseph and Dr. DeAnn Lazovich, are working to increase understanding regarding the biological and behavioral factors in the etiology of cancer. In doing so, it is hoped that it will be possible to reduce those behaviors that may lead to cancer or to enhance those behaviors that decrease cancer risk. The research group has used a multidisciplinary approach that has demonstrated more progress than previous efforts. Dr. John Wagner and Dr. Daniel Weisdorf, who lead the transplant biology and therapy program, seek to reduce or eliminate factors limiting hematopoietic stem cell transplantation. Those factors include regimen-related toxicities, graft-versus-host disease (GVHD), and delayed reconstitution of immunity. The tumor microenvironment scientists, led by Dr. Kalpna Gupta and Dr. James McCarthy, are examining those critical molecular and cellular mechanisms through which alterations in the tumor microenvironment contribute to tumor-related factors in malignant progression. To this end, the program has been organized to concentrate upon three distinct but overlapping themes that might impact tumor progression in several ways. The ways in which tumor progression might be impacted include reducing tumor burden, limiting metastasis, and lessening cancer-induced pain. Each of these factors would affect morbidity and mortality in cancer patients.

The Masonic Cancer Center has also established a number of inter-programmatic and translational research work groups to promote new discoveries. Translational work groups use Masonic Cancer Center members from a variety of research programs. These groups are each designed to address site-specific cancers, foster collaborations, and provide the necessary scientific and clinical expertise to improve outcomes for the specific disease sites. In collaboration with medical professionals from across Minnesota and the United States, these work groups have had great success in translating research findings into changes in practice that positively affect patients and their families.

University of New Mexico Cancer Research and Treatment Center

The University of New Mexico Cancer Center (UNMCC) was established in 1971 by New Mexico's state legislature. The legislature's intention was to create an advanced research and public service institution to serve the state as well as the southwestern U.S. region. In 2005, UNMCC received a designation as a National Cancer Institute (NCI) Cancer Center and is one of the 68 centers in the United States with this prestigious recognition. To achieve this designation, a cancer center must demonstrate a commitment to multidisciplinary research and treatment of cancer as well as provide training of medical professionals and prevention and control education efforts in the community. Participation in clinical trials is also required of NCI-designated cancer centers.

Currently, UNMCC is the only NCI cancer center in the state of New Mexico, but it has partnerships across the state and country. UNMCC is associated with over 100 board-certified oncology physicians covering every specialty in cancer treatment. Through partnerships with organizations like Johns Hopkins and the Mayo Clinic, the UNMCC research team works with over 130 cancer researchers who are supported with over $77 million in yearly funding. The main cancer center, located in Albuquerque, is a 206,432-square-foot facility that was designed to provide a peaceful and welcoming environment for patients.

The mission of UNMCC, as stated on the institution’s Web site, is to provide assistance to the people of New Mexico through exceptional diagnosis, treatment, and research. Service to the communities throughout New Mexico is included in the UNMCC mission statement as well. Training of future oncology health care practitioners through the UNM Medical School and other programs at UNM also is part of the center’s mission.

UNMCC also maintains several certifications and accreditations. One of the new certifications is the QOPI (Quality Oncology Practice Initiative) Certification. The certification is given to institutions that demonstrate a commitment to quality care. UNMCC has also received accreditations from the Joint Commission; the Commission on Cancer Accreditation from the American College of Surgeons; and the College of American Pathologists. Currently, UNMCC is working toward certification of the center’s radiation oncology and breast cancer suites.

Research
UNMCC actively participates in research and averages over 300 open clinical studies. In 2012, as an example, UNMCC maintained 345 research studies and recruited approximately 20 percent of their patients to participate in therapeutic research.

UNMCC has four main research programs that are aligned with NCI research categories. The research programs are: Cancer Control; Cancer Genetics, Epigenetics, and Genomics; Translational Cancer Biology and Signaling; and Cancer Therapeutics: Technology, Discovery, and Targeted Delivery. More than 125 researchers at UNMCC participate in research in these four areas. Partnerships with other organizations both outside New Mexico as well as in New Mexico provide further research opportunities. Some of the partnerships within the state include collaborations with scientists from: Sandia National Laboratories, Los Alamos National Laboratory, Lovelace Respiratory Research Institute, and New Mexico State University.

Researchers at UNMCC have also been recognized by NCI. Two UNMCC research teams won highly esteemed NCI Provocative Questions grants. One of the teams is exploring how RNA manufacture affects cancer, and the other team is studying why some non-steroidal anti-inflammatory medications have shown to have positive effects on cancer outcomes.

Patient Care
UNMCC is a unique cancer center with regard to the communities it serves. The multicultural
population of New Mexico includes tribal nations and pueblos, rural communities with limited health care access, Mexican Americans, as well as some undocumented populations. To provide education on cancer for the remote and underserved populations in New Mexico, UNMCC developed a Cancer 101 educational program that has been provided to communities throughout the state. The focus of this and other programs is to provide education on cancer as well as improve screenings and treatment so that cancer, when diagnosed, is treatable. Ethnic minorities in New Mexico tend to present with more advanced, or terminal, cancer, thus limiting treatment options. To improve cancer outcomes among the diverse populations in New Mexico, UNMCC has established collaborations with 19 of the pueblos, as well as the Jicarilla Apache Nation, the Navajo Nation, and Spanish-speaking communities in the state. UNMCC also is one of only three NCI-designated cancer centers that provides care to patients regardless of their ability to pay.

Through outreach to the state, UNMCC was able to provide care for over 65 percent of the cancer patients in New Mexico. This includes serving over 11,000 patients with over 124,000 clinic visits each year. Services provided to patients include: psychology services; oncology nutrition specialists; oncology social workers to help with logistics and financial concerns; a patient education resource library; a comprehensive Patient Guide to answer questions for patients and family members; support groups; clinical services; and other programs.

A unique newsletter, called El Oso Updates, is available online for patients and family members. It includes updates about new treatments, current treatments, and survivorship stories and events like the Think Pink Lobo Football game where fans wear pink to increase awareness and raise funds for cancer treatment and research.

Support groups both for those fighting cancer and survivors of cancer can also be found at UNMCC. Examples of these support groups include: Survivors Writing Together (a journaling support group); Arts-in-Medicine at UNM; Family and Friends of Advanced Cancer Patients; and Look Good...Feel Better for Women.

UNMCC works with the UNM Children’s Hospital to diagnose and treat children diagnosed with cancer. The UNM Children’s Hospital provides care to approximately 60,000 children and is a Children’s Miracle Network hospital. The hospital includes a pediatric oncology infusion center and Child Life Center. Patient rooms are large and comfortable to provide family and patients with a calm and secure environment during care. The Ronald McDonald House provides families with housing during extended treatments.

Training of Health Care Professionals
UNMCC, through its partnership with the University of New Mexico School of Medicine, offers training to future oncology health care specialists. The UNM School of Medicine excels at rural medicine and was ranked as second in the United States for its Rural Medicine Program by U.S. News and World Report.

Further Readings
Center in 1990, and the center is the only public comprehensive cancer center in North Carolina to have this designation. Since it was established, the aim of the center has been to reduce cancer occurrence and death through research, treatment, training, and outreach. UNC Lineberger is named after the Lineberger family of Belmont, North Carolina, because of the longstanding association between UNC and the Linebergers. In addition, four brothers of the Linebergers were key players in the creation of the Lineberger Cancer Research Center.

For the center to start operations, 315 members working at the center were drawn from more than 40 departments at the UNC and other institutions, including the College of Arts and Sciences, the Eshelman School of Pharmacy, and the Gillings School of Global Public Health. The UNC Lineberger Comprehensive Cancer Center is part of the university’s school of medicine, and the North Carolina Cancer Hospital is the focus of Lineberger’s clinical activities. The center has nine programs, through which it conducts interdisciplinary research. These programs are cancer epidemiology, cancer prevention and control, molecular therapeutics, breast cancer, cancer genetics, clinical research, cancer cell biology, virology, and immunology.

Research work by the Lineberger Center is more focused on breast cancer. Current projects in breast cancer studies are regularly supported by reports on associated molecular phenotypes, with an emphasis on the most difficult parts to treat and heal. These studies on cancer are in line with the center’s work on population studies, particularly with the African American community. Other areas of research are gastrointestinal cancer and colorectal cancer, with current research on genetic studies. Cancer is a complex disease, and it needs complex solutions: based on this realization, drug discovery scientists, physicists, oncologists, and chemists of UNC came together to create the Carolina Center of Cancer Nanotechnology Excellence (CCNE). Those who study here look to find new models used for the comparison of four critical nanoparticle formulations.

The UNC Lineberger Cancer Center is also the repository for Collaborative Cross. Collaborative Cross is an international effort investigating the genetic and environmental factors that contribute to cancer susceptibility. In the effort toward research on cancer, the UNC currently has more than 300 of the 600 inbred mouse strains that represent the genetic diversity of the human population, and is importing the remaining models in order to enable creation of population-level mouse models to inform cancer biology.

The Lineberger Center and the UNC Eshelman School of Pharmacy have established a partnership in Comprehensive Chemical Biology and Drug Discovery. Projects include potential treatments for renal cell carcinoma, gliomas, acute lymphoblastic leukemia, and basal-like breast cancer. The center is also working on the Cancer Genome Atlas (TCGA). Work through this program has been focused toward adjusting the form of breast cancer into several categories, based on how they are treated. The Lineberger Center extends its research mission by disseminating effective practices to the community. Treatment of cancer, screening for cancer, and prevention programs are provided and available at the North Carolina Cancer Hospital, where there is access to cancer clinical trials for patients.

The Lineberger Center’s clinical base, North Carolina Cancer Hospital, was completed in 2009. Through the hospital, the center is able to deliver cancer treatment to the public. The center’s physicians have offered multidisciplinary patient-centered care for more than a quarter century. The center provides patients the benefit of many medical and patient support specialists in one place, often in one visit. To ensure effective treatment, the center applies the latest technology to cancer diagnosis and treatment, offering intraoperative radiation therapy (IORT), advanced virtual and 3-D imaging for breast biopsies, intensity modulated radiation therapy (IMRT), PET scans, and laparoscopic and robotic surgeries for select surgeries. Other cancer treatment technologies used at the hospital include genetic counseling and testing for some cancers.

For North Carolina cancer patients, the Lineberger Center has support programs to ensure compassionate and effective support, not only to them, but also their family members. The mission of the support program is to provide outstanding clinical and educational programs for cancer patients and their caretakers, and a world-class training and research site for health care professionals who work with cancer patients. UNC Lineberger is not only focused on cancer research. It also has community initiatives that include programs for cancer prevention, early detection, and cancer survivorship. These programs extend throughout North Carolina, and the objective
is to reduce cancer incidence and mortality. The center also has cancer epidemiology and cancer prevention and control programs that examine patterns of cancer in the community to understand the complex interaction among biology, genetics, environmental exposures, and behaviors that cause cancer.

In the prevention of cancer, UNC research components form part of the Carolina Community Network that is funded by the National Cancer Institute (NCI). The purpose of the network is to reduce prostate, colorectal, and breast cancers in adult African Americans. In addition to the UNC, the network includes health promotion-oriented institutions and organizations and cancer treatment centers. The North Carolina–Louisiana Prostate Cancer Project is a longitudinal study of Caucasian and African American prostate cancer patients focusing on identifying reasons for racial differences in prostate cancer mortality. This project has received support from community advocates, prostate cancer survivors, state cancer registries, and the federal government through the U.S. Department of Defense Prostate Cancer Research Program. UNC Lineberger houses several international research programs in molecular carcinogenesis, virology, immunology, molecular therapeutics, cancer genetics, and cancer cell biology that investigate the genetic and molecular aspects of cancer. Researchers from the center are also conducting molecular-based analysis on cancers to establish cancer patients who stand to benefit the most from treatment. In addition, Lineberger Center researchers are seeking to identify molecular targets for new therapies and develop the methods appropriate for genetic therapy.

University of Pittsburgh Cancer Institute

The University of Pittsburgh Cancer Institute (UPCI) and the University of Pittsburgh Medical Center (UPMC) together form an integrated cancer care network that treats more than 74,000 patients annually. UPMC and UPCI partner as western Pennsylvania’s only National Cancer Institute (NCI) Comprehensive Care Center. UPCI is ranked 12th in NCI funding, including four Specialized Program of Research Excellence (SPORE) grants that focus on head and neck, lung, skin, and ovarian cancers. UPCI receives $173 million in peer-reviewed research grants.

Together, UPCI and UPMC represent more than 1,700 experts in: surgical, medical, radiation, and gynecologic oncology; otolaryngology; neuro-oncology; palliative care; behavioral medicine; scientists; and other health care professionals. There are 35 treatment centers in western Pennsylvania and Ohio associated with UPMC and UPCI, in addition to centers in Ireland, Italy, and Singapore.

The Hillman Cancer Center is the hub of the UPMC Cancer Center network. The Hillman Cancer Center was founded in 1985. It is a five-story facility that houses a full-service cancer center, disease-specific cancer centers, an education center, and a center for early detection and prevention of cancer. The Hillman Cancer Center also houses most of UPCI’s research laboratories.

There are nearly 400 research and clinical faculty who specialize in multiple disciplines including prevention, early detection, treatment, survivorship, and end-of-life care. Primarily, UPCI researchers work to advance understanding of the biological basis of cancer development and progression, develop novel treatments, and establish and implement preventive measures. There are hundreds of clinical trials available at UPCI and UPMC sites. UPCI plans
for growth with ongoing recruitment and planned expansion of clinical and laboratory space.

The Clinical Executive Advisory Committee consists of several members, which include the director of UPCI and the director of UPMC. The Research Executive Advisory Committee focuses on research-related issues. The committee is also responsible for academic activities. The primary focus of the committee includes: basic, translational, and clinical research; strategic planning; and assessment of opportunities and needs for infrastructure and recruitment. The UPCI External Advisory Board includes nationally and internationally recognized physicians, scientists, and cancer center directors. They annually review programs, shared facilities, and activities and provide detailed advice with regard to research, evaluation of programs, and recruitment. The UPCI and UPMC Cancer Center Council, which includes 50 of Pittsburgh's leaders, provides advice and support to the Clinical Executive Advisory Committee. They are ambassadors for UPCI and UPMC and promote the core missions of advancing the understanding of cancer; development of innovative methods for cancer prevention, diagnosis, and treatment; and provision of state-of-the-art cancer care. These members also help secure funding and promote relationships between UPCI and the business community that helps to guide technology.

Shared resources at UPCI are key in supporting cancer research through access to innovative and expensive technology and technical expertise while containing costs. The shared resources of UPCI are state-of-the-art and provide support in infrastructure, technology, and expertise to assist with basic, translational, and clinical cancer research. The goal is to provide outstanding service at a reasonable cost. Facility directors are available for expert consultation and may participate, in some cases, as researchers. Shared resources include the following: the Animal Facility (quality and humane animal care and services for research); the Biobehavioral Medicine Facility (biological changes associated with stress, psychological, and behavioral factors); the Biostatistics Facility (statistical and computer-related expertise); Cancer Bioinformatics Services (data management and access); the Cancer Biomarkers Facility (discovery and translation of relevant molecular biomarkers); the Cancer Pharmacokinetics and Pharmacodynamics Facility (pharmacology research services); the Cell and Tissue Imaging Facility (microscopic techniques and analysis); the Cell Culture and Cytogenetics Facility (cell culture services); the Chemical Biology Facility (potential anti-cancer compounds); Clinical Research Services (development, implementation, and completion of clinical research); the Cytometry Facility (analytical and imaging cytometry and cell sorting); the Hematopoietic Stem Cell Laboratory (therapeutic T-cell products and stem cell products); the Immunologic Monitoring and Cellular Products Laboratory (therapeutic cell product generation and banking of blood and tissues); the In Vivo Imaging Facility (MRI, PET, CT, optical, and ultrasound imaging); Investigational Drug Services (pharmacy procedures and processes); Tissue and Research Pathology Services (tissue and biological specimen procurement); and the Vector Facility (viral and non-viral vectors, cells, reagents, protocols, and technical assistance in AIDS cancer research).

Centers at UPCI include the Women's Cancer Research Center (WCRC), the Center for Environmental Oncology (CEO), and the Tumor Microenvironment Center (TMC). The WCRC is a collaboration between UPCI and the Magee Women's Research Institute (MWRI). Their mission is to reduce the incidence and number of deaths from women's cancers. The mission of the CEO is to protect public health and raise awareness regarding avoidable causes of cancer. They are committed to communicating the scientific evidence that links environmental exposures to cancer risks. The TMC is created by a collaboration between UPMC and UPCI. Preclinical and clinical scientists come together to translate basic knowledge of cancer cells' mechanisms of interaction and their microenvironment (i.e., immune, inflammatory, and patient-specific microenvironment factors).

UPCI researchers conduct laboratory-based, translational, and clinical cancer research in one (or more) of 11 UPCI programs. The Biobehavioral Oncology Program promotes innovative, interdisciplinary research on the role of the mind and brain in cancer. Goals include contributing to research that reduces the risk of cancer development, earlier detection, improved treatment response, reduced symptoms, and enhanced survival. The Breast and Ovarian Cancer Program personalizes prevention and treatment. Goals also include educating researchers, physicians, and the public about
advances in women's cancer and to train future women’s cancer researchers and physicians. The Cancer Epidemiology and Prevention Program promotes understanding the risk of cancer and innovative cancer prevention and control. Researchers are dedicated to identification, validation, and application of biomarkers, personal susceptibility, and early detection in relevant populations. The Cancer Immunology Program facilitates basic and translational research in immunoprevention, immunotherapy, and immunology. The Cancer Therapeutics Program develops innovative strategies for drug treatment of tumors and malignancies. The goal is to promote interactions along the continuum of basic, preclinical, and clinical research for novel approaches to drug treatment. The Cancer Virology Program seeks to identify and characterize cancer-causing viruses and to explore oncolytic viruses as treatment tools. The Head and Neck Cancer Program works to discover the biology of head and neck cancers and to design and implement new strategies to prevent, diagnose, and treat these cancers.

The Lung Cancer Program investigates the biology and genetics of lung cancer. Researchers work to improve the basic understanding of lung cancer and genetics and to apply this research. The Melanoma Program investigates cell biology and develops and implements new therapies. Goals include identifying and providing insight into the genes and proteins that play a role in melanoma. The Molecular and Cellular Cancer Biology Program researches the fundamental aspects of cancer cell biology. The goal is to make new discoveries about the cellular and molecular basis of cancer and cancer progression.

Further Readings

University of Southern California Norris Comprehensive Cancer Center
The USC Norris Comprehensive Cancer Center has 200 members who investigate the origins and progression of cancers while developing prevention strategies and searching for cures. USC Norris is part of the Keck School of Medicine and is designated a Comprehensive Cancer Center by the National Cancer Institute (NCI). The center’s mission is to personalize patient care, educate, and integrate research in an effort to eradicate cancer. USC Norris Comprehensive Cancer Center describes its vision as innovation in the cancer field by setting a global standard of research and accelerating all programs that prevent, treat, or cure cancer. The center has created an inclusive and engaging culture of collaboration that revolutionizes an interdisciplinary approach to the prevention and treatment of cancer.

For more than 35 years, USC Norris Comprehensive Cancer Center has been fighting against cancer. In 1971, Dr. G. Denman Hammond, a pediatric oncologist at Children’s Hospital Los Angeles, founded the USC Cancer Center. Between 1971 and 1983, the center received $2 million for facilities and $5.6 million for research. County general funds, federal appropriations, private donations, grants, and a capital campaign funded the $37 million needed for a 96-bed hospital and 125,000-square-foot research institute. Five years later, the need for expansion presented itself due to the growth of the center and its reputation for quality care. The Dr. Norman Topping Tower, name in honor of a great champion of the cancer center and USC’s seventh president, included outpatient facilities, laboratories, and offices, and was dedicated March 21, 1996. In 2009, USC purchased the Norris Cancer Hospital and the Keck Hospital, made possible from a $25 million gift from philanthropist Henrietta Lee. USC Cancer Center then became the USC Norris Comprehensive Cancer Center.

Research at the center is organized into five thematic programs and five translational research programs. The five thematic programs are: molecular genetics, epigenetics and regulation, tumor microenvironment, cancer epidemiology, and cancer control research. The five translational research programs are: genitourinary cancers, gastrointestinal cancers, women’s cancers, leukemia and lymphoma, and developmental therapeutics. Research members currently hold grants in excess of $134 million in direct costs, with $53 million funded by the NCI.

Patient care at USC Norris Comprehensive Cancer Center is comprehensive and performed at affiliated hospitals and outpatient clinics. The center conducts hundreds of clinical trials (research that involves volunteer patients). Current trials focus on testing new therapies; optimizing existing therapies; improving quality of life before, during, and after diagnosis; and discovering prevention methods. In June 2014, USC and NYU scientists developed a potential cancer-fighting compound. The researchers patented a molecule that interferes in cancer progression. Also in June 2014, researchers discovered that cycles of prolonged fasting help protect the immune system from damage that occurs during chemotherapy.

Supportive services available to researchers include: BioInformatics (provides management, mining, analysis, and visualization of biological information utilizing computational tools and methods); Bioreagent and Cell Culture (provides reagents for cell cultures and prepares bioreagents that are grown in the facility); Biostatistics (meets the statistical needs of researchers); Cell and Tissue Imaging; Clinical Investigations Support Office (assists in infrastructure of clinical research); Flow Cytometry (addresses questions in cellular immunology, biology, radiology, and mechanisms of drug
actions); Immune Monitoring (offers advice, technical support, and equipment); Cancer Research Informatics Core (provides custom programming and software support); Molecular and Cell Biology Support (provides supervision and maintenance of centralized shared equipment); Molecular Genomics; Small Animal Imaging; Transgenic/Knockout Rodent; and Translational Pathology (provides normal and tumor tissue specimens).

Patient care at the USC Norris Comprehensive Cancer Center is affiliated with several local hospitals. The Kenneth Norris Jr. Cancer Hospital is a 60-bed inpatient and outpatient facility that is devoted to cancer research and treatment. It has a laboratory-to-bedside structure that means patients receive innovative therapies and treatments. The Keck Hospital is a 401-bed research and teaching hospital. It is designed to be a comfortable facility for patients to receive advanced services, including: transplantation, bloodless surgery, neurosurgery, cardiac catheterization, and interventional cardiology. Three floors are dedicated to cancer care, and surgical specialties include: cardiothoracic, esophageal, orthopedic, and reconstructive surgeries. The Children's Hospital Los Angeles has cared for pediatric patients with cancer and blood diseases for more than 40 years. It is the largest pediatric oncology/hematology program in the United States. Programs include: leukemia, hematopoietic stem cell transplantation, neuroblastoma, bone and soft tissue tumors, brain tumors, retinoblastoma, hemophilia, and sickle cell disease. Children's Hospital Los Angeles also participates in the only nationally and internationally collaborative research network for childhood cancers, Children's Oncology Group. The Los Angeles County + USC Medical Center is one of the largest academic medical centers in the United States, serving more than 50,000 inpatients and 750,000 outpatients annually.

The future of USC Norris Comprehensive Cancer Center includes continued participation in major national and international efforts regarding cancer research. The Harlyne J. Norris Research Tower has been added and provides five new floors for basic research, two floors for research in preventive medicine, and a conference center. Children's Hospital Los Angeles has recently completed a seven-floor, 317-bed building for medical and surgical care. It has an ER, imaging facilities, a cancer day hospital, a 48-bed acute cancer care unit, and a 14-bed bone marrow transplant unit. New faculty members specialize in a variety of research, including: clinical trials and translational studies for breast cancer via a personalized and multidisciplinary approach; molecular genetic analysis of common malignancies (breast, colon, and prostate); genetic risk factors; AIDS-associated cancers; biology of stem cells; and cancer drug resistance.

Membership in the USC Norris Comprehensive Cancer Center is divided into three types: full membership, associate membership, and affiliate membership. Full membership is for faculty who have had peer-reviewed support for their cancer-focused research and national leaders of cancer-focused programs who meet the criteria for peer-reviewed support. Associate members have not yet achieved independent support for their research and are typically new recruits, junior level scientists, and physicians (who have not met criteria for peer-reviewed support). Affiliate members have a significant focus on cancer research or demonstrate an interest in cancer research and contribute to the center’s mission. All members participate in center meetings and membership is reviewed annually.

departments, and divisions that invest in clinical research, treatment, and public outreach. MDACC has had a rich history since its founding in 1941 and plays a role in the “War Against Cancer” declared by President Nixon in the National Cancer Act of 1971. MDACC’s extensive investment in a wide range of clinical and public health research has benefited the study of cancer and patients receiving cutting-edge care.

History
MDACC, located in the Texas Medical Center in Houston, Texas, was founded in 1941 and designated as one of the original three comprehensive cancer centers by the National Cancer Act of 1971. To meet federal requirements for comprehensive cancer center designation, MDACC maintains programs in laboratory, clinical, population-based, and transdisciplinary research. Comprehensive cancer centers must also sponsor professional and public educational outreach programs. The National Cancer Institute (NCI) Office of Cancer Centers is responsible for program designation and management.

The center adopted the current name in 1988, after going through four successive name changes. The previous names were Texas State Cancer Hospital and the Division of Cancer Research (1941), MD Anderson Hospital for Cancer Research of the University of Texas (1942), The University of Texas MD Anderson Hospital and Tumor Institute at Houston (1955), and The University of Texas System Cancer Center (1972).

Organization
MDACC is composed of six research institutes, 25 research centers, and 23 programs. The research institutes include: Duncan Family Institute for Prevention and Personalized Risk Reduction, Institute for Applied Cancer Science, Institute for Basic Science, Institute for Personalized Cancer Therapy, Institute for Cancer Care Innovation, and McCombs Institute for the Early Detection and Treatment of Cancer. There are over seven dozen additional departments and divisions that range from the Division of Anesthesiology and Critical Care to Veterinary Medicine and Surgery. There are approximately 50 labs that conduct basic and applied clinical research throughout the institution.

MDACC is based in the Texas Medical Center in Houston, Texas, but has additional locations throughout the state including: Bay Area, Katy, Sugar Land, The Woodlands, Bellaire, Memorial City, and Bastrop. MDACC also works with partner members at the Banner MD Anderson Cancer Center in Gilbert, Arizona, and MD Anderson Cancer Center at Cooper throughout New Jersey. Additional certified members and affiliates are spread throughout 11 U.S. states, Spain, and Istanbul.

Performance
MDACC is consistently ranked among the top cancer centers in the United States. MDACC was ranked “#1 Cancer Hospital” by U.S. News & World Report’s “Best Hospitals 2013–2014,” having been awarded the title 10 times since 2002. MDACC is also nationally ranked by U.S. News and World Report’s “Best Hospitals 2013–2014” in four specialties: ear, nose, and throat; gynecology; pediatrics; and urology. Additionally, MDACC’s specialties of geriatrics, nephrology, neurology and neurosurgery, orthopedics, and psychiatry are ranked as high performing. Professionally recognized leaders in medicine are among the hospital faculty and include seven members of the Institute of Medicine (IOM), two members of the National Academy of Sciences, and four fellows from the Academy of Arts and Sciences.

Staff Demographics
MDACC employs approximately 20,000 staff, including 1,700 faculty, 1,200 volunteers, and 6,500 trainees. The group of trainees is composed of physicians, residents, fellows, scientists, students, nurses, research trainees, and other health professionals. MDACC is among the 10 percent of medical colleges where faculty are required to reapply for tenure at the conclusion of seven-year term appointments. While tenure is traditionally reapproved in 92 percent of cases, most medical colleges do not require reapplication after full tenure has been awarded. These increasingly rare tenure practices have led to increased controversy in recent years. Nevertheless, MDACC is nationally ranked as a top company to work for by independent organizations such as the American Association of Retired Persons (AARP) and Glassdoor.

The 2014 MDACC staff demographics report indicates the following ethnic distribution: White (33 percent), Asian (26 percent), Black (25 percent), Hispanic (15 percent), and the remaining 1 percent
is categorized as mixed-race. Staff reported the following age demographics: born 1981 to 2000 (35 percent), born 1965 to 1980 (33 percent), born 1946 to 1964 (31 percent), and those born 1922 to 1945 (1 percent). Females represent 67.37 percent of all employees but only 38 percent of faculty; males represent 32.63 percent of all employees and 62 percent of faculty.

Patients, Research, and Finances
Since its first patient in 1944, MDACC has treated approximately 950,000 patients. Currently, approximately two-thirds of MDACC patients are from Texas, and one-third travel to Houston from outside the state to receive care. Those receiving inpatient treatments consistently rate MDACC highly on the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) survey.

As of 2013, there were approximately 7,500 patients enrolled in about 1,000 clinical trials throughout the hospital system. MDACC remains the highest dollar recipient of grant funding from the NCI. Clinical trials are designed and approved through the standard rigorous Institutional Review Board (IRB) processes with U.S. Food and Drug Administration (FDA) oversight. Additionally, NCI-funded grants typically result in research partnerships between awardees and NCI scientists. MDACC conducts clinical research throughout the clinical trials process from animal and lab studies through Phase IV review.

During fiscal year 2013 (FY13), MDACC reported approximately $4 billion in revenue. About 77 percent of revenue was composed of patient payments; 12 percent came from grants, contracts, and philanthropy; 3.5 percent came from state government appropriations; 4.5 percent was from investments, and 3 percent came from auxiliary or other income. MDACC has a daily operating cost of approximately $9 million dollars.

The 2012 to 2013 annual budget was set at approximately $3.5 billion. During FY13, MDACC delivered about $225 million of uncompensated care to Texas citizens who did not have health insurance or were underinsured. During FY13, MDACC treated approximately 120,000 patients, and this number is expected to rise in the future.

Further Readings

University of Virginia Cancer Center
The University of Virginia Cancer Center has two priorities: strengthening ties between its clinic and cancer research laboratories and achieving NCI (National Cancer Institute) designation as a comprehensive cancer center. The cancer center is state-of-the-art and offers outpatient oncology care at the Emily Couric Clinical Cancer Center. Goals include building upon its affiliation network throughout the state, recruiting key clinical leaders and basic scientists who focus on translational research, and developing a population research center in preparation for NCI comprehensive status. The center’s mission includes: discovery of the fundamental causes of cancer; development of knowledge to increase tools for cancer treatment, diagnosis, and prevention; delivery of the most innovative and compassionate care; and distribution of tools for cancer prevention, detection, and treatment.

The University of Virginia Cancer Center has a rich tradition in research and academic oncology care and is a regional leader in cancer prevention, education, and screening programs. The center is committed to its partnerships with referring physicians and exhibits this with prompt and frequent communication. Providing unique and comprehensive treatment and programs that support patients and their families is also a commitment.
The cancer research center includes 23 departments (schools of medicine, nursing, engineering, arts, and sciences) with more than 160 faculty members. It is a NCI-designated cancer center with more than $75 million in research annually. The goal of the center’s research is to understand, at the most basic of levels, how cancer arises, grows, and spreads. A second related goal is to utilize the knowledge to develop ways to prevent, detect, diagnose, and treat cancer.

The center’s faculty members are divided into five research programs. Each represents an area of expertise to understand how cancer begins and to detect, diagnose, treat, and prevent cancer. The five research programs are (1) the cancer cell-signaling program, (2) the chemical and structural biology program, (3) the immunology/immunotherapy program, (4) the molecular genetics and epigenetics program, and (5) the women’s oncology program.

The cancer center shares resources with the University of Virginia Health System. State-of-the-art instrumentation, scientific expertise, and technology offer distinct advantages to cancer center members. The cancer center members are able to express their individual interests and expertise to meet the needs of the research community. The following facilities are available to center members: advanced microscopic facility, biomolecular analysis facility, biorepository and tissue research facility, flow cytometry facility, gene targeting and transgenic facility, molecular assessments and preclinical studies core facility, preclinical tumor analysis and imaging, biostatistics shared resource, office for clinical research, and the office of research core administration.

The University of Virginia Cancer Center treats people and their families through a unique, illness-specific, team approach. Cancer care teams were first created in 1995, made up of pathologists, surgeons, researchers, radiologists, and other health professionals. Each team is aware of the medical, physical, spiritual, emotional, and social needs of patients and their families. Each team is available to whatever extent the patient and/or family needs.

Team members typically consist of nurses, doctors, palliative care doctors, social workers, nutritionists, clergy, patient educators, the patient, and someone the patient designates to be a primary support. The primary support person can attend appointments to think of questions to ask, offer support, and help the patient remember what is said. Nurses can answer questions about care and provide advice; they are a good resource for educational materials and information. Doctors provide specialized care and any of the following may be present on the team: a surgical oncologist is a specialist who will provide expertise about surgical removal, if appropriate; a medical oncologist specializes in medicines used to treat the whole body in cases where cancer has spread; a radiation oncologist specializes in the use of radiation to treat cancer; a reconstruction surgeon specializes in reconstructing areas of the body affected by cancer treatment, typically by surgery; and a palliative care doctor specializes in managing side effects from treatment. Social workers who specialize in oncology are also members of the team, as are nutritionists who help ensure vitamin, protein, and calorie intakes are at optimum levels during treatment. Prayer and spiritual counseling may be useful for patients or families, therefore clergy are often members of the team. Finally, a patient educator can help with information prior to, during, and after treatment for the patient and family.

The center advocates for early detection and prevention as the best defenses against cancer. Cancer discovered in the first or second stage has an 80 to 90 percent survival rate at five years follow-up. The center sponsors and participates in programs that promote screening and education in the community at health fairs and other events. The center offers annual skin cancer screenings, as well as other screenings throughout the year.

The center also offers advice regarding risk factors under an individual’s control. For example, diet and exercise are important, as being overweight increases the risk for several types of cancer: breast, colon, prostate, esophageal, endometrial, and kidney cancers. Never smoking or smoking cessation also decreases the risk of smoking-related cancers. Smoking is related to at least 10 kinds of cancers and accounts for at least 30 percent of cancer deaths. Finally, exposure to the sun is another risk factor under an individual’s control. Skin cancer is the most common cancer and is diagnosed in more than one million people each year. Sunscreen and avoiding the sun during peak times (10 a.m. to 3 p.m.) can decrease the risks associated with sun exposure.

University of Wisconsin Carbone Cancer Center

The University of Wisconsin Carbone Cancer Center (UWCCC) is an integrated, collaborative center with a rich history in cancer research, education, and treatment. Beginning with the establishment of the McArdle Laboratory for Cancer Research at the University of Wisconsin, the university subsequently started the University of Wisconsin Clinical Cancer Center. The two facilities were combined in 1973 as the University of Wisconsin Comprehensive Cancer Center. In 2006, the center was renamed the University of Wisconsin Carbone Cancer Center for Dr. Paul P. Carbone, who served as director of the center from 1978 until 1997. The center now employs more than 2,400 staff, including 280 doctors and scientists, and sees over 30,000 patients per year. Spanning a period of over 70 years, the center has evolved into a facility at the forefront of cancer research and treatment.

The McArdle Laboratory for Cancer Research, funded largely by the donations of private area residents, was established during the 1940s as the first basic science cancer center at an academic institution in the United States. The cancer research program was created by Dr. Harold P. Rusch, the first director of the McArdle Laboratory. Dr. Rusch remained as director until 1972, and did much to solidify the laboratory’s prominence, chiefly by selecting a number of talented young scientists whose work helped gain the laboratory its international standing as a premiere institution for cancer research. Much of the early research conducted at the McArdle Laboratory focused on chemical carcinogenesis, that is, potential chemical causes of cancer, and how these chemicals created genetic changes in cells, resulting in cancer. Scientists also initially concentrated on the biochemistry of malignant cells, particularly focusing on the differences between cancer cells and healthy cells.

In 1951, Dr. Charles Heidelberger began the process of synthesizing and clinically developing 5-fluorouracil (5-FU), a drug used to this day in the treatment of basal-cell carcinoma, pancreatic cancer, breast cancer, rectal cancer, colon cancer, head and neck cancer, and stomach cancer. Dr. Heidelberger received a patent for the drug in 1959. 5-fluorouracil is on the World Health Organization’s List of Essential Medicines. In 1975, Dr. Howard Temin was awarded the Nobel Prize in Physiology and Medicine, along with Drs. David Baltimore and Renato Dulbecco, for the discovery of reverse transcriptase. His experiments provided evidence of the ability of retroviruses to perform DNA synthesis from RNA within cells, and led to a flurry of research into retroviruses. Dr. Temin was subsequently appointed to the national committee whose work formed the basis of the bill that became the National Cancer Act, signed into law by former president Richard Nixon.

In the 1970s, the center began conducting Phase I trials, that is, trials involving a very small number of participants in order to determine the safety, dose range, and side effects of a treatment. Phase I trials are the first step in evaluating, researching, and approving a drug for treatment. In 1973, the same year that the University of Wisconsin Carbone Cancer Center was formed, the center also received the National Cancer Institute (NCI) designation as a comprehensive facility, one of only six in the United States. To date, the center is the only comprehensive cancer center in Wisconsin. A total of 41 of the 68 NCI-designated cancer centers in the United States are comprehensive cancer centers. In order to gain
the title of comprehensive cancer center, the highest ranking given by the NCI, a facility must meet and adhere to specific guidelines. These include a strong basis in laboratory and clinical cancer research, along with translational research, which is the practical application of research findings. Additionally, the center must offer cutting-edge cancer treatments involving clinical trials, cancer prevention and control programs, training and instruction of health care staff, cancer information services, and community outreach and instruction.

Toward this end, the UWCCC is involved in a number of programs and research areas, not only to continue to meet the rigorous guidelines set forth by the NCI, but also to provide the best care possible for its patients. The center treats an array of cancers and related issues, from breast cancer, head and neck cancer, and lymphoma, to pediatric hematology and oncology. It also provides ancillary care including genetic counseling, integrative medicine, palliative care medicine, and psychology, social work, and spiritual care. Research scientists, academic faculty, and physicians collaborate across eight different research programs: cancer control, cancer genetics, chemoprevention, experimental therapeutics, human cancer virology, imaging and radiation sciences, nuclear signaling, and tumor microenvironment. More than 250 clinical trials are open to patient accrual in a wide variety of areas.

UWCCC is also involved in research involving outside facilities. The Wisconsin Oncology Network (WON) is one example. WON provides the opportunity for patients being treated at approved community treatment centers in Wisconsin and northern Illinois to enroll in certain clinical trials run by the UWCCC. The UWCC is also a member of the Wisconsin Network for Health Research, another similar network that promotes collaboration with researchers at other facilities throughout Wisconsin. With regard to cancer prevention and control, the UWCCC collaborates with the University of Wisconsin Center for Tobacco Research and Intervention (UW-CTRI).

UW-CTRI conducts tobacco research that is applied to tobacco treatment in health care clinics throughout Wisconsin. UWCCC is also a member of the Wisconsin Comprehensive Cancer Control Program. This program focuses on coordinating the efforts of public, private, and community-member institutions in order to facilitate a statewide method to best control cancer.

Additionally, UWCCC partners with two minority outreach programs. The first is the Partnerships with Underserved/Minority Populations, a program that uses established principles of community-based research to support successful research with its population of subjects. The project is investigating community preparedness for change and assessing quality cancer care in eight underserved communities. The second outreach program, the Spirit of Eagles, works to prevent and control cancer, and use research findings to improve health outcomes in American Indian/Alaska Native populations in Wisconsin. Since the program’s creation in 2000, the UWCCC has been a principle partner and subcontractor.

Unknown Primary Site, Cancer of, Childhood

Cancer of unknown primary (CUP) is quite rare in children, representing less than 1 percent of solid tumors. CUPs are, by definition, metastatic cancers in which a primary tumor cannot be identified after routine workup. Thus, these tumors are unique in that they represent a failure to reach a conclusive diagnosis. This raises a number of issues for
the treating doctors and the patient's family. First, there is the perception that the diagnostic workup may have been deficient, which compounds the emotional suffering that the family will feel upon receiving the diagnosis. The idea that a child has a “hidden cancer” is troubling to both the family and the clinician. A second related issue is the question of just how far should doctors go in trying to locate the primary tumor. In patients who have a poor general condition and are unable to tolerate any proposed therapy, the value of extensive investigations is questionable.

The median age of diagnosis is about 8 years old. It affects boys and girls in approximately equal proportions. Cancer registry data are imprecise because of variations in the definition of CUP between countries, and even between studies. Accordingly, it is difficult to draw any meaningful conclusions regarding geographic differences in incidence. CUP is, however, a worldwide phenomenon, and the incidence appears to be falling, probably because of improved diagnostic methods. Because of the extreme heterogeneity of CUPs, it is not possible to identify risk factors or possible causes for their development. Symptoms often include general nonspecific complaints, such as generalized malaise, nausea, loss of appetite, and loss of weight or a failure to thrive (i.e., the child does not gain weight as expected). Symptoms from metastases may include lumps in the neck, armpit, or groin; pain; shortness of breath; and neurological complaints. On examination, there may be abdominal swelling from enlargement of the liver or ascites (fluid in the abdomen), anemia, jaundice, chest sign, and neurological signs.

A routine workup must already have been undertaken before the diagnosis of CUP is made. This will include a thorough medical history and physical examination of the patient. Furthermore, a tissue biopsy of the metastatic tumor must be obtained. Additional investigations will typically include routine blood counts, assessment of liver and kidney function, and urine and stool tests. Some form of imaging, such as a computerized tomography (CT) scan of the chest, abdomen, and pelvis will also have been performed. More sophisticated tests are carried out according to the clinical scenario. These tests may include gastrointestinal endoscopy and a thorough ear, nose, and throat (ENT) examination, including nasal and laryngeal endoscopy. Specialized scans, such as positron emission tomography (PET), are especially useful in locating head and neck tumors. Tumor markers, such as alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (beta-HCG), may be very useful in identifying primary liver cancers such as hepatoblastoma and hepatocellular carcinoma. B-HCG is also extremely useful in identifying possible germ cell tumors (tumors that arise from primitive embryonal cells). Urinary catecholamines are useful to identify neuroblastoma.

New molecular profiling techniques have reportedly been able to assign a tumor type to 60 to 85 percent of CUP tumors in adults. However, few studies have been performed to assess the validity of these diagnostic techniques in the pediatric population. Nonetheless, these advanced molecular profiling methods are likely to revolutionize the workup of CUP. Whether that translates to an improvement in patient outcomes remains to be seen. Depending on pathological findings, CUP is classified into several types. These types differ in the basic tissue type, for example adenocarcinoma, or squamous cell carcinoma, or germ cell tumors. Adenocarcinomas are cancers where the cells resemble glandular cells, squamous carcinomas have cells that resemble skin cells, and germ cell tumors have primitive cells that resemble those found in embryos.

Tumors that are more common in the pediatric population, such as melanoma, lymphoma, and embryonal tumors, are more frequently seen in CUP biopsies. Data is limited regarding the exact proportions, but according to one study, embryonal tumors are the predominant cancer type. Embryonal tumors arise from primitive cells that are seen during the development of the human embryo. Examples of embryonal tumors that are seen in CUP are rhabdomyosarcoma, neuroblastoma, and Ewing's sarcoma. Chemotherapy and radiotherapy are the primary modalities of treatment. Treatment depends on the histological type of tumor, the extent of disease, and the age of the patient. Embryonal tumors are mostly sensitive to chemotherapy, and even metastatic embryonal tumors can sometimes be cured with chemotherapy. Thus, treatment is often begun upon confirmation of the histology, without embarking on an exhaustive search for the primary tumor.

In some situations, where it is anticipated that radiotherapy will be useful, it is important to localize all tumor sites so that they may targeted by radiotherapy. Sometimes, if the primary site cannot
be found, a strategy of aggressive local control of the metastases is employed (using chemotherapy, local radiotherapy, and even surgery). This is then followed by a period of careful observation to detect the primary tumor, should it become apparent at a later stage. The prognosis of CUP is slightly better in children than it is in adults because of the relatively larger number of chemo-responsive tumors, such as lymphomas and germ cell tumors, which are more common in children. A five-year relative survival rate of 17 percent has been noted.

CUP is a failure to diagnose the primary underlying tumor, thus the chance of suboptimal therapy being administered is substantial. Additional work needs to be done to develop better diagnostic modalities, such as genetic profiling techniques, to further reduce the number of CUPs. More work also needs to be done to elucidate the underlying biologic mechanisms that drive these aggressive tumors.

Further Readings
Carcinoma of unknown primary (CUP) represents about 3 percent of all cancers in adults. By definition, a carcinoma of unknown primary is a tumor that has spread from an original primary tumor, but routine investigations fail to reveal the site of the primary cancer. A diagnosis of CUP often generates a great deal of anxiety among both patient and doctor because it represents a failure to fully diagnose the cancer. The metastatic nature of the tumor, coupled with the generally poor condition of the patient, only adds to the stress. Moreover, a real diagnostic and ethical dilemma exists as to how far a diagnostic workup should be taken. In the United States, CUP represents 2 percent of all cancers. Internationally, the figure is about 3 to 5 percent. The median age at diagnosis is around 60 years old. There is no significant difference in incidence between men and women. As diagnostic techniques have improved over the years, the incidence of CUP has fallen, and this trend is expected to continue. Because CUPs are an extremely heterogeneous group, it is not possible to identify risk factors or specific causes for their development.

CUPs are generally aggressive tumors that show a propensity for early spread. In fact, they usually present with more than one site of metastasis. Additionally, the pattern of spread is often unusual. For example, metastatic prostate cancer with a known primary typically spreads to bone. However, when it presents as CUP, it tends to spread to the liver or lung. Patients usually present with nonspecific symptoms such as loss of appetite, loss of weight, nausea, and fatigue. Other symptoms are from the metastases and may include a lump in the neck, throat, armpit, or groin; bone pain or fracture; vomiting; and neurological complaints (e.g., weakness, double vision, headache, and convulsions). Physical examination may reveal ascites (fluid in the abdomen) or an enlarged liver. Anemia, jaundice, and enlarged lymph nodes may also be noted. Workup usually includes a biopsy (which proves that there is a malignancy), routine blood, urine and stool tests, a chest x-ray, and a computerized tomography (CT) scan of the abdomen and pelvis.

Once this routine workup fails to reveal the primary site, a diagnosis of carcinoma of unknown primary can be made. Doctors (and patients) are then faced with the ethical question of how far to pursue the diagnostic workup. Several studies have shown that exhaustive investigations yield only minimal benefit in terms of overall survival improvement, at a huge cost. Furthermore, patients have metastatic disease and are often weak and frail. The usefulness of such extensive investigations in patients who are unlikely to be fit enough to receive aggressive chemotherapy is debatable. Moreover, even after extensive investigations, a primary tumor is found in only about 20 to 30 percent of patients. Nonetheless, an extensive workup is usually undertaken in patients who have better general health. The aim of the workup is to select the minority (about 15 percent) of patients who may have a better prognosis. This extended workup relies on clinical suspicion as to the likely location of the primary. It may include a positron emission tomography (PET) scan, gastrointestinal endoscopy (upper and lower), panendoscopy of the upper airways, and tumor markers.

The pathologic examination is the cornerstone of the workup in CUP. The pathologist will typically use several techniques to gather more information, beginning with light microscopy, which may give basic information about the cell type and the degree of differentiation (resemblance to normal cells). However, this is unlikely to be sufficient to make a diagnosis. Other more sophisticated techniques such as immunohistochemistry (antibodies to certain cell components are used to verify the presence of these cellular components in the sample), electron microscopy, and chromosomal analysis are often used, but may fail to provide a conclusive diagnosis. A far more promising technique is molecular genetic profiling (DNA fingerprinting), to match the sample to known genetic profiles of various cancers. According to some studies, these genetic profiling techniques have succeeded in identifying a tumor type in 75 to 85 percent of cases of CUP. Whether identification of the primary cancer will actually lead
to an improvement in overall survival for patients remains to be seen.

After routine pathologic examination, CUP is usually divided into five subgroups, based on the general type of cell and the degree of differentiation (the degree of resemblance to normal tissue). The first group is moderate or well-differentiated adenocarcinoma (cancer that arises from glandular tissue). The second group is poorly differentiated carcinoma, with or without features of adenocarcinoma. The third group is squamous cell carcinoma (cancer cells resemble normal skin cells). The fourth group is neuroendocrine carcinoma (cancer cells are similar to nerve and hormone-secreting cells). The fifth group is undifferentiated neoplasm (cells that are so unusual that no determination of the cell type can be made). The pathological data are coupled with clinical data to place the patient in a defined clinicopathological group. These groups or subsets are known to have different outcomes to the usual (rather dismal) outcome seen in most patients.

The treatment of CUP depends on whether a patient belongs to one of these favorable subsets or not. If a patient belongs to a favorable subset, then specific therapy can be given. However, if the patient does not belong in one of these favorable subsets, a generic treatment approach is taken with the aim of palliation only. Examples of favorable subsets include women with axillary lymph nodes (i.e., lymph node enlargement under the arm) and adenocarcinoma histology (similar to breast cancer). These women are presumed to have an occult breast cancer, and are treated accordingly. Similarly, men with high prostate-specific antigen (PSA) and typical bone metastases are treated as prostate cancer. For patients who do not fall into these favorable subsets, chemotherapy is given blindly for palliation. Chemotherapy agents that are often used include cisplatin, carboplatin, paclitaxel, docetaxel, 5-fluorouracil, etoposide, and gemcitabine.

The overall prognosis of CUP is very poor, with median survival of 6 to 10 months in favorable subsets, and 3 to 4 months in the unfavorable subset. One-year survival is around 15 percent, and five-year survival is only about 5 percent. There is a need for better diagnostic modalities to identify the primary tumor so that specific therapy can be given. In addition, progress needs to be made to understand the underlying molecular biology of these tumors, which may harbor different biological mechanisms to their metastatic counterparts.

Unusual Cancers of Childhood

Cancer among children was a rare occurrence in the past; however, the incidence of childhood cancer has increased in the last four decades. In the United States, cancer is the second-largest cause of mortality in children, after accidental injuries. An estimated 175,000 children develop cancer globally every year, and around 96,000 of these children do not survive. In 2010, the most commonly diagnosed cancers in the age group 0 to 19 were leukemia and brain and central nervous system cancer.
Prevalence of Childhood Cancer

In developed countries, around 0.5 percent of all cancers occur among children under 15 years. Whereas most adult cancers are carcinomas, cancers in children are varied and are classified based on histology. The International Classification of Childhood Cancer has identified common forms of cancer among children. The 12 major groups are leukemias, lymphomas, brain and spinal tumors, sympathetic nervous system tumors, retinoblastomas, kidney tumors, liver tumors, bone tumors, soft-tissue sarcomas, gonadal and germ-cell tumors, epithelial tumors, and other and unspecified malignant neoplasms.

Childhood cancer is a result of genetic alteration, possibly in utero, as studies on concordance between identical twins have confirmed. Besides the genetic factors familial aggregations have been studied that is the likelihood of one siblings suffering from cancer also increases the risk of cancer in the other sibling. Genetic syndromes such as Li-Fraumeni syndrome, neurofibromatosis, and Gorlin-cell syndrome are linked to childhood cancer. Children with Down's syndrome are more likely to have cancer. Retinoblastomas (a type of eye cancer) are caused by a faulty gene. The high incidence of certain childhood cancers in some regions of the world is linked with infections by viruses such as Epstein-Barr, hepatitis B, and human herpes virus 8.

Environmental factors shaping childhood cancer include exposure to prenatal obstetric irradiation; this factor was discovered almost 45 years ago, and the reduced use of diagnostic X-rays in pregnancy may have decreased the prevalence of cancer. Other factors include high levels of radiation; children who have undergone chemotherapy or radiation are more likely to develop cancer a second time. There is inconclusive evidence whether the exposure to ultrasound during pregnancy, exposure to magnetic field from power lines, use of pesticides, and occupational exposure of parents could lead to childhood cancer. Smoking habits of the father more than the mother increases the risk of a child to cancer. Little evidence exists on the relationship between viruses and childhood cancer.

There is considerable variation in the incidence of different types of childhood cancer in different regions of the world, and between ethnic groups in the same country. In some instances, a higher-than-average incidence of cancer can be easily explained: the high incidence of Kaposi's sarcoma in central and East Africa, for example, is related to the AIDS epidemic; the high incidence of thyroid carcinoma in Belarus is a result of the Chernobyl nuclear disaster. However, explanations for other differences in incidence are less clear: Why is the incidence of acute lymphoblastic leukemia (ALL) lower in developing countries? Why are children in developing countries at higher risk of retinoblastoma and Hodgkin's disease? Why do black children in the United States (but not in the United Kingdom) have a lower incidence of ALL than white children? Why is there a lower incidence of rhabdomyosarcoma among children in South and East Asia, as well as among Asian children in the United Kingdom, compared with white children?

Various tests and procedures are used for diagnosing cancer, such as a physical examination and learning the child's medical history. The study of blood chemistry includes testing of a blood sample to measure the substances being released into the blood by organs and tissues. Biopsy includes removal of cells or tissues so that they can be viewed under the microscope by the pathologist for cancerous cells. X-rays send an energy beam through the body. CT (computed tomography) scans produce detailed pictures of areas of the body taken from various angles. PET (positron emission tomography) scans use a radioactive substance called a tracer to find malignant tumor cells in the body. MRI (magnetic resonance imaging) uses a magnet and radio waves to give detailed pictures of the body from inside. An ultrasound exam is a procedure involving high-energy sound waves that generate internal pictures of the body.

