The SAGE Encyclopedia of CANCER AND SOCIETY

Second Edition
SAGE was founded in 1965 by Sara Miller McCune to support the dissemination of usable knowledge by publishing innovative and high-quality research and teaching content. Today, we publish more than 850 journals, including those of more than 300 learned societies, more than 800 new books per year, and a growing range of library products including archives, data, case studies, reports, and video. SAGE remains majority-owned by our founder, and after Sara's lifetime will become owned by a charitable trust that secures our continued independence.

About the Editor

Graham A. Colditz, M.D., Dr.PH, is Niess-Gain Professor of Surgery, and associate director of Prevention and Control at the Siteman Cancer Center, Washington University School of Medicine, in St. Louis, Missouri. He received his B.Sc., MBBS, and M.D. from the University of Queensland, Australia, and his doctorate in public health from the Harvard University School of Public Health.

From 1996 to 2006, Colditz was the principal investigator of the Nurses’ Health Study, one of the largest prospective investigations of factors that influence women’s health. He founded the Growing Up Today study (GUTS), which focuses on the diet and lifestyle of 16,883 adolescents. His epidemiologic research addresses issues of etiology and potential for prevention of chronic diseases, largely among women. He continues to pursue approaches to the translation of epidemiologic data to improve risk stratification and tailor prevention messages and screening strategies.

After 23 years at Harvard University, Colditz joined the Washington University School of Medicine, where he is now chief of the Division of Public Health Sciences in the Department of Surgery. He also serves as program director for the School of Medicine’s Master of Population Health Sciences degree.

With a commitment to identifying preventable causes of chronic disease among women and adolescents, Colditz continues to study benign breast disease and other markers for risk of breast cancer. He leads studies of adolescent diet, activity, and growth in relation to risk of benign lesions as well as invasive breast cancer. Colditz developed the award-winning Your Disease Risk Web site, which communicates tailored prevention messages to the public. He has published over 950 peer-reviewed publications, six books, and contributed to six reports for the Institute of Medicine, National Academy of Sciences.

Colditz has served in numerous leadership roles. He was the editor-in-chief of the journal Cancer Causes and Control and has contributed to reports of the U.S. Surgeon General on Tobacco and Health. He has served on several committees for the National Academy of Science and is a member of the Board of Scientific Advisors of the National Cancer Institute, among others.

In October 2006, on the basis of professional achievement and commitment to public health, Colditz was elected to membership of the Institute of Medicine, an independent body that advises the U.S. government on issues affecting public health. In 2011, he was awarded the American Cancer Society Medal of Honor for cancer control research. In 2012, he received the AACR-American Cancer Society Award for Research Excellence in Cancer Epidemiology and Prevention. In 2014, he was the recipient of the ASCO-American Cancer Society award and lecture.

Introduction

More than 12 million people were diagnosed with cancer worldwide in 2012, and more than 8 million people die from cancer each year. There is overwhelming evidence that lifestyle factors impact cancer risk and that positive, population-wide changes can significantly reduce the cancer burden. What drives the distribution of these modifiable risk factors and what slows our progress to improving the patterns of risk in our society? Broader social and political forces are a major component and are addressed in this encyclopedia. Not only do health care providers and regulatory approaches each have a role, but in addition individual behavior changes can substantially reduce the burden of cancer in our society. For example, how we design our cities and towns and how governments regulate and tax tobacco and alcohol sales all play a part in the risk of cancer in society.

Current epidemiologic evidence links behavioral factors to a variety of diseases, including the most common cancers diagnosed in the developed world—lung, colorectal, and breast cancer, for example. These cancers account for 50 percent of the cancers diagnosed in high-income countries. Tobacco causes some 30 percent of cancer, lack of physical activity 5 percent, obesity 20 percent, diet 10 percent, alcohol 3 to 5 percent, viral infections 5 to 7 percent, and excess sun exposure 3 percent. In low- and middle-income countries, infections account for more than 23 percent of new cases of cancer. Because of the tremendous impact of modifiable factors on cancer risk, especially for the common cancers, it has been estimated that at least 50 percent of cancers are preventable. Currently, in the United States, not all risk factors are really distributed across race and social class. Thus, we not only address the causes of cancer in this encyclopedia but we also have entries on the relation between race and ethnicity and cancer risk. Because race and social class also co-vary with occupation and environmental exposures, these areas are also addressed in detail.

Exposures at work have been related to cancer risk throughout history—from chimney sweeps and exposure to soot, to asbestos miners, to blast furnace operators. Many of these exposures have been reduced in Western society by regulations that reduce harm in the workplace. Within occupations, many different agents are still generated by manufacturing processes. These are described, and are related to occupations that give rise to carcinogens as they help produce the trappings of modern society. As regulations work to protect the West, are we simply exporting the manufacturing, occupational exposure, and cancer risk?