Children who are suffering from symptoms are usually diagnosed by a pediatrician, a pediatric oncologist, or a pediatric hematologist who treats blood disorders. The treatment for childhood cancer includes a synthesis of surgery, radiation, and chemotherapy, depending on the type and stage of cancer. Treatment should be a coordinated effort by a team of doctors, nurses, and social workers. Because childhood cancers are uncommon, the outcomes are likely to be more successful if managed by specialized children's centers.

Cancer treatment in children can affect puberty and fertility, the heart, and lungs; cause hearing loss, kidney problems, intellectual development,
and education problems; and cause a second cancer. For young children, being away from family and friends can be difficult to cope with, and they might become clingy, argumentative, or difficult. Managing the situation with equanimity is important, along with maintaining the regular discipline. Treatment could cause weight loss or gain or hair loss, which might adversely impact the self-esteem of the child. Parents play an important role in keeping the child’s self-esteem intact. The British Childhood Cancer Survivor Study (BCCSS) is the first national population-based study of survivors of childhood cancer to be undertaken in Britain, assessing a wide spectrum of possible adverse health outcomes of childhood cancer and its treatment.

Further Readings

Ureter and Renal Pelvis, Transitional Cell Cancer

The ureter is a long tube connecting the kidney to the urinary bladder, and the upper part of the ureter is called the renal pelvis. The kidneys are responsible for the removal of wastes from the blood, collecting it in the form of urine. The urine collects in the renal pelvis, in the middle of each kidney, and is drained out of the body, passing through the ureter into the bladder, and finally exiting through the urethra. The renal pelvis and ureter is lined with specialized cells called transitional cells, which have an ability to be stretched and change shape depending on the bladder pressure, without any damage to the cells. Transitional cell cancer (TCC) is initiated in these cells, and TCC can affect the renal pelvis, or the ureter, or both. Tumors of the renal pelvis and ureter (upper urinary tract) are relatively rare. TCC of the renal pelvis accounts for only 10 percent of all urinary tract TCCs, whereas TCC of the ureter accounts for less than 2 percent of all TCCs of the urinary tract. TCC accounts for more than 90 to 95 percent of tumors of the upper urinary tract. Although the causes of TCC are unknown, the occurrence is higher in males, and environmental irritants are believed to play an important role in the development of the disease. Arsenic contamination in drinking water has been associated with the increased risk of developing TCC of the ureter and renal pelvis.

Symptoms associated with TCC include blood in the urine, back pain and pain between the lower ribs and hip bone, weight loss, and painful and frequent passage of urine. TCC may remain asymptomatic. Cysts may be discovered on the renal pelvis or ureter during imaging, often performed for other reasons. Once a cyst is discovered, urine cytology and urine analysis may be performed, along with a biopsy for further evaluation. A computerized tomographic (CT) scan or magnetic resonance imaging (MRI) may be recommended to evaluate the lesions, along with the recommendation of ureteroscopy, where a
thin flexible tube is inserted into the urethral opening up to the urinary bladder. Ureteroscopy allows the physician to view the cells lining the ureter and the renal pelvis for the presence of any lesions and cysts. The process also allows for quantitation of the number of lesions, and a section of the lesions or cysts may be removed to conduct a biopsy and gradation of the tumor.

TCC is classified into five stages, 0 through IV. During Stage 0, cancer cells are detected and remain localized to the transitional cells lining the ureter or the renal pelvis. In Stage I, cancerous cells spread to the underlying cellular layers. Once the cancer cells have spread to the surrounding muscle tissue, the cancer is classified as Stage III. In Stage III, the cancer cells may also invade the prostate gland in men, and the uterus in women. TCC is classified as Stage IV when the cancer cells invade the abdominal cavity and metastasize to the lymph nodes, followed by invasion into the blood stream. Abuse of medications for relieving pain, also called nephropathy, is considered a potential risk factor for the development of TCC of the ureter and renal pelvis. Certain occupations involving the exposure to a class of chemical compounds known as aromatic amines in the textile and leather industry and the plastics industry are also associated with an increased risk of development of TCC of the ureter and renal pelvis. Another common potential risk factor is smoking.

Nitrites and nitrates have also been associated with the risk of development of TCC of the renal pelvis and ureter. Certain genetic polymorphisms in high-risk individuals are implicated in the increased risk of cancer development when exposed to certain chemicals. Other than the above, chronic irritants such as catheters and recurrent infections of the urinary tract also increase the risk of development of TCC of the ureter and renal pelvis. Treatment of TCC of the renal pelvis and ureter is largely dependent on the individual case and stage of cancer. Kidney function and the presence of other conditions such as high blood pressure and diabetes are important factors determining the course of treatment. Low-grade localized tumors may be treated with specialized ureteroscopy to destroy cancer tissue. This is a minimally invasive technique, and does not involve surgery. Nephrostomy, involving the insertion of a thin tube into the kidney from the posterior end, may be performed for tumors that are larger in size. High-grade TCC of Stage III and above may involve the removal of an entire affected kidney and ureter via a procedure called nephroureterectomy. The procedure may be extended to remove associated lymph nodes in order to improve the prognosis and improve patient survival. Earlier detection of TCC results in better survival of the patient, with a five-year survival rate of 85 percent. However, most TCC of the renal pelvis and ureter are diagnosed at later stages, once they have spread beyond the site of origin.

Further Readings

Urethral Cancer

The urethra is present in both males and females and functions to connect the bladder to the outside of the body. Cancers arising from the urethra may be of multiple histologic subtypes, including squamous cell, urothelial cell, and adenocarcinoma. Treatments depend largely on location and stage of the tumor, and range from surgical resection in early disease to chemotherapy and radiation in more advanced cases. While cancers of the urethra account for only a small minority of cancers of the urinary tract, it is important for clinicians
and patients alike to be aware of the early symptoms, as advanced disease is associated with a poor prognosis.

Urethral cancers are malignant tumors that arise from the cells that line the urethra, the tube that carries urine (and also semen in men) from the bladder to the external environment. These cancers are exceedingly rare, accounting for less than 1 percent of all malignancies of the urinary tract. They occur at a rate of 4.3 per million men and 1.5 per million women. Due to the paucity of cases worldwide, the epidemiologic data is largely inconsistent between studies. As with many cancers, there is a direct correlation between incidence and age, with the mean age of presentation in men occurring at 60 years of age. In most studies in the United States, this cancer tends to favor African American race and male gender.

Risk factors for development of urethral cancers are generally associated with long-term irritation and inflammation of the urethra. A large proportion of patients have a history of urethritis (inflammation of the urethra typically caused by infection), urethral strictures, prior urethral surgery, trauma, or urethral diverticula in women (an out-pouching of the wall of the urethra). Additionally, human papilloma virus (HPV), the virus responsible for cervical cancer, has been found in the squamous cell variants of urethral cancers. There is also an increased incidence in patients with history of other sexually transmitted illnesses and other cancers of the urinary tract, including bladder and ureter. Chronic exposure to arsenic (typically found in water sources) has also been shown to increase risk of urethral cancer. No hereditary component has been identified in these cancers.

The major histologic subtypes of urethral cancer include squamous cell carcinoma, urothelial cell carcinoma (formerly known as transitional cell carcinoma), and adenocarcinoma. Most data suggest that the most common subtype is squamous cell carcinoma; however, some studies indicate urothelial cell carcinomas are more common. In rare cases, melanomas, lymphomas, and small cell carcinomas have also been reported to arise as primary urethral tumors. Anatomically, urothelial cell carcinomas and adenocarcinomas tend to arise in the proximal urethra (the portion closer to the bladder), while squamous cell carcinomas arise more often in the distal urethra. In men, tumors most commonly occur in the bulbomembranous urethra, that is, the portion of the urethra between the prostate and the penis.

Clinically, male patients most often present with symptoms of urine outflow obstruction. This may manifest as difficulty initiating urination, weak stream, or urinary retention. Other common symptoms include bloody urine, bloody or pus-filled discharge from the urethra, painful urination, and the presence of a lump in the penis. Men may infrequently present with swelling of the genitals and bloody ejaculate. Female patients more often present with symptoms resembling urinary tract infection, including painful urination, bloody urine, and increased urinary frequency. Less commonly, women may experience painful intercourse, a urethrovaginal fistula (a connection between urethra and vagina), and rectal pressure.

Diagnosis of urethral cancer requires a high index of suspicion, as presenting symptoms can easily be confused with other pathologies. Cytological evaluation of a urine specimen has relatively low sensitivity, and suspicious results must be confirmed by biopsy. Approaches should begin with cystourethroscopy and retrograde urethrography. Following diagnosis, an MRI is frequently used to determine the extent of local invasion. A CT scan is then utilized for assessment of distant metastases. Urethral cancer tends to spread locally into nearby soft tissues. At the time of diagnosis, a majority of patients will have locally invasive disease, whereas approximately 10 percent will have distant metastases. Metastasis occurs via lymphatics, with the most common sites being the lungs, bone, and liver. Cancers arising in the distal urethra are often diagnosed earlier and therefore have a more favorable prognosis than those of the proximal urethra, due in large part to earlier clinical presentation.

Treatment options are based on extent of local disease, presence of distant metastases, and location within the urethra. Surgical resection is the mainstay of treatment for anterior urethral tumors. Although outcomes data are limited, surgical resection for tumors of early stage offers good local treatment, with greater than 70 percent five-year survival rates. Several approaches to resection may be used, including transurethral resection, segmental urethral resection, or penectomy (removal of all or part of the penis) in men. Potential adverse
Endometrial cancer is the fourth-most-common cancer and the seventh-most-common cause of cancer death for women in the United States. Uterine cancer affects Caucasian women in higher proportions than black women; however black women are more likely to die from the disease, according to the American Cancer Society.

There are two primary types of uterine cancer: sarcomas and endometrial. Sarcomas are considered rare and more dangerous than endometrial cancer. Sarcomas arise from the muscles and supporting tissues of the uterus and are generally separated into three categories. The first, endometrial stromal sarcoma, is found in the supporting connective tissue of the uterus (stroma) and the endometrium. This form of cancer occurs in less than one percent of uterine cancers and is considered low grade (cancer cells appear closer to normal and tend to grow slowly).

The prognosis tends to be better than other uterine sarcomas. Undifferentiated sarcoma is a type of endometrial stromal sarcoma that is the most aggressive, also affecting less than one percent of females with uterine cancers, and is associated with poor clinical outcomes. Uterine leiomyosarcomas begin in the muscular wall of the uterus (myometrium), and they affect approximately two percent of women diagnosed with uterine cancer.

Endometrial cancer is considered more common than sarcomas and generally affects women....
aged 55 and older. Approximately 600,000 women are survivors of this type of cancer. Endometrial cancers begin in the cells that line the uterus and are mostly formed in the endometrium. The most common type is known as endometrioid adenocarcinoma (endometrioid), constituting 75 to 80 percent of all cases of endometrial cancer, and the less common types include squamous cell and undifferentiated carcinoma. The less common types are considered to be more aggressive and have poorer responses to treatment. Endometrioid cancer is divided into three grades, depending upon the similarity between cancer glands and normal healthy glands; the lower grade appears in glandular form, and the higher grade appears in a disorganized manner and not having a gland form. Grade 1 tumors have 95 percent or more of the cancerous-tissue forming glands, while grade 2 tumors have 50 to 94 percent; grade 3 tumors have 49 percent and below. Grades 1 and 2 tumors are identified as “type 1” endometrial cancers and are believed to be a result of excess estrogen, are less aggressive, and are slow to spread to other tissues. The high-grade tumors tend to be most aggressive and have poorer prognosis than grades 1 and 2 because it is believed that they are not caused by excess estrogen and are more likely to grow and spread outside the uterus.

**Treatment Options**

Treatment of uterine cancers, particularly endometrial forms, can range from surgery to radiation and chemotherapy, depending upon the severity and location of the lesion. Abnormal postmenopausal bleeding is the primary symptom that is most associated with type 1 endometrial cancer. If the cancer is primarily found in the uterine region and has not metastasized to other areas, then standard treatment involves total hysterectomy and bilateral salpingo-oophorectomy (TH/BSO). In some practices a pelvic/para-aortic lymphadenectomy, which involves the removal of the pelvis and the para-aortic lymph nodes, would be considered; however, the reliability of results are a point of debate.

There is evidence that the lymphadenectomy may increase the risk of lymphoedema with no added benefits. In a randomized trial conducted by National Cancer Research Institute (NCRI) and Medical Research Council (MRC) in the United Kingdom, females who underwent lymphadenectomy and adjuvant external beam radiotherapy (RT) had no increase in survival rates, so implementing it as a routine procedure was not considered therapeutically adequate.

Higher-grade cancers that spread further than the uterus can involve other forms of surgical treatment, including radical total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH/BSO) and possible pelvic/para-aortic lymphadenectomy dissection, particularly if the cancer is in the cervical area. For those with intra-abdominal disease that involves the omental, nodal, ovarian, peritoneal, and ascites areas, treatment options such as TAH/BSO and maximal surgical debulking are considered. Those with metastatic disease involving the liver and lungs would be considered for palliative hysterectomy. Females with inoperable type 1 or 2 endometrial cancers may be treated with RT and/or brachytherapy (BT).

Black females diagnosed with uterine cancer and other chronic medical illnesses, such as diabetes or hypertension, are likely to be diagnosed later and less likely to have surgery. Radiation therapy is a primary treatment for black females with diabetes, and although chemotherapy is less utilized as a form of treatment for uterine cancer, it is more frequently used than surgery among some populations. Hormone replacement therapy has also been used to treat uterine cancer. According to a study that assessed 219 patients who underwent surgical staging, it was noted that blacks, who were less likely to use hormone replacement therapy, which was known to prolong the interval between the onset of symptoms and surgery, presented with higher prevalence of unfavorable features, even after controlling for hormone use.

**Health Disparities**

Health disparities exist in the diagnosis, treatment, and survival of women with uterine cancer. Black women tend to be diagnosed at later stages, have higher grades of uterine cancer, and have less favorable survival rates than their white counterparts.

Some researchers have begun to question if the presence of comorbid diseases like diabetes, obesity, and hypertension explain disparities in uterine cancer among black females. Obesity affects 34 percent of American females, of which 52 percent are black. Obesity is considered an antecedent of many chronic illnesses, including hypertension, diabetes, and some cancers. Body mass as noted by
BMI (kg/m²) influences the efficacy of treatment, prognosis, and survival of females with uterine cancer. Research indicates that issues related to access to care and later diagnosis potentially contribute to higher mortality rates for black women with uterine cancer. One study examining the role of socioeconomic status, race, and ethnicity in the diagnosis and treatment of women with uterine cancer found that black women were 41 percent more likely to be diagnosed with advanced stages of the disease. Delays between the onset of initial symptoms and diagnosis may result in black women’s presenting with more severe manifestations of the disease, which ultimately affects the course, efficacy, and success of treatment, and, subsequently, contribute to higher mortality rates. Delays in diagnosis and barriers to access to care may be influenced by multiple factors including sociocultural and socioeconomic determinants.

Racial barriers to health care access can, in part, be attributed to the general distrust that, historically, many blacks have with medical institutions and physicians. There is a significant history of the mistreatment of blacks in the United States by medical professionals (i.e., Tuskegee syphilis experiment). The history of overt and covert racism, discriminatory practices, and inequities between Caucasians and blacks also contribute to this distrust. Black patients may also have a communication and linguistic style that differs from their physician’s and may promote miscommunication and reduced efficacy of evaluations and cancer treatments. Black females with significant financial limitations and lack of health insurance have less access to preventative care, higher utilization of emergency health services, and later diagnoses of cancer.

In assessing a population-based Surveillance, Epidemiology, and End Results (SEER)—Medicare database, it has been noted that diabetes in both racial groups resulted in higher death rate for endometrial cancer. Interestingly, it was also found that hypertension in black women was correlated with greater rates of survival than their white counterparts.

Uterine Sarcoma

Uterine sarcoma ranks as the fourth-most-common cause of cancer-related death in women, and the number of cases diagnosed each year continues to increase. At this time, approximately 90 percent of patients diagnosed with uterine sarcoma are considered incurable and have an average survival rate ranging from six to 12 months. Based on the rapid deterioration of a uterine sarcoma patient and the lack of effective treatment strategies, an early detection method is imperative, which in turn may significantly improve patient outcomes.

Uterine sarcomas are rarely occurring neoplasms that involve the exocrine uterus cells (also known as islet cells or islets of Langerhans), which are responsible for generating chemicals that regulate specific activities of cells and organs, including the production of insulin for the maintenance of blood sugar levels. Uterine sarcomas rarely cause any symptoms, thus making it very difficult to diagnose. Furthermore, the details of its molecular pathogenesis remain elusive. In an effort to shed light on this disease, clinicians and researchers have embarked on molecular and genetic investigations to establish its mechanisms of development.

A few years ago, Giorgio Malpeli and colleagues conducted an investigation on gene silencing, mainly focusing on the Ras Association Domain Family 1 (RASSF1) gene, which is a putative tumor-suppressor gene that has been localized to chromosomal region 3p21.3. The protein product of the RASSF1 gene has been reported to suppress tumor growth using both in vitro as well as in vivo systems. RASSF1 has been regarded as a major component in the inhibitory effects of Ras on cell proliferation by regulating downstream agents, thus inactivating the entire Ras signaling pathway. The investigation was based on the fact that the RASSF1 gene harbors two CpG islands, one extending into the regulatory segment that occurs in gene types A, D, E, F, and G, whereas the other one is present in the regulatory segment of RASSF1 type C gene. The research study thus evaluated the possible role of methylation of the RASSF1A gene in regulating transcription in uterine sarcomas.

Another study involving methylation was conducted by Albertas Dauksa, who examined the significance of employing these specific epigenetic marks as predictive biomarkers in uterine tumors. In this particular study, methylation levels at specific sites within CpG-rich domains of the promoter sequences of various uterine sarcoma-related genes were assessed. The genes examined were ACIN1, APC, BCL2, CD44, DAPK1, p16, RARbeta, TNFR10C, and 30ST2. Using blood collected from
a total of 30 patients diagnosed with uterine sarcoma, methylation levels of selected CpG sites were assessed. The results of the investigation showed that several CpG areas were significantly highly methylated, whereas sites consisting of repeat sequences showed a slightly lower degree of methylation relative to that of the control. Furthermore, a positive correlation between the degree of methylation and risk for uterine sarcoma cancer was observed. Interestingly, the study also detected potentially useful correlations such as that between elevated methylation levels in TNFRSF10C and ACIN1 and a lower survival rate for a patient. This promising and significant finding could eventually be applied in clinics, although a larger-scale study should initially be conducted to further strengthen and validate this correlation. Should this be achieved in the near future, a simple blood test could assist clinicians in detecting uterine sarcoma, as well as predict the survival time of a patient.

A recent study conducted by Mingzhou Guo further strengthened the usefulness of epigenetic modifications in detecting and assessing neoplasms involving the exocrine, as well as endocrine, uterus. By extracting the DNA from a total of 48 paraffin-embedded uterine tumors, the levels of methylation were examined using nested methylation-specific polymerase chain reaction (PCR). The tissue samples used in the study consisted of acinar cell carcinomas (12 cases), adenocarcinoma (18 cases), and islet cell tumors (18 cases). This study was able to describe a methylation signature involving various uterine tumor-related genes. Thus, the pattern of methylation of specific genes involved in uterine sarcoma in a decreasing order was as follows: APC gene (50 percent), BRCA1 gene (46 percent), p16INK4a gene (35 percent), p15INK4b (35 percent), RARβ (35 percent), and p73 gene (33 percent).

In addition, a majority (94 percent) of the uterine tumors showed methylation in at least one of the studied genes, whereas 69 percent of the neoplasms showed methylation in two or more of the genes investigated in the study. Another significant finding of this particular study was that the patterns of methylation of these genes in uterine adenocarcinomas could be distinguished from those of uterine sarcomas. This difference could therefore be applied in clinics, specifically in diagnosing the type or subtype of uterine sarcoma. For decades, uterine sarcoma has been considered a very difficult neoplasm to detect, diagnose, and predict in terms of its progression. These molecular signatures involving methylation in specific genes may help in resolving the major challenges experienced by clinicians, particularly oncologists.

Uzbekistan

Uzbekistan is a unitary constitutional presidential republic, comprised of 12 provinces, one autonomous republic, and one independent city. Officially known as the Republic of Uzbekistan, the country is in central Asia. It is bordered by five countries: Afghanistan to the south, Kazakhstan and the Aral Sea to the north, Turkmenistan to the southwest, Tajikistan to the southeast, and Kyrgyzstan to the northeast. The country had a population of approximately 30.18 million in 2013. Since the Soviet era, the health care quality in Uzbekistan has plummeted. Between 1992 and 2003, spending on health care services and the number of hospital beds per capita both declined by almost half, and emigration from Russia reduced the number of physicians. As of 2004, Uzbekistan had 53 hospital beds per 10,000 people. Medical supplies such as antibiotics, anesthetics, and even needles became scarce. Even though all citizens are given free health care, bribery became a common way to navigate
the sluggish and severely limited state health care system. Early in the 2000s, policies were written that improved the quality of health care facilities and reduced the cost of inpatient facilities.

Disease in Uzbekistan is predominantly caused by polluted water, including typhoid, dysentery, hepatitis, different types of cancer, and cholera. The main causes of death are cardiovascular disease, respiratory disease, infectious diseases, parasitic diseases, and diseases of the digestive system. Reported cases of human immunodeficiency virus (HIV) increased after 2002, in large part because of drug abuse. Even though deaths from other diseases are common, cancer mortality is low, and has been steadily declining since 1986. Uzbekistan has the third-lowest rate in the region of mortality from cancer for those 0 to 64 years old, and the second-lowest rate of mortality from trachea/bronchus/lung cancer. As per World Health Organization (WHO) estimates, 15,000 people are afflicted by cancer annually in Uzbekistan. Of females with cancer, 40 percent have cervical and breast cancers. Among the male population in Uzbekistan, stomach, lung, and liver cancers cause the highest mortality. In the mid-20th century, a transition in disease burden occurred in the country: non-communicable diseases (NCDs) eclipsed infectious disease as the most widespread cause of premature death. Today, an estimated 80 percent of deaths are from NCDs. These diseases, including cancer, constitute the gravest threat to public health in Uzbekistan.

Since the mid-1990s, the International Atomic Energy Agency (IAEA) technical cooperation program has offered Uzbekistan sustained assistance in developing radiation medicine services. As a result of the program, there are now state-of-the-art radiotherapy services and the establishment of a single-photon emission computed tomography (SPECT) facility in Tashkent. As the threat of cancer diseases continues to increase with more cases, Uzbekistan’s Ministry of Health (MoH) has recently drafted a national plan to prevent and control cancer and other chronic NCDs. A delegation convened by the IAEA and commissioned by the MoH conducted a survey between March 31 and April 3, 2014, and noted that Uzbekistan’s radiotherapy and radiation medicine infrastructure faces challenges to meet national needs for diagnosis and treatment.

The findings by the delegation are substantiated by doctors in Uzbekistan, who say that their treatment solutions are not as strong as they should be because of poor diagnosis functions, lacking hospital facilities, and medicines that are either hard to find or far too expensive for general requirements. This challenge comes in the midst of increasing cancer incidences. A report by doctors in Uzbekistan showed that for the five-year period between 2003 and 2008, cancer incidences increased from 14 to 25 per 100,000 of the population. Statistics from the MoH indicate that in 2009, 90,000 cancers cases where recorded in the country. One of the areas where cancer cases are high is the Khorezm, which lies close to the Aral Sea that dried up over several decades. The high cancer cases have been linked with the Aral disaster because of harmful dust in the air from the dried up sea.

One environmental cause of cancer in Uzbekistan is the utilization of dangerous pesticides in cotton farms where children often work. According to experts in the health care system, even though this has been established, there are no mechanisms in place to prevent cancer or detect early signs among children, young women, and people who work with chemicals or other hazardous materials. This problem has been attributed to the lack of sufficient highly trained experts and inadequate state funding for cancer centers. In 2013, there were only 1,104 beds for cancer patients, so patients have to wait their turn for months on end.

Regardless of the challenges, the country has made considerable progress in the fight against cancer. The Republican Oncology Research Center, which is located in the MoH of Uzbekistan, has been in operation for more than 50 years, with the intention of studying radiology and oncology functions around the country. The facility is the head institution of oncology service of the Republic of Uzbekistan, incorporating 17 big institutions of oncology services (including city, regional, republican dispensaries), as well as 271 oncology cabinets at district and city polyclinics. Based on this program, the country has a total of 2,265 oncology beds, and 145 of them are for treating children. The aims of the institution’s activities are to offer strategically planned diagnostic, curative, and consultative treatment solutions for oncologic patients, to perform fundamental and practical research in oncology, to screen for and prevent malignant tumors, and to offer scientific-methodological supervisory assistance to regional oncologic dispensaries.

The facility also provides education and training for preparation of clinical residents, masters, trainee-researchers on oncology and clinical radiology specialties. The RORC is currently home to
18 fully registered doctors, six of whom are professors, and 55 Ph.D.s. based on these achievements, the facility is among the leading centers in the New Independent States in the area of diagnostics and treatment of oncologic diseases. Research in the RORC MoH UZB is quite wide, and includes theoretical, experimental, and clinical parts. Research is done using modern equipment and computers, and implemented by well-coordinated and highly competent groups, monitored by the Scientific Board, and under chairmanship of the director of the RORC MoH UZB, Professor S. N. Navruzov.

Vaccine Workers, HPV and HCV

Vaccine workers deliver vaccines that lessen rates of disease and death, often in conjunction with other health care professionals and community organizations (e.g., schools, community centers). Vaccines exist for human papilloma virus (HPV) under the commercial names of Gardasil (for HPV types 6, 11, 16 and 18; Food and Drug Administration (FDA)-approved in 2006) and Cervarix (for HPV types 16 and 18; FDA-approved in 2009). Currently, no vaccine exists for the Hepatitis C virus (HCV). Both HPV and HCV can be spread through sexual activity, and having the viruses increases one’s cancer risk. Vaccine workers must possess knowledge of HPV and HCV, vaccines, and treatment/risk prevention for the populations that they work with.

HCV and Hepatitis B virus (HBV) are top risk factors for cirrhosis and liver cancer. Liver cancer claims 600,000 lives each year and disproportionately affects Sub-Saharan Africa and southwest Asia. HCV screening tests, though relatively inexpensive in the West, are prohibitively expensive in the developing world. Women in developing countries die 85 percent more frequently from cervical cancer, a leading cause of which is HPV. HPV vaccine workers can reduce cervical cancer death and can direct their clients to screening and education about HCV that, like HPV, is spread through sexual activity. There is currently no HCV vaccine, though research is examining similarities between HCV and HPV to help find a vaccine. Vaccine workers might contract HCV by being accidentally stuck with needles. The Centers for Disease Control and Prevention (CDC) estimates that the risk of HCV infection with accidental needle sticks is 1.8 percent. To minimize the risk of infection, vaccine workers are recommended to practice proper hand hygiene, wear gloves, and practice care with used needles. Vaccine workers who are accidentally stuck need both immediate and follow-up testing to gauge their HCV exposure. It is recommended that vaccine workers receive the HBV vaccine (e.g., Heptavax-B; FDA approved in 1981) as a preventative measure.

Vaccine workers may come into contact with individuals with HCV in their work to vaccinate clients for HPV. Both viruses are spread by unprotected sexual contact and thus affect similar populations. A knowledgeable vaccine worker can advise HCV-infected individuals of effective health practices (e.g., avoiding alcohol and certain prescription and over-the-counter drugs that advance cirrhosis of the liver) and ways to avoid spreading the virus to others (e.g., through exposure to blood and bodily fluids).

HPV vaccinations prevent anal cancers and genital warts and require three inoculations over six months for females aged 11 to 26 and males aged 11 to 21. HPV vaccine workers face usual challenges
like vaccine resistance movements and reaching low-income clients, as well as specific challenges like religious/moral objection and misinformation. In Canada, Catholics initially objected to the HPV vaccine administration at publically funded Catholic schools in Ontario and Alberta; several schools have since allowed the vaccine though others have not. In the United States, Texas Governor Rick Perry faced religious and political opposition when he mandated the vaccine for all girls in 2007; the state legislature subsequently overturned this order. HPV vaccine workers have taken on a public advocacy and education role to overcome such cultural opposition. In the developing world, vaccine workers face the above-mentioned challenges in addition to the barriers posed by misinformation about HPV and its vaccines, even among health care workers, and the suspicion that Western medicine and vaccines actually cause the diseases they aim to guard against.

Vaccine workers in the developing world have developed strategies to overcome these barriers, such as using the media and distributing visual materials to those who may be illiterate and/or in remote areas. Vaccine workers also involve government, community, and educational leaders in their work to target the age groups appropriate for the HPV vaccines. Teachers help vaccine workers secure parental consent, keep vaccination records, and promote vaccination. Government officials, community leaders, and midwives help vaccination workers find young people who might not be reached through public school. This strategy would arguably be useful in the United States as well, where the approximately 3 percent of children who are homeschooled are considerably less likely to receive the HPV vaccination.

Vaccine workers working with populations susceptible to HPV and HCV face challenges, some of which might be experienced by vaccine workers (e.g., cost, ensuring participation) in other areas of health and some of which are unique (e.g., misinformation, social stigma). To overcome these challenges, vaccine workers require health information and communication skills. For those infected with HCV, for which there is no vaccine or cure, the vaccine worker may serve as a health information and screening resource.

Vaccines
The formulation of the vaccine for smallpox by Edward Jenner in 1796 ultimately led to the eradication of smallpox as a disease from the face of the
Vaccines

planet (1979) and the formulation of thoroughly successful vaccine formulations for a variety of other diseases caused by bacteria or viruses such as tetanus and polio, respectively. The principle of these vaccines is to expose an individual to a killed or attenuated form of the pathogen in order to generate immune responses to “foreign” sequences known as antigens that subsequently protect the individual from infection with that specific pathogen. Despite the remarkable success of vaccines against many diseases, there are diseases where vaccines have proven to be thus far unsuccessful.

These include malaria, caused by a parasite, and cancer, a malignant disease that usually is not caused by a pathogen. There are examples where certain types of cancer are caused by viruses, such as cervical cancer, which is caused by the human papilloma virus (HPV), and indeed a prophylactic vaccine for HPV has resulted in a dramatic reduction in cervical cancer incidence worldwide. However, such a vaccine is only successful prophylactically, meaning that it must be administered prior to infection and development of the cancer in order to be protective. Since most cancers are not of viral origin, the use of a prophylactic vaccine is not considered practical, since there are over 100 different types of cancer and there is usually no predicting which of these cancers an individual may acquire. Therefore, cancer vaccines are currently recognized as having to be delivered therapeutically or, in other words, subsequent to diagnosis of a patient with cancer. The remainder of this essay will focus on cancer vaccines as potential therapies for cancer.

Cancer vaccines are a relatively new application in the field of clinical oncology, although their potential as a cancer therapy has been under investigation for many decades now. The idea that the immune system may be able to assist in the eradication of tumors was first seriously entertained through the clinical efforts of William B. Coley (1862–1936), a bone surgeon at New York Memorial Hospital, who noted that administration of bacterial products to cancer patients (with bone sarcoma) resulted in remarkable recoveries. Fuelled by his direct observations, as well as historical evidence, of tumor-burdened patients experiencing dramatic tumor regressions (or spontaneous regressions) while concomitantly experiencing febrile infection, Coley ultimately developed a therapeutic cancer therapy that comprised a combination of two killed bacterial species (Streptococcus pyogenes and Serratia marcescens), which was to become known as “Coley’s toxins.” The treatment involved daily (or every alternate day) intratumoral injections of increasing doses of Coley’s toxins for at least one month followed by weekly injections for at least six months. Although at the time Coley was unaware of how the treatment was achieving its therapeutic benefits, it has subsequently been shown that the immune system played an important role. It was noted that therapeutic efficacy strongly correlated with the patient experiencing fever. We now know that fever can be caused by a range of cytokines (hormone-like proteins) such as interleukin-1β, interleukin-6, and tumor necrosis factor-α that act as endogenous pyrogens but also play important roles in triggering downstream anti-tumor immune responses as well as having direct tumoricidal effects.

Therapeutic benefit was seen using Coley’s toxins in many patients with sarcomas and, later, with patients with carcinomas (cancers of epithelial origin); however, modern medicine, primarily in the form of chemotherapeutics, along with surgery and radiotherapy, attracted most of the attention of oncologists, and since the 1940s the promising results from Coley’s therapy were largely ignored for half a century. In 1999 a retrospective comparison of the therapeutic benefit of Coley’s toxins versus conventional therapy was published and suggested there was no difference in survival rates of patients treated with Coley’s toxins (between 1890 and 1960) and those treated with conventional therapy (post diagnosis in 1983). More recently, Coley’s toxins have been renamed Mixed Bacterial Vaccine, possibly to increase marketability since the word “toxin” may be off-putting for prospective patients. However, it is a moot issue as to whether one can consider Coley’s toxins a vaccine, as it is classically defined, since the therapeutic benefit appears to result from an immediate non-specific immune response in most cases.

Although the precise mechanism of action of Coley’s toxins remains unclear, it is likely that pathogen-associated molecular patterns (PAMPs), such as lipopolysaccharides (LPS) that constitute the outer membrane of gram-negative bacteria, play a critical role. PAMPs are conserved sequence motifs expressed by pathogens, such as bacteria, viruses, and fungi, which are recognized as “danger signals” by the host’s innate immune system. During
the 1990s it was recognized that certain cells of the innate immune system possessed a range of receptors, known as Toll-like receptors, capable of recognizing different PAMPs. For instance, Toll-like receptor-9 binds to bacterial DNA motifs, while Toll-like receptor-4 binds LPS. Cells of the innate immune system expressing these receptors can be triggered to release a range of cytokines upon encountering PAMPs, which in turn can lead to a range of downstream immune effects, not the least of which is the promotion of antigen-specific immune responses. The innate immune system is found in most multicellular organisms, from plants and insects to mammals, and is considered the first line of defense against pathogenic infection.

PAMPs trigger immediate responses from innate immune cells, such as phagocytes, which not only directly eliminate or destroy the invading pathogen, they also promote the influx of other immunocytes to the site of infection. The innate immune system per se has no immunological memory, but is a vital contributor to adaptive immune responses, possessed by animals in the phylum Chordata, which do have immunological memory. It has been shown that PAMPs can activate specialized antigen-presenting cells, known as dendritic cells, so as to favor an adaptive immune response over a suppressive immune response when delivered in association with "foreign" antigen. Tumors are known to express their endogenous version of "foreign" antigens, known as tumor antigens, which are aberrantly expressed proteins that are either not expressed by healthy adult tissues or have highly restricted tissue expression thereby making them potential targets for immune-mediated therapy.

To the uninitiated it may seem anti-intuitive that a patient with cancer could potentially mount an immune response against his or her own cancer since although it may be an unwanted malignant disease, the vast majority (more than 80 percent) are not caused by viruses and therefore do not actually express foreign proteins. However, accumulating evidence over the past 20 to 30 years lends strong support for the capacity of cancer patients to develop antitumor immune responses. The current paradigm amongst tumor immunologists is that tumors (or tumor cells) gain a distinct advantage within the host once they have eluded the surveillance by the host’s immune system, which scans the body for something “foreign.” Tumor cells that are either ignored by the immune system or actively suppress the immune system, either directly or indirectly, are the ones that progress.

If tumor cells have successfully evaded the immune system, then how can the immune system subsequently be manipulated for therapeutic effect? The aim of a cancer vaccine is to overcome the immunosuppressive elements of the tumor and make the tumor “visible” to the immune system through the recognition of the tumor antigen(s) that these tumors express. For example, the prostate gland in men contains cells that express a protein aptly named prostate-specific antigen (PSA) that is exclusively expressed by prostate cells. Prostate tumors develop from prostate cells and, therefore, express prostate proteins such as PSA.

Other than being expressed in larger quantities, PSA expressed by tumor cells is generally no different to the PSA expressed by normal cells. However, it turns out that the immune system possesses a small number of T lymphocytes (“T” because they undergo their development in the thymus) that are capable of recognizing PSA-expressing cells and, if appropriately activated, these T lymphocytes can become tumoricidal. It is the role of a cancer vaccine to stimulate those PSA-specific T cells into action. Such stimulation involves promoting their expansion or proliferation such that there is an increased number of these PSA-specific T cells. Aside from promoting their expansion, the cells must also become capable of killing the cell for which they are specific. There is now strong evidence that prostate cancer patients not only possess these tumor-specific T lymphocytes but that they can also be triggered into action. Other examples of tumor antigens include a group of proteins known as the cancer testis antigens. These proteins are variably expressed by a broad range of cancer types.

One particular example is NY-ESO-1 (so called because it was discovered in New York in a patient with esophageal cancer), discovered in 1996, and expressed by about one-quarter of patients with certain types of cancer such as prostate, melanoma, and lung cancer. NY-ESO-1 is considered an attractive tumor antigen for use in cancer vaccines for multiple reasons. These include (1) that NY-ESO-1 is highly immunogenic, being capable of triggering both cellular (T lymphocyte) and antibody (B lymphocyte) responses in situ; and (2) that NY-ESO-1 is expressed almost exclusively by cancer cells with
expression by healthy tissue being restricted to testis and placenta, which are immune-privileged tissues, meaning that immune responses tend to be suppressed within such tissues and, therefore, concerns of autoimmunity are alleviated. That the cancer patient harbors tumor antigen-specific immune cells (T lymphocytes and B lymphocytes) with the potential to mediate tumor cell killing is now well documented not only for NY-ESO-1 but for a wide range of other well-characterized tumor antigens.

The evidence that the immune system can play a role in protecting the host from the development and progression of tumors has been accumulating over recent decades. Of particular note have been a number of studies in animal models where removal (“knock-out”) of specific genes, intrinsic to the immune system, has been shown to have significant influence over tumor development. Specifically, it was shown that mice made incapable of responding to the cytokine, interferon-gamma (IFN-γ), had significantly more incidences of spontaneous tumors than wild type (normal) mice. IFN-γ, previously known as immune interferon and macrophage-activating factor, plays a vital role in both innate and adaptive immunity and protects the host from a variety of infections (e.g., viral, mycobacterial) that would otherwise prove lethal. It is thought that IFN-γ promotes immune-mediated eradication of tumor cells by directly acting on the tumor cell, upregulating tumor antigen expression (specifically major histocompatibility class I antigen in association with tumor antigen) and increasing the immunogenicity of the tumor cell, thereby increasing the tumor cells’ vulnerability to tumor-specific immune attack.

The types of cancer vaccines currently under preclinical and clinical investigation include whole-cell tumor vaccines, tumor-cell lysates, viral vectors (carrying tumor antigen gene[s]), dendritic cells (pulsed with tumor antigen[s]), and biodegradable microparticles encapsulating tumor antigen(s). While most of these vaccines may have inherent adjuvant properties, meaning that they help the immune system to recognize the tumor antigens being delivered as “foreign,” in the majority of cases co-administration of an adjuvant, such as a PAMP and/or GM-CSF (granulocyte-macrophage colony stimulating factor) is considered almost obligatory. These additional adjuvants are potent activators of dendritic cells that present tumor antigen to T lymphocytes and, upon appropriate activation, will promote the production and function of tumor-specific cytotoxic T lymphocytes. Thus far, the only therapeutic cancer vaccine that has received approval from the U.S. Food and Drug Administration has been the prostate cancer vaccine sipuleucel-T (also known as Provenge). Sipuleucel-T is a cancer vaccine that comprises the patient’s own dendritic cells pulsed ex vivo (out of the body) with a fusion protein comprising GM-CSF and the tumor antigen known as prostatic acid phosphatase.

Each of the vaccine formats has its own set of advantages and limitations. For instance, the sipuleucel-T involves extensive labor and cost in acquiring the end product, a scenario that would also apply to any autologous (i.e., patient-derived) whole-tumor-cell or cell-lysate-based vaccines. In addition, cancer vaccines using autologous tumors or dendritic cells will be limited with respect to cellular yields. Cancer vaccines carrying only one tumor antigen run the risk of immune evasion by the tumor through the

William B. Coley noted that administration of bacterial products to cancer patients resulted in remarkable recoveries. He developed a cancer therapy that became known as “Coley’s toxins.” (Wellcome Library, London)
selection of tumor cell clones that no longer express that particular tumor antigen. In addition, often only certain patients may be suitable candidates for single tumor antigen vaccines due to genetic factors that may compromise the ability of the patient to generate effective cytotoxic T lymphocyte responses. This is the reason that many researchers are working with whole-tumor cells and tumor-cell lysates as a source of multiple tumor antigens, many of which may be unknown, but reduce the capacity of tumor cells evading tumor antigen-specific T lymphocyte-mediated killing.

While the various cancer vaccine modalities have generally promoted impressive tumor regressions in animal models, their translation to clinical settings has met with more modest results. One key positive outcome thus far is that most cancer vaccines have proven to be well tolerated by cancer patients. Although the reasons for the lack of significant improvements in patient survival may be multifactorial, there is a general consensus that cancer vaccines per se are unlikely to overcome the immunosuppressive environment within the tumor itself and that additional therapeutic intervention is required. It has been observed that up to 20 percent of the cytotoxic T lymphocyte population within tumors from cancer patients can be tumor antigen-specific and yet fail to provide effective killing of tumor cells. Therefore, it is clear that some cancer patients possess tumor antigen-specific T lymphocytes capable of accumulating at the tumor site but, due to the hostile tumor microenvironment, these cells fail to unleash an effective antitumoral response. One major contributor to immunosuppression is a subset of T lymphocytes known as regulatory T lymphocytes that can also accumulate at tumor sites. As a result, there have been intensive preclinical and clinical investigations into the impact of dampening Treg function (Treg cells are regulatory T cells) in tumor-bearing individuals with promising outcomes. Currently, antibodies thought to significantly reduce regulatory T lymphocyte function are being used in clinical trials for cancers where there is no established effective therapy, such as melanoma and prostate cancer. Ultimately, it is hoped that cancer patients will benefit significantly from the combined treatment of a cancer vaccine and agents that can safely reduce the suppressive arm of the immune response.

In summary, while using conventional chemotherapy against cancer may prove to extend the survival of patients with certain types of cancer (particularly testicular cancer), it has proven to be insufficient for most other types of cancer as well as severely reducing the quality of life of those treated with high doses. Cancer vaccines offer a viable alternative that can be used in combination with other treatments with the potential to systemically eradicate a patient’s cancer without causing detrimental side effects. A range of cancer vaccines is being clinically trialed for a range of cancers considered susceptible to immune attack with the ultimate hope of not only extending survival for the patient but providing a cure.

Vaginal Cancer

Vaginal cancer is a rare gynecological malignancy representing 5 to 8 percent of all gynecological neoplasms. It was identified in 1952 by Graham and Meigs, who reported three patients with carcinoma of the vagina, one invasive and two intraepithelial, 10, six, and seven years after total hysterectomy for carcinoma in situ of the cervix. Due to the rarity, there is minimal data in the literature concerning this cancer, particularly with regard to therapy.
Historically, vaginal cancer has been a disease of older women, with the peak occurring during the sixth and seventh decades. Less than 50 percent of patients are diagnosed below the age of 50 years, and less than 10 percent of these tumors occur in patients under 40 years of age.

The vagina is a fibromuscular canal composed of stratified squamous epithelium, smooth muscle, and connective tissue. The vagina extends from the cervix to the vulva. It is H-shaped in its central portion; the sidewalls are suspended by their attachment to connective tissue in which they receive their blood supply. Additionally, the vagina is attached laterally to the pelvic sidewalls by condensations of connective tissue and smooth muscle.

Physical examinations and diagnostic procedures are the most common ways to detect and diagnose vaginal cancer. However, screening programs have only recently become routine in most physical assessments. A diagnostic workup includes a complete history and a physical and pelvic examination. A pelvic examination continues to be the most important tool for evaluating and diagnosing the extent of vaginal cancer. This consists of examining the vagina, cervix, uterus, fallopian tubes, ovaries, and rectum.

A Pap smear is a procedure in which cells are removed from the surface of the cervix and examined under a microscope. In early squamous cell lesions, the diagnosis is suggested by an abnormal Pap smear. Furthermore, abnormal Pap smears often result when patients have had previous hysterectomy or HPV-related invasive cervical disease; however this is not true for cell adenocarcinomas, which often are characterized by submucosal growth. Diagnosis of vaginal cancer can be easily accomplished by biopsying the gross lesion. If no gross lesions are present, then the evaluation of the vaginal tube as vaginal intraepithelial neoplasias (VAINs) is appropriate. A colposcopy can also be utilized to detect the signs of vaginal cancer. It is important to note that vaginal cancer often does not cause early symptomatology. Symptoms of vaginal cancer include, and are not limited to, painless vaginal bleeding and discharge, tumors, urinary retention, pain, constipation, pain during sexual intercourse, lump in the vagina, blood in stool, tenesmus, hematuria, and frequency of urination.

Vaginal cancer is staged based on clinical criteria. Stage I is defined as tumor limited to vaginal mucosa. In Stage II vaginal cancer, the neoplasia involves the sub-vaginal tissue but has not extended to the pelvic wall. Stage III is defined as a tumor extended to the pelvic wall. Stage IV vaginal cancer is extremely rare; in Stage IV, a tumor extends beyond the true pelvis or involves the mucosa of the bladder or rectum. In Stage IV A, disease has spread to adjacent organs; in Stage IV B, disease has spread to distant organs.

Traditionally, the primary plan to treat vaginal cancer is radiation therapy. Radiation therapy uses radioactive substances to destroy cancer cells and shrink tumors. Radiation therapy can be used in combination with other treatments to stop the growth of cancer cells and relieve symptoms of advanced cancer. Nearly 30 to 35 percent of women diagnosed with stages III or IV vaginal cancer will require radiation therapy. Radiation therapy can be delivered externally, internally, and systemically. External radiation (e.g., IMRT, Tomotherapy) is directed onto the cancerous cells from a machine outside of the body. Internal radiation therapy is placed inside the body via a catheter or some form of carrier and is directed near the tumor or cancerous cells. Systemic radiation therapy is a substance that is administered orally or either injected which destroys cancer cells by traveling through the bloodstream to locate the cancerous cells. Depending on the targeted area that is being treated, radiation can bring a variety of side effects. Some of the most common side effects associated with radiation are fatigue, nausea, and skin changes.

In conjunction with radiation therapy, or as an alternative, chemotherapy is another treatment option to destroy cancerous cells. Chemotherapy is the use of anticancer drugs that inhibits the advancement of rapidly dividing cancer cells. Chemotherapy could be administered in several delivery methods: orally as pills or liquid, intravenously by infusion into the vein, topically as a cream, injection, or direct placement via a lumbar puncture or device placed under the scalp. The direction of a chemotherapy drug could be systematic, in which it travels through the bloodstream to target the cells throughout the body or directed to a specific region or area of the body. Although chemotherapy targets cancer cells, it can also damage healthy cells and cause side effects such as vomiting, hair loss, fatigue, and mouth sores.

In addition to radiation and chemotherapy, there are surgical treatment methods for women
diagnosed with vaginal cancer. Surgical therapy eliminates the lesion, prevents the formation of invasive cancer, and preserves the autonomy and function of the vaginal region. Surgical therapy is the ideal form of therapy for women who are in stage I or II of vaginal cancer. However, surgery for women with more advanced disease is most often used for women who have recurrent disease after radiation therapy.

Most recurrences occur in the first two years after treatment. Alternatively, no established anticancer drug has proven clinical benefit, although patients are often treated with regimens used to treat cervical cancer. Generally, the prognosis and treatment options depend on stage of cancer, size of tumor, grade of tumor cells, location of cancer in vagina, symptoms of diagnosis site, occurrence, and patient’s age and general health.

The survival outcome of vaginal cancer is related to the stage of the disease. The five-year relative survival rate is approximately 95 percent for stage 0, 75 percent for stage I, 60 percent for stage II, 35 percent for stage III, 20 percent for stage IV A, and 0 percent for stage IV B disease. The outcome of survival rate also varies among women of different race and ethnicities. In gynecological cancer, there are disparities among treatment and survival rates between African Americans and whites, in which mortality rates for African Americans are substantially higher than their white counterparts. Moreover, African American women with vaginal cancer are more likely to present at a younger age and a more advanced stage and are less likely to receive surgical treatment compared to white women.

Vaginal cancer is one of the rarest forms of cancer in women. There is no single leading cause of vaginal cancer, and it can affect women of all age ranges. Risk factors for vaginal cancer include five or more sexual partners, first intercourse before 17 years of age, smoking, low socioeconomic status, a history of genital warts, prior abnormal cytology, exposure to diethylstilbestrol, and prior hysterectomy. A combination of age, socioeconomic status, smoking, and sexual intercourse before the age of 17 years is a risk factor associated with vaginal cancer. It is important to note that vaginal cancer often does not cause early symptomatology.

Although there are several treatment methods that could either monitor or alleviate vagina cancer, a pelvic examination continues to be the most important tool for evaluating and diagnosing the extent of vaginal cancer in women.

Vanderbilt-Ingram Cancer Center

Vanderbilt-Ingram Cancer Center (VICC) is the only National Cancer Institute (NCI)–designated Comprehensive Cancer Center in the state of Tennessee that provides pediatric and adult cancer treatment and conducts clinical, translational, and basic cancer research. VICC is a member of the National Comprehensive Cancer Network and is a leader in treatment, diagnosis, and prevention of cancer.

The center’s approach is patient-centered, integrated, and personalized. Support, education,
outreach are also key components of VICC. From diagnosis through survivorship, VICC provides a wide variety of wellness programs. VICC ranks in the top 10 in the nation for cancer research grant support and is one of the 41 institutions nationwide to be designated a Comprehensive Cancer Center by the NCI. VICC is organized and led by a director, a deputy director, a team of center directors, and a chief executive officer. They are also guided by the Cancer Clinical Enterprise Committee who oversees decision-making and strategy for clinical operations, a volunteer community Board of Overseers, and an external scientific advisory board.

VICC has been a designated cancer center since 1995 and achieved the Comprehensive Cancer Center designation in 2001. To achieve this designation, VICC had to be among national leaders in outreach, education, prevention, treatment, and all types of cancer research. Strength, depth, innovation, and commitment must be demonstrated in basic laboratory research, translational research, clinical research, clinical trials, prevention research and programs, cancer information services, community outreach and education, and training for nurses, researchers, physicians, and other cancer professionals. NCI reevaluates Comprehensive Cancer Centers every three to five years to ensure that strict standards are being met, and VICC must report progress and activities annually. Recently, VICC was invited to join the National Comprehensive Cancer Network (NCCN), which consists of 25 of the world's leading cancer centers. VICC research programs focus on the discovery of new approaches for the prevention, diagnosis, and treatment of cancer.

VICC has been ranked the number one cancer center in Tennessee and 28th in the nation by U.S. News & World Report. There are over 300 researchers in seven research programs, a comprehensive team of more than 100 physicians, and six community locations in addition to the primary clinic (Henry Joyce Clinic) at the VICC. They are currently ranked seventh in competitively awarded NCI grant funding, which is in excess of $65 million. The total research funding exceeds $155 million from public and private sources. VICC has affiliate relationships with Williamson Medical Center, NorthCrest Medical Center, Baptist Memorial Health Care, and Maury Regional Medical Center. VICC serves more than 6,200 new cancer patients each year while providing for more than 151,000 outpatient visits annually. At any given time, VICC has more than 150 clinical trials in process.

The mission of VICC is to pioneer research, patient-centered care, education, evidence-based prevention, and community programs that alleviate suffering and cancer deaths. VICC's vision is to be the recognized leader both nationally and globally in the effort to treat and prevent cancers. Values include: service, compassion, collaboration, translation, discovery, and innovation. VICC describes its commitment to reducing suffering and cancer death by: pioneering research, team science, team approach, evidence-based prevention, education, community activities, and comprehensive services (physical, emotional, psychological, and practical) regardless of type of cancer, where patients receive their care, or age at diagnosis.

VICC, with the support of NCI and the American Cancer Society, provides pilot funding for research by Vanderbilt faculty. Funds are primarily for collaborative projects with emphasis on innovative basic science and translational research, established faculty, or new faculty. Pilot projects in breast cancer, gastrointestinal cancer, and lung cancer are supported as well. Philanthropic support is provided by the Ayers Institute (early detection and prevention), Robert J. Kleberg, Jr. and Helen C. Kleberg Foundation (genetics), A.B. Hancock Jr. Memorial Laboratory for Cancer Research (early diagnosis and drug development), and Frances Williams Preston Laboratories (gene discovery, basic and translational research in breast, prostate, and lung cancer).

The VICC sponsors seminar programs, lectures, and mini symposia every year. Additionally, the Orrin Ingram Distinguished Lectureship series is offered annually and features four to five investigators who present discoveries that have been key to major advances in prevention, diagnosis, and treatment of cancers, and contribute to understanding tumors. The VICC also has an annual retreat that includes all of the laboratories, students, postdocs, fellows, and principal investigators for a poster session, shared resource displays, and mini symposium.

VICC advocates and provides an interdisciplinary team approach, as cancer is a collection of many types and subtypes of disease each with unique challenges. As appropriate, treatment teams include: surgeons, oncologists, hematologists, radiation oncologists, pathologists, nurses, psychologists, social workers, and other specialists.
are multiple team-specific groups that focus on: breast cancer, colon cancer, lung cancer, head and neck cancers, leukemias and lymphomas, bone and tissue cancers, gynecologic cancers, prostate and genitourinary cancers (bladder, kidney, etc.), brain and other neurologic cancers, melanoma, bone and tissue cancers, and childhood cancers.

VICC is involved in community outreach in a variety of ways. The Office of Patient and Community Education (OPACE) plans, implements, and evaluates community education programs every year to share expertise and offer resources. Programs are planned with national, state, and community organizations concerned with cancer. Priorities of OPACE include: prevention, early detection, and risk reduction that focus on high-risk populations and areas with the highest cancer and mortality rates in Tennessee. Some of the OPACE programs include: survivorship programs, health fairs, education/awareness, and screenings. The REACH for Survivorship program is the first dedicated survivor clinic in middle Tennessee. The program provides services to all survivors regardless of age, type of cancer, or treatment location for both pediatric and adult cancer populations. The Hope Connection brings together patients, families, and trained volunteers (who have personally experienced the challenges and issues of cancer) to offer support at any time, before, during, and after treatment.

Venezuela

Venezuela is the richest country of Latin America, with the world’s largest petroleum reserves. As a founding member of OPEC, its exports consist almost entirely from its oil production, while its imports are finished products. Due to economic instability under its current government, it has also turned to importing basic necessities and food. Prior to the development of its petroleum, it was self-sufficient in agriculture, and its exports were agricultural products. The development of Venezuela’s petroleum production was originally done under the influence of the United States, specifically the Rockefeller family. Eventually, this national resource was taxed, then nationalized in 1976 with the objective of subsidizing economic and social development. The substantial oil income has subsidized the nation’s development for decades in what President Romulo Betancourt called “siembra del petróleo” [planting petroleum]. Unanticipated consequences of this extractive economy have impacted all sectors of society, including the public health system. Over many decades, the proportion of Venezuelans living in poverty has steadily declined, but only by small increments until recently.

Under populist president Hugo Chávez, the income from oil exports reached levels much higher than under previous presidents, due to the high price levels sustained over this period. The Chávez administration devoted much of the export income toward projects and subsidies for Venezuela’s poor during his years in office, 1999 to 2013. The result has been a decrease of the proportion of the population living in poverty from 50 percent to 27 percent, but at the social cost of as many as 1 million middle class Venezuelans leaving the country due to opposition to the methods of the Chávez government. At this writing, the government has continued the Chávez approach under the administration of his successor, Nicolás Maduro. A byproduct of this social and economic path has been the acceptance of a Cuban model of public health along with friction with the United States over domestic human rights issues and foreign policy, while dependence on oil exports to the United States continues.

Venezuela’s cancer morbidity and mortality are directly related to its demographic profile and to the country’s level of social and economic development. A young population will be relatively cancer
free, while an aging population will have cancer as one of the most frequent causes of mortality. As the population of Venezuela ages, it will be joining the more-developed countries with an increasing concern about cancer diagnosis and treatment. The nation has a youthful population with the median age of 27 years, so the main public health concerns are with cancer prevention.

Historically, cancer has been considered to be a product of Western, industrialized countries and their rich diet, sedentary lifestyle, and other unhealthy practices. This orientation has been strengthened by the anti-American stance of the Venezuelan ruling party. When President Chávez was stricken with cancer, he traveled to Cuba for treatment there. He was not cured, and he died in office in 2013, shortly after having been reelected to the presidency. The assertions of his successor, Maduro, that Chávez was “infected” with cancer by agents of the U.S. government have furthered the impression among his followers that cancer is a product of Western society and can be transmitted from elsewhere.

While many social critics focus on the negative side of industrialization, the rise in cancer around the world is also coming to be recognized as a product of longer life spans in all countries, and it increases with educational level, income, and life expectancy. More recently, cancer has become understood as a worldwide cause of death, and it can be expected to increase as a byproduct of a nation’s social and economic development. Cancer now is seen as a rapidly growing threat to the world’s less wealthy countries undergoing development, although this forecast has been resisted for social and political reasons. The fact remains that developing countries are not well prepared for higher rates of cancer.

The World Health Organization forecasts cancer increasing considerably in Venezuela. This has been supported in Venezuela by such trends as urbanization. Venezuela has an urbanization rate of 93 percent, one of the highest in Latin America. Venezuelans are also protected by their proximity to health facilities, access to potable water and sanitation, and high levels of education. Rates of cancer in Venezuela have begun to follow the morbidity patterns of the United States and Europe. There is pressure to adapt the national health services to respond to this forecast increased risk of cancer, especially since about one-third of cancers
are preventable and others can be treated successfully if diagnosed early.

According to the Pan American Health Organization, Venezuela’s demographic profile is an aging population of 29,436,900 people, an average life expectancy of 75 years, with a youthful median age of 27 years. The leading causes of male cancer mortality are prostate, lung, and stomach cancers. For females, the leading cancers are breast, cervix, and lung. Cancer screening services, treatment facilities, and palliative care are generally available in Venezuela, but they are in transition under Cuban influence.

The rejection of Western medicine by the Chávez government led to exchanges with Cuba of Venezuelan oil for Cuban personnel, particularly in the fields of the military, education, and health. In this “oil for doctors” program, 31,000 Cuban doctors and dentists work in Venezuela in exchange for 100,000 barrels of oil supplied daily to Cuba. Prior to the current Chávez-style government, Venezuelan medical practice was most strongly influenced by the United States, with many medical doctors trained there.

The current situation has resulted in controversy among Venezuelan professionals, while Cuban medical practice has come to have a strong influence on the treatment of cancer in Venezuela. Nonetheless, as in Cuba itself, cancer treatment is the weakest part of Cuban medical practice, which is more successful at preventive care, public health measures, and, eventually, palliative care. There is a movement in Cuba toward more standard cancer treatments, alongside experimental cancer vaccines and homeopathic treatments. Given the uncertain political situation in Venezuela and its resolution for the future, it is difficult to forecast cancer treatment and mortality in coming decades.

International Agency for Research on Cancer.

The Vermont Cancer Center (VCC) is a nonprofit clinical research and care center located in Burlington, Vermont. The VCC is operated by the University of Vermont (UVM) College of Medicine in partnership with Fletcher Allen Health Care. Founded in 1974, the VCC is the largest center of its kind in the state of Vermont. The VCC operates four multidisciplinary clinics (MDCs), including the Breast Care Center, Upper Gastrointestinal MDC, Lung MDC, and Melanoma MDC. Over 120 scientists and physicians make up the VCC’s constituency.

Members
VCC members must be full-time faculty at the University of Vermont and have served as principal investigators or co-principal investigators on a peer-reviewed cancer-relevant research grant or clinical trial. The VCC’s student members are comprised of current graduate students concentrating on cancer research as well as postdoctoral fellows.

The mission of the VCC is divided into three main programs: Mechanisms of Malignancy, Host Factors and Tumor Progression, and Cancer Control and Population Health Sciences. Each of the center’s three major programs fosters a transdisciplinary and collaborative approach to promoting discovery and advancing standards of care.

Facilities
Since July 2001, each of the VCC’s core laboratories has been centrally located at the Health Science Research Facility on the campus of the University of Vermont College of Medicine in Burlington. The center headquarters also includes an Ambulatory Care Center, Education and Conference Center, and the VCC’s clinical facility.

The VCC Core Facilities place an emphasis on delivering cancer screening and treatment to the state’s rural population as well as understanding the
impact of social and physical environments on the disease. The VCC’s major facilities and clinical center are comprised of four major facets, each of which works in concert by sharing research findings and patient assessments. The VCC’s Advanced Genome Technologies Core encompasses the facility’s DNA Analysis center and the Vermont Genetic Network Microarray group, each of which concentrates on research based on the genetic causes of the disease. The center’s Biostatistics facility is comprised of a program of research evaluating biostatistical trends in patient data and epidemiology. Researchers and students working in the VCC’s Flow Cytometry unit utilize advanced technologies for intercellular analysis. The VCC’s fourth core facility, the Microscopy Imaging core, consists of 10 microscopy-based imaging systems and an electron microscope for use in a myriad of research applications.

**Research Funding and Awards**

Each year, the VCC awards funding to members and UVM faculty for postdoctoral research related to the disease as well as other cancer-related research. The awards, determined by peer review, include the J. Walter Juckett Scholar Award, the Collaborative Cancer Translational Grant Program, and the VCC Program Grant Award. The J. Walter Juckett Scholar Award is given annually by the VCC in conjunction with the Lake Champlain Cancer Research Organization (LCCRO) and the National Institutes of Health. The grant has previously gone to extensive research trials in ovarian, lung, and breast cancers. The VCC’s biannually awarded Collaborative Cancer Transitional Grant was founded to promote and develop partnerships between cancer scientists and physician investigators in an effort to form multidiscipline research programs dedicated to prevention and early detection. The VCC Program Grant Award is a funds-matching program that also aims to foster collaborative, translational investigations throughout both the UVM College of Medicine and Fletcher Allen Health Care. Recent awards have helped fund work concentrating on the effects of genetic proteins in predicting breast cancer and the effects of chromosomal disorganization in the spread of cancer.

**Outreach Programs**

In addition to the VCC’s vast array of clinical and research efforts, the center also partners with Fletcher Allen Health Care to offer a comprehensive patient care and support network to patients in Vermont and northern New York. The VCC operates an ongoing affiliation with the UVM College of Medicine’s Program in Integrative Health, which was founded to examine and address the mind–body connection and spiritual health dimensions of the hospital’s patients.

The VCC also operates a variety of patient-oriented support groups to help patients and their family members endure their experience with cancer. Groups include the Children’s Support Group, Young Survivors Support Group, Patient Health Arts and Writing Group as the Rutland, Vermont-based Women-to-Women cancer support group. Other support groups provide help to specific groups of cancer sufferers, including those with pancreatic cancer, post thrombosis syndrome, and colorectal cancer.

The VCC is also a key partner in the annual Lake Champlain Dragon Boat Festival, the proceeds of which go to benefit a myriad of Vermont-based cancer charities. The event is comprised of time trials and head-to-head racing of large paddleboats on the Burlington, Vermont, waterfront. Over 1,600 participants take part in the festival each year across over 60 boating teams comprised of cancer survivors, local Vermont businesses, and Vermont-based non-profit groups.

**Accreditation and Future Development**

In February 2013, the VCC was awarded a three-year accreditation with commendation from the American College of Surgeons Commission on Cancer. The recognition lauded the VCC’s evaluations in quality and comprehensiveness of care, equipment, patient-treatment coordination, patient follow-up, and ongoing improvements to its facility.

Also in 2013, the University of Vermont College of Medicine and Fletcher Allen Health Care announced a $20 million dollar investment in the VCC’s basic science, clinical, and transitional research programs.

In July 2014, the VCC, in conjunction with the UVM College of Medicine and Fletcher Allen, joined the network of nationwide partners utilizing the PierianDx Network. The end-to-end informatics program offers rapid diagnosis and individualized treatment options for patients derived from its vast database of clinical interpretations of cancer cases throughout the United States. The system allows each hospital to share clinical interpretations and derives insights
into treatments, marking a next-generation approach to combatting cancer in its numerous forms. As of 2014, the VCC is helmed by co-directors Dr. Claire Verschraegen and Dr. Gary Stein.

Vietnam

Public health has become an issue of increasing concern to governments worldwide, particularly in Asia, the largest and most populous continent in the world. As in other countries around the world, however, Vietnam faces challenges from aging populations and health crises caused by noncommunicable diseases, such as cardiovascular disease, cancer, and others. There are many causes for these, such as environmental degradation, pollution, and lifestyle habits, among others. In the case of Vietnam, experts claim that health outcomes of years of warfare exposure to herbicide chemicals, such as Agent Orange during the Vietnam War, must be researched in more depth, particularly as pertains to cancer. Vietnamese doctors and scientists working to cure cancer face great resource and logistical roadblocks. Today, they work to forge local and international partnerships that will help bring modern protocols, technology, and knowledge to Vietnam in order to improve cancer treatment in the nation.

Background
Although previously one of the poorest nations, today Vietnam is categorized among the six favored emerging-market nations of the world. Statistics from the International Agency of Cancer Research (2012) show that out of Vietnam’s population of 89.7 million people, 125,000 are newly diagnosed with cancer each year. The risk of Vietnamese citizens developing cancer before age 75 is 14.5 percent. Approximately 94,700 Vietnamese die from cancer each year. A 1990 study estimated that the cancer incidence in Vietnam was about 133 per 100,000 in males and 91.7 per 100,000 in females, standardized to the world’s population.

Malnutrition and infectious diseases remain the top health problems. In comparison to these, cancer ranks relatively low in importance. The reason for this is in part due to scant reliable health statistics. The most prevalent types of cancer in the country are lung, liver, stomach, colorectal, and nasopharynx cancers in males. Among females, the leading cancers are breast, cervical, stomach, liver, colorectal, and lung. Compared with international data, statistics for Vietnam show a relatively high rate of nasopharynx, liver, and stomach cancer, and a low rate of breast and prostate cancer. There is a much higher rate of cervical and uterine cancers in south Vietnam than in the north. Liver cancer also shows a much higher incidence in the south.

Forms of cancer more prevalent in the north, although at less significant rates, are lung, stomach,
breast, and nasopharynx. Research has shown that cancer of the genital organs used to be frequent throughout the country as well, although scientists discovered important differences between the north and south. Cancer of the cervix showed higher incidence in the south, whereas cancer of the penis was more prevalent in the north. Nevertheless, the rates of genital tract cancer for both sexes have decreased notably, according to statistics gleaned from hospital records during the last two decades. Some experts ascribe the improvement to better health and hygiene conditions among the population, among other factors.

One of the most sensitive areas pertaining to cancer in Vietnam relates to children’s cancer. While the global average five-year survival rate for childhood cancer is 85 percent, Vietnamese children have a five-year survival rate of barely 10 percent.

Policy Making
The National Cancer Control Program in Vietnam has engaged in proactive government efforts in the areas of tobacco control, mass media education of the public, and improving cancer treatment. The latter includes the production of vaccine against the hepatitis B virus (HBV). Cancer control is still difficult to implement and assess because of scant data on cancer incidence, morbidity, and death rates. Vietnam also suffers from a dearth of resources for comprehensive cancer control and treatment, especially in peripheral areas. Despite its population density and relative poverty, however, Vietnam consistently achieves high scores in life expectancy, schooling level, and infant mortality rates, in comparison with other nations worldwide in the same stage of development.

Policies have also encouraged the development of registries. By 1990, cancer registries were introduced in Ho Chi Minh City and Hanoi. The reliable maintenance of these registries still faces serious challenges, due to shortages in resources, financial support, and general lack of quality in data and systems. By 1990, the country had opened two cancer centers, in Ho Chi Minh City and Hanoi. Since then, these cancer institutions have improved and expanded, but they remain inadequate to serve the health needs of the sizeable population of Vietnam.

One of the main problems, as related to the incidence of cancer, is the extremely elevated level of tobacco use. Vietnam produces large amounts of tobacco products. In the mid-1990s, the yearly consumption was approximately 600 cigarettes per capita. The tobacco industry plays a very important role in creating employment in both urban and rural areas. Education programs by way of mass media dissemination have been implemented in order to counteract the massive level of tobacco consumption. Another step forward occurred in the mid-1990s, when Vietnam began producing the vaccine against the Hepatitis B virus; liver cancer is one of the leading cancers in the nation. The primary goal of vaccination is the prevention of the disease.

Despite many challenges, efforts have been made to establish oncology training and research centers, as well as developing collaborative research agreements with institutions in other countries. Workshops and cancer control systems have been organized and implemented with the sponsorship of the World Health Organization, for example, and partnerships have been formed with research institutions and universities around the world.

Vinyl

Vinyl, the common name for polyvinyl chloride (PVC), is one of the most widespread polymer produced worldwide, next to polyethylene and polypropylene. Production of PVC involves the use of harsh toxic chemicals. The polymer is comprised of two monomers, ethylene and chlorine. When combined these two monomers combine they produce ethylene dichloride, which is then further processed into vinyl chloride, or PVC. There are two forms of PVC, rigid (RPVC) and flexible. More than half of the world’s production is in making plastics because it is relatively inexpensive to manufacture and can be used in rigid or flexible products. More than 30 billion pounds of PVC is produced every year by the vinyl industry. There is not an aspect of civilization that is exempt from the impact of PVC.

Both RPVC and flexible PVC are readily found in clothing, automotive, construction, household and kitchen items, medical and office supplies, garden furniture and other outdoor items, personal care, baby and children’s products, and much more. RPVC is used in piping, doors, windows, bottles, non-food packaging, luggage, car dashboards, strollers, and bank and membership cards. When organotins are added to RPVC products, wallpaper and flooring are produced.

Phthalates a type of plasticizer is added to the PVC polymer to make it flexible. Flexible PVC is as ubiquitous as RPVC and is found in shower curtains, plastic wrap, food containers, drinking straws, tablecloths, plumbing, electrical cables, imitation leather, inflatable products, baby teething rings, and products replacing rubber. The rubber replacing products have become common in medicine, due to the rise of allergies to Latex rubber. Some examples of PVC in medicine are blood bags, catheters, colostomy bags, tubing, draw sheets, gloves, shoe covers, and mattress covers. Diethyl hexyl phthalate (DEHP) can be found in PVC at a rate of up to 50 percent by weight.

Other additives are inserted to change the chemical structure of the polymer. Lead, mercury, and other heavy metals are added in some PVC products, such as in wire insulation. Adding the heavy metals are stabilizers or change agents giving other properties to the plastic, broadening its usage. The chemicals found in flexible PVC leach when coming in contact with moisture, such as the mucous membranes, contact with food, or in medical equipment. These chemicals have been linked to cancer formation.

PVCs emit toxins into the environment from production, through use, and when sitting in the landfill. Throughout the entire process it leaches pollutants. PVC products, for the most part, are not recyclable because of the additives and in fact, interfere with the recycling of other plastics. That “new car” smell is the off-gassing of the plastics found in car parts made from PVC.

Flexible PVC plasticizers are notorious for leaching chemicals with use. Not widely recycled, flexible PVC when burned releases hydrogen chloride gas and dioxin, one of the most toxic chemicals in modern world.

Health Effects
Learning disabilities are up 191 percent from 1977 to 1994. One in 100 American children have an autistic spectrum disorder. Eight thousand American children are diagnosed with cancer each year. Testicular cancer in young men is increased by 60 percent. Hypospadias doubled from 1968 to 1993. Breast cancer, childhood obesity, childhood asthma, autism, and attention deficit hyperactivity disorder in some studies have found links to exposure to vinyl and its components. People across the age continuum with PVC in the flooring have a much higher incidence of asthma and are twice as likely to have autism. High levels of phthalates are found in indoor dust and air, in human urine, breast milk, and blood. Organotins and phthalates are oestrogenic, or hormone mimickers, that disrupt the endocrine system leading to hormone dysregulation and obesity, and premature puberty. Premature breast development is linked to breast cancer. Reproductive issues are rising with each year: fertility treatments,
endometriosis, miscarriages, and premature births rates are up in women from 25 to 34 years of age. Sperm counts are decreasing and defect sperm rates are rising. Testosterone levels are decreasing, testes are smaller, and more undescended testes are noted.

Dioxins, 31 different chlorinated organic chemicals, are made during the production of PVC, such as when chlorine is made from salt and when plastic is made, and then during the incineration of wastes in the landfill. Because PVC is found throughout the environment, anything that contains PVC and will burn, releases dioxins into the atmosphere. Dioxins are a health threat, a known carcinogen since 1997, and classified as such in January 2001. Dioxins are also linked to diabetes.

Vinyl chloride is absorbed at a rate of 40 to 95 percent, depending on the route of exposure. Though the body excretes most of the substance within 24 hours, some of the other byproducts, such as dioxin, take much longer. Dioxins have a half-life, the rate it takes for half the original level to be decreased by half, of seven to 11 years. In addition to causing cancer, they are directly linked to reproductive, endocrine, and immune system conditions.

The Environmental Protection Agency (EPA) reports that most Americans have dioxin exposure more than 200 times above the known safe level.

Most vinyl chloride exposure occurs via the inhalation of contaminated air during production. The pollutant is expected to vaporize within hours of release, but since it does not bind to soil or biodegrade with the microorganisms found in the soil, the toxin ends up in the air and in the groundwater. Once in the groundwater it can remain a pollutant for years. Most groundwater contamination occurs through the solvents such as trichloroethene, tetrachloroethene, and 1, 1, 1-trichloroethane.

During manufacturing when workers are exposed to high levels, central nervous system depression occurs producing symptoms such as headaches, drowsiness, changes in vision and hearing, disorientation, euphoria, and dizziness.

Children appear to have more exposure than adults to the chemicals found in PVC. Young children put objects in their mouth. They spend more time on the floor or near the ground, breathing the off-gassing chemicals and ingesting the contaminated dust. People exposed to PVC dust have a 20 percent increase in lung cancer for each year...
of exposure. Phthalates levels are highest in children aged 6 to 11 and in women. One study found 100 percent of the girls aged 6 to 9 tested had toxic levels of phthalates. The plastics industry’s public relations data-sheets relate that humans are not exposed to toxic levels of chemicals in the making or disposal of PVC. The industry does agree that vinyl chloride is a carcinogen and causes liver cancer. They relate that mercury exposure, while having adverse effects of human health, is not readily used in the manufacturing of PVC, thus the levels persons are exposed to are low. The industry, though admitting dioxins are toxic to humans at low levels, claims to use less than 30 grams per year. All of the research provided to substantiate their claims is from the late 1980s to early 1990s.

Visual Pathway and Hypothalamic Glioma, Childhood

Childhood visual pathway glioma is a brain tumor originating from cells in the brain called astrocytes, which are the star-shaped cells that provide biochemical support to the cells of the blood–brain barrier and assist in the maintenance and support of the neurons. Astrocytes have an important role in the scarring process of the brain and spinal cord after traumatic brain injuries.

Generally, visual pathway glioma is classified as World Health Organization (WHO) grade I pilocytic astrocytoma, but in some younger patients it may show an aggressive clinical course and spread through the cerebrospinal fluid pathway. A visual pathway glioma occurs along the optic nerve, which carries messages from the eye to the brain. In some cases, the tumor may progress and invade neighboring structures, resulting in visual impairment or complete loss of vision; in other cases, the tumor may remain stable for several years, accompanied by a spontaneous improvement of associated symptoms. The prognosis for patients with optic nerve tumors is generally better than the prognosis for glioma of the chiasma and hypothalamus. Visual pathway gliomas account for approximately 5 percent of all brain tumors in children.

Cellular Classification
Childhood visual pathway and hypothalamic gliomas are usually low-grade (grades 1 and 2) astrocytomas,
according to the WHO classification system. The astrocytic tumors of the optic nerve, optic chiasm, and optic tract are all classified as visual pathway gliomas.

Malignant gliomas of the visual pathway are rare, and higher incidences of visual pathway gliomas have been reported in patients with neurofibromatosis type 1 (NF-1). NF-1 is a relatively common genetic condition with an incidence of 1 in every 3,000 births. Patients with a history of NF-1 have an increased risk of visual pathway glioma. The NF1 gene product neurofibromin acts as a tumor suppressor, and a lack of normal neurofibromin in NF-1 patients results in increased cell proliferation and the formation of gliomas.

NF-1 is also responsible for the development of brown spots, freckles, and tumors on the skin and nerves, accompanied by developmental changes in the nervous system, muscles, bone, and skin. Approximately 20 to 30 percent of all patients with NF-1 are at risk of developing a visual pathway glioma. Association with NF-1 is present in 50 to 70 percent of patients with isolated optical nerve tumors, while the association is present in 16 to 20 percent of patients with chiasmal or deeper optical tract tumors. Most children diagnosed with visual pathway glioma have NF-1, while the remaining cases are sporadic. In general, the tumors are observed to grow at a slower pace in patients with NF-1, and the presence of NF-1 has a positive effect on the prognosis.

The tumors may also arise in the hypothalamus in large infiltrating lesions, and the distinction between optic and hypothalamic tumors has little clinical significance. Infants and young children with visual pathway and hypothalamic glioma may exhibit the diencephalic syndrome characterized by macrocephaly, intermittent lethargy, and visual impairment, or may remain asymptomatic. Double vision is also a common associated symptom. Neurological signs and symptoms may also result from involvement of the hypothalamus with signs of precocious puberty and accelerated linear growth, as well as other symptoms associated with imbalance of the endocrine system.

Visual pathway and hypothalamic gliomas do not have a universally accepted classification system. They are generally classified as low-grade astrocytomas, characterized by slow growth, and may occur anywhere along the optic tract.

### Treatment Options

In the event of a complete loss of vision and considerable bulging of the eye, surgery is performed to remove the tumor while sparing the globe of the eye.

Radiation therapy has been shown to control gliomas in the long term for most children with chiasmatic and posterior pathway chiasmatic gliomas. However, radiation therapy may result in substantially compromised intellectual and endocrinologic functions in children, as well as damage to the cerebrovascular system in the form of Moyamoya disease symptoms. Radiation therapy also increases the risk of secondary tumor development.

Chemotherapy has been shown to result in tumor shrinkage and to delay the requirement for radiation therapy. In cases where vision is retained but the tumor has progressed, chemotherapy has been shown to be extremely effective, especially with the combination of carboplatin and vincristine (chemotherapy drugs) in cases with NF-1, and therefore it is the most widely used chemotherapy regimen in pediatric visual pathway gliomas. Other chemotherapy approaches based on multiagent platinum-based regimens have also been used to treat children with progressive optic pathway gliomas.

Radiotherapy is generally not recommended for children because of its long-term effects on their health and growth, including the development of secondary tumors and severe effects associated with cognitive function. However, radiation therapy may be recommended depending on the case and the type of glioma.

Vitamins

Vitamins are organic compounds that are essential to biological function. They are either not produced by the organism or only produced in limited quantities and thus must be obtained from the diet to sustain life. Vitamins are identified by a letter from A to K, but they also have a chemical structure name. The essential vitamins for humans are A, B, C, D, E, and K. While there is research available on the role of vitamins in the prevention and treatment of cancer, vitamin supplementation is not considered critical to either treatment or prevention by the American Cancer Society. Below is a review of each vitamin, its role in human physiology, and a summary of the cancer research from both supplementation and dietary sources. Often, studies use epidemiological data to show relationships. However, these relationships do not always match the findings of clinical trials.

Vitamin A is a fat-soluble vitamin found in meat products as well as in fruits and vegetables; it is also available as a dietary supplement. Carotenoids, compounds that give red, yellow, and orange coloration to many fruits and vegetables, can turn into a form of vitamin A. Vitamin A is important for growth and development, for immunity, and for good vision.

Some research has shown that vitamin A has been associated with a reduced risk of lung cancer. Supplementation with vitamin A has had little positive effect on reducing the risk of lung cancer. Humans can convert beta-carotene in food into vitamin A if a food source of fat or oil is present in the same meal. Conversion efficiency and absorption will depend on whether the food source is raw or cooked, the presence of fats and oils at the same time, current stores of both vitamin A and beta-carotene, and other factors such as the species of carotene, patient nutrient status, patient genetics and host specificity, and interactions with other dietary factors. In general, humans are not efficient converters of beta-carotene into vitamin A and only absorb 9 to 22 percent. Smokers should not consume vitamin A or beta-carotene supplements either on a regular basis or while undergoing chemotherapy and radiation therapy; consumption of vitamin A or beta-carotene supplements may actually increase tumor growth and lead to a poorer prognosis. Consuming food sources of beta-carotene and vitamin A is not contraindicated in smokers and may actually be beneficial. This apparent opposite effect may be due to the differences between natural and synthetic forms of these compounds. Cervical dysplasia is a pre-cancerous condition of the female cervix associated with several species of human papilloma virus. Consuming beta-carotene supplements and beta-carotene foods can reduce cervical dysplasia and may help with shedding of the virus.

Bladder cancer, for which smoking is the leading risk factor, has been studied with respect to vitamin A intake in diet and supplements. A recent meta-analysis of over 20 trials examined only studies that controlled for the effect of smoking as a possible causation of bladder cancer. They concluded that intake of dietary carotenoids with the potential to form vitamin A significantly reduced the risk of bladder cancer. Measurement of vitamin A in blood of the study subjects found an inverse relationship between the serum levels of vitamins A and the risk of bladder cancer.

Lycopene is a carotenoid without pro-vitamin A activity; it does not become vitamin A. While present in many fruits and vegetables, it is highest in tomatoes. Lycopenes are most absorbable when the tomato has been cooked and a fat is present in the same meal. Canned tomatoes, tomato paste, commercial tomato juice, and ketchup are common examples of cooked tomatoes. Epidemiological studies have found a lower risk of stomach, colon, rectal, and prostate cancers when the dietary daily intake of lycopenes exceeds 35 mg per day.

B vitamins are water-soluble and have an important role in cell metabolism, including a positive effect on metabolic rate, preservation of...
Vitamins

1291

muscle tone and skin quality, improvement of nervous and immune system function, and promotion of growth and cell division. By number and name they are B1 (thiamine), B2 (riboflavin), B3 (niacin or niacinamide), B5 (pantothenic acid), B6 (pyridoxine, pyridoxal, and pyridoxal-5-phosphate), B7 (biotin), B9 (folate), and B12 (cyanocobalamin, hydroxocobalamin, and methylcobalamin). All B vitamins, except B12, are available from plant sources. B12 is present in some bacteria and some nutritional yeasts, but it is most easily absorbed from red meat. Smaller amounts of B12 may be absorbed by consuming fish, eggs and dairy. A small amount of B12 is added to vegetarian foods such as tofu and tempeh since strict vegetarians do not consume foods containing B12. The remaining B vitamins are found in dark leafy greens, whole grains, legumes, and potatoes.

Epidemiological studies suggest that adequate folate, B6, and B12 can reduce the risk of developing breast cancer, especially in women with higher alcohol consumption. Alcohol consumption increases the need for B vitamins to metabolize ethanol and leads to the subsequent excretion of B1, B2, B3, biotin, and folic acid.

Recent studies of children with newly diagnosed leukemia found low plasma levels of pyridoxal-5-phosphate. Low levels of B12 have been found in rectal cancer and laryngeal cancer. Folate intake appears protective for colon cancer. However, taking supplemental folate once a tumor has been diagnosed may increase tumorgenesis, suggesting a dual-modulatory effect or a difference between food and synthetic sources of folic acid. Methylation influences gene expression, and folate is involved in the generation of methyl groups. Hypomethylation has been observed genetically in humans who have a deficiency of methylenetetrahydrofolate reductase and in humans who consume a low folate diet. About 10 percent of Asians and Caucasians have 70 percent less activity of this enzyme, and another 40 percent can only convert a limited amount of folic acid. The ingestion of methyltetrahydrofolate may assist those with this deficiency.

Riboflavin deficiency can disrupt the integrity of the esophagus epithelium. The best food sources of riboflavin are spinach, tempeh, yogurt, mushrooms, and eggs. Some studies show a relationship between diets low in riboflavin and esophageal cancer. Riboflavin deficiency has also been identified as a risk factor for cervical dysplasia, the precursor to cervical cancer. Low B2 and B6 levels have been found in patients with non–small cell lung cancer. B2 seems to have an important role in breast cancer. Niacin has moderate scavenging effects on invasive liver cancer in rats. A similar mechanism has been suggested for humans.

Inositol is a member of the B vitamin complex and can be produced from glucose. It is involved in biological processes such as insulin signal transduction, cell membrane maintenance, breakdown of fats, and gene expression. Inositol is found in fruit, legumes, grains, and nuts. Inositol hexaphosphate (IP6) helps the body in the use and metabolism of calcium and other minerals. Animal research has shown that it can prevent tumors from forming and slow the growth of existing tumors. Human trials using very large doses have shown that it can reduce the side effects of chemotherapy, improve quality of life, and increase survival time in breast and lung cancer patients.

B10, or para-aminobenzoic acid (PABA), is found in liver, brewer’s yeast, kidney, molasses, and whole grains. Because humans can metabolize it, it is not considered an essential vitamin. Humans cannot
metabolize it into folate, although some bacteria such as *E. coli* can. PABA can prevent ultraviolet-B damage to the skin, but taken internally it may increase the risk of ultraviolet damage and cause an allergic reaction. Its popularity as a topical and oral sunscreen to prevent skin cancers fell, but now a water-insoluble PABA derivative, padimate O, is used in some products.

B17, or amygdalin, is a glycoside isolated from the seeds of bitter almonds. When properly metabolized, one gram of amygdalin may yield 68 mg of hydrogen cyanide. Amygdalin has been confused with laevomandelonitrile, or laetrile for short. Laetrile is a semi-synthetic molecule sharing a portion of the amygdalin structure. It was popularized in the 1960s and 1970s as a cancer treatment, but it was derived from apricot pits or neo-amygdalin. Human trials have not shown laetrile to decrease tumor size or enhance survival.

Vitamin C is water-soluble, and humans, unlike most mammals, cannot synthesize it. Vitamin C is available as the reduced ascorbic acid and the oxidized dehydroascorbic acid. The latter is the most common form in the human body, but the former is the best method of ingesting it orally. Vitamin C is highest in cantaloupe, citrus fruits, kiwi, and vegetables such as broccoli, peppers, and spinach. Cooking and storage reduces the amount of vitamin C present, so these foods are best ingested fresh.

Vitamin C is important for the growth and repair of body tissue. It helps form collagen to make skin, tendons, ligaments, and blood vessels. It aids in the healing of cuts and surgical incisions and repairs and maintains bones, cartilage, and teeth. Deficiency of vitamin C is associated with anemia, bleeding gums, decreased wound healing, and ability to fight infections, nosebleeds, dry scaly skin, and swollen, painful joints. This medical condition is known as scurvy.

Vitamin C has two important and opposite roles in the human body. Ascorbic acid is a potent antioxidant that quenches free radicals produced from extracellular and intracellular processes. Free radicals protect people from smoke, radiation, and pollution, and they increase with the aging process. As a pro-oxidant, ascorbic acid promotes the formation of reactive oxygen species such as hydrogen peroxide in the presence of pro-oxidant vitamin C. In the presence of high concentration of ascorbic acid in the extracellular fluid, the absence of tumor cell catalase, and the presence of iron and/or copper, vitamin C can have a cytotoxic effect on tumor cells.

In the 1970s, Ewan Cameron, Linus Pauling, and Allan Campbell gave cancer patients high doses of intravenous vitamin C. They found longer survival times in the intravenous patients compared to controls and patients given oral vitamin C. Research that followed demonstrated that in plasma, intravenous vitamin C could exceed the concentration of oral vitamin C by 100 to 200 fold. It was these higher intravenous concentrations, not the oral doses, that led to the observed clinical effect. It has also been demonstrated that vitamin C will kill some cancer cells but not normal cells. Tumor cells selectively take up more vitamin C compared to normal cells through facilitated transport by glucose transporters. This is because tumor cells have an increased metabolic need for glucose. Intravenous ascorbic acid acts as a prodrug leading to the formation of the ascorbate radical and hydrogen peroxide in the extracellular spaces. Oral ascorbic acid acts as an antioxidant to prevent reactive oxygen species formation.

A study of patients with advanced cancerous tumors and hematological malignancy found antitumor activity. Studies have been done using intravenous vitamin C in ovarian, pancreatic, hematological, colorectal, breast, liver, lung, and prostate cancer. Tumor markers were reduced in the intravenous vitamin C group. Intravenous vitamin C has also been used in combination with paclitaxel, carboplatin, and gemcitabine with a reduction in adverse treatment effects from chemotherapy and no reduction of the clinical effects of the chemotherapeutic agent. Studies of high concentrations of vitamin C have shown it to have an additive effect on cisplatin, cyclophosphamide, doxorubicin, etopoide, fluorouracil, gemcitabine, irinotecan, paclitaxel, tamoxifen, vincristine, and FOLRIFI and FOLFOX regimens. Intravenous vitamin C may interfere with bortezomib and methotrexate. Patients with a G6PD deficiency who receive intravenous vitamin C above 15 grams are at risk for red blood cell lysis. G6PD deficiency is considered the most common enzyme deficiency in humans.
Vitamin D is a fat-soluble vitamin formed after ultraviolet radiation of the skin converts 7-dehydrocholesterol to vitamin D or 1,25 cholecalciferol.

Vitamin D can also be obtained from some foods, including fatty fish, fish liver oil and eggs, and dietary supplements. It helps the body use calcium and phosphorous to make strong bones and teeth, and a deficiency of vitamin D may weaken the bones, leading to a disease called rickets (when it occurs in children) or osteomalacia (when it occurs in adults). Two types of vitamin D important to humans are D$_2$ or ergocalciferol, which is made naturally by plants, and D$_3$ or cholecalciferol, which is made when the skin is exposed to ultraviolet radiation. The Institute of Medicine (IOM) recommends that persons between 1 and 70 years of age consume 15 micrograms (μg) per day, which is the same as 600 international units (IU) per day. For those age 71 or older, the IOM recommendation is 20 μg (800 IU) per day. D$_3$ is recommended for supplements because D$_2$ is poorly converted to the active form of the vitamin.

Initial interest in studying the relationship between vitamin D and cancer was motivated by the observation that the incidence and death rates for some cancers were lower among individuals living in the southern latitudes, where they were likely to receive more sun exposure than people living in the northern latitudes. Experimental evidence from animal studies has also suggested that vitamin D might lower cancer risk by several means, including decreasing cellular growth, stimulating apoptosis (cell death), promoting cellular differentiation, and reducing angiogenesis (tumor blood vessel formation).

Some epidemiologic studies with humans have also found associations between vitamin D and the risk of certain cancers, but results are inconsistent and based on observation rather than experimental designs. This means that observed associations might be due to reasons other than vitamin D consumption or blood levels. For instance, people who consume high levels of vitamin D might differ in other ways (such as healthier behaviors) from those with low levels of consumption, and those other differences might explain the observed relationships. Vitamin D has been included as a variable in some experimental studies, but none of those trials was designed to study cancer specifically, so further research is needed before conclusions can be drawn.

Multiple epidemiologic studies have found an association between high vitamin D intake and high bloodstream levels of vitamin D are associated with a lower risk of colorectal cancer, but these studies are all observational and thus cannot demonstrate causality for the reasons noted above. The Women's Health Initiative, a randomized trial, found no relationship between taking vitamin D and calcium supplement and reduced risk of colorectal cancer, but the results from that study have been criticized on several grounds, including the low level of vitamin D in the supplements (10 μg/100 IU daily), the short period of follow-up, and the fact that participants could have taken vitamin D on their own. There is insufficient evidence to draw any conclusions about the relationship between vitamin D and any other types of cancer at this time.

Vitamin E is a fat-soluble vitamin absorbed in the small intestine. Vitamin E is found in raw nuts and seeds, avocados, fish, and olive oil. It requires bile and pancreatic esterase for absorption, and then enters circulation via the lymphatic system where it is transported to the liver. Vitamin E is essential for cell membranes, gene expression and signaling, cell proliferation, and reproduction. Vitamin E consists of four tocopherols, alpha, beta, delta, and gamma, and four tocotrienols, alpha, beta, delta, and gamma. Research findings debate the importance of alpha-tocopherol versus the other three forms; but, in nature, the four are often found together, and gamma has been found to have clinical importance in some conditions. The synthetic or commonly supplemented form is all-racemic alpha-tocopherol, while the natural form is d-alpha-tocopherol.

The natural form has twice the biological activity of the synthetic form. A deficiency of vitamin E leads to increased peroxidation of red blood cells and fatty acids, neurological symptoms such as difficulty walking and speaking, lipoprotein abnormalities, and poor fat absorption syndrome. At high doses, vitamin E inhibits protein kinase C and tumor promotion. Protein kinase C is important in the signaling of apoptosis or normal cell death, a process absent in most cancer cells. Vitamin E at sufficient doses can reduce cell proliferation in lung cancer. Vitamin E has been shown to suppress telomerase activity in ovarian cancer cells. Thus, it could be a useful therapeutic adjuvant. In a large prostate cancer study, vitamin E and selenium
alone and together did not prevent prostate cancer in a generally healthy group of men. Many of these studies have used synthetic alpha-tocopherol rather than the natural vitamin E with its multiple forms. The natural form may have more clinical activity than synthetic alpha-tocopherol.

Many patients with cancer will develop a hypercoagulability state. The formation of clots can lead to cardiovascular accidents and strokes that complicate the lives of patients dealing with cancer. The natural mixed tocotrienols have been shown to reduce increased coagulation states, with the gamma portion appearing to be the most active. Their mechanism is different than that of aspirin, coumadin, and fish oil. Tocotrienols have been shown to inhibit the inflammatory nuclear factor kappa B when it is activated by tumor necrosis factor alpha, cigarette smoke, interleukin 1-beta, and epidermal growth factor, all of which promote cancer cell growth. Tocotrienols can also inhibit the growth of breast cancer cells—both estrogen positive and estrogen negative—and this is not via an estrogen receptor mediated pathway. In addition, they do not inhibit breast cancer cell growth by interfering with the insulin growth factor pathway or increased binding of its proteins. Similar results have also been shown for human prostate cancer cells. These findings further suggest an important role for the natural form of vitamin E.

Vitamin K consists of vitamin K1 (phyloquinone), vitamin K2 (menaquinone), and vitamin K3 (menadione). Vitamin K1 is found in green leafy vegetables and controls one of the mechanisms by which blood clots. Vitamin K2 is synthesized in the gut by intestinal flora and is involved in bone metabolism. Vitamin K3 is a synthetic analogue derived from K1, K2, and a provitamin.

Vitamin K1 has been studied for anticancer properties since 1947. It has shown activity against liver, colon, lung, stomach, nasopharyngeal, and breast cancer as well as leukemia. In a trial of hepatocellular carcinoma patients, a 20 percent tumor-response rate was observed, and several patients survived longer than one year. In a second trial with the same cancer, 20 percent of patients’ disease stabilized, and lab values normalized in half of the patients. K1 induces cancer cell apoptosis via production of a reactive oxygen species and modulation of transcription factors of cell reproduction. Epidemiological studies have found that individuals with the highest levels of K1 in the diet had a much lower risk of developing Non-Hodgkin lymphoma.

Vitamin K2 has shown to have an effect against liver, colon, stomach, lung, lymphocyte, nasopharyngeal, and breast cancer as well as leukemia. In leukemia it has been shown to induce apoptosis in leukemic blast cells. K2 may induce cell apoptosis through a nonoxidative mechanism involving transcription factors and cell cycle arrest. It also modifies growth factors and receptor molecules and freezes cell cycles, making growth and replication of tumor cells more difficult or impossible. Its activity is known as oncosis, or stress activated ischemic cell death. Tumor cells are particularly susceptible to oncosis. In patients with viral liver cirrhosis and a high risk of liver cancer, ingestion of K2 over several years reduced the development of liver cancer in the K2 group compared to control patients. In myelodysplastic syndrome, K2 has been shown to increase survival and delay onset of hematological cancers. In prostate cancer, when supplementing with vitamin C and K2 serum, cancer markers were decreased and prostate cancer cells were destroyed. Vitamin K2 may be depleted by extended use of warfarin, antibiotic use that significantly alters intestinal flora, and medications that reduce fat absorption.

K3 combined with vitamin C has been shown to cause cancer cell death. This mechanism is called autoschizis and differs from apoptosis and oxidative stress. K3 has also been shown to be effective when combined with 5-fluorouracil, bleomycin, cisplatin, and dacarbazine.

Conclusion
The field of vitamin research and cancer includes many more cell line and animal studies than it does human clinical trials. Most of the human trials are small in number. These trials have shown whether there is a clinical effect against various types of tumor cells, interactions with various chemotherapeutic agents and radiotherapy, and patient quality of life under vitamin therapy versus conventional chemotherapy and radiotherapy. More clinical trials are needed before the use of vitamins will become a part of conventional treatment of patients with cancer.

Paul Richard Saunders
Canadian College of Naturopathic Medicine
Vulvar Cancer

Vulvar cancer is a disease that affects the vulva, the external part of the female genital area. This area consists of the mons pubis (a fat pad that grows hair during puberty), the clitoris (the area that becomes erect when aroused), the labia minora and labia majora (coverings over the vaginal opening), and the vulvar vestibule (the opening to the vagina).

Vulvar cancer is a rare cancer, accounting for about four percent of cancers affecting the female genital tract. Most cases of vulvar cancer appear in postmenopausal women. However, some cases have been reported in younger women. Four main types of vulvar cancer include the following:

- **Squamous Cell Carcinoma:** The most common type of vulvar cancer (accounting for about 90 percent of cases), it starts in the squamous cells and is usually located on the labia.
- **Adenocarcinoma:** This cancer begins in the vulvar glands. About eight percent of vulvar cancers are adenocarcinomas.
- **Vulvar Melanoma:** This cancer is rare, representing about five percent of vulvar cancers.
- **Sarcoma:** This is another rare form of vulvar cancer, making up about two percent of vulvar cancers. This cancer forms in the connective tissue.

When the cancer begins in the vulva, it is referred to as primary vulvar cancer. However, if the cancer begins in another part of the body and then is found in the vulva, this condition is referred to as secondary vulvar cancer.

**Risk Factors**

Despite the fact that vulvar cancer is not as common as other cancers, there are factors that can predispose someone or be risk factors for developing this type of cancer. There are many factors that can put an individual at risk for developing vulvar cancer, including the following:

- Contraction of the human papilloma-virus (HPV) or genital warts in women younger than the age of 50
- Women who have had cervical or vaginal cancer
- Pronounced changes on the skin such as lichen sclerosis or squamous hyperplasia
- Contracting a sexually transmitted disease or infection increases the risk. Developing antibodies to fight off the herpes simplex virus 2 has been determined to be a predisposing risk factor for developing vulvar cancer.
- Having systemic lupus erythematosus has been reported to carry a three-fold risk of developing vulvar cancer.
- Women who have had a kidney transplant are put in a higher risk category to develop vulvar cancer.
- Women with psoriasis have a higher risk of developing vulvar cancer.
- Having vulvar intraepithelial neoplasia (VIN)

**Symptoms of Vulvar Cancer**

There are instances when women do not have any symptoms in the early stages of cancer or are embarrassed to report any symptoms, but a medical professional may notice some changes in the vulvar region during an examination. Women are encouraged to report changes that may occur to a doctor before the condition becomes serious and needs immediate medical treatment. If a woman...
does experience symptoms of vulvar cancer, these may include the following:

- Bleeding
- Dyspareunia (painful sexual intercourse)
- Burning during urination (dysuria) or pain only in the vulvar or genital region
- Intense itching
- Rash in the vulvar region
- Vulvar region becomes red and raw
- Strong smell coming from the vulva

Since the skin of the vulva is extremely sensitive, changes or deformities of the skin can occur in vulvar cancer. Women should be aware of any changes and report them to a medical professional. Changes or deformities to the skin may include the appearance of red, white, pink, or gray mole or freckle; the skin around the vulva may appear like a lump or begin to thicken abnormally; or an ulcer may form that can bleed and become painful and sensitive to touch.

**Diagnostic Testing for Vulvar Cancer**

Once there is a suspicion of vulvar cancer, a patient will undergo diagnostic testing. These tests are important to rule out the disease or help with determining a treatment. A medical professional will conduct a thorough pelvic examination to detect skin changes or any other problems with the genital region. Tests may include swabbing of the area, and using an ultraviolet light can aid in the detection of skin changes or the appearance of abnormal squamous epithelial cells. A biopsy of the vulva will be performed to detect the presence of abnormal cells. If a medical professional feels that there should be more testing done, a CT scan or MRI of the pelvis will be ordered. Medical professionals may consider performing a cystoscopy or proctoscopy to aid in the diagnoses of vulvar diseases or conditions that could have spread to other areas of the body. A cystoscopy is a diagnostic tool that examines the bladder, and a proctoscopy is used to examine the rectum.

**Stages of Vulvar Cancer**

As with all types of cancers, medical professionals use staging to describe the severity of the cancer as well as how to treat the patient. There are five stages of classifying vulvar cancer:

- **Stage 0:** Cancer is confined to the surface of the skin. This stage is referred to as carcinoma in situ.
- **Stage 1:** The cancer is confined in the perineum and vulvar region and has not spread to the lymph nodes.
- **Stage 2:** The cancer has spread into the lower part of the urethra, the lower part of the vagina, or the anus.
- **Stage 3:** Cancer has spread into the lymph nodes.
- **Stage 4:** Cancer has spread into the upper part of the urethra, the upper part of the vagina, or other parts of the body.

**Treatment of Vulvar Cancer**

Depending on the staging, there are several treatment options available when treating vulvar cancer. Laser surgery is a great option if the cancer is detected early. Sometimes a surgeon is able to clear out diseased tissue, but patients may have to consider a complete removal of the vulvar region in order to remove the cancer cells. Radiation and chemotherapy are other options used in treating vulvar cancer.

Waldenström's Macroglobulinemia

Waldenström's macroglobulinemia (WM) is a rare blood cancer. The Swedish physician Jan Waldenstrom first described the disease in 1944. The name macroglobulinemia refers to an excess of large proteins in the blood. Known as immunoglobulin M, or IgM, molecules, these are the largest type of antibodies produced in the body. WM shares characteristics with both lymphoma as well as multiple myeloma. The WM tumor cells are actually a mix of lymphocytes (the white cells causing lymphoma), plasma cells (the white cells causing multiple myeloma), and cells looking somewhat in between both of these, known as lymphoplasmacytic cells.

The categories of blood cancers encompassing WM are referred to as plasma cell dyscrasias, or monoclonal gammopathies. In this regard, the tumor cells arise from the same type of white cells, which make antibodies; however, WM tumor cells multiply as clones and all produce identical IgM antibody proteins. Monoclonal IgM proteins are known collectively as the m-spike, and this is a crucial component in the diagnosis of WM. These monoclonal antibodies can be visualized as a narrow band when blood proteins are sorted by weight and charged by electrophoresis (SPEP), as opposed to a wide band from normal diverse antibodies. This technique can also identify an m-spike excreted in the urine. The type of protein making up the m-spike can be characterized as IgM by immunofixation electrophoresis (IFE). Because antibodies are all composed of both heavy and light chains, another test detects excessive monoclonal free light chains in the blood (serum free light chain testing). The diagnosis of WM is made by two components: a documented m-spike and a bone marrow biopsy showing the specific characteristics described above, known as lymphoplasmacytic lymphoma.

There are 1,000 to 1,500 new cases diagnosed in the United States each year. The average age at diagnosis is 60 to 70 years. WM is more common in men than women. A benign, precursor state, known as monoclonal gammopathy of undetermined significance, can progress into WM or other blood disorders. There are no known environmental risk factors for developing WM. However, there is a familial variant in about 20 percent of patients and Ashkenazi ethnicity in 20 to 25 percent of patients. Patients may initially present with a wide variety of symptoms. Presenting symptoms may be constitutional, such as fatigue, fevers, night sweats, or weight loss. Symptoms may be related to loss of normal blood cells from overcrowding tumor cells in the bone marrow, including low red cells, white cells, or platelets. These low counts can lead to fatigue, increased infections, and bleeding.
WM patients often have other immune system dysfunction, including decreased production of normal antibodies, which further increases their risk of infection. A variety of additional symptoms may be caused by the excessive IgM protein itself, including autoimmune disorders, painful and often-debilitating nerve damage (peripheral neuropathy), or thick blood (hyperviscosity), which can lead to occlusion of small blood vessels.

The treatment of WM shares many therapies that are also utilized in either lymphomas or myelomas. WM is often an indolent disease and progresses slowly. As such, patients are observed closely and not treated until they become symptomatic. If a patient develops hyperviscosity, plasmapheresis is an acute and temporary treatment that reduces the number of IgM proteins in the blood. The mainstay of treatment is a combination of the biological therapy rituximab and single/combination chemotherapy or another anticancer medication. Active therapies include steroids, fludarabine, cyclophosphamide, bortezomib, and ibrutinib. One of the latest discoveries, by Treon et al, is a somatic mutation in over 90 percent of WM patients, known as L265P. This may pave the way to new and more effective treatments for this disease.

Chemical agents have been used as weapons of war throughout human history. It was during World War I, however, that chemical weaponry came of age. Highly toxic war gases, primarily mustard gas and phosgene, were used with devastating effectiveness on the bodies and minds of troops on both sides of the conflict. The tragedy of approximately 90,000 soldiers dying a comparatively slow and miserable death on the killing fields of the World War I, with nearly 1 million others permanently injured, generated a universal repugnance to chemical weapons. To this day, with the field of military weapons greatly expanded, when single bombs can kill millions, and ever-more-ingenious killing devices are invented, chemical weapons remain the only military hardware banned from the battlefield.

In 1925, the first international agreement banning chemical weapons from warfare, the Geneva Protocol, was drafted. Some limited use of war gases did occur thereafter (e.g., invasions of Ethiopia by Italy and China by Japan in the 1930s; Saddam Hussein on Iran in the Iraq–Iran War and against Kurdish Iraqi citizens; and in 2013 by Syria against its own citizens), but war gases were not used in World War II. The Nazis did employ poisonous gases (hydrocyanic acid) as an important method for the systematic murder of concentration camp inmates, mostly Jews, but these gases are not technically considered to be war gases since they were not used as weapons of war.
The precise definition of chemical weapons can be contentious. The Chemical Weapons Convention (CWC), introduced to the United Nations in 1992 and entered into force in 1997, defines a chemical weapon as an armament using a toxic substance in a delivery system such as a bomb or artillery shell to cause permanent harm to humans or animals. The CWC is administered by the Organisation for the Prohibition of Chemical Weapons, an independent, autonomous international organization. As of 2014, 190 countries were Member States of the Organisation. The World Health Organization (WHO) has a broader definition of chemical agents of warfare: “all substances employed for their toxic effects on man, animals or plants.” The WHO definition is not considered in establishing international law.