Trends in risk factors should also be considered when assessing the potential for cancer
prevention. To bring about dramatic reductions in cancer incidence, widespread lifestyle changes are necessary. Which strategies will likely work and how we can achieve these goals are further areas we must consider. To reduce the risk of disease in the population, substantial benefits can be achieved by a small reduction of risk for all members of society rather than just focusing on the high-risk group. Medical interventions can also reduce risk, and these are discussed in detail.

When population-wide approaches to cancer prevention are considered, one must address the etiologic process, which covers a different time course and sequence from coronary heart disease. Although cardiovascular disease is the endpoint of the chronic process of atherosclerosis, treatment focuses on the reversal and subsequent prevention of the acute thrombotic process of myocardial infarction. Cancer, on the other hand, is the result of a long process of accumulating DNA damage, leading ultimately to the clinical detectable lesion such as in situ and invasive cancer. For example, studies of the progression in colon cancer from the first mutation to invading malignancy suggest that DNA changes accumulate over a period of at least 40 years. The goal of cancer prevention is to arrest this progression; different interventions interrupt carcinogenesis at different points in the process.

Age is the dominant factor that drives cancer risk; for all major malignancies, risk rises markedly with age. The importance of age is exemplified by the fact that the aging U.S. population, together with projected population growth, will result in a doubling of the number of cases diagnosed annually by the year 2050, assuming that incidence rates remain constant. With this estimated growth in cancer from 1.3 million to 2.6 million new cases per year, it is expected that both the number and proportion of older persons with cancer will also rise dramatically. Entries in this encyclopedia help place this increase in cancer in context.

Population-wide prevention strategies for cancer do work. For example, reductions in lung cancer rates in the United States mirror changes in smoking patterns, with marked decreases seen first in young men, then older men, and finally in women. In fact, lung cancer mortality has fallen by over one-third since 1991. Introduction of the Papanicolaou test for cervical cancer in the 1950s was followed by a dramatic decline in cervical cancer in those countries that made widespread screening available. The decline in Australian melanoma mortality for those born after 1950 is an additional example of effective intervention at the population level. Behavior change is possible and offers great potential for cancer prevention. The recommendations for cancer risk reduction include reducing tobacco use, increasing physical activity, maintaining a healthy weight, improving diet, limiting alcohol, avoiding excess sun exposure, utilizing safe sexual practices and vaccination against the human papillomavirus (HPV) infection, and obtaining routine cancer screening tests. Vaccination against the hepatitis B infection also protects against liver cancer. Emerging science in the prevention of cancer through drugs and vaccines in the past 20 years adds to our opportunities for prevention. They must also be considered as a prevention priority at a local, national, and international level. What are the barriers beyond costs that would limits access to these new preventive strategies for those most at risk of cancer?

The Encyclopedia
Over 600 entries, written for this second edition (90 percent of which are new articles) by experts from an incredible diversity of fields, is a first step to understanding the emerging knowledge and the burden of cancer in different countries, on cancer causes, strategies for prevention, placing these in the context of societal underlying forces that respond or ignore the role of industry and social structure driving the burden of cancer in society. The volume brings together an enormous range of topics, from causes of cancer, the biologic processes and treatment strategies, the places where treatment is delivered, and to organizations working to advance knowledge and conquer cancer. Together these entries provide a sweeping array of insightful perspectives that will be useful for students encountering issues in cancer causes and prevention, for those organizations and providers who are not yet aware of the scope of the problem, and those training in the many disciplines that relate to the challenges of addressing cancer in its full societal context.

The encyclopedia was designed to include a vast range of different types of entries. This gives
the reader the scope of the cancer problem and includes, what the editors believe, an integrated vision of cancer society. By bringing these entries together in one encyclopedia, we helped place in context the issue of cancer in society and provide a resource that will be useful for readers from around the world. By providing increase for many countries, we also offer the opportunity to compare and contrast the state of cancer and the potential for prevention that fairly substantially from region to region.

The authors have included sample cancer incidence rates from many country articles from the International Agency for Research on Cancer (IARC). Readers are encouraged to visit the IARC Web site, www.iarc.fr, for more information.

We live in a time when the cancer burden is rising globally, and the majority of cancers are diagnosed in low- and middle-income countries with less access to diagnosis and treatment. Yet advances in understanding the potential for prevention and the impact of social structures on the underlying risk of disease rapidly inform strategies to reduce the burden around the world. The editors hope the second edition of *The SAGE Encyclopedia of Cancer and Society* helps map out the lessons from past victories and strategies that can be applied to understand the problem and minimize the burden as we move forward.

Graham A. Colditz
*Editor*
ca. 3000 B.C.E.: The first known mention of cancer in the written record, in the Edwin Smith Papyrus; written in ancient Egypt, it describes surgical procedures including using cauterization to treat breast cancer.

ca. 400 B.C.E.: Hippocrates uses the term carcinos to describe tumors; the term is derived from the Greek work for crab, and refers to the pattern of blood vessels, resembling the claws of a crab, observed on tumors.