In general, chemicals like napalm, magnesium, and white phosphorus smoke that act as incendiary substances to create physical force, smoke, or fire are not considered chemical weapons. Riot control agents are specifically prohibited from warfare by the CWC, but they are not outlawed for use by domestic police forces in crowd control. The United States sprayed about 20 million gallons of military herbicides on the Republic of Vietnam, its ally, during the Vietnam War, but such herbicide spray missions are not classified as chemical warfare under the CWC. The reasoning is that the chemicals were used as tactical weapons to destroy foliage and “unfriendly” crops that fed the enemy forces and were not designed to inflict harm on human beings or animals. For purposes of discussion here, the herbicides will be included as war chemicals because of their potential human health effects, regardless of the stated military reason for their having been employed.

Biological agents are often classified with chemical agents, and there is a narrow borderline between the two weapons types because many biological agents exert their toxic effect with poisonous chemicals. For example, botulism is caused by a toxic chemical released by *Clostridium botulinum*, the microorganism associated with the disease. This article does not include biological agents.

The CWC classifies chemical weapons into the following types:

- Choking agents
- Blister agents
- Blood agents
- Nerve agents
- Riot control agents
- Mustard agents

The chemicals are generally used in warfare as “lethal agents” designed to kill or injure an enemy severely enough to necessitate evacuation and medical treatment; as “incapacitating agents” to put the enemy out of action for hours or days, but to allow recovery without medical intervention; or as “harassing agents” to incapacitate an enemy for as long as he or she remains exposed.

Many chemicals, like mustard gas and the arsenical vesicants, can be absorbed percutaneously (i.e., enter the body by skin absorption), thus making respirators ineffective, and also increasing their toxic potency. Nerve gases known as G-agents are both much more toxic and quicker acting than agents like the lung gas phosgene. Nerve gases can penetrate eyes and skin, as well as poison the victim through inhalation. Tabun (or GA) is an example of a G-agent. It was discovered by the Germans in 1936 and is a nerve gas that acts as a cholinesterase inhibitor. Many nerve gases, and organophosphate pesticides, share this toxic pathway. Cholinesterase is an enzyme that breaks down acetylcholine, a compound formed at nerve junctions to transmit nervous signals. Cholinesterase inhibition does not permit the nerve cells to return to their resting state and leads to serious—even fatal—neurological dysfunction.

Soman and sarin also belong to this family. Sarin was the chemical used in 1995 by the Japanese cult Aum Shinrikyo for an attack in the Tokyo subway system that killed 12 people and injured about 1,000 commuters. By the beginning of World War II, massive quantities of tabun had been manufactured and stockpiled, but sarin became the G-agent of choice after the manufacturing processes were improved. Sarin is 50 times more lethal than phosgene.

The alphabetical code names for the chemicals were assigned to them by U.S. military authorities. In the United States, the committees of scientists assembled by the National Academy of Sciences to aid the government during World War II followed this alphabetic naming tradition. The first committee was called the ABC Committee, followed by the DEF Committee. Records of meetings and reports are now declassified and open for public inspection in Washington, D.C., at the Academy.

In 1955, another class of nerve gases, V-agents, was discovered. V-agents are 10 times more lethal

</table>
than sarin and are more readily absorbed percutaneously. The WHO estimates a human lethal dose of mustard gas, via skin absorption, to be 5,000 mg; sarin to be 1,000 to 2,000 mg; and V-agent to be as low as about five mg. V-agents are remarkably effective in penetrating skin and causing death. These agents are also persistent, so that their use requires effective decontamination procedures following a military assault to prevent further poisoning.

Table 1 provides chemical and health data on a number of important war gases and chemicals.

Public Health Considerations

In the 1970s, the WHO produced a document on chemical warfare agents that is still relevant today because of the limited research and development of war gases and chemicals that has taken place since then. The WHO summarizes characteristics of chemical weapons relevant to public health as follows.

Chemical weapons differ from conventional weapons in their potential for unintended consequences on civilian populations, both those living within the target area and those living at considerable distances from the target, and “pose a special threat to civilians.”

Very small quantities of chemical weapons may have devastating ecological and public health consequences on the populations and environments in targeted areas, as well as distant from the battlefield.

There may be unintended long-term consequences of exposure to chemical gases and sprays, sometimes decades after hostilities have ended. Some war gases and sprays are associated with the development of chronic diseases, like cancer, which may take years to manifest after the initial exposure. This is particularly true of highly bioreactive alkylating chemicals like the mustard gases used during World War I.

Chemical weapons can pose grave dangers to large populations and ecologies through sabotage and non-conventional warfare terrorist attacks that do not require large scale sophisticated weapons for their launching.

The WHO considers that for those who survive a chemical attack, “the long-term effects of the military use of agents that are not directly lethal may be considered more important than their immediate effects.” The lethality of chemical weapons and their ability to cause long-term chronic diseases, like cancer, is related to their innate chemical activity and to the dose of exposure. It has, however, proven difficult to identify precisely the long-term effects, except for a few agents such as mustard gas. Standard epidemiological methods require that the at-risk population be accurately identified (i.e., the true denominator for a risk calculation); that the exposure be quantified (i.e., the doses of toxins delivered); and that relevant diseases and causes of death be accurately diagnosed and recorded. For substances for which a good deal of either clinical or epidemiological data exist on civilian or occupational cohorts, the dissimilarity of scenarios between wartime exposures and non-combat exposure make it difficult to extrapolate potential effects among combatants or exposed civilians.

Exposure dose is particularly problematic. The amount of the chemicals delivered to the target will vary with weather conditions. The same weapon may deliver different effective doses at different times. War gases and chemicals may persist in the environment and their rate of decay will vary with the environmental characteristics of the terrain, making calculation of an exposure rate problematic. The chemical agents may spread over large, poorly defined areas. Accurate data on the at-risk population and its health status may also be difficult to ascertain. People who live in war zones are apt to be very mobile, and recordkeeping of transient populations is poor.

With regard to health effects in military personnel who may have been exposed to the agents, few countries maintain records of the environmental exposures that troops may have encountered. In the United States, it is extraordinarily difficult to even identify the names of individual soldiers at risk.

Water Treatment

Concerns over drinking water contaminants and human health date back centuries. However, it was only beginning in the 1970s that contaminant sampling became more common and extensive. Since that time, scientists have discovered that hundreds of manufactured chemicals can be found in various drinking water supplies, such as groundwater and rivers. Many of these substances are known or suspected human carcinogens.

History

Although treating water for consumption dates back as far as 4000 B.C.E., treatments initially focused on improving the aesthetic qualities of drinking water, such as taste and odor. It was not until the 19th century that scientists began to understand the health effects of drinking water and the sources of health problems due to microscopic organisms and other invisible constituents. Water treatment systems in the United States created in the early 20th century focused on reducing turbidity to remove microbial contaminants that could cause epidemics such as typhoid, dysentery, and cholera.

Although water filtration methods could reduce turbidity, disinfectants ultimately proved to be more effective in reducing waterborne-disease outbreaks. Chlorine was first used as a water disinfectant in 1908 in a water treatment plant in Jersey, New Jersey. Federal regulations concerning drinking water began in 1911 with bacteriological quality standards set by the U.S. Public Health Service (PHS). Standards have been revised and expanded over the years.

Concern over drinking water supplies grew in the late 1960s as the PHS began to investigate the presence of man-made chemicals in drinking water. These chemicals were from sources such as factory discharges, runoff from farms and streets, and underground storage and disposal tank leaks. In 1960, a PHS water system survey found that only 60 percent of water treatment systems produced water that met all PHS standards.

In 1973, the U.S. Congress began to debate issues regarding water treatment and supply safety. These debates led to passage of the Safe Drinking Water Act of 1974 to regulate public water supplies. Amendments were added to the act in 1986 and 1996. The act addressed threats to the drinking water supply, including chemicals, animal wastes, pesticides, naturally occurring contaminants, and other threats to human health. The act also addressed health risks from water that is not properly treated or travels through a distribution system that is improperly maintained.

In 2009, a New York Times analysis of federal data found that key provisions of the Safe Drinking Water Act had been violated by 20 percent of water treatment systems in the United States. These violations had occurred over the previous five years beginning in 2004. Among the violations found were increased concentrations of arsenic, radioactive substances such as uranium, and the solvent tetrachloroethylene. All have been linked to increased risk for cancer.

Contaminants

Chemical contaminants in drinking water come from various sources, from the improper disposal of household products and cleaning solvents to increased pesticide use in the last half of the 20th century. The U.S. Environmental Protection Agency (EPA) regulates more than 40 contaminants known carcinogens. For some scientists, no level of carcinogens in drinking water is thought to be safe. Over the years, the EPA has regulated many of these carcinogens in drinking water by limiting allowable concentrations of these substances.

The EPA’s list of contaminants in drinking water includes microorganisms, disinfectants, disinfection
Water Treatment

400 cases of the disease are diagnosed in the United States each year in children and teenagers. Several epidemiological studies have found a connection between nitrate in drinking water and an increased risk for colon cancer. A 2010 study conducted in Iowa studied nitrogen leaching in drinking water and found an increased risk for colon cancer in people exposed to drinking water exceeding 25 mg/L of nitrate for more than 10 years and who were above average meat consumers. Another study, the Iowa Women's Health Study, found an increased risk for bladder cancer in older women in Iowa due to exposure to nitrate in drinking water.

In 2010, a study published in *Environmental Science & Technology* reported that dishwashing detergents and shampoos found in drinking water supplies might be a precursor of harmful nitrosamines. Furthermore, neither ozone nor chlorine treatments reduce nitrosamines. Of particular concern is the nitrosamine, N-nitrosodimethylamine (NDMA) because it is suspected as a human carcinogen. Concerns focus on particularly high levels due to large consumer use. In general, a variety of detergents also contain benzene, which is associated with blood cell cancers such as leukemia, and 1,4 dioxane and acetaldehyde, which has been found to cause cancer in animal studies.

U.S. Geological Survey (USGS) and EPA researchers conducted an analysis of 25 U.S. water utilities and found 18 unregulated chemicals in the water supplies. One of the perfluorinated compounds found was linked to several health problems. An increased risk for cancer was found in a West Virginia water supply contaminated by a chemical plant.

Wastewater Workers

Studies have also shown that wastewater workers are at a higher risk for developing cancer than the general population. A retrospective study conducted in 1991 of sewer authority workers employed between 1950 and 1979 found that workers exposed to chemicals in sewage effluent, sludge, or wastewater had an increased cancer risk. This risk included mortality from lung, larynx, and liver cancer. Another study in Copenhagen, Denmark, found that wastewater workers experienced a small increase in cancer incidence, as well as a rare but strong increase of primary liver cancer.

Another later study in Sweden found no overall increase in the cancer risk in wastewater workers but did find a slight increase in prostate cancers. A study byproducts, inorganic chemicals, organic chemicals, and radionuclides. Disinfectant byproducts found in drinking water that increase risk for cancer include bromate, haloacetic acids, and trihalomethanes (THMs), which enter the water supply via the use of chlorine treatment. More than 20 organic chemicals in water supplies are associated with increased cancer risk, including benzene, chlorobenzene, dioxin, polychlorinated biphenals (PCBs), and tetrachloroethylene. Arsenic is an inorganic chemical and carcinogen found in water supplies. Radionuclides found in some water drinking supplies include radium and uranium.

Oral exposure to radium increases the risk for tumors in the bones, head, and nasal passages of humans. Uranium has been associated with lung cancer and tumors of the lymphatic and hematopoietic tissues. According to the American Cancer Institute, arsenic exposure can lead to several types of cancers in humans, including bladder, lung, skin, stomach, kidney, and prostate cancer, as well as leukemia and lymphomas.

The addition of chlorine to water leads to the formation of disinfection byproducts, such as THMs, which have been associated with an increase in several cancers, including anal, bladder, and liver cancer. Disinfectants in swimming pools have been found to react with other water contaminants, such as sunscreen. These interactions are associated with several health risks, including a higher incidence of bladder cancer.

A 2013 report released by the Environmental Protection Group stated that chemicals used in water treatment plants could raise the risk of cancer. As a result, the group has petitioned the EPA to consider reevaluating certain standards associated with the byproducts resulting from disinfecting water with chlorine and other substances. Although some dangerous compounds that are used in or result from water treatment are regulated, an estimated 600 disinfection byproducts have still not been identified.

Fluoridation of drinking water to help prevent cavities began in the United States in the early 1960s following a 1962 recommendation by the Public Health Service. A 1990 report by the U.S. National Toxicology Program found fluoridated drinking water increased cancer in male rats, particularly osteosarcoma (a type of bone cancer). Most studies, however, have not found a strong link between fluoridation and cancer. Furthermore, osteosarcoma, which is the cancer of most concern connected with fluoridation, is extremely rare. Only about one in 400 cases of the disease are diagnosed in the United States each year in children and teenagers.
published in 2011 in *Environmental Health* found that when workplace air concentrations of polycyclic aromatic hydrocarbons and volatile organic compounds (VOCs) were elevated, it translated into an increased lifetime cancer risk. Nevertheless, because of the still relatively small number of studies in this area, the general scientific consensus is that more studies have to be performed on this population to determine if there is an increased risk for cancer among wastewater workers.

**Protection**

One dilemma in solving the problem of cancer and other health risks associated with drinking water is that many of the substances used in water treatment protects people’s health in other ways, such as fluoridation. Researchers have noted that there is a risk trade-off. For example, chlorination of drinking water protects against serious waterborne microbial diseases.

Reducing the risk of protecting against a potential higher risk for cancer in the long term because of chlorination is counterbalanced by the potential for higher incidence of waterborne diseases. Such diseases can immediately affect human health, including death in severe cases. Several approaches are being researched to seek alternatives to chlorination, including alternative disinfectants such as chloramines, chlorine dioxide, and ozone.

Despite advanced water treatment technologies, some have suggested that, depending on the data for specific water supplies, individuals may want to take further measures to protect their health. For example, individuals can install home water treatment systems. According to Cornell University’s Program on Breast Cancer and Environmental Risk Factors in New York State, the first step is to have the drinking water tested for its contents and levels of detectable contaminants.

The Cornell University program notes that activated carbon filters help remove radon and some organic chemicals, including VOCs, pesticides, and THMs, which are used in some industries. Reverse osmosis is recommended for removing carcinogens such as suspended asbestos particles and some pesticides. Aeration is also an option for removing high levels of VOCs and radon.

Treating water through distillation is connected with the removal of arsenic, certain pesticides, and some organic chemicals. Anion exchange devices remove negatively charged compounds, such as nitrate and some forms of arsenic, from drinking water. Methods for reducing fluoride exposure in water include boiling and home fluoride water filtration systems.

**Western Diet**

The Western diet (WD) has been described as the eating pattern typical of developed nations and industrialized societies. In populations consuming the WD, substantial amounts of total nutrient intake are often provided by sweets, fried foods, high-sodium processed foods, red and processed meats, and refined forms of grains, sugars, and
vegetable oils. The WD pattern does not include recommended amounts of fruits, vegetables, whole grains, and healthful fat sources such as nuts, seeds, and fish. Excessive energy intake is common among populations consuming the WD, since low-calorie nutrient sources such as fruits and vegetables comprise a suboptimal proportion of total food consumption. Some researchers have proposed that chronic diseases, including cancer, have emerged as a major public health problem in conjunction with the adoption of the WD over the past century by large populations in developed nations.

There is no standard definition of the WD, although the diet has been described in the scholarly literature. Epidemiological studies have indicated that individuals from traditional societies who enter industrialized nations quickly begin developing Western-style chronic diseases including cardiovascular disease and cancer, suggesting a dietary connection. Some experts advise that rejecting the WD in favor of a diet pattern providing a substantial proportion of total intake in the form of fruits, vegetables, legumes, fish, poultry, nuts, seeds, and whole grains may play a role in the prevention of chronic diseases. Research indicates that diet is a key factor in the pathogenesis of chronic diseases, although associations among specific foods, dietary patterns, and chronic diseases remain unclear.

**Development of the Western Diet Pattern**

The development and industrialization of agriculture following the Neolithic period and the Industrial Revolution resulted in significant dietary changes for which the human genome may be poorly adapted. Hunter-gatherer populations prior to the Neolithic age subsisted on diets consisting of meat, nuts, seeds, and gathered fruits and vegetables. Epidemiological studies suggest that when individuals from contemporary hunter-gatherer societies are subjected to a WD, chronic diseases appear in previously disease-free people. Thus, it appears that human phenotypes may be highly dependent on environmental, including dietary, factors.

Prior to the Industrial Revolution, there was a lack of food processing technology and economic systems to facilitate the efficient distribution of staple foods across population groups. To a large extent, access to food was dependent on locality and season. Food was minimally processed. Meats, sugar, sweets, and refined grains such as white flour were expensive and often difficult to obtain. Low-technology food preservation methods such as drying and salting were common and were important for survival. The lack of large factory-type facilities for food processing meant that food preparation and preservation took place in the context of family homes or local communities. The labor and expense involved in growing, obtaining, processing, and preserving food tended toward self-limitation of energy intake. The Industrial Revolution stimulated the mass production of cheap, easily available, highly processed foods with stable shelf life. Such foods became the basis of the WD. As food processing became more industrialized, overall consumption of fruits and vegetables as a proportion of total diet declined.

**The Western Diet and Chronic Diseases of Westernized Populations**

During the past 100 years, obesity, cardiovascular disease, certain types of cancer, diabetes, and hypertension have been identified as chronic diseases of developed countries. A majority of older adults in industrialized nations are afflicted with multiple chronic diseases, and Westernized young adults often exhibit subclinical manifestations of chronic disease. Epidemiological studies report increased risk of cardiovascular and non-cardiovascular mortality in older adults who follow a WD pattern and decreased risk in older adults who consume diets rich in fruits, vegetables, and fish. Relationships among chronic disease, diet, genotype, phenotype, and environmental factors are complex and poorly understood; however, it appears that on a population-wide basis, the WD pattern is positively associated with the development of chronic diseases.

**The Western Diet and Cancer Risk**

Based on observational studies, it is thought that about 30 percent of overall cancer risk in developed countries can be explained by dietary factors. Obesity related to overconsumption of energy typical of the WD is associated with increased risk of a number of cancers. Consumption of particular foods common in the WD may be associated with higher rates of certain cancers; for example, colorectal cancer has been linked with intake of processed and red meat. The WD pattern has been associated with increased recurrence and reduced survival in colorectal cancer treated with surgery and chemotherapy.

Substantial evidence indicates that in contrast to the WD, a diet rich in plant-based foods reduces the risk of some types of cancer. Fruit and vegetable
consumption appears to be inversely related to population risk of certain cancers, including esophageal, oral, and colorectal cancers. The specific nutrients or food components responsible for reduction of cancer risk are not well understood, although researchers speculate that fiber, vitamin D, calcium, and antioxidants may play important roles in cancer prevention. Studies investigating the effects of nutrient supplementation for cancer prevention have been disappointing. It is recommended that most individuals should obtain adequate but not excessive amounts of nutrients from food sources rather than supplements.

Alternatives to the Western Diet
It remains unknown if there is any one superior dietary pattern for humans. However, it is likely that any of the following dietary patterns will result in improved health outcomes when compared to the typical WD. All healthful dietary patterns are characterized by moderation or avoidance of alcohol.

The prudent diet, represented by dietary guidance tools such as MyPlate and the now-obsolete Food Guide Pyramid, encourages liberal consumption of fruits, vegetables, and whole grains while recommending moderate consumption of healthful fats and proteins. Limiting intake of foods high in added sugars and solid fats is characteristic of the prudent diet pattern.

The American Institute for Cancer Research has developed the “New American Plate” as a research-based dietary guidance tool for healthful eating and cancer prevention. The New American Plate is similar to the prudent diet, but it places a greater emphasis on consumption of fruits, vegetables, and legumes while limiting intake of animal protein.

The Mediterranean diet includes fruits, vegetables, legumes, grains, fish and poultry, and red wine in moderation. Red meat consumption is minimal, and fat sources include olive oil, nuts, and seeds. The Mediterranean diet has been associated with health benefits including reduced incidences of cardiovascular disease, type II diabetes, and some cancers.

Hunter-Gatherer Diet
Chronic diseases, including cancer, are not often seen in persons from hunter-gatherer populations that have reached or exceeded 60 years of age. A hunter-gatherer diet, sometimes called the Paleolithic diet, encourages consumption of eggs, meat, shellfish, fish, roots, seeds, nuts, and fruits and vegetables, and de-emphasizes grains, added sugar, dairy, and vegetable oils. Some studies have shown favorable outcomes for a hunter-gatherer diet pattern in regards to glucose tolerance, blood pressure, and inflammation. However, because evidence links red meat consumption to risk for some cancers, further research is needed to determine any effects of the hunter-gatherer diet pattern in regards to cancer.

Contrasting Opinions
It has been suggested that a return to pre-industrial diets ignores the positive aspects of the industrialization of agriculture, which include the attainment of the safest, most abundant food supply in human history. The development of public sanitation, food safety innovations, population-wide vaccination programs, and new medical treatments has greatly lengthened the human life span. Longer life, rather than the WD, may be responsible for increased rates of chronic illness, since chronic diseases are associated with aging. Future developments in nutrition are likely to include dietary recommendations and nutraceuticals specifically tailored to maximize each individual’s genetic potential for avoidance of chronic diseases including cancer.

Conclusion
Relationships among dietary patterns, cancer risk, and human genetics are complex and poorly understood overall. The WD pattern appears to be associated with increased risk for chronic diseases including cancer. Risk for particular cancers may be reduced by shifting from a WD pattern to a more healthful diet based on moderation in the use of alcohol, routine consumption of a variety of fruits, vegetables, whole grains, and legumes, and reduced consumption of processed/red meats and refined carbohydrates.

**Wilms’ Tumor**

Renal tumors account for approximately 7 percent of all malignancies in children under 15 years of age in the United States. Wilms’ tumor in particular accounts for the overwhelming majority of childhood renal tumors. In many cases, Wilms’ tumor exists as part of a congenital syndrome, presenting with several other extra-renal findings. Nearly all cases of Wilms’ tumor arise sporadically, making new cases of this rare malignancy difficult to predict. Given the excellent response to treatment, the prognosis is largely dependent on early detection, making familiarity with the presentation and index of suspicion of utmost importance for clinicians.

Wilms’ tumor, or nephroblastoma, is a malignant tumor that arises from the primitive tissue of the kidney during fetal development. It accounts for 95 percent of all childhood renal cancers and nearly six percent of all childhood cancers. There are approximately 500 newly diagnosed cases per year in the United States, with 75 percent occurring in children less than 5 years of age, and a peak incidence of 2 to 3 years of age. Wilms’ tumor is exceedingly rare in the adult population. There is also ethnic disparity, with greatest incidence among African Americans and the least among Asians. Genetic analysis has linked Wilms’ tumor with loss of function of several tumor-suppressor genes including WT1, p53, FWT1, and FWT2. Familial Wilms’ tumor occurs in less than five percent of cases and is associated with mutations in BRCA2 or p53.

Furthermore, there are several congenital syndromes associated with Wilms’ tumor. WAGR syndrome is associated with a mutation of the WT1 gene and is named for the presence of Wilms’ tumor, aniridia (absence of iris of the eye), genitourinary abnormalities, and mental retardation. Beckwith-Wiedemann is another rare syndrome associated with mutations of chromosome 11 and is characterized by Wilms’ tumor, macroglossia (enlarged tongue), macrosomia (large body), hypoglycemia (low blood sugar), and other anomalies. Denys-Drash syndrome involves a different mutation of the WT1 gene and is characterized by the triad of male pseudohermaphroditism (genitalia do not match genotype), progressive kidney disease, and Wilms’ tumor.

There are classically three types of cells found on histologic analysis of these tumors: blastema cells (undifferentiated), stromal cells (often consisting of skeletal muscle, cartilage, and bone), and epithelial cells (cells that line the renal tubules). Examination of the mass often reveals hemorrhage, cysts, and large amounts of dead cells. Most Wilms’ tumors exist as solitary renal masses; however, there can be bilateral renal involvement (five to seven percent) and multiple tumors within one kidney (10 percent).

The most common presentation of Wilms’ tumor is an asymptomatic abdominal mass, often found incidentally by a parent. Patients may also present with abdominal pain, hematuria (bloody urine), hypertension, fatigue, and fever. Rupture of the tumor by trauma may additionally result in a rapidly expanding abdominal mass and anemia. Physical examination yields a large, firm, and non-tender mass on the child’s flank. If occurring as part of a congenital syndrome, often times the other findings associated with the syndrome will be discovered first. The most common location of Wilms’ tumor metastasis is the lungs; however, children rarely present with respiratory symptoms. Metastatic disease is present in up to 12 percent of patients at the time of diagnosis. When index of suspicion is high, diagnostic workup typically begins with an ultrasound of the abdomen and kidneys to confirm the presence of a renal mass. This is often followed by an abdominal CT scan to confirm the presence of a solid mass in the kidney. Once confirmed, a chest CT should be performed to determine the presence of lung metastases. Due to the ability of these tumors to invade nearby blood vessels, a Doppler ultrasound of the renal vein and inferior vena cava should also be performed. A definitive diagnosis of
Wilms’ tumor can only be made by biopsy, typically after the tumor is surgically removed. At the time of diagnosis, patients should be screened for von Willebrand’s disease (in which patients have difficulty forming blood clots to stop bleeding), found in approximately eight percent of patients.

The prognosis of Wilms’ tumor is a testament to the achievements of modern medicine. Five-year survival rates have increased from 30 percent in the 1930s to nearly 90 percent today. Prognosis is based on several factors including tumor histology, stage, age, and genetic markers. Tumor histology is the strongest predictor of survival. The presence of anaplasia, or cells that are highly undifferentiated, is associated with poorer outcomes. Tumor staging is based on the extent of gross anatomic involvement and is assigned after imaging and surgical resection. Higher stages indicate more extensive disease involvement and are associated with more adverse outcomes. Multiple studies have shown that a younger patient age at diagnosis is associated with improved outcomes, particularly those diagnosed before the age of two. Recent studies indicate that adults with Wilms’ tumor have similar outcomes to pediatric patients, although adults generally experience greater toxicity from chemotherapy. The most well-defined genetic marker associated with recurrence and mortality is a loss of heterozygosity of chromosomes 1p and 16q.

Surgical resection, chemotherapy, and radiation are the mainstays of treatment of Wilms’ tumor. Initial therapy typically involves surgical resection followed by chemotherapy; however, similar outcomes can be achieved by initiating treatment with chemotherapy to shrink the tumor, followed by surgery. Patient groups that benefit from preoperative chemotherapy include those with bilateral renal tumors, involvement of the inferior vena cava, and tumors too large to be safely resected. Surgery involves removal of the affected kidney, although care must be taken not to rupture the tumor or leave tumor fragments behind, as these are associated with a higher rate of recurrence. Radiation therapy is generally reserved for higher stages. The most effective chemotherapy regimens involve different combinations of vincristine, dactinomycin, and doxorubicin. Even with adequate treatment, tumors will recur in 15 percent of patients with favorable histology and nearly 50 percent of patients with anaplastic histology. Survival rate with recurrence declines to less than 60 percent. Screening for recurrent disease involves interval chest CT scans and abdominal ultrasonography.

Wistar Institute
Now considered among the elite biomedical research centers dedicated specifically to cancer research, one of only seven such institutes nationwide designated and funded by the National Cancer Institute, Philadelphia’s Wistar Institute Cancer Center began as a teaching facility dedicated to advancing anatomical studies among medical students in post–Revolutionary War America. Indeed, the Wistar Institute began actually as a kind of museum for wax-preserved human body parts that Dr. Caspar Wistar (1761–1818) had collected and catalogued.

Wistar considered himself not merely a physician and certainly not a researcher but rather a philosopher of science (he was a good friend of Thomas Jefferson who held a similar view about the appropriate public role of doctors). Wistar took the broad view of research and formulated several treatises on the importance of observation and diligent note-taking in the sciences. Not surprisingly, Wistar’s Institute also served as a medical school, the first institution in America independent of any university that focused on medical research and teaching. The institute would be led for more than two decades by Wistar, himself known as America’s first anatominist (his textbook on human anatomy, published in
1787, the first such textbook in America, remained the standard text in the field for nearly a century). His students found Wistar a mesmerizing, even inspirational, lecturer who used the specimen collection (as well as papier-mâché models of anatomical parts) to give his students, among the best and brightest of the era, the opportunity to actually see and handle body parts—at the time a revolutionary teaching methodology.

By the late 1880s, however, the institute, which had since added animal bones and fossils, had become something of a natural history museum and was still a major attraction not only for premed students but also for the general public curious about such eccentric objets d’art. The building had been loosely made into a de facto adjunct facility to the University of Pennsylvania. But the collection, despite careful management, had started to deteriorate to the point that Penn administrators began an effort to close it. After a fire destroyed nearly one-third of the collection, the university rethought its position and began a massive citywide fundraiser to reestablish the institute as a teaching and research facility that would be entirely independent of the university.

The two-year campaign came to be spearheaded by Wistar’s great-nephew, Isaac, a prominent attorney who had made a fortune as chief executive officer of Pennsylvania Canal Company, which shipped the state’s abundant coal resources nationwide. Officially reopened in 1894, the Wistar Institute of Anatomy and Biology was dedicated to fulfilling the vision of Caspar Wistar: promoting original research in the fight against a variety of diseases and teaching promising medical students through hands-on instruction. Among its earliest achievements, in 1906, was focusing on the problem with inconsistent data because scientists and researchers worldwide used a wide variety of rats as experimental subjects. Wistar’s researchers developed a single specialized strain of rat, which came to be known as the Wistarat, that would, in turn, help to standardize research. Today, close to 60 percent of all lab rats in the world are genetic descendants of the original Wistarat. In post-World War II America, following the heroic narrative of the polio vaccine that had riveted the nation throughout the 1950s, immunology became a global campaign. The institute quickly established a name for itself through its wide-ranging research into immunology, including vaccines licensed during the 1950s and the 1960s to treat, among other feared conditions, rabies, rubella, hepatitis C, malaria, and influenza. Indeed, its rubella vaccine is largely credited with eradicating German measles, relatively mild in children but a real fear for pregnant women. Today, Wistar has maintained that interest and has pioneered research into a vaccine against AIDS.

In the 1970s, given the growing national awareness of the potential to fight cancer, the Wistar Institute opted to convert nearly all of its laboratories specifically to cancer research thanks largely to a significant endowment awarded to the institute in 1975 that went to creating the wing of the research facility now known as the Wistar Institute Cancer Center. Over the next three decades, the institute developed three primary research programs: the study of genetics and the mechanics of genes, the changes in genetic makeup that caused cancers to develop, and how they might be manipulated in the earliest stages of development; the study of the molecular and cellular changes involved in the process of the creation of tumors and specifically the critical process of metastasis; and the study of tumor growth, tumor environment, and tumor spread, specifically the roles of cells in that process and the possibility of introducing cellular counterattacks that might halt the development by changing the cellular environment itself. These were ambitious, cutting-edge research divisions—genetics, molecular biology, and cellular structures—and Wistar established itself as a premiere research facility with more than 30 laboratories, able to attract a cadre of some of the world’s most respected oncology researchers and to recruit the most promising postdoctoral biomedical technicians.

At a time when a national debate raged over the medical ethics of stem cell research, Wistar pioneered cancer research using stem cells harvested from unwanted, discarded, or damaged embryos—part of the facility’s dedication to tracing how genetic malfunctions or misdirection led to the first stages of cancers. As a natural extension of its long history into anatomy and medical research, Wistar’s laboratories became far more involved with early cancer detection than with either prevention or treatment. Indeed, one of its earliest successes was a simple blood test that could detect lung cancer earlier than ever before—a critical element in lung cancer treatment, as it remains the most deadly form of cancer and is often mistaken for much milder conditions in patients reluctant to acknowledge the implications of
persistent coughing, thus rendering treatment virtually useless by the time the diagnosis is made.

Wistar research teams also investigated the cancer with the widest patient population: melanomas associated with skin cancer. Again, the research teams attempted to trace the development of the melanomas, the stages of the process through which UV rays alter the cell structures and begin the furious business of metastasizing. Perhaps its signature achievement was the introduction of a monoclonal antibody capable of tracking down and actually destroying cancer cells. Although its research accomplishments have been significant, the institute plays up its role in the Philadelphia community, promoting science in high schools, offering a variety of prestigious internships for college students, and developing a program for post-doctoral candidates who show promise in the field of biomedical research.

Women’s Cancers

The American Cancer Society’s two main characterizations of cancer—as abnormal cell growth and the ability to spread to other parts of the body—offer guidance to a discussion of women’s cancers. Viewed from the point of location, several cancers are indeed women’s cancers. The National Cancer Institute identifies the following as women’s cancers: breast, cervical, endometrial, gestational trophoblastic disease, ovarian, uterine, vaginal, and vulvar. Notably, these cancers are location-specific. While women’s susceptibility to other cancers—lung, skin, bone, and brain, etc.—is not greater or less than men’s, cancer’s ability to spread to other sites raises the risk of metastases.

Sylvia Estrada-Claudio in Gender Issues in Cancer Care discussed the long history of bias against women. She asserted that the medical profession’s antipathy toward women and their reproductive organs dates back to beginnings of the discipline, and was shared by some most illustrious members: Barker-Benfield, Ehrenreich and English, and Scully, to name a few. In Spanish-speaking countries, medical students use the term pudenda to indicate the female vulva. The term pudenda is derived from the Latin pudendus meaning “something to be ashamed of.” Similarly, the term hysteria comes from the Greek hystér meaning the womb. From Hippocrates to Freud, hysteria has been associated with women’s reproductive organs: ovaries and the uterus. These examples of the early perspectives held by medical practitioners have influenced the research, care, and treatment of women’s cancers.

Healthy People 2020 identifies “health disparity” as a concern which refers to differences between groups of people and how frequently the group is affected. Women’s health disparities are embedded in Healthy People 2020 health disparities lists of (1) racial and ethnic minorities; (2) residents of rural areas; (3) women, children, the elderly; and (4) persons with disabilities.

An example of the concerns of women’s cancer is highlighted in the case of Henrietta Lacks, an African-American woman who was diagnosed with terminal cervical cancer in 1951. She was treated at Johns Hopkins University, where cells were removed from her cervix without her knowledge. Her cells—known as HeLa—have been used in medical research for the past 60 years. Only in the recent past was her family informed. The Immortal Life of Henrietta Lacks evokes questions concerning research and medical care, ethics and morality, and marginalized members of society.

The definitions and data used in this article were gleaned from the American Cancer Society, the Mayo Clinic, the National Cancer Institute, and Healthy People 2020. Some of the technical terms are used multiple times. It is useful to recall that cancer is abnormal cell growth that can spread: the
notion of cancer as first in situ (site-specific) and second as metastatic (having spread) is helpful to the discussion.

In 2014, the American Cancer Society reported adjusted death rates (per 100,000) for women for the years 1930 and 2010 as the following: breast cancer deaths declined from 30.1 to 29.1; ovarian cancer death rates doubled from 4.4 to 8.1; and uterine cancer death rates declined from 36.3 to 6.7. Since 2001, women's cancers have risen from the fourth to the second leading cause of death for all females in the United States.

The National Institutes of Health (NIH) reported the most common type of breast cancer as ductal carcinoma (70 percent of cases). Ductal carcinoma begins in the lining of the milk ducts (thin tubes that carry milk from the lobules of the breast to the nipple). A second type of breast cancer is lobular carcinoma (15 percent of cases), which, as the names suggest, begins in the lobules (milk glands) of the breast. Both ductal and lobular are location-specific.

There are other rare types of breast cancers, including medullary carcinoma, Paget's disease (which affects the nipple and areola), tubular carcinoma, inflammatory breast cancer, and phyllodes tumors. When a doctor speaks of invasive breast cancer, it means that the cancer has spread, or metastasized, to surrounding tissue.

Advances in breast cancer research have led to the identification of BRCA1 and BRCA2 as the most common genes involved in hereditary breast and ovarian cancers. Genetic testing is a simple procedure involving collecting a blood or cheek swab sample. Results can indicate whether or not the patient carries one of the genes. It is important to note that tests for BRCA1 and BRCA2 can neither diagnose the presence of cancer nor predict future development of either breast or ovarian cancer.

Breast cancer management has evolved from radical mastectomies to a triad of management approaches, including surgery, medication, and radiation. Jerome Urban (1914–1991) practiced the super-radical mastectomy until 1963 when he became convinced that less-mutilating procedures resulted in survival rates equal to the super-radical approach. Current approaches of breast cancer management include the following methods. One is mastectomy (removal of the whole breast and some of the surrounding tissue), or a quadrantectomy (removal of one-quarter of the breast), or a lumpectomy (removal of a small part of the breast); removal of (some) nodes is used as a sentinel (indicator) node removal. A second method is adjuvant chemotherapy, which has been practiced with success for the past 30 years. It is administered solely or in combination.

The following are more commonly prescribed chemotherapy drugs: cyclophosphamide, methotrexate, fluorouracil, doxorubicin, docetaxel, and epirubicin. In some cases, patients receive neoadjuvant therapy (before surgery) to reduce the tumor's size. Depending upon the cancer staging, some patients will receive hormone-blocking therapies to reduce estrogen production, including tamoxifen, anastrozole, and letrozole. The third method is radiation, which can be delivered as an external beam radiotherapy or brachytherapy (internal radiotherapy). It is intended to eradicate microscopic cancer cells that remain after surgery.

Researchers observe two notable health outcomes of breast cancer: first, that white women have a higher incidence of breast cancer than
that in the United States in 2104, about 52,630 new cases of cancer the uterus will be diagnosed and that some 8,590 women will die from cancers of the uterine body. These estimates include endometrial and uterine cancers. Generally speaking, endometrial cancer in women under the age of 45 is rare. And, as with breast cancer, endometrial cancer is slightly more common in white women, but African American women are more likely to die from it.

Ovarian, fallopian tube, uterine, vaginal, and vulvar cancers are localized in the highly vascularized and hormone-rich environment of the pelvis. While each is a different cancer, it is appropriate to introduce the following three because of their location.

According to the Mayo Clinic, ovarian cancer is a type of cancer that begins in the tissues of the ovaries: epithelial cells (covering of the ovary), germ cells (develop into the egg, or ovum, produced monthly), and stromal cells (the supporting tissue) of the ovary. Ovarian cancer often goes undetected until it has spread within the pelvis and abdomen. Late stage ovarian cancer is difficult to treat and often is fatal. Fallopian tube cancer is often connected to ovarian cancer. Researchers have identified fallopian tube tissue-specific cancers of the fimbrias (fingers) of the tube, the smooth muscle of the fallopian tube (which moves the ovum trough the tube), and supporting tissue involvement. Often due to the interconnectedness of these cancers, the term ovarian cancer is used to describe cancer that begins in the fallopian tube and travels to the ovary.

Uterine cancer, which forms in tissues of the uterus (small, hollow, pear-shaped organ in a woman's pelvis), is identified as endometrial cancer (cancer that begins in cells lining the uterus) and uterine sarcoma (a rare cancer that begins in muscle or other tissues in the uterus). Endometrial cancer usually occurs post-menopause, but not always.

Vaginal cancer forms in the tissues of the vagina (also known as the birth canal). The vagina leads from the cervix (the opening of the uterus) to the outside of the body. The most common type of vaginal cancer is squamous cell carcinoma, which starts in the thin, flat cells lining the vagina. Another type of vaginal cancer is adenocarcinoma, cancer that begins in glandular cells in the lining of the vagina.

Vulvar cancer is cancer of part or all of the external female genitalia, including the clitoris, labia (vaginal lips), and the opening to the vagina. Vulvar cancer usually forms slowly over a number of years and is mostly asymptomatic. However, when
Wood Dust

In 1981, the International Agency for Research on Cancer (IARC) found strong evidence of a causal relationship between sino-nasal adenocarcinoma and occupations in woodworking industries, particularly furniture and cabinetmaking. It did not, however, find at the time sufficient causal evidence of a link between specific types of cancer and working in sawmills, carpentry, and joinery, and in the pulp and paper industries. Adenocarcinoma of the nasal cavities is a rare type of tumor. It constitutes about three percent of tumors in the upper respiratory tract. The sinus is the most common location for adenocarcinomas related to wood dust. The proximity of adenocarcinoma tumors of the sinus to organs of vital importance such as the brain, optic nerves, and carotid arteries poses significant risks. Initially, gleaned from information available in the late 1960s and early 1970s when studies were first initiated, the average annual incidence reported in people older than age 15 was approximately zero to eight per million in men and zero to four per million in women. The disease today is more common in people between 45 and 85 years of age, and after many studies, continues to be linked to wood dust. Other causes for sinus tumors are viral infections, such as the human papillomavirus, which can produce a benign tumor.

The first study on adenocarcinoma of the nasal cavity, published in Britain in the early 1970s, showed evidence of the relationship between working in the furniture industry and adenocarcinoma. Follow-up studies sought to find out if the increased risk for this tumor, associated with the woodworking industry, occurred in other parts of the country. After that, similar studies were performed in other regions of Europe, all showing similar results.

In 1981, IARC considered the woodworking and related industries in the category of occupational and cancer hazards. In the beginning, scientists at the IARC considered the possibility that
carcinogens in wood were the culprits for cancers, rather than chemicals used in processing wood. Despite some deficiencies in the research results, which left some questions unanswered, the IARC scientists established that their finding that nasal adenocarcinoma is caused by breathing wood dust—especially hardwood dust—was reasonable. They also found that there was no indication that dust wood caused other forms of cancer.

In 1987, the IARC classified cabinetmaking as Group 1, that is, establishing that sufficient evidence had been found of carcinogenicity, largely on sino-nasal adenocarcinoma, in humans related to this occupation. Other related woodworking occupations, such as carpentry and joinery, were classified as Group 2B, that is, of possible carcinogenicity to humans. Lumber, sawmill, and the pulp and paper industries were classified as Group 3, that is, not classifiable as to its carcinogenicity to humans. In general, carcinogenic risks to humans in the woodworking industries are related to exposure to wood dust, and other related forms of cancer can be linked to chemicals used in woodworking, such as formaldehyde. Workers may be exposed to formaldehyde in the manufacture of plywood particleboard and furniture, and during wood floor sanding and varnishing. Cancer risks linked to chemicals used in woodworking affect areas such as the oral cavity, larynx, pharynx and respiratory tract. However, studies have proven inconclusive.

The most common exposure to wood dust occurs in the manufacture of furniture and cabinetmaking, in particular during machine sanding. In plywood and particleboard mills, the highest level of exposure occurs in the finishing occupations, and in sawmills, in the workshop air, especially near saws, planers, and related equipment.

Symptoms for early nasal cancer are the same as for noncancerous conditions, and include: nosebleeds from one nostril, blockage of a nostril, and runny nose on one side. Tumor advances can cause persistent headaches and double vision or other changes in vision.

Background
Death and disease from occupational cancers usually take place several years, even decades, after initial exposure to the carcinogenic agents. Therefore, many scientists state that it is important to consider the pattern of particular industries at least two decades before beginning a study period. In the 1950s, furniture manufacturers in London hired large numbers of workers. Based on previous anecdotal evidence, it was not unexpected to find an association between nasal cancer and trades related to woodworking. The first link between cancer and woodworking occupations was found in 1965 among male British woodworkers. Many other studies since then have shown that high exposure to wood dust is related to the highest risk for nasal adenocarcinoma, particularly in Europe. Other types of cancer, such as nasopharynx, larynx, and lung cancers and Hodgkin's disease, have also been associated with exposure to wood dust; most of the evidence for these other types of cancer, however, is still inconclusive.

The prevalence of nasal cancer has been linked to the type of wood dust to which individuals are exposed. Wood dust falls into two general categories: softwood and hardwood. Softwoods, such as pine, are inexpensive and easier to work with. Hardwoods are heavy, harder woods and come mostly from deciduous trees. Wood dust is created during the cutting, sanding, and shaping of wood materials, and the type of dust generated varies according to tree species. The most deleterious effects for sinonasal cancer among woodworkers have been observed in those who work with oak and beech wood. In 2001, a European study titled “Risk Assessment of Wood Dust: Assessment of Exposure, Health Effects and Biological Mechanisms” was launched in Europe with the aim of measuring exposure to wood dust. An occupational exposure database—WOODEX—was developed, providing information on wood dust exposure in 24 European Union states. The database offers estimates of exposure to inhalable wood dust classified by state and industry, as well as level of exposure and type of wood. The European Union, which recognizes hardwood dust as a carcinogen, has set the occupational exposure limit to five mg of inhalable dust per cubic meter of workroom air. The WOODEX database estimates that approximately five million workers in the European Union are possibly exposed to dust levels exceeding five mg.

Cancer related to wood dust is rare. Studies have been performed to find out if, besides exposure to hardwood dust, cancer may also be related to the textile, leather, and other industries that produce chemicals and dust. Other supposed factors for nasal cancer are exposure to formaldehyde, nickel compounds, and chromates, although the evidence remains limited. Wood dust may also cause or exacerbate non-cancer diseases, such as asthma.
Millions of workers are exposed at work to inhalable wood dust, the majority of them woodworkers who must often use machinery indoors with no general ventilation or exhaust systems. Carpenters are believed to be the largest group of workers with significant exposure to wood dust, although the duration and level of exposure is still not clearly known. The concentration of wood dust is higher in the furniture and cabinetmaking industries than in other areas, such as in sawmills. Sawmills probably also offer a different level of exposure, because they tend to work with green softwoods. Furniture plants tend to use dried hardwoods.

In the United States, 25 states abide by the Occupational Safety and Health Administration (OSHA) federal standards, which support the five-mg-per-cubic-meter airborne particle standard established by the European Union. In other states, the industries have adopted their own standards and enforcement policies; these, however, tend to be similar to federal OSHA standards.

Research
A study performed in Denmark found double the risk for sino-nasal cancer in male workers in wood-related occupations than for those who had never worked in a wood-related job. No such excess risk was observed among workers in forestry, logging, and pulp and paper mills. A series of studies in Britain up to 1986 reiterated that a surge of male mortality in London in the 1960s and 1970s was related to excessive exposure to wood dust. Bladder cancer was also associated with occupations in road transport driving, as well in leather-working, and a consistent relative risk was also found for woodworkers, machinists, plumbers, and mechanics. These findings not only reinforce, directly or peripherally, the role of wood dust in occupational-related nasal cancer, but also the role of occupational factors in cancer causation. According to a number of studies, overall, the only occupational category with a significantly increased risk for nasal cancer was woodworking. The studies controlled for other possible cancer-causing factors and activities, such as smoking. No evidence was found in this type of cancer linked to other dusty trades, such as textile and clothes manufacturing.

By the mid-1990s, wood dust had been classified as carcinogenic to humans, and evidence with nasal cancer had been observed in a large number of studies. Besides confirming previous findings, some suggested further research into other occupational sectors possibly at risk, such as shipbuilding and repairing.

In general, wood dust is the most frequent carcinogen found in occupational exposures reported not only by the IARC but also by Italian Information System on Occupational Exposure to Carcinogens (SIREP), which confirmed the results of distinct European studies that found this widespread risk exposure in all of the European Union member states. The SIREP database, which is available for research, contains records from 1,822 companies and 11,322 workers exposed to wood dust, collected from 1996 to 2006.

Following the publication of the SIREP study, a 2006 research project performed among sawmill workers in Finland found an excess of pharyngeal cancer but just a slight excess of nasal cancer. This study is of interest because Finnish woodworking industries rely mostly on softwood, such as pine and spruce. According to scientists, the small risk for nasal cancers produced by wood dust represented among workers in this study seems to corroborate that softwood pine dust presents fewer risks than hardwood for sino-nasal cancer. However, the same study found a higher rate of lung cancer linked to dust in paper mills.

Studies have also been made in several other countries. They all corroborate that risk for
adenocarcinoma from wood dust increases with duration of exposure. These studies also shed light on different types of cancer possibly related to wood dust. An increased risk of squamous cell carcinoma, for example, was found solely among workers employed for 39 or more years in jobs with exposure to fresh wood. The results of different studies strongly support the association of the exposure to wood dust in a variety of wood-related occupations and specific types of nasal cancer. The magnitude of risk, however, has varied across different studies.

Wood Preserver

There are many types of wood preservers available on the market, for use in a variety of settings, from industrial and commercial to residential. Agencies in the United States, such as the Occupational Safety and Health Administration (OSHA) and the Environmental Protection Agency (EPA), Australian Department of Agriculture, and the International Agency for Research on Cancer (IARC) have determined that many wood preservatives are carcinogenic and are causal agents in many acute and chronic health conditions. Wood preservatives frequently contain arsenicals, copper, chromium, creosote, formaldehyde, naphthenate, and penta compounds. Exposure to these compounds cause impaired immune systems, cancer, infertility, birth defects, fetal death, genetic mutations, hormone dysregulation, and peripheral nerve degeneration, making them an environmental concern.

Creosote is the most common oil-type preservative, used industrially, commercially, medicinally, and residentially. As a wood preservative, creosote is now only approved for commercial applications. Creosote is and has been used medicinally in many cultures. In the United States, the Native Americans living in the southwest used larrea tridentate, the creosote bush, to treat tuberculosis. It was also used as an antibacterial, an antiseptic poultice, and a caustic agent for wounds and sores, for joint and limb stiffness, snake bites, menstrual cramps, intestinal complaints, and as an emetic. In the Caribbean, it was used to treat tropical diseases and syphilis.

Farther back in history, substances such as pitch and resins were used for toothaches, to kill parasites, and to treat phthiriasis, porrigo, elephantiasis, and ulcers. Medical books written in the 1800s recommend using creosote to treat dyspepsia, induce vomiting, improve wound healing, and decrease tumors. During the 1900s, it was sold in pharmacies as aqua creosoti. Physicians believed that it was an effective treatment for gastrointestinal complaints, detoxification, to kill entozoa parasites, treat ulcer and abscess, epilepsy, neuralgias, diabetes, and glanders, and stimulate throat mucosal tissue. Livestock was dipped in a solution of creosote to kill external parasites. McDougall’s Powder was sold as a sewer deodorant.

Despite wood preservatives being listed as a toxic agent, including creosote and its chemical byproducts, it can be found in medications such as guaifenesin, an over-the-counter expectorant found in cough syrups. In Japan, seirogan, a popular Kampo medicine prescribed as an antidiarrheal, is made from
133 milligrams of creosote from beech, pine, maple, and oak trees. Forms such as kreosotum, chaparral, or kreosote are found in herbal supplements.

From the 1830s on, wood preservatives have been used in food processing. Liquid smoke is a commercially available additive designed to add a smoky flavor to meats. This product is primarily comprised of creosote. In 1987, the United States restricted the use of pentachlorophenol (PCP) as a pesticide. However, PCP is still used in restricted applications, such as utility poles, railroad ties, and wharf pilings. It is a toxic substance that is labeled a human carcinogen, and is linked to other serious health risks. Other oil-based wood preservatives are copper naphthenate, oxine copper (copper-8-quinolinolate), and 3-lodo-2-propynyl butylcarbamate (IPBC).

**Formaldehyde**

Waterborne preservatives are compounds that are water soluble or readily mix with water. One of the most common water-soluble wood preservatives is formaldehyde. This chemical is pervasive in the environment. It is classified as a preservative and a disinfectant. One will find formaldehyde in drinking water, cosmetics, plastics, fungicides, resin glues, embalming fluid, carpets, clothing, tobacco, and combustion appliances. In construction, pressed woods that are glued together with adhesives are made of urea-formaldehyde (UF) or glued together using resin glues have the highest concentrations. Some examples of pressed wood are particle board, paneling, hardwood plywood, and medium-density fiberboard.

UF is measured in parts per million (ppm), and reactions in adults are seen in as little as 0.1 ppm. The elderly, children, and those with allergies and respiratory problems are even more susceptible to reactions at lower doses than 0.1 ppm. At levels of 1,000 ppm or higher, or with chronic exposure, it can be carcinogenic. In most settings, levels are well below the recommended 0.1 ppm, but levels can be higher in mobile homes, manufactured homes, and newer construction because of the large amount of pressed wood or UF foam insulation used in the construction. Off gassing of the UF occurs within the enclosed space, so proper ventilation is necessary. When UF foam insulation is used, holes and cracks should be filled with spackle or caulk, and walls painted or wallpapered with vinyl to reduce gas exposure.

**Copper**

Comprised of chromium, copper, and arsenic, chromated copper arsenate (CCA) was once heavily used in residential settings. Because of its tendency to leach into the surrounding environment and transfer through dermal contact with the treated wood, it is no longer approved for residential uses, but it is still used. When an individual comes into contact with the treated wood, and then eats, smokes, or has any hand to mucous membrane contact, ingestion of CCA can occur. Long-term exposure to the arsenic found in this compound increases the risk of cancer. Acid copper chromate (ACC) is only used in industrial and commercial settings. Treated wood contains hexavalent chromium, also called chromium VI. This substance has the highest EPA toxicity rating for oral, dermal, and inhalation toxicity. Chromuim VI has been shown to cause cancers in the lungs, nasopharynx, oropharynx, and nasal passages, liver damage, leukcytosis, leukopenia, eosinophilia, chronic obstructive airways diseases (COPD), dermatitis, ulcerations, and kidney disease.

Alkaline copper quaternary (ACQ) compounds have four classifications: A, B, C, and D. All classes are made using various percentages of copper oxide (62–71 percent) and aquaternary ammonia (29–38 percent). This chemical is listed as an insecticide and a fungicide. As a water-based preservative, ACQ leaves the surface dry and paintable. Because this compound does not contain arsenic or chromium, it is found in residential settings such as lumber, fence posts, decking, landscape ties, wooden play structures, utility poles, sea walls, wood shingles, pilings (land, freshwater, and marine), and other wooden structures. When exposures remain below toxicity levels, there are minimal health risks. Bis-(N-cyclohexyldiazeniumdioxy)-copper (Cu-HDO) is composed of copper and N-cyclohexyldiazeniumdioxy (HDO). Pressure-treated lumber, poles, millwork, and pilings are oftentimes coated with this preservative. It does not readily leach into the soil, but it is highly toxic in aquatic environments. If used in the packaging of food, livestock feed, or construction of beehives, toxicity can arise.

Copper azoles (CA) comes in two forms: Type A known as CBA-A because it contains copper, boric acid, and tebuconazole, and Type B, called CA-B, which lacks boric acid, but has higher concentrations of copper and tebuconazole. This substance is approved as a wood preservative in above and
belowground and fresh and saltwater applications. Micronized copper is a newer form of ACQ and CA. The difference in micronized copper is the presence of tiny particles of solid copper carbonate, instead of the soluble copper found in ACQ and CA. Because the copper is still in a solid state, there is some likelihood the particles will leach from the treated wood, leading to health and environmental risks.

**Borates, Azoles, and Fire Retardants**

Disodium octoborate tetrahydrate are naturally occurring minerals that comprise borate wood preservatives. These are used to protect wood from fungus, termites, and other wood-boring organisms. Because of the low toxicity of borates, they are used on interior applications such as joists, sheathing, and sill plates. Cyproconazole is used on above-ground wood products and as a fungicide on crops. Currently, cyproconazole is approved by the EPA for surface application of siding, plywood, millwood, lumbar, and shingles. The antimicrobial didecyldimethylammonium chloride (DDAC) is found in some of the cyproconazole products. Propiconazole is an antifungus designed to prevent wood decay. It is used to treat above-ground wood. It is also a fungicide for turf, ornamental plants, and food and livestock feed crops, and as an antimicrobial preservative. The Food and Drug Administration (FDA) approved this compound for surface application and pressure treatment of siding, plywood, millwork, shingles and, and above-ground timber and lumber. Other water-soluble wood preservatives include copper sulfate, sodium fluoride, mercuric chloride, arsenic compounds containing fluorine, chromium, ammoniacal copper zinc arsenate (ACZA), and phenol.

In laboratory tests, wood treated with fire retardant chemicals (FRT), including formaldehyde phosphoric acid, amine-aldehyde-phosphorus, and phospho-ammonium boron compounds, are highly effective in suppressing the spread of flames and decreasing smoke, and will withstand combustion for approximately 30 minutes when directly exposed to flames. They are used for the interior of structures requiring fire retardant construction materials, and when required by building codes. FRT can be found on trusses, plywood sheathing, decking, rafters, studs, walls, subfloors, joists, beams, stairways, and paneling. Classified as a Group 1 human carcinogen and a skin and lung irritant, FRT wood should not be burned nor used as chips, mulch, or sawdust. Occupational exposure can cause adenocarcinomas of the nasal cavities and paranasal sinuses. The OSHA considers the dust to be a potential explosive hazard when combined with air and an ignition source.

**Health Risks and Protection**

The health risks associated with wood preservatives vary by compound. Statistically, there is a significant increase in the incidence of adenomas, carcinomas, adrenal medulla pheochromocytomas, malignant pheochromocytomas, hemangiosarcomas, and hemangiomas when exposed to pentachlorophenols in wood preservatives. Creosote has a high likelihood of causing cancer, and arsenicals have been proven to cause cancer in humans. In animals studies, cresols, a component in creosote, intensifies the effect of some carcinogenic chemicals. Arsenic, either ingested or inhaled, increases the risk of liver, bladder, kidney, and lung cancers. Occupational exposures to wood products containing penta have a direct link with acute leukemias, Hodgkin’s and non-Hodgkin’s lymphoma, and multiple myelomas. The hexachlorobenzene and hexachlorodibenzo-p-dioxins, penta components, cause soft-tissue sarcoma and non-Hodgkin’s and Hodgkin’s lymphoma.

When working with any wood treated with preservatives, personal protective equipment should be used. This type of equipment includes leather gloves, safety glasses, or chemical goggles, a NIOSH approved P95 or P100 particulate filter respirator, and a long-sleeved shirt, pants, and steel-toed boots. Hands should be thoroughly washed prior to any mucosal membrane contact. Disposal of all wood treated with preservatives or its byproducts fall under municipal, state, and federal guidelines, and may be considered hazardous waste. In order to avoid environmental contamination, all unused materials, residues, and containers must be properly disposed of.

Workplace Wellness Programs

Workplace wellness can be defined as a program or set of programs organized and supported by firms and other organizations, designed to lend support to employees (and sometimes their families), as they adopt and maintain lifestyle and personal behaviors aimed at reducing health risks and increasing personal quality of life. These benefits are understood to transcend the individual and benefit the organization at large. In other words, healthy employees cost less and produce more.

Modern firms today understand that human capital is their most important resource. Therefore, having employees who are healthy in mind and body is important for the long-term survival and competitiveness of most organizations. Cutting-edge firms often increase the quality of their labor resources by way of corporate wellness programs, which results in increased productivity, creativity, and commitment from employees and other stakeholders or interested parties. Evidence-based research shows that wellness programs also reduce levels of stress and absenteeism, as well as medical expenses. According to the World Economic Forum (2008), businesses that implement wellness and health programs obtain the following rates of return upon investment: 30 percent increase in productivity; 35 percent increase in creativity and innovation; 40 percent decrease in employee turnover; and 60 percent increase in employee sense of ownership.

Wellness Program Implementation
According to published Harvard studies in the area of workplace wellness, providing medical personnel in the workplace—a doctor or nurse—achieved a decrease of up to 80 percent in absenteeism for a period of six years. The authors of one study (2010) explained that providing access to a gym and to nutritional information in the workplace is simply not enough. A firm must invest more in developing an effective and sustainable workplace wellness program. Experts also recommend these six pillars for an effective workplace wellness program: (1) multilevel leadership, (2) alignment, (3) scope, relevance and quality, (4) accessibility, (5) partnerships, and (6) communication.

Leadership works to create and integrate a health culture in the organization. This requires, at all levels, leadership that is dedicated, persuasive, and persistent. It requires commitment and strategizing from upper-level management, and also that middle management act in order to integrate wellness goals into organizational strategies and goals. Alignment refers to actions and strategies that reinforce the natural extension of the firm’s identity and its goals. These should include wellness programs. It is important to bear in mind that cultural changes—including wellness program integration—take some time to develop properly and to produce outcomes.

Scope, relevance, and quality refer to designing wellness programs that are holistic or comprehensive and attractive. Otherwise, employees will not feel engaged, and the program will lack participation. Accessibility refers to services that are either low cost or free of charge. Making it as accessible and as user-friendly as possible should be a priority. Partnerships refer to active and constant collaboration with internal and external associates, including providers and vendors. These partnerships can help provide some of the essential components to a wellness program and many enhancements as well.

Finally, communication is a very important component of the wellness program strategy. Wellness is not just a goal; it is also a culture, and communication is key. The delivery of the message can
produce a marked difference in how it is received by the target audience. It is important to create messages that are not only informative but also creative, attractive, and sensitive to diversity. It is also important to consider a wide variety of media options for the dissemination of the message.

Research has also shown the following outcomes:

1. Lower costs. Savings in health services, just by themselves, show significant rates of returns on investments.
2. Higher rates of productivity. Participants in wellness programs show reduced levels of absenteeism and higher workplace performance than employees in organizations that do not participate in wellness programs.
3. Higher levels of morale. Pride, trust, and commitment among employees have been shown to grow.

A wellness program, then, is not just about workers’ health. It also includes organizational actions that serve to increase workplace safety, productivity, organizational culture, and work-family integration.

**Research Outcomes.**

Workers today are increasingly at risk for noncommunicable diseases related to aging and lifestyle. These include diabetes, cancer, cardiovascular and chronic pulmonary diseases, and mental health issues as well. The World Economic Forum’s Workplace Wellness Alliance estimates that as rising economies grow, talent gaps for up to 45 million workers in Western Europe are forecasted for 2030. This trend must be considered in light of the growing risks for aging and disease, which decrease productivity in the workplace. In fact, it is estimated that noncommunicable diseases will cost about $47 million over the next two decades. Studies done in 2010 show that workplace absenteeism and underperformance had already caused productivity losses worth up to $16.8 trillion, mostly related to cardiovascular disease and mental illness combined. These numbers, according to experts, could double by 2030.

In 2008, the World Health Organization estimated that 36 million of the 57 million global deaths were due to noncommunicable diseases, mainly cardiovascular disease, cancer, chronic respiratory disease, and diabetes. The United Nations noted with considerable concern that these noncommunicable diseases were among the leading causes of preventable mortality. In 2011, the United Nations’s Political Declaration on the Prevention and Control of Non-Communicable Diseases convened a General Assembly in order to address the prevention and control of noncommunicable diseases worldwide, focusing on developmental and other challenges at the social and economic levels, especially for developing nations. It also issued a call for the private sector to lead workplace wellness initiatives as part of the solution to these worldwide challenges. The Workplace Wellness Alliance was born in 2010 as a response to this call for action. Currently, it numbers 150 members from across industries and aims to improve health and productivity in the workplace.

Today, there is a growing understanding that government and workplace policies and alliances are of crucial importance in reducing levels of exposure to modifiable risk factors for noncommunicable diseases, such as smoking and exposure to secondhand smoke, unhealthy dietary habits, low levels of physical activity, abuse of intoxicants, and others. They are also of critical importance in encouraging and supporting healthy lifestyle habits, so that individuals and groups may make healthier informed choices and follow healthful lifestyles. This would not only result in tangible and intangible benefits for firms, but enhance the quality of life in society at large.

World Health Organization

The World Health Organization (WHO) is an agency within the United Nations (UN) responsible for directing and coordinating health for the UN. The responsibilities of the WHO include: establishing health policies for the UN, providing leadership in health issues worldwide, setting the international health research agenda, monitoring and assessing health throughout the world, and providing assistance to individual regions that may require aid. Member states have agreed upon a set of categories of work for the WHO to focus their attention on communicable diseases, noncommunicable diseases, promoting health through the life course, healthy systems, and preparedness, surveillance, and response. These categories help to determine the WHO’s priorities and agenda. The overall WHO agenda consists of six points of response to global public health: promoting development, fostering health security, strengthening health systems, harnessing research information and evidence, enhancing partnerships, and improving performance.

All countries that are members of the UN may become members of the WHO simply by accepting the WHO constitution. To date, all UN member states have accepted the WHO constitution and are therefore also a part of the WHO. Countries that are not members of the UN may also be admitted as members of the WHO by a majority vote of the World Health Assembly. Territories may also apply to be Associate Members through the country that is responsible for their international relations. There are 194 member states of the WHO. The headquarters of the WHO are located in Geneva, Switzerland, with regional offices found around the globe. The regions of the WHO are the African region, region of the Americas, European region, eastern Mediterranean region, and the western Pacific region.

World Health Organization and Cancer

The WHO reports that cancer accounted for 8.2 million deaths worldwide in 2012. The leading types of cancer worldwide are: lung, liver, stomach, colorectal, breast, and esophageal cancers, accounting for 4.673 million cancers. More than 60 percent of the world’s new annual cases of cancer occur in Africa, Asia, and Central and South America, with those regions accounting for 70 percent of the world’s cancer deaths.

The WHO supports many countries in all facets of health, with one such targeted area being cancer. This disease is addressed in the WHO Cancer Control Programme. The WHO Cancer Control Programme’s mission is to promote national cancer control policies, plans, and programmes. The WHO Cancer Control Programme’s core tenets are to encourage evidence-based prevention, early detection, treatment, and palliative care tailored to different regions of the WHO member states.

Contrary to the belief that cancer is a disease that mainly occurs in industrialized countries, it is estimated that half of all cancer patients are in developing countries. However, unlike industrialized countries, developing countries lack the resources for systemic cancer control. In low- to middle-income countries, people tend to develop chronic diseases like cancer at a younger age and suffer longer, often from preventable complications, and die younger than those in high-income countries.

The WHO clusters member countries together by region. Each region has different foci for cancer intervention strategies based on what is most relevant to that area.

Fifty-five percent of the member states report having capable health system response and capacity to address and respond to noncommunicable diseases as well as having an operational policy/strategy/action plan for chronic cancer. Thirty-eight percent of member countries report not having a clear operational policy/strategy/action plan for chronic cancer. The member countries without these plans are most often low- to middle-income countries.
While the WHO does not create national action plans on cancer for every member country, it does offer insights into what each of the tenets of the WHO Cancer Control Programme entails. The WHO has created an overarching plan to help guide member countries as to what a successful detailed plan of action would look like.

At the core of the WHO Cancer Control Programme lies the cancer priority ladder. This ladder is what the WHO believes to be the most pressing issues when it comes to cancer control in a country. The ladder includes the steps of tobacco control, a curable cancer program, a healthy eating program, effective pain control, referral guidelines, clinical care guidelines, nurse education, national cancer networks, clinical evaluation, basic and clinical research programs, and an international aid program. By focusing on each of these aspects of the cancer priority ladder, countries are better equipped to handle cancer epidemics. More broadly based, the WHO Cancer Control Programme includes the four main tenets of prevention, early detection, treatment, and palliative care.

**Prevention**
The first and largest step to cancer control is preventing cancer from developing. The WHO highlights tobacco, obesity and physical inactiveness, alcohol use, infections, environmental pollution, occupational carcinogens, and radiation as preventable causes to cancer. One-third of all cancers stem from a preventable cause, and by reducing incidence of these things, a country can lower its incident rate of cancer. While each of these preventable causes can be found across the world, certain causes are more prevalent among higher-income countries versus lower-income countries. Low-income countries are more prone to cancer from infections such as HBV/HCV and HPV, and environmental pollutants such as indoor coal use for cooking than high-income countries. Obesity and physical inactiveness is more often a cause of cancer in high-income countries, especially those with high-processed-food diets.

**Early Detection**
Detecting cancer in early stages greatly increases the chances of survivability and successful treatment. Early detection comes in two parts: educating the population about cancer signs and symptoms as well as screening for cancer. It is important to note that screening may be used as an early diagnostic tool, but that is not the sole purpose of screening for cancer. Screening healthy populations can trace the risk factors of a population as a whole. Screening campaigns are often initiated by governments, public health entities, or health service providers, and not by the individuals being screened. Therein lies the difference between true diagnostic tools and screening campaigns.

Screening is an aspect that many countries even with health action plans lack due to limited resources and funds. Screening is only effective if it can be broadly employed in nearly the entire targeted group without causing resource depletion. Screening facilities and tools can often be expensive and unsustainable for remote low-resource areas. Early detection screening should only be concerned with detecting diseases and disorders that cause significant suffering, disability, or death, not in detecting trivial or untreatable conditions. Detecting these trivial conditions can cause unwarranted anxiety and waste resources, especially in low-resources regions.

The WHO only recommends undertaking screening programs if they can be fully supported by the community. Not only does the implementation and execution of screening processes need to be supported, but also the evaluation of the data collected. Communities may have the resources to carry out screening measures, but they must also have the resources to understand and apply the data collected. The WHO looks to studies on low-cost screening to inform the low resource countries as to how to best offer screening programs to their region’s populations.

**Treatment**
The WHO offers less advice for how countries should implement treatment in their action plans, as this is a highly subjective part of the cancer experience. Initial diagnosis is integral in the treatment of cancer, regardless of the cancer or the region. However, the next steps are subjective to the type of cancer, the stage of cancer, and the resources available to the population. The most effective treatment plans are often those that (1) are sustained and equitable, (2) are linked to early detection, and (3) follow evidence-based standards of care and utilize a multidisciplinary approach.
Typical treatment options include surgery, radiotherapy, and chemotherapy. These treatment methods are used independently or in conjunction with one another. All of these options may not be available to lower-resource communities that will need to adapt different strategies to cancer eradication. The ultimate goal of cancer treatment is either to cure or prolong the life of patients and provide the best quality of life to survivors.

**Palliative Care**

Palliative care is an interdisciplinary approach to improving the life of patients and families facing life-threatening diseases. Palliative care provides pain and symptom relief, as well as spiritual and psychosocial support. Using a team approach to dealing with cancer offers support to both patients as well as their families. Palliative care is an integral part of coping with cancer for patients and their families as it is intended to provide relief from the burden of cancer. In most of the world, cancer is not detected and diagnosed until late stages of the disease. This means that palliative care is mostly focused on end-of-life care, and how to cope with pain management, death, and bereavement for patients and their surviving families.

The WHO offers a cancer pain ladder to those patients in end-of-life palliative care. This ladder is a means to make patients feel more comfortable and explains how medication should be administered to provide the greatest relief from pain.

**WHO Cancer Research**

The WHO offers specialized guidance to low- and middle-income countries. In addition to the WHO Cancer Control Programme as a guide, the WHO also offers a guide directed at those countries with lower socioeconomic standing. This guide offers six modules that provide practical advice to policy makers and programme implementers. The guide follows the four main tenets of the Cancer Control Programme, with the two additional modules of planning and policy/advocacy. These two extra modules are especially important in low-income countries, as there may be little experience with forming national programmes and a potentially difficult bureaucracy to go through. This guide is of great importance to the WHO, as 70 percent of world-reported deaths from cancer come from low-to middle-income countries.

Not only does the WHO offer guidance to its member states as to how to handle cancer incidence on the individual level, but it also conducts its own research on a broader level. The WHO traces epidemiology on different types of cancers and also does in-depth research on factors that may cause different cancers.

The main WHO research center for cancer is located in Lyon, France, at the International Agency for Research on Cancer (IARC). The IARC’s main objectives in cancer research are: monitoring global cancer occurrence, identifying the causes of cancer, explaining mechanisms of carcinogens, and developing scientific strategies for cancer control.

The WHO has offered in-depth looks at the histories of most major cancers including lung cancer, cervical cancer, and breast cancer among others. The WHO has also researched specific environmental causes to cancer such as air pollution and cell phone use as well as world events such as environmental carcinogens from the meltdown at the Japanese nuclear power plant in 2011 that was caused by a tsunami triggered by an earthquake.

The WHO is a multidimensional organization that uses all facets of public health to eradicate suffering caused by cancer. With the global cancer epidemic on the rise, the WHO uses every resource available to aid in the reduction of cancer worldwide and to help countries take the cancer epidemic into their own hands through program and policy implementation as well as general education about the deadly disease.

World Health Organization Framework Convention on Tobacco Control

The idea for the World Health Organization's Framework Convention on Tobacco Control, or WHO FTCT, was born in 1993, with a recommendation by Ruth Roemer and Allyn Taylor. They proposed that the World Health Organization (WHO) use its standing in order to develop international conventions to promote public health at the international level. Roemer and Taylor also proposed the concept of the framework convention and protocol, which they designed to develop international coordination to fight against the tobacco epidemic. After some initial resistance, the idea was gradually accepted by the WHO; after negotiations with member states, it was discussed at the World Health Assembly in May 2003 so that it could be formally voted upon. The WHO Framework was adopted by consensus that same year, and was enacted in 2005.

The WHO FTCT was the first treaty negotiated by the WHO. The treaty is based on empirical evidence and takes a new angle to the traditional way of addressing addictive products. As opposed to other treaties on addictive substances, the WHO FTCT focuses not only on supply issues, but also on ways to reduce demand. The objective of the convention and its protocols is to protect people from the catastrophic consequences of consuming tobacco and exposure to secondhand tobacco smoke. These consequences cover the areas of health, social, and environmental damage. In order to achieve this, the WHO FTCT provides a framework for tobacco control measures to be implemented by the convention signatories at all levels—national, regional, and international—so that the prevalence of tobacco use, consumption, and exposure to its smoke can be significantly reduced.

The trigger for the inception of the WHO FTCT was the growing worldwide expansion of the tobacco epidemic. The global increase of tobacco occurs due to a wide range of social and economic factors, including the prevalence of lifting trade regulations. Other contributing elements are global tobacco marketing, sponsorships, advertising, and promotion, and the increasing illegal trade of tobacco products. The latter includes contraband and counterfeiting of tobacco products.

The FTCT provides a global coordinated action meant to combat the tobacco epidemic, setting distinct steps for states to use in developing policies related to tobacco use. To summarize, the provisions of the WHO FTCT that aim to reduce tobacco use and its effects are listed in articles 6 to 14 of the published document: protection from exposure to tobacco smoke; regulation of contents of tobacco products; regulation of tobacco product disclosures; packaging and labeling of tobacco products; education and other measures of public awareness; issues of tobacco advertising, promotion, and sponsorship; and demand of reduction measures concerning tobacco dependence and quitting. It also
includes price and taxation measures in order to decrease the demand for tobacco.

The principal reduction provisions in the WHO FCTC are published in articles 15 to 17 and include illicit trade in tobacco products, sales to and by minors, and support for economically viable alternative activities.

The Convention
A treaty or convention is an agreement enacted between nations and international entities that have been given treaty-creating rights. Treaties are meant to fall within the framework of international law, and nations that become signatories commit to following its rules. Treaties may take many forms and become known under other denominations, such as conventions, protocols, charters, acts, statutes, and others. Conventional international law requires treaties to be ratified by all signatory parties. Therefore, additions such as amendments and protocols must be unanimously agreed upon by all signatories to the main treaty.

The WHO FCTC, the first international treaty created under the WHO, was opened for signature in June 2003 in Geneva, Switzerland. From then until June 2004, the institution in charge of the treaty was the United Nations. The treaty has 168 signatories, making it one of the mostly widely accepted treaties in the history of the United Nations. Signatory states commit to working to ratify, accept, and approve the treaty. Although the document has been closed for signatures, states that wish to sign on may do so by way of a process called accession, which is equivalent to ratification of the treaty. The convention was enacted on February 27, 2005, after being approved or ratified by 40 nations. It provides a new stepping-stone for broader dimensions of international cooperation for public health. It was signed by 168 of the 192 WHO member states.

The Protocols
Humanitarian treaties are often followed by protocols, which are annexed or adopted to provide tools and procedures for a treaty or convention, or to a specific part of a treaty. These protocols are considered treaties by themselves. As with the original treaty for which they provide support, they are opened for signature and ratification by states that are parties to the main treaty. The first protocol to the WHO FCTC was accepted in November 2012 at the Conference of the Parties in Seoul, South Korea. The protocol was opened for signature from January 2013 to January 2014. The protocol counts 53 signatory states as well as the European Union. The Protocol has been opened for ratification and approval by all WHO FCTC parties. As with the treaty, it will be enacted as soon as it is ratified by 40 states.

The purpose of the Protocol is to eliminate all forms of illegal trade in tobacco products. It offers resources for the prevention and fight against illegal trade, including licensing for the manufacture, import, and export of tobacco products and related manufacturing equipment, as well as a tracking system for all tobacco products made in a specific area or region.

Summary of Core Areas
The convention is fact-based; it relies on scientific evidence that establishes that exposure to tobacco is directly linked to death, disease, and disability. It is also concerned with the deleterious consequences of tobacco use worldwide. Therefore, it urges all signatories to commit to the adoption and implementation in their respective national jurisdictions, of legislative, executive, economic, and other measures that protect the public from the use of tobacco, and the exposure to secondhand tobacco smoke in the environment. It encourages the formation of policies that will provide protection from exposure to tobacco smoke in indoor public places, public transportation, and other public places deemed appropriate.

The convention document is divided into 11 parts and two annexes. The core issues are laid out in Parts II (articles 3–5), III (articles 6–14), IV (articles 15–7), and V (article 18). Part II provides the objective, guiding principles, and general obligations; Part III lists the measures relating to the reduction of demand for tobacco; Part IV refers to measures relating to the reduction of supply of tobacco; and Part V deals with environment protection. Among the strategies for the reduction of tobacco demand, for example, are price and tax measures, which are expected to deter consumption particularly among young people. It also incorporates financial and nonfinancial measures to reduce consumption.

Other important articles list the scientific and technical cooperation measures that will be
undertaken to develop, promote, and coordinate tobacco control-related research programs at the regional and international levels. The signatories commit to create scientific programs that will establish surveillance of patterns, factors, and consequences of tobacco consumption and exposure to tobacco smoke; to establish national systems for epidemiological surveillance of tobacco; to cooperate with government and nongovernment international health efforts in the development of procedures and guidelines; and to share and publish any relevant findings. It also establishes that, within the framework of national laws, the parties will promote the exchange of scientific, socioeconomic, legal, and commercial information, including information regarding the practices of the tobacco industry. Finally, the WHO FCTC provides for taking legal action, either by supporting existing laws or creating them when necessary, in order to address judicial liability, including compensation, in reference to tobacco control.

Wynder, Ernst

Ernst Wynder was a pioneer cancer researcher with notable achievements in tobacco and nutrition epidemiology that began in medical school, when he co-authored a seminal paper on smoking and lung cancer. He had a strong interest in prevention-oriented health education, especially for schoolchildren. Wynder began his career in an era when there was little scientific basis for prevention of chronic diseases like cancer and heart disease, and he played a significant role in developing the principles and practice of cancer control that still guide the field today. He was a tireless advocate of policies that integrated the roles of government, medical institutions, and individuals in using studies of disease causes to develop prevention and control strategies. He was an influential adviser on cancer policy to many U.S. government and international organizations, and he was founder and editor-in-chief of a major medical journal, Preventive Medicine, one of the first academic journals in the field. He died of thyroid cancer in 1999.

Early Years
Born in Herford, Germany, he immigrated with his family to the United States in 1938 to escape Nazi persecution. He received a B.A. from New York University (1943), served as a U.S. Army Intelligence officer in World War II, and received an M.D. at Washington University in St. Louis (1950). In 1948, while still a medical student, he began collecting case histories of lung cancer victims. He eventually convinced Dr. Evarts Graham, a prominent surgeon at Washington University who was also a smoker and strongly skeptical, to allow him to interview
patients there and, importantly, to support a successful application for funding from the American Cancer Society. Their data became the basis for a landmark paper in the *Journal of the American Medical Association* linking lung cancer to cigarette smoking that was noteworthy for unusually rigorous attention to methodological detail, such as pathological confirmation of diagnoses, distinguishing different lung cancer types, and handling potential biases.

Although cancer had been caused experimentally in animals using chemicals found in tobacco smoke as early as 1918, by the 1950s lifestyle and environmental causes of cancer were still poorly understood, and the pervasiveness of smoking, along with aggressive support of medical research by the tobacco industry, left many researchers unconvinced that the statistical associations represented disease causation. Wynder believed that these questions could not be answered by epidemiology alone, but required a coordinated approach involving experimental biology and chemistry, and, above all public education. He continued studies of cancer patients beginning in 1951, as a medical resident at Memorial Hospital and researcher at the Sloan-Kettering Institute for Cancer Research, where he and chemist Dietrich Hoffmann (1924–2011) began a collaboration on experimental studies on tobacco chemistry and air pollution that would become one of the most enduring partnerships in cancer research.

More than 20 of their studies were cited in the cancer chapter of the first “Surgeon-General’s Report on Smoking and Health” (1964). At Memorial, Wynder carried out definitive studies of cancers of the mouth, larynx, breast, and other sites. However, his unrelenting focus on harmful effects of tobacco at an institution that was receiving substantial support from tobacco company Philip Morris made him the target of threats to censor or suppress his studies, thwarted only by the intercession of board member and Nobel laureate Peyton Rous. Although Wynder maintained an affiliation at Memorial Sloan-Kettering until his death (the two institutions merged in 1960), he eventually decided to strike out on his own.

**American Health Foundation**

In 1969, Wynder founded the American Health Foundation (AHF), serving as its president and medical director for almost 30 years. The foundation’s epidemiology and health behavior divisions were headquartered in the Ford Foundation building in Manhattan, near Memorial Sloan-Kettering and other hospitals where epidemiological studies could be done. Its basic science divisions were housed in a specially designed building in Valhalla, New York, also known as the Naylor Dana Institute after the Eleanor Naylor Dana Foundation, which, with the National Cancer Institute (NCI), provided major construction support. The AHF, supported largely by competitive grants from the NCI, the American Cancer Society, and other agencies, was built on extensive multidisciplinary research programs in epidemiology, tobacco and chemical carcinogenesis, nutrition, pathology, and health behavior and promotion, and was the only NCI-designated cancer center devoted exclusively to prevention. At its peak, it employed over 200 scientists and technicians, with sophisticated state-of-the-art instrumentation and animal research facilities and a scientific library.

In 1972, Wynder recruited John Weisburger (1921–2014), then director of the NCI’s bioassay program, to be vice president and director of research. Hoffmann served as associate director and chief of the Division of Environmental Carcinogenesis, where he made numerous contributions including identification (along with Dr. Stephen Hecht) of an important class of carcinogens—nitrosamines—in tobacco smoke. Other major epidemiological initiatives included studies of the impact of dietary change on both breast and prostate cancer, with special emphasis on the possible impact of dietary fat on survival from both cancers.

Concerned about the fragmented state of school health education, Wynder directed substantial foundation efforts toward developing, implementing, and evaluating K–12 curricula and materials in a program called “Know Your Body” (KYB) in at least eight countries. A central prop of KYB was a health passport for each child that was intended to track key health measurements. This concept was eventually adopted by many organizations as a useful record-keeping device.

**Preventive Medicine**

In 1972, Wynder founded *Preventive Medicine*, the first academic journal devoted to the topic, and served as its editor-in-chief for 25 years during
which he oversaw publication of hundreds of influential articles. In his opening editorial, he quoted a Greek adage: “It is the function of medicine to help people to die young as late as possible,” an epigram that he often repeated in writings and speeches.

**Awards and Publications**

**Personal**
Wynder was a noted international traveler who frequented elite social circles, often with research funding in mind. The American Health Foundation Board of Directors at times included representatives of Norton Simon, Inc., Merrill Lynch, Perrier, the Miami Dolphins, and various entertainment industry figures. He was once linked romantically with actress Kim Novak. He eventually married Sandra Miller, his companion of 25 years.

**Further Readings**
Half of the male population and one-third of the female population in the United States will develop cancer in their lifetimes. X-rays are an indispensable tool in both the diagnosis and treatment of cancer. Computed tomography (CT) is the most widely used diagnostic tool for the localization and planning procedures necessary in the cancer treatment process. Megavolt X-ray photons are generated by an accelerator for the actual treatment of the cancer site and can be combined with CT to verify the treatment site. This type of X-ray treatment is called external beam radiation therapy (EBRT).

History
Wilhelm Conrad Roentgen discovered X-rays in November 1895. A mere 17 days later, on January 12, 1896, Emil Grubbe supposedly used X-rays to treat breast cancer for palliation. Since he did not publish this event until much later, claims that he was the first to use X-rays for radiotherapy purposes is highly disputed. A more reliable first record of radiotherapy treatment is that of French physician Victor Despeignes, who treated a male with stomach cancer in July 1896. In 1903, two physicians, Drs. Senn and Pusey, reported on the effects of radiation on the lymph nodes. From then, X-rays had forever changed the face of cancer treatment.

The treatment given at the time was less than ideal with high morbidity and mortality rates. The doses given were extremely high, with single exposures typically lasting up to an hour. The energy of the X-rays was not sufficient to reach deep-seated tumors.

In 1914, an Austrian physician mentioned that radiotherapy side effects could be reduced if the dose was given in smaller portions. The medical profession was divided on the topic until Claudius Regaud, employed by the Curie Institute, proved in 1922 that fractionated radiation therapy delivered the same positive outcome with less severe side effects.

Linear Accelerators
Linear accelerators (LINACs) are used to generate high-energy X-ray photon beams used in EBRT. The first concept for a linear accelerator was conceived by Rolf Wideroe in 1930. The first LINAC, installed at Stanford University in 1950, could generate deep-penetrating megavoltage X-rays.

Since then, the greatest advancements made in X-ray treatment were the invention of the CT scan, the perfecting of the LINAC with the addition of multileaf collimators (MLCs), and, more recently, image-guided radiation therapy (IGRT) and intensity-modulated radiation therapy (IMRT).

A LINAC consists of a negatively charged cathode and a positively charged anode. The cathode
is an electron beam gun that emits electrons. A potential difference is applied between the cathode and the anode, which moves electrons from the cathode to the anode. The electrons pass through a waveguide where they are accelerated by radio-frequency electromagnetic waves. A bending magnet bends the electron beam just before they impact on the anode. When the electrons collide with a tungsten anode, an X-ray beam is emitted. This X-ray beam is shaped by an MLC, which consists of multiple separate lead strips. Each lead strip is driven by its own individual motor to a pre-specified position. The MLC can also move during the treatment process, as seen in more dynamic types of treatment like IMRT.

A gantry head aims the emitted X-ray beam at the patient. The gantry can move 360 degrees around the patient. The patient is positioned on a couch, which can also move 180 degrees to ensure that the X-ray beam can enter the patient at any angle.

**Computerized Axial Tomography (CAT)/Computed Tomography (CT)**

Before the invention of the CT scan, cancer was diagnosed by two-dimensional X-ray imaging. As a result of superimposition, the margins of the lesions were not well defined. There was also no way of knowing how large the tumors were. This left a lot of room for uncertainties.

In 1930, the Italian radiologist Alessandro Vallecbona invented X-ray tomography. He overcame the problem by creating multiple virtual cross sections of a certain body part. By simultaneously moving both the X-ray tube and the radiographic film, he recorded a sharper image of the specified area, while the rest of the unnecessary image was blurred due to the motion. With the development of computers and their incorporation into the medical discipline, CT as we know it today became a reality.

In 1967, Sir Godfrey Hounsfield, who was working as an electrical engineer at Electric and Musical Industries (EMI), wondered if it was possible to determine what a box contained by collecting X-ray readings at multiple angles through the box. He soon realized that it would be possible in a medical setting, using finely collimated X-ray beams. The first prototype of a head scanner, called Mark 1, was built in 1972 at the Atkinson Morley's Hospital in Wimbledon. A cystic brain tumor was the first image ever obtained by the scanner. In 1975, a general scanner was available which could create three-dimensional images of most parts of the human body.

At the time that Hounsfield and EMI were developing the CT scanner, the Beatles were EMI's greatest success story. It is believed by some that it was due to the band's success that EMI could help fund Hounsfield's research on the scanner.

In addition to its three-dimensional imaging ability, the CT scan can also provide electron density information of examined human tissue. This is important because it can demonstrate how different tissues will react to an X-ray beam passing through them. The name used to describe the electron density of various types of tissue is the Hounsfield unit. This electron density information is at the heart of every computerized radiation planning algorithm.

A CT scanner uses a cone-shaped X-ray beam that rotates on the inside of a round opening. Multiple detectors are positioned opposite the cone-shaped beam to acquire the data necessary to produce an image. A patient is positioned on a mobile couch that enters the opening of the scanner while the beam rotates around the patient. The size of the incident X-ray beam can range from 1 mm to 10 mm. Each rotation takes approximately one second. Ten to 50 rotations may be necessary to acquire enough data. The recorded data is sent to a computer where it is used to reconstruct an axial slice of the patient's internal anatomy.

Spiral CT scanners acquire data in a continuous mode without the couch needing to stop for
each slice increment. A major advantage is that the acquisition time is greatly reduced.

**Image Guided Radiotherapy**

Accurate patient setup is crucial to ensure that the tumor receives the maximum possible radiation dose while the surrounding normal tissue is spared. To achieve this, the patient's position should be easily reproducible for every fraction of treatment. There are radiotherapy treatments that require as many as 35 fractions. The patient’s position needs to be exactly the same for all 35 treatments. Internal organ movement is another challenge to the reproducibility of patient setup.

A CT scanner placed in the same room as the LINAC is the newest form of IGRT. The patient’s position, as well as the internal organ position, can be verified right before treatment commences.

**Ionization**

X-rays cause ionization by interacting with the electrons in the atoms of tissue. Compton scattering occurs when an incident X-ray photon transfers some of its energy to an electron, but undergoes a change in direction as a result of the collision. A recoiling electron is released.

X-ray photons with adequate energy can eject an electron from its orbit. This is termed the photoelectric effect. The ejected electrons act as free radicals to further damage surrounding atoms.

Very-high-energy photons can interact with an atom’s nucleus, resulting in an electron and positron pair. This process is called pair production.

The change in the cells’ atomic structures causes DNA damage. If the cells do not repair the DNA damage before they enter their next cell cycle, the cells will die.

**X-Rays and Society**

X-rays have the ability to both cure and cause cancer. Of all the imaging modalities, the CT scan delivers the highest dose to the patient. There has been a drastic increase in the use of CT scanning for medical diagnostic purposes.

According to the U.S. Food and Drug Administration, the radiation dose per individual has risen approximately 500 percent since 1982. According to one study, it is estimated that 29,000 future cancers could be as a result of CT scans done in the United States during 2007.

The average effective dose for an adult undergoing a CT examination is 2 to 16 millisievert. This dose is equivalent to that of 100 to 800 chest X-rays.

The accumulated radiation dose increases as a person undergoes more and more X-ray examinations, increasing lifetime risk for cancer. The younger a person is when receiving an X-ray dose, the higher the risk of developing cancer. Female patients are at a higher risk of developing cancer from the same radiation exposure at the same age as men.

X-rays are essential for the diagnosis and treatment of many conditions, especially cancer. The benefits of using X-rays, either for diagnosis or treatment, should always outweigh the risks. Approximately half of all patients diagnosed with cancer will need radiotherapy as part of their treatment regime.

Yale Cancer Center

Yale Cancer Center (YCC) was founded in 1974 as a result of an act of congress in 1971, which declared the nation’s “war on cancer.” Combining the tradition of innovative cancer treatment and quality care, YCC strives to provide exceptional patient-centered care. YCC brings together the resources of the Yale School of Medicine (YSM), Yale-New Haven Hospital (YNHH), the Yale School of Public Health (YSPH), and Yale University. For over 40 years, YCC has been a National Cancer Institute (NCI)-designated comprehensive cancer center, one of only 41 throughout the country and the only one in southern New England. These comprehensive cancer centers play a vital role in the advancement of the NCI’s goal of reducing morbidity and mortality from cancer through scientific research, cancer prevention, and innovative cancer treatment. The National Comprehensive Cancer Network (NCCN), an alliance of the world’s leading cancer centers dedicated to improving the quality, effectiveness, and efficiency of care provided to patients with cancer, recognized YCC/Smilow Cancer Hospital at Yale-New Haven, New Haven, Connecticut, as an NCCN member institution in March 2014.

History

YSM pioneered the modern concept of chemotherapy over 60 years ago with the efforts of faculty by administering the very first anticancer agent, nitrogen mustard, to a patient with cancer. Scientists and clinicians at YCC today are collaborating to design and develop the latest cancer therapeutics and combination therapy for patients in Phase I, II, and III clinical trials. The National Cancer Act of 1971, from its inception, has mandated that comprehensive cancer centers like Yale develop fundamental basic science that translates into innovative cancer therapies.

Mission Statement

YCC and Smilow Cancer Hospital aim to prevent and cure cancer through groundbreaking research, scientific discovery, and compassionate patient care. The collaboration of over 450 scientists and physicians focused on cancer research at YCC provides a strong foundation for breakthroughs in cancer prevention, diagnosis, and treatment.

YCC seeks to capitalize on the scientific strengths of Yale University to benefit cancer patients throughout the world, while providing the very best in clinical cancer care to the patients at Smilow Cancer Hospital at Yale-New Haven. Smilow Cancer Hospital at Yale-New Haven is part of the nationally recognized Yale-New Haven Hospital and is affiliated with YCC. Smilow Cancer Hospital, the most comprehensive cancer facility in New England, is a 14-story, 500,000-square-foot cancer hospital, which includes 168 private inpatient rooms,
outpatient multidisciplinary treatment centers, 12 operating rooms, infusion suites, diagnostic imaging services, a floor for children with cancer, a specialized women’s cancer center, and diagnostic and therapeutic radiology services for children and adults. YNHH’s York Street campus and associated ambulatory sites are magnet-designated by the American Nurses Credentialing Center.

Strategic Goals

1. Remain committed to developing a cure for all cancers.
2. Become a leader in personalized cancer care through innovative tumor-profiling techniques used to analyze every patient’s cancer.
3. Ensure every patient has an outstanding and positive cancer care experience at Smilow Cancer Hospital at Yale-New Haven, with a steadfast focus on patient- and family-centered care.
4. Build on the scientific traditions of Yale University, with continued investment in interdisciplinary cancer research in basic science, translational research, and prevention and control.
5. Maintain and support the expertise of the physicians, nurses, and clinical staff at Smilow Cancer Hospital and YCC.

Research

Yale School of Medicine was home to the nation’s first university-based Medical Oncology Section. Its faculty has since pioneered many breakthrough cancer treatments. Today, there are seven research programs at YCC, including: developmental therapeutics, genetics and genomics, cancer immunology, molecular virology, cancer prevention and control, radiobiology and radiotherapy, and signal transduction. Cancer research at Yale began decades before the center was founded. The first research program in developmental therapeutics began in 1974, representing the foundation of the clinical translational research efforts at YCC. Laboratory/research-based discoveries are taken into the clinical setting and observations. These are returned to the laboratories for further refinement into improved cancer treatments.

Basic research in cancer is a hallmark of YCC, drawing approximately $140 million in cancer research funding to Yale annually. Yale is home to some of the leading international investigators in cancer research, who have provided a steady stream of advances in a number of disciplines, contributing to the basic understanding of cancer and to the development of new therapies and diagnostic strategies.

YCC’s Developmental Therapeutics Research Program has been successful in discovering a wide range of novel therapeutics, many of which are now undergoing preclinical and clinical testing. The recent initiative of the Developmental Therapeutics Program, a Phase I research team, focuses on the application of promising laboratory discoveries in the design and conduct of clinical trials at YCC.

Clinical Care

YCC brings the convergence of science and medicine as the latest research directly applicable to patient care. Led by Roy S. Herbst, M.D., Chief of Medical Oncology and Associate Director for Translational Research, Yale medical oncologists care for patients in Smilow Cancer Hospital at Yale-New Haven. Twelve multidisciplinary programs have been developed at YCC and Smilow Cancer Hospital to organize patient care. These provide physicians and specialists at YCC with the opportunity to focus their expertise on specific types of cancers.

Clinical trials and research studies are available for appropriate patients with early or late-stage diseases who are under the care of the YCC’s oncology staff. Currently 64 clinical trials are available for patients in over 15 different disease areas.

Other services provided at the center include access to clinical trials covering the majority of cancer types as well as assistance for cancer survivors. On completion of their treatment, patients are offered services through the Connecticut Challenge Survivorship Clinic. The clinic provides medical care, nutritional and lifestyle guidance, and support for cancer survivors throughout the state.

Yemen

While Yemen has sought to improve its health care system over the past 10 years, its system is still substantially lacking. Yemen only has 3 doctors for every 10,000 people. For people living in rural areas, emergency services are nonexistent. A quarter of the people living in rural areas have access to health services, whereas 80 percent of the urban population has access. The mortality rate in childhood is largely from diseases for which there is a vaccine or that would have been preventable if there had been adequate health services available. In 2003, it was estimated that 12,000 people were living with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS). Per capita, Yemen's total health expenditure is one of the lowest in the world. It spends $40 per person on health care needs each year.

According to the National Anti-Cancer Corporation (NACC), more than 12,000 cases of cancer emerged in Sana'a in 2012. Logistics, lack of infrastructure, and lack of funding are obstacles preventing Yemen from taking action to help alleviate this large number of cases. Yemen has among the highest cancer rates of any Middle Eastern or north African country, up to 10 times higher than most Arabic countries. This burden has become so out of control that vice president Abduh Raboh Mansor Hadi has asked about the practicality of using a portion of funds from mobile phone revenue to fund the fight against cancer. The high cancer rates in Yemen are attributable to lifestyle choices and farming practices. Consumers smoke more tobacco, and Yemeni farmers use more herbicides and pesticides than before. The NACC reports that 25 to 30 cases are discovered each day, and this only accounts for the cases that have been reported to the corporation. It is likely that many more cases are not reported.

The NACC has attempted to arrange free access to pharmaceuticals and health services for cancer patients who otherwise would not be able to afford treatment. In addition to this, it intends to provide between 30 and 50 percent of the cost of medication and health services for those who are able to contribute partially to their treatment. The corporation also intends to sponsor awareness campaigns and other cultural projects for the Yemeni people. Because of a lack of infrastructure and health services, more than half of all new cases are fatal. Because there are no adequate early detection screenings available, many cancer cases are discovered in the late stages, when treatment options are severely limited. People are also unaware of the signs and symptoms of cancer, so they do not know when or if they should seek treatment. For those who are treated, many stop taking medications when their symptoms have improved, against the recommendation of physicians. For cancer patients who seek treatment in hospitals, they are provided medical treatment and lab tests to determine the cause of their illness and its progression. In addition to medical support, emotional and psychological support is available.

Yemen is composed of 555,000 square kilometers, but it only has 2,000 reproductive health centers, with 60 percent providing different services such as labor and pregnancy, care after delivery, and family planning assistance. There are 520 centers that provide people with emergency services, and 69 hospitals for other purposes, according to the national Yemeni Ministry of Health. According to international standards, there should be a comprehensive emergency delivery hospital for every 500,000 persons, and four basic health centers. However, Yemen is an exception because the majority of its population lives in inaccessible rural areas. Yemen has about 130,000 residential areas, but many are in nearly impassable locations. Some places barely have roads. These locations are so far from medical facilities that the Yemeni people only go to health centers when they are having emergencies. Unfortunately, the long trip and time spent before arriving at the health center means that individuals come in too late for most treatment.

The patient mortality rate is very high in rural Yemen, especially for individuals who make their
homes near the Saudi Arabian and Omani borders. As of December 2014, according to the United Nations Office for the Coordination of Humanitarian Care, an estimated 8.4 million people in Yemen lack access to basic health care, a 1 percent increase from 2013. While the Ministry of Health is seeking to resolve the problems faced by the health care services in Yemen, geographic and cultural difficulties in rural areas present an extremely difficult challenge. Currently, the government is aiming to build facilities so that one comprehensive emergency center and four basic emergency centers exist for every 250,000 people. Other obstacles in the way of an effective health care system include lack of funding, scarcity of medicine, lack of equipment, and lack of medical professionals. All of these difficulties together form a large impediment to extending health care services to rural Yemen. Because most of the health care centers in Yemen have a shortage of doctors, one general practitioner may have to take on the responsibility as physician, pharmacist, and labor and delivery doctor.

There are extreme difficulties when it comes to recruiting staff. There are not enough doctors to facilitate shift rotations, and there are very few physicians in Yemen altogether. With only one doctor on staff, it becomes extremely difficult to attend regular patient visits as well as emergencies. Severe lack of funding is largely to blame for the rarity of doctors. The immense problems facing health services are known to local politicians and councils, but no substantial steps have been taken to fund them. Even with what financial aid local communities could muster, the health centers would not be fully supported. However, committees have been formed to investigate the health service needs in these areas. The Ministry of Health has made mothers and children a high priority. They are endorsing midwives to make house calls, especially where there are insufficient facilities to care for these patients. This is an attempt to combat the lack of facilities and personnel. There are also mobile teams who make the difficult trek into rural Yemen in order to provide health care services several times each year. In 2013, the Ministry of Health donated funds to support 10 governorates. This action had the effect of adding 24 new medical facilities in the area.

Young Adult Cancer Prevention

Cancer is often thought of as something that develops later in life. Many people think that cancer is a health issue that only affects older people. Unfortunately, this type of thinking leads many young people to neglect focusing on their own health in terms of cancer prevention and screening. Some cancers that develop in young adults have no known cause, but others are linked to certain lifestyle risk factors and can be prevented. Because of this, researchers and educators have increasingly devoted effort to cancer education and prevention in the young adult population.

The Myth That Young Adults Are Impervious to Cancer
Young adulthood (approximately 15 to 39 years old) is usually characterized by good overall health, as many of the diseases and conditions that people face do not manifest until later in life. In fact, young adults are sometimes referred to as “young invincibles,” illustrating the fact that many believe they are impervious to diseases and health issues that older adults face. In addition, young adulthood is often characterized by engaging in risky health behaviors; people this age often want to explore their
Young Adult Cancer Prevention

Independence and experiment with different life experiences (e.g., drinking, drugs, sex). However, in believing that they are invincible at this age, many young adults do not think about some of the short- and long-term effects of these risky behaviors. Specifically, many of these risky health behaviors have direct links to cancer. The following are some examples:

- Young adults are not only engaging in more sexual activity than older or younger age groups, but they are also more likely to have more than one sexual partner; both of these behaviors increase their risk for contracting genital human papillomavirus (HPV). Genital HPV infections are the most common sexually transmitted diseases in the United States, specifically among young adults. Persistent genital HPV infections have been shown to lead to the development of cervical and other cancers (e.g., anal, penile, head, and neck).

- Many people start smoking during late adolescence and early adulthood. Research shows that the more years a person smokes (i.e., the younger they start) and the more frequently they smoke, the higher their chances are for developing lung cancer later in life.

- Exposure to high levels of ultraviolet (UV) radiation, whether from the sun or a tanning bed, significantly increases one's risk for developing skin cancer. The risk of getting skin cancer from UV radiation increases for young adults, as their skin is particularly susceptible to the damage caused by the radiation. Young, adult, white (Caucasian) women report frequent sunbathing and tanning bed use, which significantly increases their chances of developing skin cancer. Much like smoking and lung cancer, the frequency (i.e., repetitive exposure) and timing (i.e., earlier exposure) of excessive UV radiation exposure is related to a higher risk of developing skin cancer.

- Having a low-fiber/high-fat diet as well as a sedentary lifestyle are both factors that increase one's risk for developing colon cancer. These diet and activity habits are often developed early in adulthood, and years of poor diet and exercise significantly increases one's risk for colon cancer later in life.

- Substantial and repetitive exposure to any form of radiation earlier in life can increase the risk for many different kinds of cancer. Ironically, many people are exposed to increased amounts of radiation because of medical procedures like positron emission tomography (PET) scans, computed tomography (CT) scans, fluoroscopies, and X-rays.

In addition to engaging in these risky behaviors that can lead to certain types of cancer, research also shows that young adults are significantly less likely to seek out and use preventive health services compared to other age groups. This includes being less likely to follow the recommended guidelines for cancer screening or clinical preventive measures (e.g., Pap testing, HPV vaccination for cervical cancer, skin cancer counseling, etc.).

On the other hand, there are many types of cancers that occur in young adults that have no known cause and therefore cannot really be prevented. In other words, they develop spontaneously, usually due to some type of gene mutation within the body.

Preventing and Screening to Reduce Cancer Risks

Drawing attention to the risk factors that can lead to cancer and the ways that young adults can prevent cancer are important at two levels. First, when young adults engage in risky behaviors and fail to focus on preventive health, this can lead to cancer developing later in life. In fact, for all of the cancer examples listed above, it is often noted that the cause or root of the cancer stems from unhealthy or risky behaviors enacted during early adulthood. Second, while most of these preventable cancers do not develop until later in life, it does not mean that they will not develop in early adulthood.

For example, the American Academy of Dermatology notes that melanoma skin cancer is the most common form of cancer for young adults ages 25 to 29, and rates among young adult women (those under 44 years old) have been increasing 6.1 percent annually. Another example is cervical cancer; the
National Cancer Institute reports that HPV-associated cervical cancer is most frequently diagnosed among women 35 to 44 years old. Other HPV-associated cancers, lung cancer, and colon cancer are less commonly diagnosed among young adults.

Therefore, research and education focusing on preventing (and screening) for these types of cancers in young adulthood is not only important for the “now,” but also for the long-term health of individuals.

**Education and Promotion in This Population**

One of the best tools to fight cancer is education. People face barriers to preventing cancer if they do not think they are at risk for a certain cancer, if they are ignorant that their behavior or lifestyle choices could lead to cancer, or if they do not know about the preventive measures and early screening tools available to them. Recently, there has been increased research on cancer prevention in young adults. Many medical researchers as well as social scientists have devoted time and attention to not only understanding young adults’ cancer knowledge, attitudes, and behaviors, but also to developing cancer prevention interventions to reduce young adults’ chances of developing cancer. One organization that is a leader in this area is the Prevent Cancer Foundation. It generates public discussions about cancer prevention, promotes research on the topic, increases access to knowledge and early detection services (particularly in underserved communities), and collaborates with others working in this area. An infographic developed by the Prevent Cancer Foundation sums up seven important lifestyle behaviors related to reducing the risk for cancer. Obviously, the earlier that people adopt these behaviors, the lower their risks for developing cancers even more.

In addition to increasing general education about cancer prevention among young adults, some organizations and researchers have focused on places that young adults frequent in order to better address young adult cancer prevention. One such place is college campuses. For example, many college campuses have focused on tobacco use prevention and tobacco cessation. Because of this, the Tobacco Technical Assistance Consortium, which focuses on assisting organizations developing their own tobacco control programs, created a page called the College Tobacco Prevention Resource (http://www.ttac.org/services/college/index.html); this Web site serves as a clearinghouse for resources about tobacco-related programs at colleges and tips for colleges that want to develop their own programs.

**Conclusion**

Young adult cancer prevention is an important topic. Not only do young adults often engage in risky behaviors that can lead to cancer, some young adults also do not believe that they are susceptible to cancer. Educating young adults on the importance of life choices made now can help to reduce their cancer burden both earlier and later in life.

**Yul Brynner Head and Neck Cancer Foundation (Head and Neck Cancer Alliance)**

The Yul Brynner Head and Neck Cancer Foundation was incorporated in 1984 by actor Yul Brynner and medical specialist Dr. George Sisson (1920–2006). Its primary purpose was to educate the public about the dangers of tobacco use in relation to incidences of throat and mouth cancers.
Today, the foundation is referred to as the Head and Neck Cancer Alliance.

Yul Brynner, who had over 40 movie roles and was best known for his role in the Rodgers and Hammerstein musical, *The King and I*, developed lung cancer and died on October 10, 1985. Before he had lung cancer, he was diagnosed with a precancerous growth of his vocal cord (larynx). By all accounts, Brynner always recognized that smoking could cause him to develop lung cancer, but he had not realized that it could cause symptoms and that treatment would affect his voice. While he kept his vocal cord lesion secret since he was best known for his singing and acting, the radiation therapy needed to treat his lung cancer greatly affected his voice. He eventually dedicated monies for the development of the foundation that bore his name.

Before Yul Brynner died, he recorded a public service announcement sponsored by the American Cancer Society and extracted from a *Good Morning America* interview in which Brynner warned the audience not to smoke in a hoarse and harsh voice. He had quit smoking in 1971, knowing all too well that despite stopping smoking, his risk of lung cancer was still high. The finalized public service announcement aired after his death.

Initially, the foundation developed educational programs and secured funding from numerous research grants in head and neck cancer. It went through a period of inactivity in the late 1980s and early 1990s. The Association for Head and Neck Cancer Awareness and the Yul Brynner Foundation combined in 1997, to be called the Head and Neck Cancer Alliance, and was directed by Dr. Terry Day, the current president. The Head and Neck Cancer Alliance is a nonprofit organization mainly dependent on donations. In 1998, the alliance organized and directed the first annual Head and Neck Cancer Awareness Week, officially changed to Oral, Head, and Neck Cancer Awareness Week® (OHANCAW®), to communicate awareness about oral cancer, the most common of head and neck cancers. The Head and Neck Cancer Alliance plans to continue to sponsor this awareness week until these types of cancer are no longer detectable. As of 2014, several organizations and educational institutions have sponsored awareness events including the University of Florida College of Dentistry 5K Awareness Walk, Johns Hopkins Education Day, and Anchorage Alaska’s Mission of Mercy.

Presently, the overall mission of the Head and Neck Cancer Alliance is to support and educate oral, head, and neck cancer patients and their families; sponsor new and groundbreaking research; and educate children and adults in the preventative measures of head and neck cancer. The foundation encourages people to become involved in the organization. It posts cancer resources to its Web site (including news articles, clinical trials, events, and conferences) and provides information for hosting a head and neck cancer screening day. In fact, the main focus of Oral, Head, and Neck Cancer Awareness Week is to encourage preventative screenings of the head and neck areas. Head and neck cancers are defined as cancers that occur in the head and neck region, including the nasal cavity, sinuses, lips, tongue, mouth, salivary glands, throat, and vocal regions.

The Head and Neck Cancer Alliance National Board member, and the author of *My Voice: A Physician’s Personal Experience With Throat Cancer*, Dr. Itzhak Brook offered his book about his own laryngectomy at no cost to many professionals in the United States through a generous grant from the Head and Neck Cancer Alliance. His book focuses on his complete journey as a throat cancer patient, with the added knowledge of that of a physician. Readers of the book are taken through his journey from cancer discovery, to removal of his voice box, to learning how to speak again with an assistive speech device. Details about the experience, the professionals he met, and the lessons he learned along the way are carefully detailed. Awareness is the key of the alliance, and this book brings the experience of throat cancer to professionals and the public alike. Kathy Brynner-Hifl er, the widow of Yul Brynner, has always been and continues to be active with the foundation as chair, emeritus, of the Advisory Board.

Yul Brynner’s lung cancer diagnosis and his own discovery of a lump on his vocal cords resulted in the development of the Head and Neck Cancer Alliance (formerly known as the Yul Brynner Head and Neck Cancer Foundation). At a time when little emphasis was placed on oral, head, and neck cancers, Yul Brynner’s experience shaped this foundation to shed light on an often less-discussed cancer.

Zambia

The Republic of Zambia is a landlocked country in southern Africa that is surrounded by the Democratic Republic of the Congo to the north; Tanzania to the northeast; Malawi to the east; Mozambique, Zimbabwe, Botswana, and Namibia to the south; and Angola to the west. It is part of what is known as sub-Saharan Africa. Zambia became a British colony known as Northern Rhodesia in 1911, and in 1953 it became part of the Federation of Rhodesia and Nyasaland until 1963. The country gained its independence in 1964 as Zambia. Zambia’s population, as of July 2014, is estimated at 14.6 million, with a life expectancy at birth of 51.8 years. For every 100,000 citizens, there are 10 doctors, 80 nurses, and 30 community health workers.

As with most African countries, access to quality or adequate health care was reserved for Europeans during the time of colonization and occupation, with few indigenous people having access to medicine and quality health care. Folk remedies and herbal cures still compete with modern medicine, particularly in remote regions of Zambia, to treat all manner of illness. This includes cancer.

Zambia has some of the highest rates of cancer in Africa, and cancer incidence is on the rise. Estimates suggest there are more than 7,000 new cases a year, the most common being cervical cancer. Zambia has one of the highest cervical cancer rates in the world, with 90 out of every 100,000 women contracting cervical cancer. The World Health Organization ranks Zambia as having the third highest mortality rate from cervical cancer, a preventable disease.

Cervical cancer in Zambia is closely linked to the human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS) and the human-papilloma virus (HPV). It has been reported that women infected with HIV are thought to be three to five times more likely to develop cervical lesions that can become cancerous. The increased attention of the incidence of cervical cancer among Zambian women has brought awareness to the causal link between cervical cancer, HPV, and male circumcision. Some are skeptical that this can be a contributing factor to cervical cancer’s being more common in Zambian women than in women from other countries, while others consider this a significant factor, as the vast majority of Zambian men are not circumcised. The Center for Infectious Disease Research is home to one of the largest cervical cancer screening initiatives in the world as well as to Zambia’s HPV vaccination campaign, which began in 2013 to reduce incidence of cervical cancer, including public education and outreach.

A growing cancer burden in Zambia is the increasing rate of childhood cancers. Lymphomas have been the most reported, followed by retinoblastoma, kaposi, and sarcomas. Many cancers
are presented and diagnosed at an advanced stage while others are left undetected, adding to the poor survival rates and high mortality. With early detection, children diagnosed with cancer have a 70 to 85 percent chance of being cured.

The Kayula Childhood Cancer Foundation was established in March 2012. It is a Non-Governmental Organization established in memory of Kayula Zina Sata who passed away in 2009 at the age of 4 from neuroblastoma, a rare form of cancer. The foundation was created to support the University Teaching Hospital’s Pediatric Cancer Ward. The University Teaching Hospital in Lusaka is the only hospital in the country that has a pediatric oncology department. Patients come from all ten provinces of Zambia to seek treatment, sometimes spending more than a year. One of the main contributions of the foundation is the Parent House, where parents stay while their children undergo treatment. Children who are well enough are able to stay at the Parent House in between their chemotherapy and other treatments. This is beneficial to the family and helps the parents feel at home and also give the children a “home away from home” feeling, as a majority of the patients come from far beyond Lusaka. The Cancer Diseases Hospital (CDH) also treats some children’s cancer cases but only on an outpatient basis.

Organizations and Institutions
The National Council for Scientific Research in Lusaka and the School of Medicine at the University of Zambia coordinate cancer research in Zambia. The Zambia Cancer Foundation, operating from the University Teaching Hospital in Lusaka, is involved in raising money for cancer treatment and caring for patients and their families. The University Teaching Hospital is the biggest hospital in Zambia.

In July 2007, the CDH opened in Zambia. The CDH marked a milestone in cancer treatment, as it was the first of its kind in Zambia and was designed to house facilities to treat patients who previously had to travel great distances to South Africa for cancer treatment. The hospital houses five scanners, the largest of which is a linear accelerator. The rooms where the majority of scanners are kept were constructed with reinforced concrete walls up to 700 mm thick. The walls of the room that house the linear accelerator range from 1,200 mm to 2,500 mm. Thicker walls contain radiation more effectively. However, thicker walls produce more heat, increasing the tendency for walls to crack and allow radiation to escape. The health risks for the hospital staff and the general public are great. As such, the International Atomic Energy Agency frequently visited the site to monitor the design and construction of the rooms.

The International Atomic Energy Agency supports cancer care and treatment through a variety of initiatives and partnerships. The Technical Cooperation Program is the key mechanism for planning and delivery of radiotherapy assistance to Africa and other regions. The Program of Action for Cancer Therapy (PACT) is a broad-based global partnership that aims to help developing countries build a comprehensive, sustainable cancer control program.

Other organizations provide support to cancer patients and their families. The Zambian Cancer Society (ZCS), founded in 2007, seeks to provide access to and disseminate information on cancer, offer psychosocial support to cancer patients and their families, and increase awareness of the programs, products, and services provided by the ZCS and other resources. The Zambian Childhood Cancer Foundation was established to provide holistic care for children with cancer and life-threatening blood disorders (such as hemophilia and sickle cell disease) and also provide assistance to their families through practical and psychosocial support programs.

Many countries in the developing world are facing a cancer crisis; with few resources to fight the increasing cancer burden, many individuals and organizations work together to fill a variety of needs.

Zimbabwe

The Republic of Zimbabwe is a southern African country located between the Zambezi and Limpopo rivers. It is bordered by South Africa to the south, Botswana to the southwest, Zambia to the northwest, and Mozambique to the east. Zimbabwe has 16 official languages, with English, Shona, and Ndebele being the most common. The history of Zimbabwe is one of European colonization and contemporary political turmoil. The United Kingdom annexed Southern Rhodesia from the British South Africa Company in 1923. A 1961 constitution was formulated that favored whites in power. In 1965, the government unilaterally declared its independence, but the United Kingdom did not recognize the act and demanded more complete voting rights for the black African majority in the country then called Rhodesia. UN sanctions and a guerrilla uprising finally led to free elections in 1979 and independence as Zimbabwe in 1980.

Robert Mugabe, the nation’s first prime minister, has been in power since 1987 as president and has dominated the country’s political system since independence with devastating effects. His chaotic land redistribution campaign, which began in 1997 and intensified after 2000, caused an exodus of white farmers, crippled the economy and ushered in widespread shortages of basic commodities. Ignoring international condemnation, President Mugabe rigged the 2002 presidential election to ensure his win. In April 2005, the capital city of Harare embarked on Operation Restore Order, which destroyed the homes or businesses of 700,000 mostly poor supporters of the opposition. President Mugabe in June 2007 instituted price controls on all basic commodities, which caused panic buying and left store shelves empty for months; a period of increasing hyperinflation ensued. General elections held in March 2008 contained irregularities but still amounted to a censure of the Zimbabwe African National Union Patriotic Front-led government, with the opposition winning a majority of seats in parliament. Opposition leader Morgan Tsvangirai won the most votes in the presidential polls. In the lead up to a runoff election in late June 2008, considerable violence took place against opposition party members, which led to the withdrawal of Tsvangirai from the ballot. There was evidence of violence and intimidation, resulting in international condemnation of the election process. Difficult negotiations ensued over sharing power, control, and creating a truly unified government in which Mugabe remained president and Tsvangirai became prime minister. A settlement was reached in February 2009, although both men failed to agree upon several key governmental issues. Mugabe was reelected president in June 2013 in balloting that was severely flawed and once again internationally condemned.

Politics influence the human services provided in a country with a growing cancer burden, as government support is needed to provide the necessary resources. The population of Zimbabwe is estimated at approximately 14 million, with a life expectancy of 56 years. For every 100,000 people, there are 10 doctors and 130 nurses and midwives. These numbers decrease when medical specialization is factored in.

The Zimbabwe National Cancer Registry (ZNCR) was established in 1985 as a result of a collaborative agreement between the Zimbabwean Ministry of Health and the International Agency for Research on Cancer (IARC). Operations began in Harare in 1986, with complete coverage of the population of the city by 1990. Recognized as one of the few well-established registries in Africa, the ZNCR provides technical support to other registries in the region at the request of the IARC, the World Health Organization’s African Regional Office (WHO/AFRO), and the International Network for Cancer Treatment and Research (INCTR).

The registry is strategically located in the Parirenyatwa Group of Hospitals complex, a large government referral center that provides most of the specialized cancer management services for the country and is also one of the two teaching hospitals used by the University of Zimbabwe College of Health Sciences. The Ministry of Health and Child Welfare, the IARC, the INCTR, and other organizations support the registry.

Eric Chokunonga, the registrar of the ZNCR, along with other researchers completed a study that
examined the incidence rates of different cancers in the black population of Harare over a 20-year period (1991 to 2010), along with social and lifestyle changes and the peak and subsequent wane of the HIV/AIDS epidemic. The results indicate that the overall risk of cancer increased in both sexes during the period, with rates of cervical and prostate cancers showing dramatic increases of 3.3 percent and 6.4 percent annually, respectively. By 2004, prostate cancer had become the most common cancer of men. The incidence of cancer of the esophagus, formerly the most common cancer of men, remained relatively constant, whereas rates of breast and cervical cancers, the most common malignancies of women, showed significant increases at 4.9 percent and 3.3 percent annually, respectively.

The incidence of Kaposi's sarcoma increased to a maximum around 1998 to 2000 and then declined in all age groups and in both sexes. The incidence of squamous cell cancers of the conjunctiva (eye) is relatively high, with temporal trends similar to those of Kaposi's sarcoma. Non-Hodgkin's lymphoma, the fifth most common cancer of men and fourth of women, showed a steady increase in incidence throughout the period (6.7 percent to 6.9 percent annually), although rates in young adults (aged 15 to 39) have decreased since 2001. Cancer control in Zimbabwe, as elsewhere in sub-Saharan Africa, involves meeting the challenge of emerging cancers associated with Westernization of lifestyles (large bowel, breast, and prostate), while the incidence of cancers associated with poverty and infection (liver, cervix, and esophagus) shows little decline, and the residual burden of the AIDS-associated cancers remains significant.

The National Cancer Prevention and Control Strategy for Zimbabwe 2013–2017 recognizes that cancer is a major cause of morbidity and mortality in Zimbabwe, with over 5,000 new diagnoses being made and over 1,000 deaths per year. The number of people developing cancer is expected to increase due to an increasingly aging population, HIV and AIDS, a Westernized diet, and other unhealthy lifestyle choices in the population. The Ministry of Health and Child Welfare and its partners in cancer control are prioritizing cancer policy and implementation of relevant advances, with the vision that Zimbabwe will have a system for cancer control that will reduce cancer incidence, morbidity, and mortality rates. The goal is for the people of Zimbabwe to practice health-promoting and cancer-prevention behaviors and have access to early cancer detection. This strategy ultimately seeks to enhance the range, capacity, and quality of cancer services comprising prevention, early detection, diagnosis, treatment, palliative care, rehabilitation, surveillance, and research.

Further Readings
Abdomen: The part of the body that contains the pancreas, stomach, intestines, liver, gallbladder, and other organs.

Accelerated phase: Refers to chronic myelogenous leukemia that is progressing. The number of immature, abnormal white blood cells in the bone marrow and blood is higher than in the chronic phase, but not as high as in the blast phase.

Achlorhydria: A lack of hydrochloric acid in the digestive juices in the stomach. Hydrochloric acid helps digest food.

Actinic keratosis: A precancerous condition of thick, scaly patches of skin; also called solar or senile keratosis.

Acute leukemia: Leukemia that progresses rapidly.

Adenocarcinoma: Cancer that begins in cells that line certain internal organs.

Adenoma: A noncancerous tumor.

Adjuvant therapy: Treatment given in addition to the primary treatment to enhance the effectiveness of the primary treatment.

Adrenal glands: A pair of small glands, one located on top of each kidney. The adrenal glands produce hormones that help control heart rate, blood pressure, the way the body uses food, and other vital functions.

Aflatoxin: A substance made by a mold that is often found on poorly stored grains and nuts. Aflatoxins are known to cause cancer in animals.

Agranulocyte: A type of white blood cell; monocytes and lymphocytes are agranulocytes.

Allogeneic bone marrow transplantation: A procedure in which a patient receives bone marrow from a compatible, though not genetically identical, donor.

Alpha-fetoprotein: A protein often found in abnormal amounts in the blood of patients with liver cancer.

Alveoli: Tiny air sacs at the end of the bronchioles.

Anal cancer: Anal cancer, an uncommon cancer, is a disease in which cancer (malignant) cells are found in the anus. The anus is the opening at the end of the rectum (the end part of the large intestine) through which body waste passes.
Anaplastic: A term used to describe cancer cells that divide rapidly and bear little or no resemblance to normal cells.

Anastomosis: A procedure to connect healthy sections of the colon or rectum after the diseased portion has been surgically removed.

Androgen: A hormone that promotes the development and maintenance of male sex characteristics.

Anemia: A decrease in the normal amounts of red blood cells.

Anesthesia: Loss of feeling or awareness. A local anesthetic causes loss of feeling in a part of the body. A general anesthetic puts the person to sleep.

Anesthetic: A substance that causes loss of feeling or awareness. A local anesthetic causes loss of feeling in a part of the body. A general anesthetic puts the person to sleep.

Angiogenesis: Blood vessel formation, which usually accompanies the growth of malignant tissue.

Angiogram: An X-ray of blood vessels; the patient receives an injection of dye to outline the vessels on the X-ray.

Angiography: A procedure to X-ray blood vessels. The blood vessels can be seen because of an injection of a dye that shows up in the X-ray pictures.

Angiosarcoma: A type of cancer that begins in the lining of blood vessels.

Antiandrogen: A drug that blocks the action of male sex hormones.

Antibiotics: Drugs used to treat infection.

Antibody: A protein produced by certain white blood cells in response to a foreign substance (antigen). Each antibody can bind only to a specific antigen. The purpose of this binding is to help destroy the antigen. Antibodies can work in several ways, depending on the nature of the antigen. Some antibodies disable antigens directly. Others make the antigen more vulnerable to destruction by white blood cells.

Anticonvulsant: Medicine to stop, prevent, or control seizures (convulsions).

Antigen: Any foreign or “non-self” substance that, when introduced into the body, causes the immune system to create an antibody.

Antithymocyte globulin: A protein preparation used to prevent and treat graft-versus-host disease.

Aplastic anemia: A deficiency of certain parts of the blood caused by a failure of the bone marrow’s ability to generate cells.

Apoptosis: A normal cellular process involving a genetically programmed series of events leading to the death of a cell.

Arterial embolization: Blocking an artery so that blood cannot flow to the tumor.

Arteriogram: An X-ray of blood vessels, which can be seen after an injection of a dye that shows up in the X-ray pictures.

Asbestos: A natural material that is made up of tiny fibers. If the fibers are inhaled, they can lodge in the lungs and lead to cancer.

Ascites: Abnormal buildup of fluid in the abdomen.

Aspiration: Removal of fluid from a lump, often a cyst, with a needle and a syringe.

Astrocytoma: A type of brain tumor that begins in the brain or spinal chord in small, star-shaped cells called astrocytes.

Ataxic gait: Awkward, uncoordinated walking.

Atypical hyperplasia: A benign (noncancerous) condition in which tissue has certain abnormal features.

Autologous bone marrow transplantation: A procedure in which bone marrow is removed from a patient and then is given back to the patient following intensive treatment.
Axilla: The underarm.

Axillary: Pertaining to the lymph nodes under the arm.

Axillary dissection: Surgery to remove lymph nodes under the arm.

B cells: White blood cells that develop in the bone marrow and are the source of antibodies. Also known as B lymphocytes.

Barium enema: A series of X-rays of the lower intestine. The X-rays are taken after the patient is given an enema with a white, chalky solution that contains barium. The barium outlines the intestines on the X-rays.

Barium solution: A liquid containing barium sulfate that is used in X-rays to highlight parts of the digestive system.

Barrett’s esophagus: A change in the cells of the tissue that lines the bottom of the esophagus. The esophagus may become irritated when the contents of the stomach back up (reflux). Reflux that happens often over a long period of time can lead to Barrett’s esophagus.

Basal cell carcinoma: A type of skin cancer that arises from the basal cells.

Basal cells: Small, round cells found in the lower part, or base, of the epidermis, the outer layer of the skin.

Basophil: A type of white blood cell. Basophils are granulocytes.

BCG (Bacillus Calmette-Guerin): A substance that activates the immune system. Filling the bladder with a solution of BCG is a form of biological therapy for superficial bladder cancer.

Benign: Not cancerous; does not invade nearby tissue or spread to other parts of the body.

Benign prostatic hyperplasia: A noncancerous condition in which an overgrowth of prostate tissue pushes against the urethra and the bladder, blocking the flow of urine. Also called benign prostatic hypertrophy or BPH.

Benign tumor: A noncancerous growth that does not spread to other parts of the body.

Beta-carotene: A substance from which vitamin A is formed; a precursor of vitamin A.

Bilateral: Affecting both the right and left side of body.

Bile: A yellow or orange fluid made by the liver. Bile is stored in the gallbladder. It passes through the common bile duct into the duodenum, where it helps digest fat.

Bioimmunotherapy: Treatment to stimulate or restore the ability of the immune system to fight infection and disease.

Biological response modifiers: Substances that stimulate the body’s response to infection and disease. The body naturally produces small amounts of these substances. Scientists can produce some of them in the laboratory in large amounts and use them in cancer treatment.

Biological therapy: The use of the body’s immune system, either directly or indirectly, to fight cancer or to lessen side effects that may be caused by some cancer treatments. Also known as immunotherapy, biotherapy, or biological response modifier therapy.

Biopsy: The removal of a sample of tissue, which is then examined under a microscope to check for cancer cells.

Bladder: The hollow organ that stores urine.

Bladder cancer: Bladder cancer is a disease in which cancer (malignant) cells are found in the bladder. The bladder, a hollow organ in the lower part of the abdomen, stores urine.

Blast phase: Refers to advanced chronic myelogenous leukemia. In this phase, the number of immature, abnormal white blood cells in the bone marrow and blood is extremely high. Also called blast crisis.
**Blasts:** Immature blood cells.

**Blood-brain barrier:** A network of blood vessels with closely spaced cells that makes it difficult for potentially toxic substances (such as anticancer drugs) to penetrate the blood vessel walls and to enter the brain.

**Bone marrow:** The soft, spongy tissue in the center of large bones that produces white blood cells, red blood cells, and platelets.

**Bone marrow aspiration or biopsy:** The removal of a small sample of bone marrow (usually from the hip) through a needle for examination under a microscope to see whether cancer cells are present.

**Bone marrow biopsy:** The removal of a sample of tissue from the bone marrow with a large needle. The cells are checked to see whether they are cancerous. If cancerous plasma cells are found, the pathologist estimates how much of the bone marrow is affected. Bone marrow biopsy is usually done at the same time as bone marrow aspiration.

**Bone marrow transplantation:** A procedure in which doctors replace marrow destroyed by treatment with high doses of anticancer drugs or radiation. The replacement marrow may be taken from the patient before treatment or may be donated by another person.

**Bone scan:** A technique to create images of bones on a computer screen or on film. A small amount of radioactive material is injected and travels through the bloodstream. It collects in the bones, especially in abnormal areas of the bones, and is detected by a scanner.

**Bowel:** Another name for the intestine. There is both a small and a large bowel.

**Brachytherapy:** Internal radiation therapy using an implant of radioactive material placed directly into or near the tumor.

**Brain stem:** The stemlike part of the brain that is connected to the spinal cord.

**Brain stem glioma:** A type of brain tumor that occurs in the lowest, stemlike part of the brain.

**Brain tumor—astrocytoma:** Astrocytomas are tumors that start in brain cells called astrocytes. There are different kinds of astrocytomas, which are defined by how the cancer cells look under a microscope.

**Brain tumor—ependymoma:** Ependymal tumors are tumors that begin in the ependyma, the cells that line the passageways in the brain where special fluid that protects the brain and spinal cord (called cerebrospinal fluid) is made and stored. There are different kinds of ependymal tumors, which are defined by how the cells look under a microscope.

**Brain tumor—glioblastoma:** Glioblastoma multiformes are tumors that grow very quickly and have cells that look very different from normal cells. Glioblastoma multiforme is also called grade IV astrocytoma.

**Brain tumor—medulloblastoma:** Medulloblastomas are brain tumors that begin in the lower part of the brain. They are almost always found in children or young adults. This type of cancer may spread from the brain to the spine.

**BRCA1:** A gene located on chromosome 17 that normally helps to restrain cell growth. Inheriting an altered version of BRCA1 predisposes an individual to breast, ovary, and prostate cancer.

**Breast reconstruction:** Surgery to rebuild a breast’s shape after a mastectomy.

**Bronchi:** Air passage that leads from the windpipe to the lungs.

**Bronchioles:** The tiny branches of air tubes in the lungs.

**Bronchitis:** Inflammation (swelling and reddening) of the bronchi.

**Bronchoscope:** A flexible, lighted instrument used to examine the trachea and bronchi, the air passages that lead into the lungs.
**Bronchoscopy:** A test that permits the doctor to see the breathing passages through a lighted tube.

**Buccal mucosa:** The inner lining of the cheeks and lips.

**Burkitt’s lymphoma:** A type of non-Hodgkin’s lymphoma that most often occurs in young people between the ages of 12 and 30. The disease usually causes a rapidly growing tumor in the abdomen.

**Bypass:** A surgical procedure in which the doctor creates a new pathway for the flow of body fluids.

**Cancer:** A term for diseases in which abnormal cells divide without control. Cancer cells can invade nearby tissues and can spread through the bloodstream and lymphatic system to other parts of the body.

**Cancer screening:** Different tests may show whether a person has a higher than normal risk for getting certain types of cancer. The person’s family history and medical history are also key parts of the cancer screening process.

**Carcinogen:** Any substance that is known to cause cancer.

**Carcinogenesis:** The process by which normal cells are transformed into cancer cells.

**Carcinoma:** Cancer that begins in the lining or covering of an organ.

**Carcinoma in situ:** Cancer that involves only the cells in which it began and has not spread to other tissues.

**Cartilage:** Firm, rubbery tissue that cushions bones at joints. A more flexible kind of cartilage connects muscles with bones and makes up other parts of the body, such as the larynx and the outside of the ears.

**Cauterization:** The use of heat to destroy abnormal cells.

**CEA assay:** A laboratory test to measure the level of carcinoembryonic antigen (CEA), a substance that is sometimes found in an increased amount in the blood of patients with certain cancers.

**Cell:** The basic unit of any living organism.

**Cell differentiation:** The process during which young, immature (unspecialized) cells take on individual characteristics and reach their mature (specialized) form and function.

**Cell motility:** The ability of a cell to move.

**Cell proliferation:** An increase in the number of cells as a result of cell growth and cell division.

**Cellular adhesion:** The close adherence (bonding) to adjoining cell surfaces.

**Central nervous system:** The brain and spinal cord.

**Cerebellum:** The portion of the brain in the back of the head between the cerebrum and the brain stem.

**Cerebral hemispheres:** The two halves of the cerebrum.

**Cerebrospinal fluid:** Watery fluid flowing around the brain and spinal cord.

**Cerebrum:** The largest part of the brain. It is divided into two hemispheres, or halves.

**Cervical cancer:** Cancer of the cervix, a common kind of cancer in women, is a disease in which cancer (malignant) cells are found in the tissues of the cervix. The cervix is the opening of the uterus (womb).

**Cervical intraepithelial neoplasia:** A general term for the growth of abnormal cells on the surface of the cervix. Numbers from 1 to 3 may be used to describe how extensive the abnormal cells are and how deeply they penetrate through the epithelium. Also called CIN.

**Cervix:** The lower, narrow end of the uterus that forms a canal between the uterus and vagina.

**Chemoprevention:** The use of natural or laboratory made substances to prevent cancer.
Chemotherapy: Treatment with anticancer drugs.

Cholangiosarcoma: A type of cancer that begins in the bile ducts.

Chondrosarcoma: A cancer that forms in cartilage, occurring mainly in the pelvis, femur, and shoulder areas.

Chordoma: A form of bone cancer that usually starts in the lower spinal column.

Chromosome: Part of a cell that contains genetic information. Normally, human cells contain 46 chromosomes that appear as a long thread inside the cell.

Chronic leukemia: Leukemia that progresses slowly.

Chronic phase: Refers to the early stages of chronic myelogenous leukemia or chronic lymphocytic leukemia. The number of immature, abnormal white blood cells in the bone marrow and blood is higher than normal, but lower than in the accelerated or blast phase.

Clinical trials: Research studies that involve patients. Each study is designed to find better ways to prevent, detect, diagnose, or treat cancer and to answer scientific questions.

CNS (central nervous system): The brain and the spinal cord.

CNS prophylaxis: Chemotherapy or radiation therapy to the central nervous system (CNS). This is preventive treatment. It is given to kill cancer cells that may be in the brain and spinal cord, even though no cancer has been detected there.

Colectomy: An operation to remove all or part of the colon. In a partial colectomy, the surgeon removes only the cancerous part of the colon and a small amount (called a margin) of surrounding healthy tissue.

Colon: The long, coiled, tubelike organ that removes water from digested food. The remaining material, solid waste called stool, moves through the colon to the rectum and leaves the body through the anus.

Colon cancer: Cancer of the colon, a common form of cancer, is a disease in which cancer (malignant) cells are found in the tissues of the colon. The colon is part of the body's digestive system. The last six feet of intestine is called the large bowel or colon.

Colonoscope: A flexible, lighted instrument used to view the inside of the colon.

Colonoscopy: An examination in which the doctor looks at the colon through a flexible, lighted instrument called a colonoscope.

Colony-stimulating factors: Substances that stimulate the production of blood cells. Treatment with colony-stimulating factors (CSF) can help the blood-forming tissue recover from the effects of chemotherapy and radiation therapy.

Cryosurgery: Treatment performed with an instrument that freezes and destroys abnormal tissues.

Cryptorchidism: A condition in which one or both testicles fail to move from the abdomen, where they develop before birth, into the scrotum; also called undescended testicles.

CT (or CAT) scan: A series of detailed pictures of areas inside the body; the pictures are created by a computer linked to an X-ray machine. Also called computed tomography scan or computed axial tomography scan.

Curettage: Removal of tissue with a curette.

Curette: A spoon-shaped instrument with a sharp edge.

Cutaneous: Related to the skin.

Cutaneous T-cell lymphoma: Cutaneous T-cell lymphoma is a disease in which certain cells of the lymph system (called T lymphocytes) become cancer (malignant) and affect the skin. Lymphocytes are infection-fighting white blood cells that are made in the bone marrow and by other organs of the lymph system. T-cells are special lymphocytes that help the body's immune system kill bacteria and other harmful things in the body.
Cyst: A sac or capsule filled with fluid.

Cystectomy: Surgery to remove the bladder.

Cystoscope: An instrument that allows the doctor to see inside the bladder and remove tissue samples or small tumors.

Cystoscopy: A procedure in which the doctor inserts a lighted instrument into the urethra (the tube leading from the bladder to the outside of the body) to look at the bladder.

Dermis: The lower or inner layer of the two main layers of cells that make up the skin.

Diabetes: A disease in which the body does not use sugar properly. (Many foods are converted into sugar, a source of energy for cells.) As a result, the level of sugar in the blood is too high. This disease occurs when the body does not produce enough insulin or does not use it properly.

Dialysis: The process of cleansing the blood by passing it through a special machine. Dialysis is necessary when the kidneys are not able to filter the blood.

Diaphanography: An exam that involves shining a bright light through the breast to reveal features of the tissues inside. This technique is under study; its value in detecting breast cancer has not been proven. Also called transillumination.

Diaphragm: The thin muscle below the lungs and heart that separates the chest from the abdomen.

Diathermy: The use of heat to destroy abnormal cells. Also called cauterization or electrodiathermy.

Diethylstilbestrol: A drug that was once widely prescribed to prevent miscarriage. Also called DES.

Differentiation: In cancer, refers to how mature (developed) the cancer cells are in a tumor. Differentiated tumor cells resemble normal cells and grow at a slower rate than undifferentiated tumor cells, which lack the structure and function of normal cells and grow uncontrollably.

Digestive system: The organs that take in food and turn it into products that the body can use to stay healthy. Waste products the body cannot use leave the body through bowel movements. The digestive system includes the salivary glands, mouth, esophagus, stomach, liver, pancreas, gall-bladder, intestines, and rectum.

Dilation and curettage: A minor operation in which the cervix is expanded enough (dilation) to permit the cervical canal and uterine lining to be scraped with a spoon-shaped instrument called a curette (curettage). This procedure also is called D and C.

Dilator: A device used to stretch or enlarge an opening.

DNA: The protein that carries genetic information; every cell contains a strand of DNA (deoxyribonucleic acid).

Ductal carcinoma in situ: Abnormal cells that involve only the lining of a duct. The cells have not spread outside the duct to other tissues in the breast. About 15 to 20 percent of breast cancers are sometimes called carcinoma in situ. They may be either ductal carcinoma in situ (sometimes called intraductal carcinoma) or lobular carcinoma in situ. Even though it is referred to as a cancer, it is not actually cancer. However, patients with this condition have a 25 percent chance of developing breast cancer in either breast in the next 25 years. Also called DCIS or intraductal carcinoma.

Dumping syndrome: A group of symptoms that occur when food or liquid enters the small intestine too rapidly. These symptoms include cramps, nausea, diarrhea, and dizziness.

Duodenum: The first part of the small intestine.

Dysplasia: Abnormal cells that are not cancer.

Dysplastic nevi: Atypical moles; moles whose appearance is different from that of common moles. Dysplastic nevi are generally larger than ordinary moles and have irregular and indistinct borders. Their color often is not uniform, and ranges from pink or even white to dark brown...
or black; they usually are flat, but parts may be raised above the skin surface.

**Edema:** Swelling; an abnormal buildup of fluid.

**Electrodesiccation:** Use of an electric current to destroy cancerous tissue and control bleeding.

**Electrolarynx:** A battery-operated instrument that makes a humming sound to help laryngectomees talk.

**Embolization:** Blocking an artery so that blood cannot flow to the tumor.

**Encapsulated:** Confined to a specific area; the tumor remains in a compact form.

**Endocervical curettage:** The removal of tissue from the inside of the cervix using a spoon-shaped instrument called a curette.

**Endometrial cancer:** Cancer of the endometrium, a common kind of cancer in women, is a disease in which cancer (malignant) cells are found in the lining of the uterus (endometrium). The uterus is the hollow, pear-shaped organ where a baby grows. Cancer of the endometrium is different from cancer of the muscle of the uterus, which is called sarcoma of the uterus.

**Endometriosis:** A benign condition in which tissue that looks like endometrial tissue grows in the abdomen.

**Endometrium:** The layer of tissue that lines the uterus.

**Endoscope:** A thin, lighted tube through which a doctor can look at tissues inside the body.

**Endoscopic retrograde cholangiopancreatography:** A procedure to X-ray the common bile duct. Also called ERCP.

**Endoscopy:** An examination of the esophagus and stomach using a thin, lighted instrument called an endoscope.

**Ependymoma:** A type of brain tumor that usually develops in the lining of the ventricles but may also occur in the spinal chord.

**Enterostomal therapist:** A health professional trained in the care of urostomies and other stomas.

**Environmental tobacco smoke:** Smoke that comes from the burning end of a cigarette and smoke that is exhaled by smokers. Also called ETS or second-hand smoke. Inhaling ETS is called involuntary or passive smoking.

**Enzyme:** A substance that affects the rate at which chemical changes take place in the body.

**Ependymoma:** Ependymal tumors are tumors that begin in the ependyma, the cells that line the passageways in the brain where special fluid that protects the brain and spinal cord (called cerebrospinal fluid) is made and stored. There are different kinds of ependymal tumors, which are defined by how the cells look under a microscope.

**Epidermis:** The upper or outer layer of the two main layers of cells that make up the skin.

**Epidermoid carcinoma:** A type of lung cancer in which the cells are flat and look like fish scales. Also called squamous cell carcinoma.

**Epiglottis:** The flap that covers the trachea during swallowing so that food does not enter the lungs.

**Epithelial carcinoma:** Cancer that begins in the cells that line an organ.

**Epithelium:** A thin layer of tissue that covers organs, glands, and other structures in the body.

**ERCP (endoscopic retrograde cholangiopancreatography):** A procedure to X-ray the common bile duct.

**Erythrocytes:** Cells that carry oxygen to all parts of the body. Also called red blood cells (RBCs).

**Erythroleukemia:** Leukemia that develops in erythrocytes. In this rare disease, the body produces large numbers of abnormal red blood cells.

**Erythroplakia:** A reddened patch with a velvety surface found in the mouth.
Glossary

**Esophageal cancer:** Cancer of the esophagus is a disease in which cancer (malignant) cells are found in the tissues of the esophagus. The esophagus is the hollow tube that carries food and liquid from the throat to the stomach.

**Esophageal speech:** Speech produced with air trapped in the esophagus and forced out again.

**Esophagectomy:** An operation to remove a portion of the esophagus.

**Esophagoscopy:** Examination of the esophagus using a thin, lighted instrument.

**Esophagram:** A series of X-rays of the esophagus. The X-ray pictures are taken after the patient drinks a solution that coats and outlines the walls of the esophagus. Also called a barium swallow.

**Esophagus:** The muscular tube through which food passes from the throat to the stomach.

**Estrogen:** A female hormone.

**Ewing's sarcoma:** Ewing's sarcoma/primitive neuroepithelial tumor is a rare disease in which cancer (malignant) cells are found in the bone. The most common areas in which it occurs are the pelvis, the thigh bone (femur), the upper arm bone (humerus), and the ribs. Ewing's sarcoma/primitive neuroepithelial tumor most frequently occurs in teenagers.

**External radiation:** Radiation therapy that uses a machine to aim high-energy rays at the cancer from outside of the body.

**Fallopian tubes:** Tubes on each side of the uterus through which an egg moves from the ovaries to the uterus.

**Familial polyposis:** An inherited condition in which several hundred polyps develop in the colon and rectum.

**Fecal occult blood test:** A test to check for hidden blood in stool. (Fecal refers to stool. Occult means hidden.)

**Fibroid:** A benign uterine tumor made up of fibrous and muscular tissue.

**Fibrosarcoma:** A type of soft tissue sarcoma that begins in fibrous tissue, which holds bones, muscles, and other organs in place.

**Fluoroscope:** An X-ray machine used to view internal organs in motion.

**Fluoroscopy:** An X-ray procedure that makes it possible to see internal organs in motion.

**Fluorouracil:** An anticancer drug. Its chemical name is 5-fluorouracil, commonly called 5-FU.

**Fractionation:** Dividing the total dose of radiation therapy into several smaller, equal doses delivered over a period of several days.

**Fulguration:** Destroying tissue using an electric current.

**Gallbladder:** The pear-shaped organ where bile from the liver is stored. The gallbladder is located beneath the liver.

**Gamma knife:** Radiation therapy in which high-energy rays are aimed at a tumor from many angles in a single treatment session.

**Gastrectomy:** An operation to remove all or part of the stomach.

**Gastric:** Having to do with the stomach.

**Gastric atrophy:** A condition in which the stomach muscles shrink and become weak. It results in a lack of digestive juices.

**Gastric cancer:** Cancer of the stomach, also called gastric cancer, is a disease in which cancer (malignant) cells are found in the tissues of the stomach.

**Gastrointestinal tract:** The part of the digestive tract where the body processes food and eliminates waste. It includes the esophagus, stomach, liver, small and large intestines, and rectum.
Gastroscope: A thin, lighted instrument to view the inside of the stomach.

Gastroscopy: An examination of the stomach with a gastroscope, an instrument to view the inside of the stomach.

Gene: The biological or basic unit of heredity found in all cells in the body.

Gene deletion: The total loss or absence of a gene.

Gene therapy: Treatment that alters genes (the basic units of heredity found in all cells in the body). In studies of gene therapy for cancer, researchers are trying to improve the body’s natural ability to fight the disease or to make the tumor more sensitive to other kinds of therapy.

Genetic: Inherited; having to do with information that is passed from parents to children through DNA in the genes.

Genetic testing: Specific tests can be done to see whether a person has changes in certain genes that are known to be associated with cancer.

Genitourinary system: The parts of the body that play a role in reproduction, in getting rid of waste products in the form of urine, or in both.

Germ cells: The reproductive cells of the body, specifically, either egg or sperm cells.

Germ cell tumors: A type of brain tumor that arises from primitive (developing) sex cells, or germ cells.

Germinoma: The most frequent type of germ cell tumor in the brain.

Germline mutation: See hereditary mutation.

Gestational trophoblastic disease: Gestational trophoblastic tumor, a rare cancer in women, is a disease in which cancer (malignant) cells grow in the tissues that are formed following conception (the joining of sperm and egg). Gestational trophoblastic tumors start inside the uterus, the hollow, muscular, pear-shaped organ where a baby grows. This type of cancer occurs in women during the years when they are able to have children.

Gland: An organ that produces and releases one or more substances for use in the body. Some glands produce fluids that affect tissues or organs. Others produce hormones or participate in blood production.

Glioblastoma multiforme: A type of brain tumor that forms in the nervous (glial) tissue of the brain. They grow very quickly and have cells that look very different from normal cells. Glioblastoma multiforme is also called grade IV astrocytoma.

Glioma: A name for brain tumors that begin in the glial cells, or supportive cells, in the brain. “Glia” is the Greek word for glue.

Glottis: The middle part of the larynx; the area where the vocal cords are located.

Grade: Describes how closely a cancer resembles normal tissue of its same type, and the cancer’s probable rate of growth.

Grading: A system for classifying cancer cells in terms of how malignant or aggressive they appear microscopically. The grading of a tumor indicates how quickly cancer cells are likely to spread and plays a role in treatment decisions.

Graft: Healthy skin, bone, or other tissue taken from one part of the body to replace diseased or injured tissue removed from another part of the body.

Graft-versus-host disease: A reaction of donated bone marrow against a patient’s own tissue. Also called GVHD.

Granulocyte: A type of white blood cell. Neutrophils, eosinophils, and basophils are granulocytes.

Hairy cell leukemia: A rare type of chronic leukemia in which the abnormal white blood cells appear to be covered with tiny hairs.

Helicobacter pylori: Bacteria that cause inflammation and ulcers in the stomach.
Hematogenous: Originating in the blood, or disseminated by the circulation or through the bloodstream.

Hepatitis: Inflammation of the liver.

Hepatitis B: A type of hepatitis that is carried and passed on through the blood. It can be passed on through sexual contact or through the use of “dirty” (bloody) needles.

Hepatoblastoma: A type of liver tumor that occurs in infants and children.

Hepatocellular carcinoma: The most common type of primary liver cancer.

Hepatocyte: A liver cell.

Hepatoma: A liver tumor.

Hereditary mutation: A gene change in the body’s reproductive cells (egg or sperm) that becomes incorporated into the DNA of every cell in the body of offspring; hereditary mutations are passed on from parents to offspring.

Herpes virus: A member of the herpes family of viruses. One type of herpes virus is sexually transmitted and causes genital sores.

HER-2/neu: Oncogene found in some breast and ovarian cancer patients that is associated with a poor prognosis.

Hodgkin’s disease: Hodgkin’s disease is a type of lymphoma. Lymphomas are cancers that develop in the lymph system, part of the body’s immune system.

Hormonal therapy: Treatment of cancer by removing, blocking, or adding hormones.

Hormone receptor test: A test to measure the amount of certain proteins, called hormone receptors, in breast cancer tissue. Hormones can attach to these proteins. A high level of hormone receptors means hormones probably help the cancer grow.

Hormone therapy: Treatment that prevents certain cancer cells from getting the hormones they need to grow.

Hormones: Chemicals produced by glands in the body and circulated in the bloodstream. Hormones control the actions of certain cells or organs.

Human papillomaviruses: Viruses that generally cause warts. Some papillomaviruses are sexually transmitted. Some of these sexually transmitted viruses cause wart-like growths on the genitals, and some are thought to cause abnormal changes in cells of the cervix.

Hydrocephalus: The abnormal buildup of cerebrospinal fluid in the ventricles of the brain.

Hypercalcemia: A higher-than-normal level of calcium in the blood. This condition can cause a number of symptoms, including loss of appetite, nausea, thirst, fatigue, muscle weakness, restlessness, and confusion.

Hyperfractionation: Giving radiation therapy in smaller-than-usual doses two or three times a day.

Hyperplasia: A precancerous condition in which there is an increase in the number of normal cells lining the uterus.

Hypertermia: Treatment that involves heating a tumor.

Hypothalamus: The area of the brain that controls body temperature, hunger, and thirst.

Hysterectomy: An operation in which the uterus and cervix are removed.

Ileostomy: An opening created by a surgeon into the ileum, part of the small intestine, from the outside of the body. An ileostomy provides a new path for waste material to leave the body after part of the intestine has been removed.

Imaging: Tests that produce pictures of areas inside the body.

Immune system: The complex group of organs and cells that defends the body against infection or disease.

Immunodeficiency: A lowering of the body’s ability to fight off infection and disease.
**Immunology:** A science that deals with the study of the body’s immune system.

**Immunosuppression:** The use of drugs or techniques to suppress or interfere with the body’s immune system and its ability to fight infections or disease. Immunosuppression may be deliberate, such as in preparation for bone marrow or other organ transplantation to prevent rejection by the host of the donor tissue, or incidental, such as often results from chemotherapy for the treatment of cancer.

**Immunotherapy:** Treatment that uses the body’s natural defenses to fight cancer. Also called biological therapy.

**Implant radiation:** Radiation therapy that places radioactive materials in or close to the cancer.

**Infiltrating cancer:** See invasive cancer.

**Inflammatory breast cancer:** A rare type of breast cancer in which cancer cells block the lymph vessels in the skin of the breast. The breast becomes red, swollen, and warm, and the skin of the breast may appear pitted or have ridges.

**Inguinal orchiectomy:** Surgery to remove the testicle through the groin.

**Insulin:** A hormone made by the islet cells of the pancreas. Insulin controls the amount of sugar in the blood.

**Interferon:** A type of biological response modifier (a substance that can improve the body’s natural response to disease). It stimulates the growth of certain disease-fighting blood cells in the immune system.

**Interleukin:** A substance used in biological therapy. Interleukins stimulate the growth and activities of certain kinds of white blood cells.

**Interleukin 2:** A type of biological response modifier (a substance that can improve the body’s natural response to disease). It stimulates the growth of certain blood cells in the immune system that can fight cancer. Also called IL-2.

**Internal radiation:** Radiation therapy that uses radioactive materials placed in or near the tumor.

**Intestine:** The long, tube-shaped organ in the abdomen that completes the process of digestion. It consists of the small and large intestines.

**Intraepithelial:** Within the layer of cells that forms the surface or lining of an organ.

**Intrahepatic:** Within the liver.

**Intrahepatic bile duct:** The bile duct that drains bile from the liver.

**Intraoperative radiation therapy:** Radiation treatment given during surgery. Also called IORT.

**Intraperitoneal chemotherapy:** Treatment in which anticancer drugs are put directly into the abdomen through a thin tube.

**Intrathecal chemotherapy:** Chemotherapy drugs infused into the thin space between the lining of the spinal cord and brain to treat or prevent cancers in the brain and spinal cord.

**Intravenous:** Injected in a vein. Also called IV.

**Intravenous pyelogram:** A series of X-rays of the kidneys and bladder. The X-rays are taken after a dye that shows up on X-ray film in injected into a vein. Also called IVP.

**Intravenous pyelography:** X-ray study of the kidneys and urinary tract. Structures are made visible by the injection of a substance that blocks X-rays. Also called IVP.

**Invasion:** As related to cancer, the spread of cancer cells into healthy tissue adjacent to the tumor.

**Invasive cancer:** Cancer that has spread beyond the layer of tissue in which it developed. Invasive breast cancer is also called infiltrating cancer or infiltrating carcinoma.

**Invasive cervical cancer:** Cancer that has spread from the surface of the cervix to tissue deeper in the cervix or to other parts of the body.

**Islet cell cancer:** Cancer arising from cells in the islets of Langerhans.
Islets of Langerhans: Hormone-producing cells in the pancreas.

IV (intravenous): Injected in a vein.

Jaundice: A condition in which the skin and the whites of the eyes become yellow and the urine darkens. Jaundice occurs when the liver is not working properly or when a bile duct is blocked.

Kaposi's sarcoma: A relatively rare type of cancer that develops on the skin of some elderly persons or those with a weak immune system, including those with acquired immune deficiency syndrome (AIDS).

Kidney cancer: Renal cell cancer (also called cancer of the kidney or renal adenocarcinoma) is a disease in which cancer (malignant) cells are found in certain tissues of the kidney. Renal cell cancer is one of the less common kinds of cancer. It occurs more often in men than in women.

Kidneys: A pair or organs in the abdomen that remove waste from the blood. The waste leaves the blood as urine.

Krukenberg tumor: A tumor of the ovary caused by the spread of stomach cancer.

Laparoscopy: A surgical procedure in which a lighted instrument shaped like a thin tube is inserted through a small incision in the abdomen. The doctor can look through the instrument and see inside the abdomen.

Laparotomy: An operation that allows the doctor to inspect the organs in the abdomen.

Large cell carcinomas: A group of lung cancers in which the cells are large and look abnormal.

Laryngectomy: A person who has had his or her voice box removed.

Laryngectomy: An operation to remove all or part of the larynx.

Laryngoscope: A flexible lighted tube used to examine the larynx.

Laryngoscopy: Examination of the larynx with a mirror (indirect laryngoscopy) or with a laryngoscope (direct laryngoscopy).

Larynx: An organ in the throat used in breathing, swallowing, and talking. It is made of cartilage and is lined by a mucous membrane similar to the lining of the mouth. Also called the voice box.

Larynx cancer: Cancer of the larynx (or voice box) is a disease in which cancer (malignant) cells are found in the tissues of the larynx. Your larynx is a short passageway shaped like a triangle that is just below the pharynx in the neck. The pharynx is a hollow tube about five inches long that starts behind the nose and goes down to the neck to become part of the tube that goes to the stomach (the esophagus).

Leiomyosarcoma: Leiomyosarcoma is a tumor of smooth muscle tissue. This cancer affects the uterus, lower abdomen, and extremities (hands and feet) most often.

Lesion: An area of abnormal tissue change.

Leukemia: Cancer of the blood cells.

Leukemia—Acute lymphoblastic: Acute lymphocytic leukemia (also called acute lymphoblastic leukemia or ALL) is a disease in which too many infection-fighting white blood cells called lymphocytes are found in the blood and bone marrow.

Leukemia—Acute myeloblastic: Acute myeloid leukemia (AML) is a disease in which cancer (malignant) cells are found in the blood and bone marrow. Normally, the bone marrow makes cells called blasts that develop (mature) into several different types of blood cells that have specific jobs to do in the body. AML affects the blasts that are developing into white blood cells called granulocytes. In AML, the blasts do not mature and become too numerous.

Leukemia—Chronic myelogenous: Chronic myelogenous leukemia (also called CML or chronic granulocytic leukemia) is a disease in which too many white blood cells are made in
the bone marrow. CML affects the blasts that are developing into white blood cells called granulocytes.

**Leukocytes:** Cells that help the body fight infections and other diseases. Also called white blood cells (WBCs).

**Leukoplakia:** A white spot or patch in the mouth.

**Li-Fraumeni Syndrome:** A rare family predisposition to multiple cancers, caused by an alteration in the p53 tumor suppressor gene.

**Ligation:** The process of tying off blood vessels so that blood cannot flow to a part of the body or to a tumor.

**Limb perfusion:** A chemotherapy technique that may be used when melanoma occurs on an arm or leg. The flow of blood to and from the limb is stopped for a while with a tourniquet, and anticancer drugs are put directly into the blood of the limb. This allows the patient to receive a high dose of drugs in the area where the melanoma occurred.

**Liver:** A large, glandular organ located in the upper abdomen that cleanses the blood and aids in digestion by secreting bile.

**Liver cancer:** Liver cancer is a disease in which cancer (malignant) cells start to grow in the tissues of the liver. The liver is one of the largest organs in the body, filling the upper right side of the abdomen and protected by the rib cage.

**Liver scan:** An image of the liver created on a computer screen or on film. For a liver scan, a radioactive substance is injected into a vein and travels through the bloodstream. It collects in the liver, especially in abnormal areas, and can be detected by the scanner.

**Lobe:** A portion of the liver, lung, breast, or brain.

**Lobectomy:** The removal of a lobe.

**Lobular carcinoma in situ:** Abnormal cells in the lobules of the breast. This condition seldom becomes invasive cancer. However, having lobular carcinoma in situ is a sign that the woman has an increased risk of developing breast cancer. Also called LCIS.

**Lobule:** A small lobe.

**Local:** Reaching and affecting only the cells in a specific area.

**Local therapy:** Treatment that affects cells in the tumor and the area close to it.

**Lower GI series:** A series of X-rays of the colon and rectum that is taken after the patient is given a barium enema. (Barium is a white substance that outlines the colon and rectum on the X-ray.)

**Lumbar puncture:** The insertion of a needle into the lower part of the spinal column to collect cerebrospinal fluid or to give intrathecal chemotherapy. Also called a spinal tap.

**Lumpectomy:** Surgery to remove only the cancerous breast lump; usually followed by radiation therapy.

**Luteinizing hormone-releasing hormone (LHRH) agonist:** A substance that closely resembles LHRH, which controls the production of sex hormones. However, LHRH agonists affect the body differently than does LHRH. LHRH agonists keep the testicles from producing hormones.

**Lymph:** The almost colorless fluid that travels through the lymphatic system and carries cells that help fight infection and disease.

**Lymph nodes:** Small, bean-shaped organs located along the channels of the lymphatic system. The lymph nodes store special cells that can trap bacteria or cancer cells traveling through the body in lymph. Clusters of lymph nodes are found in the underarms, groin, neck, chest, and abdomen.

**Lymphangiogram:** An X-ray of the lymphatic system. A dye is injected to outline the lymphatic vessels and organs.
**Lymphangiography:** X-ray study of lymph nodes and lymph vessels made visible by the injection of a special dye.

**Lymphatic system:** The tissues and organs that produce, store, and carry white blood cells that fight infection and disease. This system includes the bone marrow, spleen, thymus, and lymph nodes and a network of thin tubes that carry lymph and white blood cells. These tubes branch, like blood vessels, into all the tissues of the body.

**Lymphedema:** A condition in which excess fluid collects in tissue and causes swelling. It may occur in the arm or leg after lymph vessels or lymph nodes in the underarm or groin are removed.

**Lymphoma:** Cancer that arises in cells of the lymphatic system.

**Lymphocytes:** White blood cells that fight infection and disease.

**Lymphocytic:** Referring to lymphocytes, a type of white blood cell.

**Lymphoid:** Referring to lymphocytes, a type of white blood cell. Also refers to tissue in which lymphocytes develop.

**M proteins:** Antibodies or parts of antibodies found in unusually large amounts in the blood or urine of multiple myeloma patients.

**Magnetic resonance imaging:** A procedure in which a magnet linked to a computer is used to create detailed pictures of areas inside the body. Also called MRI.

**Maintenance therapy:** Chemotherapy that is given to leukemia patients in remission to prevent a relapse.

**Malignant:** Cancerous; can invade nearby tissue and spread to other parts of the body.

**Mammogram:** An X-ray of the breast.

**Mammography:** The use of X-rays to create a picture of the breast.

**Mastectomy:** Surgery to remove the breast (or as much of the breast as possible).

**Mediastinoscopy:** A procedure in which the doctor inserts a tube into the chest to view the organs in the mediastinum. The tube is inserted through an incision above the breastbone.

**Mediastinotomy:** A surgical procedure in which a small opening is made in the upper chest in order to allow examination of the lungs and chest.

**Mediastinum:** The area between the lungs. The organs in this area include the heart and its large veins and arteries, the trachea, the esophagus, the bronchi, and lymph nodes.

**Medical oncologist:** A doctor who specializes in treating cancer. Some oncologists specialize in a particular type of cancer treatment. For example, a radiation oncologist specializes in treating cancer with radiation.

**Medulloblastoma:** A type of brain tumor that recent research suggests develops from primitive (developing) nerve cells that normally do not remain in the body after birth. Medulloblastomas are sometimes called primitive neuroectodermal tumors. They are almost always found in children or young adults.

**Melanin:** A skin pigment (substance that gives the skin its color). Dark-skinned people have more melanin than light-skinned people.

**Melanocytes:** Cells in the skin that produce and contain the pigment called melanin.

**Melanoma:** Cancer of the cells that produce pigment in the skin. Melanoma usually begins in a mole.

**Membrane:** A thin layer of tissue that covers a surface.

**Meninges:** The three membranes that cover the brain and spinal cord.

**Meningioma:** A type of brain tumor that develops in the meninges. Because these tumors grow very slowly, the brain may be able to adjust to their
presence; meningiomas often grow quite large before they cause symptoms.

**Mesothelioma**: Malignant mesothelioma, a rare form of cancer, is a disease in which cancer (malignant) cells are found in the sac lining the chest (the pleura) or abdomen (the peritoneum). Most people with malignant mesothelioma have worked on jobs where they breathed asbestos.

**Metastasize**: To spread from one part of the body to another. When cancer cells metastasize and form secondary tumors, the cells in the metastatic tumor are like those in the original (primary) tumor.

**Microcalcifications**: Tiny deposits of calcium in the breast that cannot be felt but can be detected on a mammogram. A cluster of these very small specks of calcium may indicate that cancer is present.

**Mole**: An area on the skin (usually dark in color) that contains a cluster of melanocytes.

**Monoclonal antibodies**: Substances that can locate and bind to cancer cells wherever they are in the body. They can be used alone, or they can be used to deliver drugs, toxins, or radioactive material directly to tumor cells.

**Monocyte**: A type of white blood cell.

**Morphology**: The science of the form and structure of organisms (plants, animals, and other forms of life).

**MRI (magnetic resonance imaging)**: A procedure in which a magnet linked to a computer is used to create detailed pictures of areas inside the body.

**Mucus**: A thick fluid produced by the lining of some organs of the body.

**Multiple myeloma**: Cancer that affects plasma cells. The disease causes the growth of tumors in many bones, which can lead to bone pain and fractures. In addition, the disease often causes kidney problems and lowered resistance to infection.

**Mutations**: Changes in the way cells function or develop, caused by an inherited genetic defect or an environmental exposure. Such changes may lead to cancer.

**Mycosis fungoides**: A type of non-Hodgkin’s lymphoma that first appears on the skin. Also called cutaneous T-cell lymphoma.

**Myeloid**: Referring to myelocytes, a type of white blood cell. Also called myelogenous.

**Myelogram**: An X-ray of the spinal cord and the bones of the spine.

**Myelogenous**: Referring to myelocytes, a type of white blood cell. Also called myeloid.

**Myelodysplastic syndrome**: Myelodysplastic syndromes, also called pre-leukemia or “smoldering” leukemia, are diseases in which the bone marrow does not function normally and not enough normal blood cells are made. (See Preleukemia)

**Myometrium**: The muscular outer layer of the uterus.

**Nasopharynx cancer**: Cancer of the nasopharynx is a disease in which cancer (malignant) cells are found in the tissues of the nasopharynx. The nasopharynx is behind the nose and is the upper part of the throat (also called the pharynx). The pharynx is a hollow tube about five inches long that starts behind the nose and goes down to the neck to become part of the tube that goes to the stomach (the esophagus).

**Nephrectomy**: Surgery to remove the kidney. Radical nephrectomy removes the kidney, the adrenal
gland, nearby lymph nodes, and other surrounding tissue. Simple nephrectomy removes just the affected kidney. Partial nephrectomy removes the tumor, but not the entire kidney.

**Nephrotomogram:** A series of special X-rays of the kidneys. The X-rays are taken from different angles. They show the kidneys clearly, without the shadows of the organs around them.

**Neuroblastoma:** Neuroblastoma is a disease in which cancer (malignant) cells are found in certain nerve cells in the body. Neuroblastoma most commonly starts in the abdomen, either in the adrenal glands (located just above the kidney in back of the upper abdomen) or around the spinal cord. Neuroblastoma can also start around the spinal cord in the chest, neck, or pelvis.

**Neuroma:** A tumor that arises in nerve cells.

**Neurosurgeon:** A doctor who specializes in surgery on the brain and other parts of the nervous system.

**Neutrophil:** A type of white blood cell.

**Nevus:** The medical term for a spot on the skin, such as a mole. A mole is a cluster of melanocytes that usually appears as a dark spot on the skin. The plural of nevus is nevi (NEE-vye).

**Nitrosoureas:** A group of anticancer drugs that can cross the blood–brain barrier. Carmustine (BCNU) and lomustine (CCNU) are nitrosoureas.

**Non-Hodgkin’s lymphoma:** Adult non-Hodgkin’s lymphoma is a disease in which cancer (malignant) cells are found in the lymph system. There are many types of non-Hodgkin’s lymphomas. Some types spread more quickly than others. The type is determined by how the cancer cells look under a microscope.

**Nonmelanoma skin cancer:** Skin cancer that does not involve melanocytes. Basal cell cancer and squamous cell cancer are nonmelanoma skin cancers.

**Nonseminoma:** A classification of testicular cancers that arise in specialized sex cells called germ cells. Nonseminomas include embryonal carcinoma, teratoma, choriocarcinoma, and yolk sac tumor.

**Non-small cell lung cancer:** A form of lung cancer associated with smoking, exposure to environmental tobacco smoke, or exposure to radon. Non-small cell lung cancer is classified as squamous cell carcinoma, adenocarcinoma, and large cell carcinoma depending on what type of cells are in the cancer.

**Oat cell cancer:** A type of lung cancer in which the cells look like oats. Also called small cell lung cancer.

**Oligodendrogloma:** A rare, slow-growing type of brain tumor that occurs in the cells that produce myelin, the fatty covering that protects nerves.

**Ommaya reservoir:** A device implanted under the scalp and used to deliver anticancer drugs to the fluid surrounding the brain and spinal cord.

**Oncogene:** The part of the cell that normally directs cell growth, but which can also promote or allow the uncontrolled growth of cancer if damaged (mutated) by an environmental exposure to carcinogens, or damaged or missing because of an inherited defect.

**Oncologist:** A doctor who specializes in treating cancer. Some oncologists specialize in a particular type of cancer treatment.

**Oncology:** The study of tumors encompassing the physical, chemical, and biologic properties.

**Oophorectomy:** The removal of one or both ovaries.

**Ophthalmoscope:** A lighted instrument used to examine the inside of the eye, including the retina and the optic nerve.

**Optic nerve:** The nerve that carries messages from the retina to the brain.

**Oral cavity cancer:** Cancer of the oral cavity is a disease in which cancer (malignant) cells are
found in the tissues of the lip or mouth. The oral cavity includes the front two-thirds of the tongue, the upper and lower gums (the gingiva), the lining of the inside of the cheeks and lips (the buccal mucosa), the bottom (floor) of the mouth under the tongue, the bony top of the mouth (the hard palate), and the small area behind the wisdom teeth (the retromolar trigone).

**Orchiectomy:** Surgery to remove the testicles.

**Organisms:** Plants, animals, and other forms of life that are made up of complex and interconnected systems of cells and tissue.

**Oropharynx:** The area of the throat at the back of the mouth.

**Osteosarcoma:** A cancer of the bone that is most common in children. Also called osteogenic sarcoma. It is the most common type of bone cancer.

**Ostomy:** An operation to create an opening from an area inside the body to the outside. See Colostomy.

**Ovarian cancer:** Cancer of the ovary is a disease in which cancer (malignant) cells are found in the ovary. Approximately 25,000 women in the United States are diagnosed with this disease each year. The ovary is a small organ in the pelvis that makes female hormones and holds egg cells that, when fertilized, can develop into a baby.

**Ovaries:** The pair of female reproductive glands in which the ova, or eggs, are formed. The ovaries are located in the lower abdomen, one on each side of the uterus.

**p53:** A gene in the cell that normally inhibits the growth of tumors, which can prevent or slow the spread of cancer.

**Palate:** The roof of the mouth. The front portion is bony (hard palate), and the back portion is muscular (soft palate).

**Palliative treatment:** Treatment that does not alter the course of a disease but improves the quality of life.

**Palpation:** A technique in which a doctor presses on the surface of the body to feel the organs or tissues underneath.

**Pancreas:** A gland located in the abdomen. It makes pancreatic juices, and it produces several hormones, including insulin. The pancreas is surrounded by the stomach, intestines, and other organs.

**Pancreatic cancer:** Cancer of the pancreas is a disease in which cancer (malignant) cells are found in the tissues of the pancreas. The pancreas is about six inches long and is shaped something like a thin pear, wider at one end and narrowing at the other. The pancreas lies behind the stomach, inside a loop formed by part of the small intestine.

**Pancreatectomy:** Surgery to remove the pancreas. In a total pancreatectomy, the duodenum, common bile duct, gallbladder, spleen, and nearby lymph nodes also are removed.

**Pancreatic juices:** Fluids made by the pancreas. Pancreatic juices contain proteins called enzymes that aid in digestion.

**Papillary tumor:** A tumor shaped like a small mushroom with its stem attached to the inner lining of the bladder.

**Papilledema:** Swelling around the optic nerve, usually caused by pressure on the nerve by a tumor.

**Pap test:** Microscopic examination of cells collected from the cervix. It is used to detect changes that may be cancer or may lead to cancer, and it can show noncancerous conditions, such as infection or inflammation. Also called Pap smear.

**Paraneoplastic syndrome:** A group of symptoms that may develop when substances released by some cancer cells disrupt the normal function of surrounding cells and tissue. Such symptoms do not necessarily mean that the cancer has spread beyond the original site.

**Parotid cancer:** Cancer of the salivary gland is a disease in which cancer (malignant) cells are found
in the tissues of the salivary glands. Your salivary glands make saliva, the fluid that is released into your mouth to keep it moist and to help dissolve your food. Major clusters of salivary glands are found below your tongue (sublingual glands), on the sides of your face just in front of your ears (parotid glands), and under your jawbone (submaxillary glands).

**Pathologist:** A doctor who identifies diseases by studying cells and tissues under a microscope.

**Pelvis:** The lower part of the abdomen, located between the hip bones.

**Penile cancer:** Cancer of the penis, a rare kind of cancer in the United States, is a disease in which cancer (malignant) cells are found on the skin and in the tissues of the penis.

**Percutaneous transhepatic cholangiography:** A test sometimes used to help diagnose cancer of the pancreas. During this test, a thin needle is put into the liver. Dye is injected into the bile ducts in the liver so that blockages can be seen on X-rays.

**Perfusion:** The process of flooding fluid through the artery to saturate the surrounding tissue. In regional perfusion, a specific area of the body (usually an arm or a leg) is targeted, and high doses of anticancer drugs are flooded through the artery to reach the surrounding tissue and kill as many cancer cells as possible. Such a procedure is performed in cases in which the cancer is not thought to have spread past a localized area.

**Perineal prostatectomy:** Surgery to remove the prostate through an incision made between the scrotum and the anus.

**Peripheral blood stem cell transplantation:** A procedure that is similar to bone marrow transplantation. Doctors remove healthy immature cells (stem cells) from a patient's blood and store them before the patient receives high-dose chemotherapy and possibly radiation therapy to destroy the leukemia cells. The stem cells are then returned to the patient, where they can produce new blood cells to replace cells destroyed by the treatment.

**Peripheral stem cell support:** A method of replacing blood-forming cells destroyed by cancer treatment. Certain cells (stem cells) in the blood that are similar to those in the bone marrow are removed from the patient’s blood before treatment. The cells are given back to the patient after treatment.

**Peristalsis:** The rippling motion of muscles in the digestive tract. In the stomach, this motion mixes food with gastric juices, turning it into a thin liquid.

**Peritoneal cavity:** The lower part of the abdomen that contains the intestines (the last part of the digestive tract), the stomach, and the liver. It is bound by thin membranes.

**Peritoneum:** The large membrane that lines the abdominal cavity.

**Pernicious anemia:** A blood disorder caused by a lack of vitamin B12. Patients who have this disorder do not produce the substance in the stomach that allows the body to absorb vitamin B12.

**Petechiae:** Tiny red spots under the skin; often a symptom of leukemia.

**Pharynx:** The hollow tube about five inches long that starts behind the nose and ends at the top of the trachea (windpipe) and esophagus (the tube that goes to the stomach).

**Photodynamic therapy:** Treatment that destroys cancer cells with lasers and drugs that become active when exposed to light.

**Pigment:** A substance that gives color to tissue. Pigments are responsible for the color of skin, eyes, and hair.

**Pineal gland:** A small gland located in the cerebrum.

**Pineal region tumors:** Types of brain tumors that occur in or around the pineal gland, a tiny organ near the center of the brain. The pineal region is very difficult to reach, therefore these tumors often cannot be removed.
Pineoblastoma: A fast-growing type of brain tumor that occurs in or around the pineal gland, a tiny organ near the center of the brain.

Pineocytoma: A slow-growing type of brain tumor that occurs in or around the pineal gland, a tiny organ near the center of the brain.

Pituitary cancer: Pituitary tumors found in the pituitary gland, a small organ about the size of a pea in the center of the brain just above the back of the nose. Your pituitary gland makes hormones that affect your growth and the functions of other glands in your body. Most pituitary tumors are benign. This means that they grow very slowly and do not spread to other parts of the body.

Pituitary gland: The main endocrine gland; it produces hormones that control other glands and many body functions, especially growth.

Plasma: The liquid part of the blood.

Plasma cells: Special white blood cells that produce antibodies.

Plasmacytoma: A tumor that is made up of cancerous plasma cells.

Plasmapheresis: The process of removing certain proteins from the blood. Plasmapheresis can be used to remove excess antibodies from the blood of multiple myeloma patients.

Platelets: Blood cells that help clots form to help control bleeding. Also called thrombocytes.

Pleura: The thin covering that protects and cushions the lungs. The pleura is made of two layers of tissue separated by a small amount of fluid.

Pleural cavity: A space enclosed by the pleura, thin tissue covering the lungs and lining the interior wall of the chest cavity. It is bound by serous membranes.

Pneumatic larynx: A device that uses air to produce sound to help a laryngectomee talk.

Pneumonectomy: An operation to remove an entire lung.

Polyp: A mass of tissue that projects into the colon.

Positron emission tomography scan: For this type of scan, a person is given a substance that reacts with tissues in the body to release protons (parts of an atom). Through measuring the different amounts of protons released by healthy and cancerous tissues, a computer creates a picture of the inside of the body. Also called PET scan.

Postremission therapy: Chemotherapy to kill leukemia cells that survive after remission induction therapy.

Precancerous: A term used to describe a condition that may or is likely to become cancer.

Precancerous polyps: Growths in the colon that often become cancerous.

Prednisone: A drug often given to multiple myeloma patients along with one or more anticancer drugs. Prednisone appears to act together with anticancer drugs in helping to control the effects of the disease on the body.

Preleukemia: A condition in which the bone marrow does not function normally. It does not produce enough blood cells. This condition may progress and become acute leukemia. Preleukemia also is called myelodysplastic syndrome or smoldering leukemia.

Primitive neuroectodermal tumors: A type of brain tumor that recent research suggests develops from primitive (developing) nerve cells that normally do not remain in the body after birth. Primitive neuroectodermal tumors are often called medulloblastomas.

Proctoscopy: An examination of the rectum and the lower end of the colon using a thin, lighted instrument called a sigmoidoscope.

Proctosigmoidoscopy: An examination of the rectum and the lower colon using a thin, lighted instrument called a sigmoidoscope.

Progesterone: A female hormone.
**Prognosis:** The probable outcome or course of a disease; the chance of recovery.

**Prophylactic cranial irradiation:** Radiation therapy to the head to prevent cancer from spreading to the brain.

**Prostatectomy:** An operation to remove all or part of the prostate.

**Prostate cancer:** Cancer of the prostate, a common form of cancer, is a disease in which cancer (malignant) cells are found in the prostate. The prostate is one of the male sex glands and is located just below the bladder (the organ that collects and empties urine) and in front of the rectum (the lower part of the intestine). It surrounds part of the urethra, the tube that carries urine from the bladder to the outside of the body. The prostate makes fluid that becomes part of the semen, the white fluid that contains sperm.

**Prostate gland:** A gland in the male reproductive system just below the bladder. It surrounds part of the urethra, the canal that empties the bladder. It produces a fluid that forms part of semen.

**Prostate-specific antigen:** A protein whose level in the blood goes up in some men who have prostate cancer or benign prostatic hyperplasia.

**Prostatic acid phosphatase:** An enzyme produced by the prostate. Its level in the blood goes up in some men who have prostate cancer. Also called PAP.

**Proteins:** Substances that are essential to the body’s structure and proper functioning.

**PTC (percutaneous transhepatic cholangiography):** A test sometimes used to help diagnose cancer of the pancreas. During this test, a thin needle is put into the liver. Dye is injected into the bile ducts in the liver so that blockages can be seen on X-rays.

**Radiation fibrosis:** The formation of scar tissue as a result of radiation therapy to the lung.

**Radiation oncologist:** A doctor who specializes in using radiation to treat cancer.

**Radiation therapy:** Treatment with high-energy rays (such as X-rays) to kill cancer cells. The radiation may come from outside the body (external radiation) or from radioactive materials placed directly in the tumor (implant radiation). Also called radiotherapy.

**Radical cystectomy:** Surgery to remove the bladder as well as nearby tissues and organs.

**Radical prostatectomy:** Surgery to remove the entire prostate. The two types of radical prostatectomy are retropubic prostatectomy and perineal prostatectomy.

**Radionuclide scanning:** An exam that produces pictures (scans) of internal parts of the body. The patient is given an injection or swallows a small amount of radioactive material. A scanner then measures the radioactivity in certain organs.

**Radiosensitizers:** Drugs that make cells more sensitive to radiation.

**Rectal cancer:** Cancer of the rectum, a common form of cancer, is a disease in which cancer (malignant) cells are found in the tissues of the rectum. The rectum is part of the body’s digestive system. The last six feet of intestine is called the large bowel or colon. The last eight to 10 inches of the colon is the rectum.

**Rectum:** The last 8 to 10 inches of the large intestine. The rectum stores solid waste until it leaves the body through the anus.

**Red blood cells:** Cells that carry oxygen to all parts of the body. Also called erythrocytes.

**Reed-Sternberg cell:** A type of cell that appears in patients with Hodgkin’s disease. The number of these cells increases as the disease advances.

**Reflex:** The term used when liquid backs up into the esophagus from the stomach.

**Regional chemotherapy:** Treatment with anticancer drugs that affects mainly the cells in the treated area.
Relapse: The return of signs and symptoms of a disease after a period of improvement.

Remission: Disappearance of the signs and symptoms of cancer. When this happens, the disease is said to be “in remission.” A remission can be temporary or permanent.

Remission induction therapy: The initial chemotherapy a patient with acute leukemia receives to bring about a remission.

Renal capsule: The fibrous connective tissue that surrounds each kidney.

Renal cell cancer: Cancer that develops in the lining of the renal tubules, which filter the blood and produce urine.

Renal pelvis: The area at the center of the kidney. Urine collects here and is funneled into the ureter.

Respiratory system: The organs that are involved in breathing. These include the nose, throat, larynx, trachea, bronchi, and lungs.

Respiratory therapy: Exercises and treatments that help patients recover lung function after surgery.

Retinoblastoma: An eye cancer caused by the loss of both gene copies of the tumor-suppressor gene RB; the inherited form typically occurs in childhood, because one gene is missing at birth.

Retropubic prostatectomy: Surgical removal of the prostate through an incision in the abdomen.

Rhabdomyosarcoma: Rhabdomyosarcoma is a disease in which cancer (malignant) cells begin growing in muscle tissue somewhere in the body. Rhabdomyosarcoma is a type of sarcoma, which means a cancer of the bone, soft tissues, or connective tissue (e.g., tendon or cartilage). Rhabdomyosarcoma begins in the soft tissues in a type of muscle called striated muscle. It can occur anywhere in the body.

RNA (ribonucleic acid): One of the two nucleic acids found in all cells. The other is DNA (deoxyribonucleic acid). RNA transfers genetic information from DNA to proteins produced by the cell.

Salivary glands: Glands in the mouth that produce saliva.

Salpingo-oophorectomy: Surgical removal of the fallopian tubes and ovaries.

Sarcoma: A malignant tumor that begins in connective and supportive tissue.

Scans: Images of the organs or other parts of the body. Scans are often used in diagnosing, staging, and monitoring patients include liver scans, bone scans, and computed tomography (CT) or computed axial tomography (CAT) scans. In liver scanning and bone scanning, radioactive substances that are injected into the bloodstream collect in these organs. A scanner that detects the radiation is used to create pictures. In CT scanning, an X-ray machine linked to a computer is used to produce detailed pictures of organs inside the body.

Schiller test: A test in which iodine is applied to the cervix. The iodine colors healthy cells brown; abnormal cells remain unstained, usually appearing white or yellow.

Schwannoma: A type of benign brain tumor that begins in the Schwann cells, which produce the myelin that protects the acoustic nerve the nerve of hearing.

Seminal vesicles: Glands that help produce semen.

Seminoma: A type of testicular cancer that arises from sex cells, or germ cells, at a very early stage in their development.

Shunt: A catheter (tube) that carries cerebrospinal fluid from a ventricle in the brain to another area of the body.

Sigmoidoscope: An instrument used to view the inside of the colon.

Sigmoidoscopy: A procedure in which the doctor looks inside the rectum and the lower part of the colon (sigmoid colon) through a lighted tube. The
doctor may collect samples of tissue or cells for closer examination. Also called proctosigmoidoscopy.

**Sinus cancer**: Sinus cancer is a disease in which cancer (malignant) cells are found in the tissues of the paranasal sinuses or nasal cavity. Your paranasal sinuses are small hollow spaces around your nose. The sinuses are lined with cells that make mucus, which keeps the nose from drying out; the sinuses are also a space through which your voice can echo to make sounds when you talk or sing.

**Skin cancer**: Skin cancer is a disease in which cancer (malignant) cells are found in the outer layers of your skin. The skin has two main layers and several kinds of cells. The top layer of skin is called the epidermis. It contains three kinds of cells: flat, scaly cells on the surface called squamous cells; round cells called basal cells; and cells called melanocytes, which give your skin its color.

**Skin graft**: Skin that is moved from one part of the body to another.

**Small cell lung cancer**: A type of lung cancer in which the cells are small and round. Also called oat cell lung cancer.

**Small intestine**: The part of the digestive tract that is located between the stomach and the large intestine.

**Smoldering leukemia**: See Preleukemia.

**Soft tissue sarcoma**: A sarcoma that begins in the muscle, fat, fibrous tissue, blood vessels, or other supporting tissue of the body.

**Somatic cells**: All the body cells except the reproductive cells.

**Somatic mutations**: See mutation.

**Sperm banking**: Freezing sperm before cancer treatment for use in the future. This procedure can allow men to father children after loss of fertility.

**SPF (sun protection factor)**: A scale for rating sunscreens. Sunscreens with an SPF of 15 or higher provide the best protection from the sun’s harmful rays.

**Spinal tap**: A test in which a fluid sample is removed from the spinal column with a thin needle. Also called a lumbar puncture.

**Spleen**: An organ that produces lymphocytes, filters the blood, stores blood cells, and destroys those that are aging. It is located on the left side of the abdomen near the stomach.

**Splenectomy**: An operation to remove the spleen.

**Sputum**: Mucus from the lungs.

**Squamous cell carcinoma**: Cancer that begins in squamous cells, which are thin, flat cells resembling fish scales. Squamous cells are found in the tissue that forms the surface of the skin, the lining of the hollow organs of the body, and the passages of the respiratory and digestive tracts.

**Squamous cells**: Flat cells that look like fish scales; they make up most of the epidermis, the outer layer of the skin.

**Squamous intraepithelial lesion**: A general term for the abnormal growth of squamous cells on the surface of the cervix. The changes in the cells are described as low grade or high grade, depending on how much of the cervix is affected and how abnormal the cells are. Also called SIL.

**Stage**: The extent of a cancer, especially whether the disease has spread to other parts of the body.

**Staging**: Doing exams and tests to learn the extent of the cancer, especially whether it has spread from its original site to other parts of the body.

**Stem cells**: The cells from which all blood cells develop.

**Stereotaxis**: Use of a computer and scanning devices to create three-dimensional pictures. This method can be used to direct a biopsy, external radiation, or the insertion of radiation implants.

**Steroids**: Drugs used to relieve swelling and inflammation.
Stoma: An opening in the abdominal wall; also called an ostomy or urostomy.

Stool test: A test to check for hidden blood in the bowel movement.

Subglottis: The lowest part of the larynx; the area from just below the vocal cords down to the top of the trachea.

Supportive care: Treatment given to prevent, control, or relieve complications and side effects and to improve the patient’s comfort and quality of life.

Supraglottis: The upper part of the larynx, including the epiglottis; the area above the vocal cords.

Systemic: Reaching and affecting cells all over the body.

Systemic therapy: Treatment that uses substances that travel through the bloodstream, reaching and affecting cancer cells all over the body.

Systemic treatment: Treatment using substances that travel through the bloodstream, reaching and affecting cancer cells all over the body.

T-cell lymphoma: A cancer of the immune system that appears in the skin; also called mycosis fungoides.

Testicular cancer: Cancer of the testicle (also called the testis), a rare kind of cancer in men, is a disease in which cancer (malignant) cells are found in the tissues of one or both testicles. The testicles are round and a little smaller than golf balls. Sperm (the male germ cells that can join with a female egg to develop into a baby) and male hormones are made in the testicles. There are two testicles located inside of the scrotum (a sac of loose skin that lies directly under the penis).

Testosterone: A male sex hormone.

Thermography: A test to measure and display heat patterns of tissues near the surface of the breast. Abnormal tissue generally is warmer than healthy tissue. This technique is under study; its value in detecting breast cancer has not been proven.

Thoracentesis: Removal of fluid in the pleura through a needle.

Thoracic: Pertaining to the chest.

Thoracotomy: An operation to open the chest.

Thrombocytes: See Platelets.

Thrombophlebitis: Inflammation of a vein that occurs when a blood clot forms.

Thymoma: Malignant thymoma is a disease in which cancer (malignant) cells are found in the tissues of the thymus. The thymus is a small organ that lies under the breastbone. It makes white blood cells called lymphocytes, which travel through your body and fight infection. People with malignant thymoma often have other diseases of their immune system. The most common disease in people with thymoma is one in which the muscles are weak, called myasthenia gravis.

Thymus: An organ in which lymphocytes mature and multiply. It lies behind the breastbone.

Thyroid cancer: Cancer of the thyroid is a disease in which cancer (malignant) cells are found in the tissues of the thyroid gland. Your thyroid gland is at the base of your throat. It has two lobes, one on the right side and one on the left. Your thyroid gland makes important hormones that help your body to function normally.

Tissue: A group or layer of cells that together perform specific functions.

Tonsils: Small masses of lymphatic tissue on either side of the throat.

Topical chemotherapy: Treatment with anticancer drugs in a lotion or cream.

Total pancreatectomy: Surgery to remove the entire pancreas.
Toxins: Poisons produced by certain animals, plants, or bacteria.

Trachea: The airway that leads from the larynx to the lungs. Also called the windpipe.

Tracheoesophageal puncture: A small opening made by a surgeon between the esophagus and the trachea. A valve keeps food out of the trachea but lets air into the esophagus for esophageal speech.

Tracheostomy: Surgery to create an opening (stoma) into the windpipe. The opening itself may also be called a tracheostomy.

Tracheostomy button: A small plastic tube placed in the stoma to keep it open.

Tracheostomy tube: A two- to three-inch-long metal or plastic tube that keeps the stoma and trachea open. Also called a trach (“trake”) tube.

Transformation: The change that a normal cell undergoes as it becomes malignant.

Transfusion: The transfer of blood or blood products from one person to another.

Transitional cell carcinoma: Cancer that develops in the lining of the renal pelvis. This type of cancer also occurs in the ureter and the bladder.

Transitional cells: Cells lining some organs.

Transplantation: The replacement of an organ with one from another person.

Transrectal ultrasound: The use of sound waves to detect cancer. An instrument is inserted into the rectum. Waves bounce off the prostate and the pattern of the echoes produced is converted into a picture by a computer.

Transurethral resection: Surgery performed with a special instrument inserted through the urethra. Also called TUR.

Transurethral resection of the prostate: The use of an instrument inserted through the penis to remove tissue from the prostate. Also called TUR or TURP.

Tumor: An abnormal mass of tissue that results from excessive cell division. Tumors perform no useful body function. They may either be benign (not cancerous) or malignant (cancerous).

Tumor debulking: Surgically removing as much of the tumor as possible.

Tumor marker: A substance in blood or other body fluids that may suggest that a person has cancer.

Tumor necrosis factor: A type of biological response modifier (a substance that can improve the body’s natural response to disease).

Tumors of unknown primary origin: This is a disease in which cancer (malignant) cells are found somewhere in the body, but the place where they first started growing (the origin or primary site) cannot be found.

Tumor-suppressor gene: Genes in the body that can suppress or block the development of cancer.

Ulcerative colitis: A disease that causes long-term inflammation of the lining of the colon.

Ultrasound: A test that bounces sound waves off tissues and internal organs and changes the echoes into pictures (sonograms). Tissues of different densities reflect sound waves differently.

Ultrasonicography: A test in which sound waves (called ultrasound) are bounced off tissues and the echoes are converted into a picture (sonogram).

Ultraviolet (UV) radiation: Invisible rays that are part of the energy that comes from the sun. UV radiation can burn the skin and cause melanoma and other types of skin cancer. UV radiation that reaches the Earth’s surface is made up of two types of rays, called UVA and UVB rays. UVB rays are more likely than UVA rays to cause sunburn, but UVA rays pass further into the skin. Scientists have long thought that UVB radiation can cause melanoma and other types of skin cancer. They now think that UVA radiation also may add to skin damage that can lead to cancer. For this reason, skin specialists recommend that people use...
sunscreen that block or absorb both kinds of UV radiation.

**Upper GI series**: A series of X-rays of the upper digestive system that are taken after a person drinks a barium solution, which outlines the digestive organs on the X-rays.

**Ureter**: The tube that carries urine from the kidney to the bladder.

**Urethra**: The tube that empties urine from the bladder.

**Urinalysis**: A test that determines the content of the urine.

**Urinary tract**: The organs of the body that produce and discharge urine. These include the kidneys, ureters, bladder, and urethra.

**Urostomy**: An operation to create an opening from inside the body to the outside, making a new way to pass urine.

**Uterine cancer**: Cancer of the endometrium, a common kind of cancer in women, is a disease in which cancer (malignant) cells are found in the lining of the uterus (endometrium). The uterus is the hollow, pear-shaped organ where a baby grows. Cancer of the endometrium is different from cancer of the muscle of the uterus, which is called sarcoma of the uterus. Sarcoma of the uterus, a very rare kind of cancer in women, is a disease in which cancer (malignant) cells start growing in the muscles or other supporting tissues of the uterus.

**Vaginal cancer**: Cancer of the vagina, a rare kind of cancer in women, is a disease in which cancer (malignant) cells are found in the tissues of the vagina. The vagina is the passageway through which fluid passes out of the body during menstrual periods and through which a woman has babies. It is also called the birth canal.

**Ventricles**: Hollow chambers within the body; the heart has two ventricles, and the brain has four ventricles.

**Vinyl chloride**: A substance used in manufacturing plastics. It is linked to liver cancer.

**Viruses**: Small living particles that can infect cells and change how the cells function. Infection with a virus can cause a person to develop symptoms. The disease and symptoms that are caused depend on the type of virus and the type of cells that are infected.

**Vocal cords**: Two small bands of muscle within the larynx. They close to prevent food from getting into the lungs, and they vibrate to produce the voice.

**Waldenstrom’s macroglobulinemia**: This is a rare, chronic cancer that affects white blood cells called B lymphocytes, or B cells. These cells form in the lymph nodes and the bone marrow, the soft, spongy tissue inside bones, and are an important part of the body’s immune (defense) system. Some B cells become plasma cells, which make, store, and release antibodies. Antibodies help the body fight viruses, bacteria, and other foreign substances. In Waldenstrom’s macroglobulinemia, abnormal B cells multiply out of control. They invade the bone marrow, lymph nodes, and spleen and produce excessive amounts of an antibody called IgM.

**Wart**: A raised growth on the surface of the skin or other organ.

**Whipple procedure**: A type of surgery used to treat pancreatic cancer. The surgeon removes the head of the pancreas, the duodenum, a portion of the stomach, and other nearby tissues.

**White blood cells**: Cells that help the body fight infection and disease. These cells begin their development in the bone marrow and then travel to other parts of the body.

**Wilms’ tumor**: Wilms’ tumor is a disease in which cancer (malignant) cells are found in certain parts of the kidney. The kidneys are a “matched” pair of organs found on either side of the backbone. Inside each kidney are tiny tubes that filter and clean the blood, taking out unneeded products, and making urine. Wilms’ tumor occurs most commonly in children under the age of 15 and is curable in the majority of affected children.

**Xerogram**: An X-ray of soft tissue.
Xeroradiography: A type of mammography in which a picture of the breast is recorded on paper rather than on film.

X-ray: High-energy radiation used in low doses to diagnose diseases and in high doses to treat cancer.

CANCER STATISTICS REVIEW 1975-2011: INTRODUCTION

The annual SEER Cancer Statistics Review (CSR) contains incidence, mortality, prevalence, and survival statistics from 1975 through the most recent year for which data are available. This report is published by the Surveillance Research Program of the National Cancer Institute, which manages the Surveillance, Epidemiology, and End Results (SEER) Program. The scope and purpose of the CSR follow a report to the Senate Appropriations Committee (Breslow, 1988), which recommended that a broad profile of cancer be presented regularly to the American public.

The SEER program is an authoritative source of information on cancer incidence and survival in the United States. SEER collects and publishes these statistics from population-based registries covering 28% of the US population. The 18 SEER registries routinely collect data on patient demographics, primary tumor site, tumor morphology, extent of disease, first course of treatment, and active follow-up for vital status. Detailed information describing these fields can be found at http://seer.cancer.gov/resources/.

This report presents statistics on 29 primary sites and subsites, organized into site-specific chapters. Detailed statistics on cancer incidence, mortality, survival, and prevalence are reported by sex, race and ethnicity, age, stage at diagnosis, and geographic area. Information on tumor morphology is also presented. In addition, the CSR features a chapter on adolescent and young adult cancers and a chapter on childhood cancers. Information on some rare cancers can be found in the summary tables of section I. For a detailed list of primary sites, the summary tables provide incidence and death rates for the most recent 5-year period, trends from 1975 to the most recent year, median age at diagnosis, median age at death, and survival rates.

Delay-adjusted cancer incidence rates are a distinctive feature of the CSR. Delay-adjustment corrects the current case count to account for underreporting and corrections to the data. The final delay-adjusted rates are valuable in more precisely estimating trends.

New features added to the CSR include:
- Statistics for lung and bronchus cancer are shown by new histology groupings in Chapter 15 (Lewis DR, et al., 2014).
- Confidence intervals for state ranks in mortality were added (Zhang S, et al., 2014).

Changes in methodology to CSR include:
- New standard error calculation for delay-adjusted incidence rates was used. See http://surveillance.cancer.gov/reports/tech2014.01.pdf for more information.
- The default censoring age for survival calculations has changed from 199 to 99 years when using newly available expected survival tables. For most survival calculations there are no changes. Minimal changes may occur in survival for older age groups. See http://seer.cancer.gov/expsurvival/ for more information.
The CSR files are provided in both PDF and HTML formats. The HTML format is provided as an alternative and accessible version of the SEER Cancer Statistics Review. The current edition of the CSR is available on the web at http://seer.cancer.gov/csr/. Statistics from SEER may also be obtained via FastStats (http://seer.cancer.gov/faststats/) or Cancer Query Systems (http://seer.cancer.gov/canques/), which allow the user to access over 10,000,000 cancer statistics. The SEER Research Data file (http://seer.cancer.gov/data/) may be accessed by the public, either through SEER*Stat software or in an ASCII text format that can be analyzed with standard statistical software.

While most of the rates in this publication have been age-adjusted to the 2000 US standard population, some previous SEER publications have used the 1970 US standard million population. Therefore, rates given in this publication cannot be compared to rates given in those publications. This change conforms to a federal policy for reporting disease rates; it allows for the age-adjusted rate to more accurately reflect the current age distribution and burden of cancer.

**INTERPRETATION OF CANCER STATISTICS**

A number of factors may affect the interpretation of cancer incidence, mortality, and survival statistics provided in this report.

**Survival rates for all cancers combined:** The mix of cancers changes over time as the incidence of some cancers increases and the incidence of others decreases. The overall cancer survival rate can fluctuate even when the survival rates for site-specific cancers remain unchanged. (While it is possible to adjust the survival rate for all cancers combined on the basis of the relative frequencies of the component cancers, rates adjusted in this manner differ by only a small amount from unadjusted rates. In the future, such an adjustment may become more important if there are substantial changes in the incidence of various cancers.)

**Early detection/screening:** The improved earlier detection and diagnosis of cancers caused by new screening procedures may produce an increase in both incidence rates and survival rates. These increases can occur as a result of the introduction of a new procedure to screen subgroups of the population for a specific cancer; they need not be related to whether use of the screening test results in a decrease in mortality from that cancer. As the proportion of cancers detected at screening increases, presumably as a result of increased screening of the population, patient survival rates will increase, because they are based on survival time after diagnosis. The interval between the time a cancer is diagnosed by a screening procedure and the time when the cancer would have been diagnosed in the absence of screening is called lead-time (Zelen, 1976). (Screening for breast cancer has been demonstrated to result in increased survival over and above that resulting from lead-time alone and to reduce breast cancer mortality. The benefit of screening is being studied for some other cancers.)
If a new screening procedure consistently detects cancer in a preinvasive phase, it may result in a decrease in survival rates for invasive cancer. In this case, length-biased sampling (Zelen, 1976) may be operating. Length-biased sampling would result in the preferential detection—in a preinvasive phase—of those cancers that would have had a relatively good prognosis had they progressed to invasive disease; these potentially invasive cancers would be systematically eliminated. If this occurs, the mix of cancers that are not detected at screening and then progress to invasive behavior may become less prognostically favorable, resulting in a decrease in survival rates for patients with invasive cancers. (Length-biased sampling may at least partially explain survival trends for cervical cancer. Other cancers possibly affected include breast, colon, rectum, and prostate.)

Changes in diagnostic criteria: Early detection of cancer resulting from either screening or earlier response to symptoms may result in the increasing diagnosis of small tumors that are not yet life-threatening. This may have the effect of raising the incidence rates and survival estimates without changing the mortality rates. Breast, colon, prostate, cervix uteri, bladder, and skin (melanoma) are the cancer sites most likely to be affected.

Technological advances in diagnostic procedures: In this report, trends in survival by stage at diagnosis for specific cancers are not presented; trends in stage distributions are presented rarely. However, it is possible to compare survival by stage.

The assignment of a given stage to a particular cancer may change over time due to advances in diagnostic technology. Introduction of new technology can give rise to a phenomenon known as stage migration. Stage migration occurs when diagnostic procedures change over time, resulting in an increase in the probability that a given cancer will be diagnosed in a more advanced stage. For example, certain distant metastases that would have been undetectable a few years ago can now be diagnosed by a computer tomography (CT) scan or by magnetic resonance imaging (MRI). Therefore, some patients who would have been diagnosed previously as having cancer in a localized or regional stage are now diagnosed as having cancer in a distant stage. The likely result would be to remove the worst survivors, those with previously undetected distant metastases, from the localized and regional categories and put them into the distant category. As a result, the stage-at-diagnosis distribution for a cancer may become less favorable over time, but the survival for each stage may improve: The early stage will lose cases that will survive shorter than those remaining in that category, while the advanced stage will gain cases that will survive longer than those already in that category. However, overall survival would not change (Feinstein et al., 1985). Stage migration is an important concept to understand when examining temporal trends in survival by stage at diagnosis as well as temporal trends in stage distributions; it could affect the analysis of virtually all solid tumors.

Evolution of stage classifications: Every few years, the American Joint Committee on Cancer produces a new cancer-staging manual; the seventh edition is the most recent (Edge et al., 2010). The evolution of such classifications reflects the identification of new prognostic factors that may influence choice of treatment. Historically, the SEER Program has only collected data
on extent of disease (EOD), rather than stage. EOD is more specific than stage and usually determines stage, even when stage definitions change. Thus, SEER easily adapts to changes in stage definitions; moreover, trends in a newly redefined stage can usually be calculated. Recently the SEER Program has begun collecting Collaborative Stage. Collaborative Stage has the advantage of being a consolidated data collection system of three main staging systems (TNM, EOD, and Summary Stage) and allows combined pathological and clinical stage to be captured. New prognostic variables are introduced into staging for some cancers and so previously collected EOD data cannot determine new stage categories. There can be problems in assessing trends in stage of disease for these cancers. Only by reviewing the evolution of staging for a given cancer is it possible to determine what effects changes in stage definitions have had on stage-specific survival and on stage-at-diagnosis distributions. Stage migration (mentioned above) and EOD migration need also be taken into account. For some sites, the historic stage (localized, regional, or distant) is not shown, either because of inconsistencies in its definition over time or because stage is not appropriate (such as for leukemias, which are all considered to be distant at diagnosis).

Interpreting relative survival: The relative survival estimate is the ratio of observed survival to expected survival for a given patient cohort. Expected survival is based on mortality rates for the entire population, taking into account, as appropriate, the age, sex, race, and year of diagnosis of the patients. Assuming that the presence of cancer is the only factor that distinguishes the cancer patient cohort from the general population, relative survival estimates the probability that a patient will not die of the diagnosed cancer within the given time interval. This is the same as the probability that the patient will either survive the interval or die of a different cause.

A factor related to the risk of a cancer may also be related to the risk of dying from causes unrelated to the cancer. An example of such a factor is smoking. Smoking is a major risk factor for lung cancer; therefore, a cohort of lung cancer patients will contain a much higher proportion of smokers than the general population. However, smoking is also a risk factor for other diseases so smokers have a shorter life expectancy than nonsmokers. For this reason, expected survival estimates for lung cancer patients based on life tables for the general population will be unrealistically high; since relative survival = observed / expected, this will result in relative-survival estimates that are lower than they would be if the population consisted only of smokers. The problem cannot be easily corrected because separate life tables for smokers and nonsmokers are not available. Moreover, amount of smoking (usually measured in pack-years) is an important variable and cannot be easily quantified. In addition, expected survival may not be appropriate for patients with cancers of the cervix uteri or breast because the risk of these cancers has been associated with socioeconomic status (Baquet et al., 1991) which may be related to life expectancy. This should be considered when interpreting relative survival for these cancers.

Previous to the CSR for 1973–1996, the expected survival tables used were for 1970 and 1980; there were separate tables for whites, blacks, American Indians, Chinese, Japanese, Filipinos, white Hispanics, and Hawaiians. In updating the tables for 1990, several problems emerged.
The US life tables are based on age, race, and sex information from death certificates. The information on race on the death certificate may not be accurate (Rosenberg et al., 1999). One reason is that funeral directors may inaccurately report race on a death certificate. Also, reported age at death, especially for those older than 85, may not be accurate because birth certificates were not issued with as much regularity in the early 1900s as they are today. Although race misclassification and age-at-death misreporting exist across all races, they may be more problematic for races other than white or black because of those races' smaller population sizes. Therefore, life tables were generated for 1970, 1980, 1990, and 2000 only for white, black, and other; these life tables were used to produce the relative survival estimates in this review. There may be small variations among survival estimates calculated in this CSR and those in CSRs prior to 1973–1996.

Comparison with other databases: The SEER data are obtained from population-based cancer registries covering about 28 percent of the US population. It is sometimes of interest to compare cancer statistics for SEER areas with those from other registries both in the US and worldwide. In making such comparisons, one must carefully consider the factors mentioned above for both data sources. In addition, one should assess all of the following: (1) completeness of case ascertainment, (2) rules used to determine multiple primaries, (3) follow-up, (4) rules used in assigning and coding cause of death, and (5) the sources and procedures used in obtaining population estimates. Depending on the rates being compared, there could be other confounding factors which should be considered. The same standard or standard million population should be used for the age-adjustment of each group being compared; most statistics from outside the US are based on the 2000 world standard million population. Examples of other databases are US Cancer Statistics (http://apps.nccd.cdc.gov/uscs) and CINA+ Online (http://www.cancer-rates.info/naaccr/).

It is sometimes of interest to compare survival for cancer patients in SEER areas with data from clinical trials. This must be done with great caution. Survival data from clinical trials may have been obtained from a patient population that differs from that of SEER patients in prognostic factors for the given cancer; any survival comparisons would have to adjust for such differences. Also, it is necessary to verify that the methodology used in computing survival is the same for both data sources. Furthermore, patients on clinical trials may differ from SEER patients in characteristics that may be related to survival but are not recorded in either database. If this were true for a given cancer, it would not be possible to make valid comparisons of this type.

Errors in data collection: In the process of registering cancer patients, errors may be made in abstracting and coding the data, which include demographic information, cancer site, histology, extent of disease, treatment, and patient survival. Quality control studies are periodically carried out to detect and correct this type of error, but no attempt is made to incorporate this source of error into the variance estimates of cancer rates reported here.

Comparison of this report with previous reports: The cancer registries that participate in the SEER Program submit data on all cancers diagnosed in their coverage areas to the NCI each
Because of the dynamic nature of the registries' databases, the reported number of new cancer cases in a particular race, sex, age, cancer category in a given calendar year may change from that which has been reported in a previous publication. For a given diagnosis year, additional cancer cases that were previously overlooked may have been found and reported to the central registry. There may have been follow-back of cancers diagnosed by death certificate only; successful efforts to establish the dates of diagnosis for such patients will change the number of patients reported for a given diagnosis year. Code changes may occur when a patient dies; for example, information on race is generally available on the death certificate and may be used to update a previously unknown value. There may have been elimination of duplicate records for the same patient, often due to name changes or misspellings.

Thus, a recent report may have a different number of cases for a given diagnosis year than an earlier report, with resulting effects on incidence and possibly survival. Population estimates may also change from one report to another for some calendar years. This occurs because the NCI receives population estimates that are regularly revised and updated by the Bureau of the Census (BOC). Such changes may result in some differences between incidence and mortality rates for a given calendar period as published in different reports. See our website for the most current information about the population estimates (http://seer.cancer.gov/popdata/).

REFERENCES

TECHNICAL NOTES

There are four measures commonly used to assess the impact of a cancer in the general population and are reported in this review. The incidence rate is the number of new cases per year per 100,000 persons. The death (or mortality) rate is the number of deaths per year per 100,000 persons. The survival estimate is the proportion of patients alive at some point subsequent to the diagnosis of their cancer. The prevalence count is the number of people alive that have ever been diagnosed with a cancer. The Surveillance, Epidemiology, and End Results (SEER) Program (http://seer.cancer.gov) (based within the Surveillance Research Program (SRP) at the National Cancer Institute (NCI) collects incidence and survival data for all areas that participate in the Program. The National Center for Health Statistics (NCHS) provides mortality data for the entire United States (US). All incidence and mortality rates in this report are age-adjusted (see below) to the 2000 US standard population (see Appendix) unless otherwise specified. Age-adjustment minimizes the effect of a difference in age distributions when comparing rates.

THE SEER PROGRAM

The National Cancer Act of 1971 mandated the collection, analysis, and dissemination of data useful in the prevention, diagnosis, and treatment of cancer. This mandate led to the establishment of the SEER Program. The population-based cancer registries participating in NCI’s SEER Program routinely collect data on all cancers occurring in residents of the participating areas. Trends in cancer incidence and patient survival in the US are derived from this database. See the SEER Research Data (http://seer.cancer.gov/data/) for more information.

The SEER Program is a sequel to two earlier NCI programs—the End Results Program and the Third National Cancer Survey. The initial SEER reporting areas were the States of Connecticut, Iowa, New Mexico, Utah, and Hawaii; the metropolitan areas of Detroit, Michigan, and San Francisco-Oakland, California; and the Commonwealth of Puerto Rico. Case ascertainment began with January 1, 1973, diagnoses.

In 1974-1975, the program was expanded to include the metropolitan area of New Orleans, Louisiana, the thirteen-county Seattle-Puget Sound area in the State of Washington, and the metropolitan area of Atlanta, Georgia. New Orleans participated in the program only through the 1977 data collection year. In 1978, ten predominantly African-American counties in rural Georgia were added. American Indian residents of Arizona were added in 1980. In 1983, four counties in New Jersey were added with coverage retrospective to 1979. New Jersey and Puerto Rico participated in the program until the end of the 1989 reporting year. The National Cancer Institute also began funding a cancer registry that, with technical assistance from SEER, collects information on cancer cases among Alaska Native populations residing in Alaska. In 1992, the SEER Program was expanded to increase coverage of minority populations, especially Hispanics, by adding Los Angeles County and four counties in the San Jose-Monterey area south of San Francisco. In 2001, the SEER Program expanded coverage to
include Kentucky, Greater California (the counties of California that were not already covered by SEER), New Jersey, and Louisiana. In 2012, Greater Georgia (the parts of Georgia not included in Atlanta and Rural Georgia) was added to the SEER Program, with data retroactive to 2000.

The long-term incidence trends and survival data for this report are from five states (Connecticut, Hawaii, Iowa, New Mexico, and Utah) and four metropolitan areas (Detroit, Atlanta, San Francisco-Oakland, and Seattle-Puget Sound) (Fig. I-1); this set of registries is called the SEER 9. Additional tables show more recent incidence trends for the SEER 13 areas (the 9 areas above plus Los Angeles, San Jose-Monterey, Alaska Native Registry, and rural Georgia) since 1992 and additional information on race and ethnicity. Other tables give statistics for the SEER 18 areas; these are the SEER 13 plus Kentucky, Greater California, New Jersey, Louisiana, and Greater Georgia.

The participating regions were selected principally for their ability to operate and maintain a population-based cancer reporting system and for their epidemiologically significant population subgroups. With respect to selected demographic and epidemiologic factors, they are when combined a reasonably representative subset of the US population. Data from the 9, 13, or 18 SEER geographic areas are used in this report; the given groups contain, respectively, approximately 9, 14, or 28 percent of the US population. By the end of the 2011 diagnosis year, the database of the 18 SEER registries (plus Arizona Indians) contained information on over 7 million cases diagnosed since 1973. New cases added in the most recent data year numbered over 449,000.

The goals of the SEER Program are:
1) to assemble and report, on a periodic basis, estimates of cancer incidence, mortality, survival, and prevalence in the US;
2) to monitor annual cancer incidence trends to identify unusual changes in specific forms of cancer occurring in population subgroups defined by geographic and demographic characteristics;
3) to provide continuing information on trends over time in the extent of disease at diagnosis, trends in therapy, and associated changes in patient survival; and
4) to promote studies designed to identify factors amenable to cancer control interventions, such as: (a) environmental, occupational, socioeconomic, dietary, and health-related exposures; (b) screening practices, early detection and treatment; and (c) determinants of the length and quality of patient survival.

DATA SOURCES

INCIDENCE AND SURVIVAL DATA

The SEER Program contracts with nonprofit, medically-oriented organizations having statutory responsibility for registering diagnoses of cancer among residents of their respective geographic coverage areas. Each SEER contractor:
1) maintains a cancer information reporting system;
2) abstracts records for resident cancer patients seen in every hospital both inside and outside the coverage area;
3) abstracts all death certificates of residents (dying both inside and outside the coverage area) on which cancer is listed as a cause of death;
4) strives for complete ascertainment of cases by searching records of private laboratories, radiotherapy units, nursing homes, and other health services units that provide diagnostic service;
5) registers all in situ and malignant neoplasms (with the exceptions of certain histologies for cancer of the skin and—beginning in 1996—in situ neoplasms of the cervix uteri);
6) records data on all newly diagnosed cancers, including selected patient demographics, primary site, morphology, diagnostic confirmation, extent of disease, and first course of cancer-directed therapy;
7) provides active follow-up on all living patients (except for those with in situ cancer of the cervix uteri);
8) maintains confidentiality of patient records;
9) at least annually submits electronically to NCI data on all reportable diagnoses of cancer made in residents of the coverage area.

For 1992 to 2000 diagnoses, the SEER program codes site and histology by the International Classification of Diseases for Oncology, second edition (ICD-O-2) (Percy et al., 1990). All cases before 1992 were machine-converted to ICD-O-2. Cases diagnosed 2001-2009 have been coded according to the third edition (ICD-O-3) (Fritz et al., 2000). Starting with patients diagnosed in 2007, the new multiple primary and histology coding rules may impact their incidence data for some cancer sites (e.g., female breast). However, the impact of the new rule on observed incidence is negligible for a majority of the cancer sites. To learn more about the multiple primary rules, visit: http://seer.cancer.gov/tools/mphrules/. Beginning with 2010 diagnoses, cases are coded based on ICD-O-3 updated for hematopoietic codes based on WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues (2008). The primary site groupings used for incidence are found in the Appendix. Changes were made to the site recode for ICD-O-2 for comparability with cases coded to ICD-O-3. Follow-up rates are also in the Appendix.

Underreporting Adjustment for Veterans Affairs Cases: A CSR section on Department of Veterans Affairs (VA) underreporting (Howlader et al., 2009) was included in recent versions of the CSR. As of the current CSR this section was removed since available evidence indicates that VA underreporting is resolved as of diagnosis year 2010. The section of the CSR introduction about the reporting delay describes measures to address any backlog of VA cases reported after the initial reporting year.

Excluded cancers: Some cancers were excluded from most of the analyses. Myelodysplastic syndrome (MDS), for example, was reclassified in ICD-O-3 (effective diagnosis year 2001) from nonmalignant to malignant; other cancers so reclassified include endometrial stromal sarcoma (low grade), papillary ependymoma, papillary meningioma, polycythemia vera, chronic myeloproliferative disease (NOS), myelosclerosis with myeloid metaplasia,
essential thrombocythemia, refractory anemia, refractory anemia with sideroblasts, refractory anemia with excess blasts, and refractory anemia with excess blasts in transformation. In contrast, borderline tumors of the ovary were reclassified from malignant to nonmalignant at the same time. In addition, benign brain/CNS tumors were collected beginning for 2004 diagnoses. All of these cancers were excluded from most of the analyses, especially time trends. Pilocytic astrocytoma, although reclassified in ICD-O-3, was not excluded. Separate tables for MDS and benign brain/CNS are shown.

MORTALITY DATA

The SEER Program annually obtains from the National Center for Health Statistics (NCHS) a file containing information on all deaths occurring in the US by calendar year. Information on each death includes age at death, sex, geographic area of residence, and underlying and contributing causes of death. For this publication, only the underlying cause of death is used in the calculation of death rates. Cause of death for 1969-1978 was coded according to ICD-8; for 1979-1998, ICD-9 was used; beginning with deaths in 1999, ICD-10 was used. Mortality rates for the SEER geographic areas, for each state, and for the entire US are obtained from these data. A list of the mortality site groupings used in this publication is in the Appendix and reflects updates made in 2004.

POPULATION DATA

The population estimates used in the SEER*Stat software to calculate cancer incidence and mortality rates for this report are a modified version of the intercensal and Vintage 2011 annual time series of July 1 county population estimates by age, sex, race, and Hispanic origin that are produced by the Population Estimates Program of the US Census Bureau (http://www.census.gov/popest/) with support from the NCI through an interagency agreement. Descriptions of the methodologies employed by the Census Bureau for various sets of estimates may be found on the same website. Vintage 2011 population estimates were used; these estimates were developed from the actual 2010 census results.

County population estimates for 2000 and later years must be bridged from 31 race categories used in Census 2000 to the four race categories specified under the 1997 OMB standards in order to report long-term cancer trends. The bridging methodology was developed by the National Center for Health Statistics and is described in a report (Ingram et al., 2003) and on their website http://www.cdc.gov/nchs/nvss/bridged_race.htm

Modifications made by the NCI to the population estimates are documented in “Population Estimates Used in NCI’s SEER*Stat Software” (http://seer.cancer.gov/popdata/methods.html) and the population data files are available for download (see “Download US Population Data” from http://seer.cancer.gov/popdata/download.html). Several of the modifications pertaining to the grouping of specific counties needed to assure the compatibility of all incidence, mortality and population datasets. Another modification affects only population estimates for the State of Hawaii. The Epidemiology Program of the Hawaii Cancer Research Center has developed its own set of population estimates, based on sample survey data collected by the Hawaii
Department of Health. This effort grew out of a concern that the native Hawaiian population has been vastly undercounted in previous censuses. The "Hawaii adjustment" to the Census Bureau's estimates has the net result of reducing the estimated white population and increasing the estimated Asian and Pacific Islander population for the state. The estimates for the total population, black population, and American Indian and Alaska Native populations in Hawaii are not modified.

The cancer incidence and mortality rates for American Indians and Alaska Natives (AI/AN) are based on the geographic areas (counties) included in the Indian Health Service's Contract Health Service Delivery Area (CHSDA). This reflects a concern that previously reported AI/AN rates were underestimated due to racial/ethnic misclassification of American Indian cases in geographic areas outside of CHSDA. This change has the net effect of higher, and more accurate, incidence and mortality rates for this population. Beginning in 2013, CSR reporting diagnoses 1975-2010, CHSDA counties were updated with 9 new counties designated as CHSDA. Four of these are in SEER areas. This addition was made to better reflect AI/AN populations that had been living in these counties.

Usually the use of a population estimate for July 1 of a particular year reflects the average population of that area for the year. Both Hurricane Katrina and Hurricane Rita struck the Gulf Coast area of the United States in 2005. This had the effect of displacing large populations. Since there weren't any population estimates by age, race, sex, and county for time periods just after the hurricanes, it is very difficult to estimate the actual population at risk for certain areas along the Gulf Coast for 2005. For Louisiana, only the first six months of incidence data for 2005 coupled with ½ of the population estimate for July 1, 2005, were used to calculate cancer incidence. For death rate calculations, no adjustments were made to the total US population, but for the Gulf area, an adjustment for displaced populations was made for 2005 state rates. For more details, see http://seer.cancer.gov/popdata/methods.html.

2000 US STANDARD POPULATION

Starting with the November 2004 SEER submission of data (diagnoses through 2002), the SEER Program age-adjusts using the 2000 US standard population based on single years of age from the Census P25-1130 series estimates of the 2000 US population (Day, 1996). For the CSR, 19 age groupings were used for age-adjustment: <1, 1–4, 5–9, … , 80–84, 85+.

STATISTICAL METHODS

ESTIMATED CANCER CASES AND DEATHS IN 2014

The American Cancer Society (ACS) projects the numbers of new cancer cases and cancer deaths in the US in 2014 (American Cancer Society, 2012). The ACS projects incidence in 2014 based on incidence rates for 1995-2009 from 49 states and the District of Columbia, representing about 98% of the US population. These high-quality incidence data were submitted to the North American Association of Central Cancer Registries (NAACCR) by 49 states (and District of Columbia) belonging to the SEER Program and/or the National Program of Cancer
Registries (NPCR). For additional details please refer to
http://www.cancer.org/docroot/STT/STT_0.asp

LONG-TERM TRENDS, 1950-2011

Trends in cancer mortality from 1950 to 2011 are summarized by age both for all cancers combined and for lung cancer (Table 1-2). These cancer mortality trends are based on the mortality experience in the entire US. Summaries of long-term trends back to 1950 in cancer survival are also shown for whites.

Use caution when interpreting these statistics. Evaluating trends over a long period of time may hide recent changes in the trends.

YEARS OF LIFE LOST DUE TO PREMATURE DEATH FROM VARIOUS CAUSES

Death rates alone give an incomplete picture of the burden that deaths impose on the population. Another measure is the years of life lost due to premature death. This shows the extent to which life is cut short by a particular cause or disease.

This measure is estimated by linking life table data to each death of a person of a given age and sex. The life table permits a determination of the number of additional years an average person of that age, race, and sex would be expected to live. In this report, the age groups used in the calculation were 1-year intervals. These remaining years of life left are summed over all deaths due to a particular cause, yielding the estimate of the number of person-years of life lost (PYLL). The average years of life lost (AYLL) is obtained by dividing the PYLL by the number of deaths. Both of these measures can be calculated for any cause of death.

RELATIVE SURVIVAL

Relative survival (Ederer, 1961) was developed to provide an objective measure of the probability of survival of cancer in the absence of other causes of death. It is a measure that is not influenced by changes in mortality from other causes and, therefore, provides a useful measure for both tracking survival across time and comparisons between racial/ethnic groups or between registries. For most cancer registries, cause-of-death information obtained from death certificates is either unavailable or unreliable due to misclassification error. Therefore, instead of calculating the probability of surviving cancer in the usual (cause-specific) way, considering deaths from other causes as censoring events, relative survival compares the observed survival proportion of a group of cancer patients with the survival of a “similar” theoretical cancer-free group. Relative survival is formally defined as the ratio of the observed survival (all causes of death) of a cohort of cancer patients to the expected survival of a comparable set of cancer-free individuals. Since a cohort of cancer-free individuals is difficult to obtain, life tables representing survival of the general population are used instead. The underlying assumption is that the cancer deaths are a negligible proportion of all deaths. To learn more on this topic, visit:
Expected survival can be calculated using different methods which vary with respect to the definition of the matching group. The three most common methods are: Ederer I (Ederer, et al., 1961), Ederer II (Ederer and Heise, 1959) and Hakulinen (Hakulinen, 1982). In previous versions of SEER*Stat, relative survival has been calculated using Ederer I and Hakulinen methods, Ederer I being the default for calculations in the Cancer Statistics Review. In the Ederer I and Hakulinen methods, theoretical individuals are matched to each patient and are considered to be at risk for the entire follow-up. Hakulinen adjusts for potential follow-up times. Relative survival using expected rates derived via these two methods are very similar. However, recent research on relative survival has resuscitated the initial method to estimate expected rate: the Ederer II method. Although none of the three methods can be considered a gold standard, the Ederer II method has been shown to be in better alignment with the concept of net cancer survival. For that reason, as of 2011, we have switched to Ederer II as our default choice for calculating expected rate in SEER*Stat and the CSR. For more detail regarding this topic, read Cho et al., 2011 at: http://surveillance.cancer.gov/reports/. As of 2013, Survival time was calculated using pre-calculated months based on the exact day information. See http://seer.cancer.gov/survivaltime/. As of 2014, the default censoring age for survival calculations has changed from 199 to 99 year when using newly available expected survival tables. Minimal changes may occur in survival for older age groups. See http://seer.cancer.gov/expsurvival/ for more information.

CAUSE-SPECIFIC SURVIVAL

Cause-specific survival is a net-survival measure representing survival of a specified cause of death in the (theoretical) absence of other causes of death. Estimates are calculated by specifying the cause of death. Individuals who die of causes other than the specified cause are censored. This requires a cause-of-death variable that accurately captures all causes related to the specific cause. Cancer registries use algorithms to process causes of death from death certificates in order to identify a single, disease-specific, underlying cause of death. In some cases, attribution of a single cause of death may be difficult and misattribution may occur. For example, a death may be attributed to the site of metastasis instead of the primary site (Percy et al., 1981).

To capture deaths related to the specific cancer but not coded as such, the SEER cause-specific death classification variable is defined by taking into account causes of deaths in conjunction with tumor sequence (i.e., only one tumor or the first of subsequent tumors), site of the original cancer diagnosis, and comorbidities (e.g., AIDS and/or site-related diseases). To learn more on this topic, please read the recent article published at the Journal of National Cancer Institute (Howlader et al., 2010) or visit: http://seer.cancer.gov/causespecific/.

CANCER PREVALENCE

Methods: In this report prevalence is calculated at 1/1/2011. Limited-duration prevalence is calculated using the counting method implemented in the SEER*Stat software. This method calculates the number or proportion of people alive at the prevalence date who had a diagnosis of the disease within the past x years (e.g., x = 5, 10, 20, or the full history of the registry).
Because SEER has available information for the various racial/ethnic groups for different numbers of years, different years and registries were used to estimate limited-duration prevalence. Prevalence estimates for all races combined, for whites, and for blacks use cases from 1975 through 2010 from the SEER 9 registries; prevalence estimates for Asian Pacific Islanders and Hispanics use cases diagnosed from 1990 through 2011 from the SEER 11 areas and rural Georgia.

The limited-duration prevalence method includes a correction for people lost to follow-up. For each individual lost to follow-up, a probability of being alive at the prevalence date is estimated from an appropriate survival function stratified by age at diagnosis (0–59, 60–69, 70+), sex, cancer site, year of diagnosis, and race, conditional on being alive at the time of loss to follow-up. Year of diagnosis is stratified into 5-year groups from the prevalence date, with the least recent interval being of varying length (4-8 years), depending on the length of years used to calculate prevalence. Race is stratified into white, black, other (American Indian/Alaska Native, Asian/Pacific Islander), and unknown/other-unspecified. When we use the SEER 11 registries, the same stratification as before is used, with American Indian/Alaska Native separated from Asian/Pacific Islander. Prevalence calculations for Hispanics use race stratified into: white, non-white, and unknown.

Different methods can be used to determine which tumors are to be included for people diagnosed with multiple tumors. Unless otherwise specified, prevalence calculations include only the first malignant tumor per person; that is, in situ cancers and second-or-later primary cancers were not included. Thus, if a woman had a melanoma prior to a breast cancer diagnosis, her melanoma would contribute to the prevalence of melanoma and to the prevalence of all sites, but the breast cancer would not contribute to the prevalence of breast cancer. Counting only one cancer per individual avoids some ambiguity in prevalence counts, and allows the counts for individual sites to sum to the all sites total. Prevalence using different selection criteria is compared in a table in the overview chapter. For more information on tumor selection criteria refer to http://surveillance.cancer.gov/prevalence/methods.html.

Complete prevalence is an estimate of the number of persons (or the proportion of population) alive on a specified date who had been diagnosed with the given cancer, no matter how long ago that diagnosis was. It was estimated for all races, whites, and blacks by applying the completeness index method (Capocaccia & De Angelis, 1997; Merrill et al., 2000; Mariotto et al., 2002) to limited-duration prevalence. The completeness index method is implemented in the COMPREV software, which can be found at http://surveillance.cancer.gov/comprev/. Validation of the completeness index for all races and for whites was made by using data from the Connecticut Tumor Registry (CTR) beginning with 1940. For blacks, SEER 9 data beginning with 1975 were used; identification of blacks is not possible in the CTR data prior to 1970. To validate the completeness index for blacks, we have compared the performance of the method to obtain 24-year prevalence from 10-year limited-duration prevalence. For all races combined and for whites, in cases where the validation indicated some lack of fit of the model, an approximation to the completeness index was derived from the CTR data. If there was a lack of
fit for blacks, no estimate of complete prevalence was reported. Complete prevalence for Asian/Pacific Islanders and Hispanics is not available at this time. Complete prevalence by age for all races combined was validated by comparing estimated 10-year complete prevalence with observed prevalence from the CTR data. Prevalence by age is reported for the sites that validated well.

The US cancer prevalence counts at 1/1/2011 were estimated by multiplying the SEER age- and race-specific prevalence proportions by the corresponding US population estimates based on the average of 2010 and 2011 population estimates from the US Census Bureau. US cancer prevalence counts for all races were estimated by summing the US estimated counts for whites/unknown, blacks, and other races. For Hispanics, the estimates for Hispanics of white or unknown race and for Hispanics of other races were summed.

Complete prevalence estimates of the number of individuals in the US diagnosed with cancer as children (ages 0-19), including those surviving for more than 36 years, is calculated using a statistical method that estimates the number of childhood survivors diagnosed before 1975 (Simonetti et al., 2008; Mariotto et al., 2009). Limited-duration prevalence proportions by age at prevalence are not shown for childhood cancers (age at diagnosis 0-19) since many of these estimates are not informative. For example, the number of people diagnosed with childhood cancers in the last 25 years and who are currently age 50-59 is zero by definition. For more details on available prevalence estimates, see http://surveillance.cancer.gov/prevalence/.

The overview chapter contains two prevalence tables. The first table reports US complete prevalence counts by age at prevalence and sex for some main cancer sites. The second table reports US prevalence counts for people diagnosed in the 5 years and 36 years prior to the prevalence date using different tumor inclusion criteria. Each site-specific chapter contains a prevalence table that reports limited-duration US prevalence counts by time since diagnosis for different racial/ethnic groups. US complete prevalence estimates are also reported when available. The second part of the site-specific tables displays the percent of the population in the SEER 11 areas diagnosed in the previous 19 years with the specific cancer by 10-year age groups for the different racial/ethnic groups.

**PROBABILITY OF BEING DIAGNOSED WITH OR DYING FROM CANCER**

*Lifetime and interval risks of being diagnosed with cancer:* The probability of being diagnosed with cancer is computed by applying cross-sectional age-specific 2008-2011 incidence rates from the SEER 17 areas and death rates from those same areas to a hypothetical cohort of 10,000,000 live births. This cohort is considered to be at risk for two mutually exclusive events: (1) developing the specified cancer, and (2) dying of other causes without developing the specified cancer. Using these two types of events, a standard multiple decrement life table (with 20 age groups from 0-4 to 90-94 and 95+) is derived. For each age interval, the number alive and free of the specified cancer at the beginning of the interval is decremented by the number who develop the specified cancer and the number who die of other causes. The lifetime
risk of being diagnosed with the specified cancer is derived by summing all cancer cases from age 0-4 through age 95+ and dividing by 10,000,000. This calculation does not assume that an individual lives to any particular age; rather, it is the sum over all age intervals of the probability of living to the beginning of that interval without developing the given cancer times the probability of developing the cancer in that interval. The probability of developing cancer during any time period (e.g., between age 50 and age 60) is calculated by adding up all the cancers in the life table over the specified age range and dividing by the number of individuals alive and free of the specified cancer at the beginning of the period. The methodology is described in detail in (Fay et al., 2003) and (Fay, 2004). To improve the precision of the calculations, rates were calculated beyond the usual last open ended age interval (i.e. 85+) for the age groups 85-89, 90-94, and 95+.

**Lifetime risk of dying from cancer:** The lifetime risk of dying from a specified cancer is derived using a standard multiple decrement life table (Elandt-Johnson & Johnson, 1980). For each age, the risks of dying of the specified cancer and of all other causes are calculated, based on mortality data from the entire United States.

**Detailed methodology and software:** The estimates of developing and dying from cancer are implemented in DevCan (Probability of DEVeloping or dying from CANcer software). More details on the software, various databases, and the methodology can be found at [http://surveillance.cancer.gov/devcan/](http://surveillance.cancer.gov/devcan/).

**US CANCER DEATH RATES BY STATE**

Each cancer-site-specific section presents the death rate for the given cancer for each state and the District of Columbia, specifying the five highest and the five lowest death rates by state for the most recent 5-year period for all persons, males only, and females only. The rates are per 100,000 persons; they are age-adjusted to the 2000 US standard population. (In some previous editions of the CSR, the 1970 US standard million population was used; death rates standardized to the 2000 US standard million population cannot be compared to death rates standardized to the 1970 US standard million population.)

The **percent difference (PD)** between a state rate and the rate for the total US is given by the formula:

\[
PD = \frac{\text{(State Rate} - \text{Total US Rate})}{\text{Total US Rate}} \times 100
\]

The **standard error** for each age-adjusted state death rate is calculated, based on the assumptions that (1) for each age-specific rate, the number of deaths is a Poisson random variable (Keyfitz, 1966) and (2) the variance of the age-adjusted rate is a linear combination of the variances of the age-specific rates (Snedecor & Cochran, 1980; pp. 188-9).

The **standard error of the difference (SEd)** between a state rate and the total US rate is given
Appendix 1397

by the formula

\[ SE_d = \text{Square Root of} \left( SE_s^2 + SE_U^2 - 2 \times \text{Cov}_{s,U} \right) \]

where \( SE_s \) and \( SE_U \) are the standard errors of a state rate and of the total US rate, respectively, and \( \text{Cov}_{s,U} \) is the covariance between the two rates. The variance of each rate (i.e., the square of the standard error) and the covariance between the two rates are based on the Poisson assumption. The standard error does not represent the total error that may be present in the age-adjusted rate; it is merely the square root of the variance associated with the rates. In addition to this variance, there also exist potential biases and errors in the measurement of the rate that are difficult to assess accurately and probably impact differently on the error calculations for different states.

The difference between each age-adjusted state rate and the age-adjusted US rate is tested for statistical significance (see below) by calculating a \( Z \) (standard normal) statistic from the formula:

\[ Z = \frac{\text{State rate} - \text{Total US rate}}{SE_d} \]

Although the rates being compared are not independent because each state is part of the US, the statistical test may not be substantially affected if the state represents a small proportion of the total US. There is also an adjustment for multiple comparisons; see below under Statistical Significance.

JOINPOINT REGRESSION ANALYSIS OF CANCER TRENDS

An advance in the presentation of cancer trends is the use of joinpoint models (Kim et al., 2000). In some past issues of the Cancer Statistics Review, certain time intervals (e.g., 1973–1996) were specified and the annual percent changes (APC) were computed over those intervals. The choices of where to start and where to end an interval were arbitrary and sometimes did not give an accurate picture of the trend for a given cancer site. For example, the rates might be increasing and decreasing in different parts of the same interval. For some sites, increases occurred in the earlier years, followed by declines in more recent years.

To achieve greater descriptive accuracy, a statistical algorithm finds the optimal number and location of places where a trend changes. The point (in time) when a trend changes is called a joinpoint. Trends may change in different ways at a joinpoint: from up to down, from down to up, from up to up at a different rate, or from down to down at a different rate. A joinpoint regression model describes the trends by a continuous, piecewise-exponential function. Adjacent segments are connected at a joinpoint. The segments are connected because we assume that rates generally change smoothly, rather than “jump” abruptly. In each segment, the rates are assumed to grow or decay exponentially \((y = e^{mx+b})\), i.e., to change by a constant percentage each year. Thus the “slope” \(m\) in each segment can be associated with a fixed annual percent change (APC) by \( APC = 100(e^m - 1) \).

Joinpoint analysis first assumes no joinpoints are needed to describe the data accurately, i.e.,
the trend over the entire interval 1975-2011 does not change. Joinpoints are added in turn if they are statistically significant. Thus, in the final model, each joinpoint represents a significant change in trend. Smoother polynomial models may provide a good fit overall, but are less sensitive to what is occurring at the ends of the data.

In running the Joinpoint program, we set the program parameters as follows:

1. Joinpoints occur only at exact years; the joinpoint is not necessarily the same as the data point for that year;
2. The minimum time interval between consecutive joinpoints is three years;
3. The first joinpoint is not earlier than two years after the first year of data;
4. The last joinpoint is not later than two years before the last year of data;
5. The maximum number of joinpoints is five for 1975-2011 (SEER 9) data and three for 1992-2011 (SEER 13) data.

These restrictions provide some added stability to the resultant models. Different values for these parameters may yield a different joinpoint model. Since the test statistic to determine if additional joinpoints are necessary cannot be compared against any known standard distribution to determine significance (e.g., the normal, t, or f), a permutation test is used which simulates the distribution of the test statistic under the null hypothesis. Thus an element of randomness is introduced by the random number stream used. However, for greater consistency in the p-values obtained if one were to change the random seed for each run, we run the program for 4499 permutations.

A Windows-based program, Joinpoint, is freely available at http://surveillance.cancer.gov/joinpoint; it accepts data from the SEER*Stat program, as well as user-defined data. Further details on joinpoint regression may be found at the website. Starting with the 2011 edition of CSR, we have generated all our cancer trend statistics using a Linux-based Joinpoint program as opposed to the downloadable Windows-based program. As a result of using a different platform, in rare instances the results (e.g., # of joinpoints) may differ.

Average Annual Percent Change (AAPC) is a summary measure of a trend over a pre-specified fixed interval based on an underlying joinpoint model. It allows us to use a single number to describe the average trend over a period of multiple years. It can be estimated even if the joinpoint model indicates that there were changes in trends during those years, since it is estimated as a geometric weighted average of the joinpoint APCs, with the weights equal to the lengths of each segment over the pre-specified fixed interval. In this report, we have included AAPCs as an addendum to the underlying joinpoint trends, and as a summary measure to compare fixed interval trends by race/ethnicity. For more information on how the AAPC is calculated and the advantages of reporting an AAPC over APCs, see http://surveillance.cancer.gov/joinpoint/aapc.html.

REPORTING DELAY

Timely and accurate calculation of cancer incidence rates is hampered by reporting delay,
time lapse before a diagnosed cancer case is reported to the NCI or the delay in receiving updated information for an existing case. Currently, the NCI allows a standard delay of 22 months between the end of the diagnosis year and the time the cancers are reported to the NCI in November, almost two years later. The data are released to the public in the spring of the following year. For example, cases diagnosed in 2011 were first reported to the NCI in November 2013 and released to the public in April 2014. However, in each subsequent release of the SEER data, records from all prior diagnosis years (e.g., diagnosis years 2010 and earlier in the 2013 submission to the NCI) are updated as either new cases are found or new information is received about previously submitted cases.

The submissions for the most recent diagnosis year are, in general, about two percent below the total number of cancers that will eventually be submitted for that year, although this varies by cancer site and other factors.

The idea behind modeling reporting delay is to adjust the recent rates to anticipate future corrections (additions, changes, and deletions) to the data. These adjusted rates and the associated delay model are valuable in more precisely determining current cancer trends, as well as in monitoring the timeliness of data collection—an important aspect of quality control (Clegg et al., 2002). Reporting delay models have been previously used in the reporting of AIDS cases (Brookmeyer & Damiano, 1989; Pagano et al., 1994; Harris, 1990).

In this report, we show SEER age-adjusted incidence rates and trends, along with their calculated delay adjustments for SEER 9 and SEER 13 areas. The adjusted rates, factors, and trends are available for all cancers combined (malignant only except for urinary bladder), for female breast in situ, for urinary bladder (in situ and malignant combined), and for 22 malignant cancer sites: melanoma (for all races combined and whites only), lung/bronchus, colon/rectum, prostate, female breast, liver and intrahepatic bile duct, pancreas, cervix uteri, corpus and uterus, ovary, testis, kidney and renal pelvis, brain and other nervous system, Hodgkin lymphoma, non-Hodgkin lymphoma, all leukemias, esophagus, larynx, myeloma, oral cavity and pharynx, thyroid, and stomach.

For more information on cancer incidence rates adjusted for reporting delay, see http://surveillance.cancer.gov/delay/. Estimates of observed incidence rates, delay-adjusted incidence rates, and delay-adjustments factors may be found in the Cancer Query Systems at http://seer.cancer.gov/canques/.

Adjustment for VA Case Backlog, Submission Year 2011

A policy change of the Department of Veterans Affairs (VA) regarding data sharing on VA cancer cases resulted in underreporting on VA hospital cases for submission years 2007-2011. Some special adjustments to case counts are necessary to fit the delay adjustment model. Beginning with the 2009 submission of SEER data, some SEER registries began accounting for the backlog of VA cases that would have been reported in 2006-2008. This upsurge in cases could cause perturbation in the delay model if fit in the usual manner.
As with the 2009 to 2011 submissions, to take account of the effect of the VA backlog in the 2012 submission on the delay adjustment model, the counts are adjusted by re-distributing VA cases to previous submission years according to the expected counts from the delay distribution conditional on the current submission. Specifically, for each of the diagnosis years 2004-2009, given the total cancer count in submission year 2012, the proportion of cumulative cancer count in each subsequent submission year is calculated based on the estimated parameters from previous year’s reporting delay model. The VA cases in the 2012 submission are re-distributed to each of the prior submission years according to this proportion. The adjusted total cancer count in that submission year was then calculated by combining the non-VA cases and the re-distributed VA counts.

Delay-adjusted incidence rates and trends are reported for all cancers combined (malignant only except for urinary bladder), for female breast in situ, for urinary bladder (in situ and malignant combined), and for 22 malignant cancer sites: melanoma (for all races combined and whites only), lung/bronchus, colon/rectum, prostate, female breast, liver and intrahepatic bile duct, pancreas, cervix uteri, corpus and uterus, ovary, testis, kidney and renal pelvis, brain and other nervous system, Hodgkin lymphoma, non-Hodgkin lymphoma, all leukemias, esophagus, larynx, myeloma, oral cavity and pharynx, thyroid, and stomach.

**STATISTICAL SIGNIFICANCE**

Errors may be made in the estimation of a given statistic. In order to test whether two groups (such as the populations of a state and the entire US) have the same or different actual rates, the observed rates for the groups are compared. Statisticians consider that a difference in observed rates can be explained by one of two hypotheses: (H₀) The actual rates are really the same, but the observed rates are different because of some combination of error-causing factors, or (H₁) the actual rates of the groups are really different. H₀ is called the null hypothesis (because it says there is no real difference); H₁ is called the alternate hypothesis. Typically, H₀ is rejected only if there is strong evidence in favor of H₁. (Thus, if the observed rates are equal, we cannot reject H₀.)

Using statistical theory, one can determine the distribution of the rate difference under the assumption that H₀ is true. Then values of the rate difference that are very unlikely to occur if H₀ is true are identified. More specifically, a small positive number, called alpha (α), is chosen; usually, α is 0.05 or 0.01. (Alpha is called the significance level of the hypothesis test.) One can then identify limits for the difference in rates such that, if H₀ is true, the probability of the difference being outside of those limits is α. If the observed difference is outside of these limits, then the observed result is very unlikely to happen if H₀ is true, so H₀ is rejected.

Another way of looking at the same process is to calculate, assuming H₀ is true, the probability that the observed difference or any greater difference would occur; this number is called the P-value of the observed result. If the P-value of a comparison is less than α (that is, the observed difference is very unlikely to happen if the null hypothesis is true), H₀ will be rejected. If the P-value of a test is greater than the significance level α, H₀ will not be rejected. When a difference
in rates is sufficiently large to cause the null hypothesis to be rejected for a given value of \( \alpha \) (usually 0.05), it is called a **statistically significant** difference.

When a null hypothesis is rejected, there remains a small chance that a wrong decision has been made. If many statistical comparisons are done, even with \( \alpha = 0.01 \), the chance of making at least one wrong decision becomes a concern. In testing the differences between the total US rate and the rate for each state (or for the District of Columbia) for a given cancer, 51 statistical comparisons of the type described above are performed. Based on one of Bonferroni's inequalities (if there are \( n \) events and \( p_i \) is the probability of success in event \( i \), then \( P(\text{at least 1 success}) < p_1 + \ldots + p_n \) (Snedecor & Cochran, 1980; p. 115-117), the significance level \( \alpha \) for each individual comparison was set equal to \( 0.01/51 \approx 0.0002 \). Thus, only individual-state-to-total-US comparisons with an associated \( P \)-value less than 0.0002 are considered to be statistically significant. That is, a **very small** significance level \( \alpha \) (0.0002) is used in order to minimize the total risk (0.01) of falsely deciding that some pair of equal rates are unequal.

*Use caution in assessing statistically significant differences.* Population size has an important role in any calculation of statistical significance. Some states may have estimated rates that are very close to the estimated total US rate, but because of their large population, the difference between their estimated rate and the estimated total US rate is found to be statistically significant. In this case, the true state rate and the true US rate are almost certainly different, because the observed difference, though small, is nearly impossible if the null hypothesis (equal rates) is true. A small difference in rates, however, may have no practical importance. On the other hand, some smaller states may have estimated rates that differ substantially from the estimated total US rate, but because of their relatively small population, the differences are found to be statistically nonsignificant. When this happens, if the true state rate and the true US rate were equal, the probability of obtaining a difference at least as large as what has been observed is greater than \( \alpha \approx 0.0002 \). Therefore, *because the evidence against it isn't strong enough, the null hypothesis (equal rates) is not rejected.*

If the percent difference (PD) between the two rates is small, there may be some question about the importance of the difference. It is difficult to specify a minimally significant absolute PD, below which the difference would always be unimportant, because the observed PD will depend on the populations of the areas involved. It may be of value to consider the size of the PD between a state rate and the US rate in assessing the importance of a statistically significant difference.

Comparing individual state rates with the US rate and assessing statistical significance is not an appropriate procedure for assessing geographic clustering of state rates. Identification of states which may represent regional clusters of high or low rates would require additional statistical and graphical analyses.

For a number of cancers, the District of Columbia has the highest death rates. *Use caution when comparing cancer rates for the District with those from the 50 states.* The District is an entirely urban area, whereas a state includes urban, suburban, and rural areas. Mortality rates
for many cancers are higher in urban areas. Also, the District has a higher percentage of blacks—51% of the total population in 2010 (US Census Bureau, 2013)—than any state. In addition, their higher mortality rates for several types of cancer elevate the overall rate for the District.

**STANDARD ERRORS OF RATES**

**Survival rates:** In the tables presenting survival estimates, the magnitude of the standard error is given as a measure of the reliability of a given rate: the greater the standard error, the more uncertainty associated with the estimated rate. In addition, if there were fewer than 25 diagnoses in the first interval of the life table constructed to calculate survival, or if all cases became lost to follow-up within an interval, a valid survival estimate could not be calculated, as is noted in the table footnotes.

The **standard error (SE)** of a relative survival estimate is obtained as follows (Ederer et al., 1961):

\[
SE(CR_t) = CR_t \times \text{square root of } \left[ \frac{q_1}{e_1-d_1} + \frac{q_2}{e_2-d_2} + \ldots + \frac{q_t}{e_t-d_t} \right]
\]

where \( CR_t \) is the \( t \)-year relative survival estimate, and for \( i = 1, \ldots, t \),
\( q_i \) is the probability of dying in year \( i \) after diagnosis,
\( e_i \) is the effective number of patients at risk in year \( i \) after diagnosis, and
\( d_i \) is the number of deaths in year \( i \) after diagnosis.

**Incidence and mortality rates:** The standard errors of age-adjusted incidence and mortality rates are often not specified. However, the reader can approximate the SE of a particular incidence or mortality rate by the SE of a crude incidence or mortality rate (Keyfitz, 1966), that is, the SE can be approximated by the rate divided by the square root of the number of cancer cases (or the number of deaths).

Appendix tables provide numbers of cancer diagnoses within SEER areas and numbers of deaths in the entire US, respectively, by race and sex for the most recent 5-year period. These can be used to obtain approximations of the standard errors for associated age-adjusted rates for the same time period using the above formula. To approximate the standard error of a rate for a single year, use the formula but replace the number of cancer cases or deaths with the number of cancer cases or deaths divided by 5.

**DEFINITIONS**

Several technical terms are used in presenting the data in this report. Their definitions are presented here to clarify them for the reader.

**Incidence rate:** The cancer incidence rate is the number of new cancers of a specific site/type occurring in a specified population during a year, usually expressed as the number of cancers
Appendix 1403

per 100,000 persons at risk. That is,

\[ \text{Incidence rate} = \left( \frac{\text{New cancers}}{\text{Population}} \right) \times 100,000. \]

The numerator of the incidence rate is the number of new cancers; the denominator of the incidence rate is the size of the population. The number of new cancers may include multiple primary cancers occurring in one patient. The primary site reported is the site of origin and not the metastatic site. In general, the incidence rate would not include recurrences. The population used depends on the rate to be calculated. For cancer sites that occur in only one sex, the sex-specific population (e.g., females for cervical cancer) is used.

The incidence rate can be computed for a given type of cancer or for all cancers combined. Except for 5-year age-specific rates, all incidence rates in this report are age-adjusted (see below) to the 2000 US standard population (or, where appropriate, to the world standard million population). (In some previous editions of the CSR, the 1970 US standard million population was used; therefore, incidence rates in this edition cannot be compared to rates published in those editions.) Incidence rates are for invasive cancer only, unless otherwise specified. (Exceptions are the incidence rate for cancer of the urinary bladder (where both in situ and invasive cancers are counted) and breast cancer in situ, which is shown separately.)

Death rate: The cancer death (or mortality) rate is the number of deaths with cancer given as the underlying cause of death occurring in a specified population during a year, usually expressed as the number of deaths due to cancer per 100,000 persons. That is,

\[ \text{Death Rate} = \left( \frac{\text{Cancer Deaths}}{\text{Population}} \right) \times 100,000. \]

The numerator of the death rate is the number of deaths; the denominator of the death rate is the size of the population. As with the incidence rate, the population used depends on the rate to be calculated. The death rate can be computed for a given cancer site or for all cancers combined. Except for 5-year age-specific rates, all death rates in this report are age-adjusted (see below) to the 2000 US standard population (or, where appropriate, to the world standard million population). (In some previous editions of the CSR, the 1970 US standard million population was used; therefore, death rates in this edition cannot be compared to rates published in those editions.)

Age distribution: A table showing a partition of the entire lifespan into disjoint age intervals, along with the proportion of the population in each interval.

Median age: The age at which half of a population is younger and half is older.

Standard population: A standard population for a geographic area, such as the US or the world, is a table giving the proportions of the population falling into the age groups 0, 1-4, 5-9, ..., 80-84, and 85+. A standard million population for a geographic area is a table giving the number of persons in each age group 0, 1-4, ..., 85+ out of a theoretical cohort of 1,000,000 persons that is distributed by age in the same proportions as the standard population. Table A-7 shows the US 2000 standard population and the world standard million population. (Some
World Health Organization mortality publications use a different world standard million population.)

**Age-adjusted rate:** An age-adjusted incidence or mortality rate is a weighted average of the age-specific incidence or mortality rates, where the weights are the counts of persons in the corresponding age groups of a standard population. The potential confounding effect of age is reduced when comparing age-adjusted rates based on the same standard population. For this report, the 2000 US standard population (or, where appropriate, the world standard million population) is used in computing age-adjusted rates, unless otherwise noted.

**Percent change:** The percent change (PC) in a statistic over a given time interval is

\[ \text{Percent change} = \frac{\text{Final value} - \text{Initial value}}{\text{Initial value}} \times 100. \]

A positive PC corresponds to an increasing trend, a negative PC to a decreasing trend.

**Annual percent change:** The annual percent change (APC) is calculated by first fitting a regression line to the natural logarithms of the rates (r) using calendar year (x) as a regressor variable. In this report the method of weighted least squares is used to calculate the regression equation. If \( \ln(r) = mx + b \) is the resulting regression equation (with slope \( m \)), then

\[ \text{APC} = 100 \times (e^m - 1). \]

A positive APC corresponds to an increasing trend, a negative APC to a decreasing trend.

Because the methods used in their calculation are mathematically different, *the signs of the PC and the APC for a given statistic and time interval may differ*, as occurs in a few of the tables presented. That is, one of these statistics may show an increasing trend, the other a decreasing trend.

Testing the hypothesis that the actual mean annual percent change is 0 is equivalent to testing the hypothesis that the theoretical slope estimated by the slope \( m \) of the line representing the equation \( \ln(r) = mx + b \) is 0. The latter hypothesis is tested using the \( t \) distribution of \( m / SE_m \) with \( n - 2 \) degrees of freedom. The standard error of \( m \), called \( SE_m \), is obtained from the fit of the regression (Kleinbaum et al., 1988). (This calculation assumes that the rates increased or decreased at a constant rate over the entire calendar year interval; the validity of this assumption was not assessed.) In those few instances where at least one of the rates was 0, the linear regression was not calculated.

**Average Annual Percent Change:** The average annual percent change (AAPC) is a summary measure of a trend over a pre-specified fixed interval based on an underlying joinpoint model. It allows us to use a single number to describe the average trend over a period of multiple years. It can be estimated even if the joinpoint model indicates that there were changes in trends during those years, since it is estimated as a weighted average of the joinpoint APCs, with the weights equal to the lengths of each subinterval over the pre-specified fixed interval.

**Life table:** A table for a given population listing, for each sex and each age from 0 to 120, how many members die at that age and how many survive one more year.
**Observed survival:** The observed survival estimate represents the proportion of cancer patients surviving for a specified time interval after diagnosis. Note that some of those not surviving died of the given cancer and some died of other causes.

**Relative survival:** The relative survival estimate is calculated using a procedure (Ederer et al., 1961; Ederer and Heise, 1959) whereby the observed survival estimate is adjusted for expected mortality. The relative survival estimate approximates the likelihood that a patient will not die from causes associated specifically with the given cancer before some specified time after diagnosis. It is always larger than the observed survival estimate for the same group of patients.

**Standard error:** The standard error of a rate is a measure of the sampling variability of the rate.

**Person-years of life lost:** The person-years of life lost (PYLL) is calculated as follows: For each individual who dies of the cancer of interest, the number of years of expected additional life for an average person of that age, race, and sex is obtained from life tables for the US population (available from the NCHS). The PYLL in the general population associated with a particular cancer for a given year is simply the sum of this expectation over all those individuals who died of that cancer in that year.

**Average years of life lost:** The average years of life lost (AYLL) associated with a particular cancer for a given year is the PYLL associated with that cancer in the general population divided by the number of deaths from that cancer in the general population in that year.

**Prevalence:** Prevalence is defined as the number or percent of people alive on a certain date in a population who previously had a diagnosis of the disease. It includes new (incident) and pre-existing cases and is a function of past incidence, past survival, and the size and age structure of the population. **Limited-duration prevalence** represents the proportion of people alive on a certain day who had a diagnosis of the disease within the past $x$ years (e.g. $x = 5, 10, \text{ or } 20$ years). **Complete prevalence** is an estimate of the number of persons (or the proportion of the population) alive on a specified date who had been diagnosed with the given disease, no matter how long ago that diagnosis was. For more details on cancer prevalence definitions and methods, refer to [http://surveillance.cancer.gov/prevalence/](http://surveillance.cancer.gov/prevalence/).

**Stage of disease at diagnosis:** Extent-of-disease information determines stage of disease at diagnosis. The **SEER summary stage** presented has four levels. An invasive neoplasm confined entirely to the organ of origin is said to be **localized**. A neoplasm that has extended beyond the limits of the organ of origin, either directly into surrounding organs or tissues or into regional lymph nodes, is said to be **regional**. A neoplasm that has spread to parts of the body remote from the primary tumor, either by direct extension or by discontinuous metastasis, is said to be **distant**. When information is not sufficient to assign a stage, a neoplasm is said to be **unstaged**. In situ tumors (except those of the cervix uteri) are also collected by SEER but generally are not published in this series. For some cancers and diagnosis years, the extent of
disease information can also be converted to Stages 0-IV as defined by the American Joint Committee on Cancer (Greene et al, 2002; Edge et al., 2010).

SOFTWARE USED TO GENERATE THE SEER CANCER STATISTICS REVIEW

The SEER Cancer Statistics Review includes statistics generated by a variety of statistical software including:

- **SEER*Stat**, statistical software for the analysis of SEER and other cancer databases, was used to generate incidence, mortality, prevalence, and survival statistics presented in the CSR.
- Analysis generated by the **Joinpoint Regression Program** are presented to better describe trends that are not constant over time.
- The **DevCan** system generated the probability of developing cancer from twelve SEER areas and the probability of dying from cancer from the total United States.
- The **ComPrev** software was used to calculate complete prevalence estimates.

Additional statistics can be obtained via SEER’s **Cancer Query Systems**. These data retrieval applications provide access to pre-calculated cancer statistics stored in online databases.

</table>

*Estimated deaths for colon & rectum cancers are combined.

More deaths than cases suggests lack of specificity in recording underlying causes of death on death certificates.

Cancer Facts & Figures - 2014, American Cancer Society (ACS), Atlanta, Georgia, 2014.

*Excludes basal and squamous cell skin and in situ carcinomas except urinary bladder.

Incidence projections are based on rates from the North American Association of Central Cancer Registries (NAACCR) from 1995-2010, representing about 89% of the US population.

*Estimated deaths are based on data from US Mortality Data, 1995-2010, National Center for Health Statistics, Centers for Disease Control and Prevention.

*Estimated deaths for colon & rectum cancers are combined.

*Estimated deaths for colon & rectum cancers are combined.

*Studies in situ accounts for about 63,770 new cases annually.

*More deaths than cases suggests lack of specificity in recording underlying causes of death on death certificates.

</table>

The APC is the Annual Percent Change over the time interval.  
Rates used in the calculation of the APC are age-adjusted to the 2000 U.S. standard population (18 age groups - Census P25-1130).  
Due to coding changes throughout the years: Colon excludes other digestive tract; Rectum includes anal canal; Liver & intrahepatic bile duct includes gallbladder & biliary tract, NOS; Lung & bronchus includes trachea & pleura; Ovary includes fallopian tube; Urinary bladder includes other urinary organs; Kidney & Renal pelvis includes ureter; NHL and myeloma each include a small number of leukemias; NHL includes a small number of ill-defined sites.

Survival estimates for 1950-54 are from NCI Survival Report 5 with the exception of All Sites, Oral cavity & pharynx, Colon & rectum, Non-Hodgkin lymphoma and Childhood cancers which come from historical Connecticut data.

Survival estimates for 2004-2010 are from the SEER 9 areas (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, and Atlanta).

Rates are based on follow-up of patients into 2011.

* The APC is significantly different from zero (p<.05).

The APC is the Annual Percent Change over the time interval. Trends are based on rates age-adjusted to the 2000 US Std Population (19 age groups - Census P25-1130).

a SEER 18 areas (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, Atlanta, San Jose-Monterey, Los Angeles, Alaska Native Registry, Rural Georgia, California excluding SF/SJM/LA, Kentucky, Louisiana, New Jersey and Georgia excluding ATL/RO).

b US Mortality Files, National Center for Health Statistics, Centers for Disease Control and Prevention.

c Ovary excludes borderline cases or histologies 8442, 8451, 8462, 8472, and 8473.

d Due to coding changes, Brain & Nervous System mortality are no longer shown separately.

* Trend not shown for mortality. Category did not exist in mortality coding until 1999.

* The APC is significantly different from zero (p<.05).

- Statistic could not be calculated. Trend based on less than 10 cases for at least one year within the time interval.

</table>

<sup>a</sup> Underlying incidence data for American Indian/Alaska Native are based on the CHSDA (Contract Health Service Delivery Area) counties.

<sup>b</sup> Hispanic is not mutually exclusive from whites, blacks, Asian Pacific Islanders, and American Indians/Alaska Natives.

<sup>c</sup> Underlying incidence data for Hispanics are based on NHIA and exclude cases from the Alaska Native Registry.

A percent or confidence interval value of 0.00 represents a value that is below 0.005.

</table>

\(^a\) U.S. 2011 cancer prevalence counts are based on 2011 cancer prevalence proportions from the SEER 9 registries and 1/1/2011 U.S. population estimates based on the average of 2010 and 2011 population estimates from the U.S. Bureau of the Census.

\(^b\) Prevalence estimates are ambiguous for those with multiple cancers, unless the tumor inclusion criteria are understood. Depending on the application, different inclusion criteria may be appropriate. This table provides three different methods of tumor inclusion:

\(^c\) First invasive tumor ever

\(^d\) First invasive tumor for each cancer site diagnosed during the previous 36 years (1975-2010)

\(^e\) First invasive tumor for each cancer site diagnosed during the previous 5 years (2006-2010)

\(^f\) Ovary excludes borderline cases or histologies 8442, 8451, 8462, 8472, and 8473.
Prevalence estimates are ambiguous for those with multiple cancers, unless the tumor inclusion criteria are understood. Depending on the application, different inclusion criteria may be appropriate. This table provides three different methods of tumor inclusion:

- **(c)** First invasive tumor ever
- **(d)** First invasive tumor for each cancer site diagnosed during the previous 36 years (1975-2010)
- **(e)** First invasive tumor for each cancer site diagnosed during the previous 5 years (2006-2010)

For definitions (d) and (e) all sites is treated as a separate cancer "site".

Consider a woman who had three invasive cancers: Melanoma in 1981; Breast cancer in 2006; Melanoma in 2007.

In method (c) the melanoma is the woman’s first cancer, and is counted for the melanoma and all sites 36-year limited duration prevalence. For 5-year limited duration prevalence, the woman is not counted at all since her first cancer occurred more than 5 years prior to 1/1/2011.

In method (d) the 1981 melanoma is counted for the melanoma and all sites 36-year limited duration prevalence. The 2006 breast cancer is counted for the breast 5-year and 36-year limited duration prevalence.

In method (e) the 2006 breast cancer is counted for the breast cancer and all sites 5-year limited duration prevalence. The 2007 melanoma is counted for 5-year limited duration prevalence for melanoma.

*a* U.S. 2011 cancer prevalence counts are based on 2011 cancer prevalence proportions from the SEER 9 registries (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, and Atlanta) and 1/1/2011 U.S. population estimates based on the average of 2010 and 2011 population estimates from the U.S. Bureau of the Census. Prevalence was calculated using the First Malignant Primary Only for a person.

*b* Cases diagnosed more than 36 years ago were estimated using the completeness index method (Capocaccia et. al. 1997, Merrill et. al. 2000).

*c* Due to rounding, the sum of the age specific estimates may not equal the all ages estimate.

Source: SEER 18 areas (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, Atlanta, San Jose-Monterey, Los Angeles, Alaska Native Registry, Rural Georgia, California excluding SF/SJM/LA, Kentucky, Louisiana, New Jersey and Georgia excluding AT/RO).  
\(^a\) Top 15 cancer sites selected based on 2007-2011 age-adjusted rates for the race/ethnic group.  
\(^b\) Rates are per 100,000 and age-adjusted to the 2000 US Std Population (19 age groups - Census P25-1130).  
\(^c\) The APC is the Annual Percent Change over the time interval.  
\(^d\) Trends are based on rates age-adjusted to the 2000 US Std Population (19 age groups - Census P25-1130).  
\(^e\) Rates for American Indian/Alaska Native are based on the CHSDA (Contract Health Service Delivery Area) counties.  
\(^f\) Hispanic is not mutually exclusive from whites, blacks, Asian/Pacific Islanders, and American Indians/Alaska Natives.  
\(^g\) Incidence data for Hispanics are based on HNTHA and exclude cases from the Alaska Native Registry.  
\(^h\) The rates for sex-specific cancer sites are calculated using the population for both sexes combined.  
\(^i\) IBD = Intrahepatic Bile Duct. ONS = Other Nervous System.  
\(^j\) Ovary excludes borderline cases or histologies 8442, 8451, 8462, 8472, and 8473.  
\(^k\) The APC is significantly different from zero (p < .05).  
\(^l\) Statistic not shown. Rate based on less than 16 cases for the time interval. Trend based on less than 10 cases for at least one year within the time interval.

Rates are age-adjusted to the 2000 US Std Population (19 age groups - Census P25-1103). Regression lines are calculated using the Joinpoint Regression Program Version 4.1.0, April 2014, National Cancer Institute.

Incidence rates for American Indian/Alaska Native (AI/AN) are based on the CHSDA(Contract Health Service Delivery Area) counties.

Hispanic is not mutually exclusive from whites, blacks, Asian/Pacific Islanders, and American Indians/Alaska Natives.

Incidence data for Hispanics are based on NHIA and exclude cases from the Alaska Native Registry.