168 C.E.: The Roman physician Galen discusses the prevention and treatment of cancer; he suggests that food and climate were both related to the occurrence of cancer, and that cancer could be treated by surgery or cauterization.

1675: The Dutch scientist Anton van Leeuwenhoek uses a microscope to examine many natural objects, and publishes descriptions of cells and bacteria.

1713: The Italian physician Bernardino Ramazzino observes that nuns have a relatively high rate of breast cancer, and a low rate of cervical cancer, a discovery later understood to be related to hormones.

1761: The English botanist John Hill publishes “Cautions Against the Immoderate Use of Snuff,” perhaps the first publication linking tobacco and cancer; he notes that nasal polyps occurred in patients who used nasal snuff.

1775: In an early example of occupational medicine, the English physician Percival Pott noted scrotal cancer was common among chimney sweeps, and connects the disease to their exposure to soot.

1779: The first hospital dedicated to treating cancer is created in Reims, France.

1798: In the United States, the Marine Hospital Service is created, marking an early instance of federally funded public health and medical care.

1836: Opening of the Library of the Office of the Surgeon General of the Army, which later becomes the National Library of Medicine.

1887: The Laboratory of Hygiene is established at the Marine Hospital in Staten Island, New York; it is a precursor of the Centers for Disease Control and Prevention.

1889: The English surgeon Steven Paget notes non-random patterns in breast cancer metastasis, which he explains through his “seed and soil” theory, arguing that specific tumor cells (seeds) will only grow in certain organs (the soil).
1890: The German pathologist David Paul von Hansemann describes the mitotic figures of 13 carcinoma samples, and hypothesized that the observed aberrations caused the abnormal amounts of chromatin found in the cells.

1890: The American physician William Stewart Halstead pioneers the radical mastectomy as a treatment for breast cancer in the United States. (it was already in use in France); Halstead was also noted for his role in developing the residency system of physician training in the United States.

1901: French scientist Pierre Curie suggests the idea that tumors could be treated by putting a source of radiation directly into the tumor; an approach that later came to be known as brachytherapy.

1903: The Austrian chemist Richard Adolf Zsigmond'y develops the ultramicroscope, making it possible to study objects below the wavelength of light; he is awarded the Nobel Prize in Chemistry in 1925.

1903: Radium is first used to treat skin cancer in two patients; this pioneers the way for radiation therapy to use many types of cancer, including breast, prostate, and cervical tumors.

1909: The American biologist Paul Ehrlich suggests that the immune system normally suppressed the development of tumors in the body.

1910: The viral theory of cancer receives support when the American physician Francis Peyton Rous successfully induces tumors in chickens by injecting them with the cells of tumors from other chickens.

1913: The American Society for the Control of Cancer is founded in New York City by a group of businessmen and physicians; it is later renamed the American Cancer Society.

1915: The American biologist Thomas Hunt Morgan demonstrates that the somatic mutation theory of cancer, which was originally proposed by the German biologist Theodor Boveri, is in fact correct.

1922: The U.S. Public Health Service establishes a Cancer Investigations Laboratory at Harvard Medical School.

1933: The Women’s Field Army joins the fight against cancer, raising money and educating people about the disease.

1937: U.S. president Franklin Roosevelt signs the National Cancer Institute Act, legislation creating the National Cancer Institute, with a budget of $400,000 for the first year.

1938: The German physicist Ernst Ruska develops the electron microscope, improving resolution; he is awarded the Nobel Prize in Physics in 1986.

1939: Charles Brendon Huggins, while studying prostate cancer and androgen in dogs, discovers that hormones were influential in the growth of some types of cancer.

1939: Gordon Ide and colleagues suggest that tumors might produce a substance fostering the creation of new blood vessels; their work is based on observing the growth of transplanted tumors in rabbits. Later research by Melvin Greenblatt and Philippe Shubik demonstrates that transplanted tumors cause blood vessels to proliferate even when a Millipore filter is used to create a physical barrier.

1940: In August, the first issue of the Journal of the National Cancer Institute is published.

1945: In Science: The Endless Frontier, Vannevar Bush argues for increased federal government funding for science and technology while allowing the community of scientists to be self-governing, without government interference.

1946: Led by the philanthropist Mary Lasker, the American Cancer Society begins a research program with a budget of $1 million.

1946: At the National Institutes of Health, the Research Grants Office is created to operate a program of fellowships and extramural research grants; it is later renamed the Division of Research Grants.

1947: The Nuremberg Code is developed following evidence of Nazi abuse of humans, including prisoners, in the name of scientific research; it sets a precedent in establishing ethical guidelines for human research.

1947: The physician and researcher Sidney Farber, working with funding from the American Cancer Society, develops the first successful chemotherapy treatment for cancer. Farber successfully treats a 4-year-old leukemia patient with aminopterin and later reports on additional cases of remission in a disease that at the time normally resulted in death soon after diagnosis.

1948: The National Cancer Institute begins a program of grants to medical, osteopathic, and medical schools to improve the training of professionals in cancer diagnosis, research, and treatment.

1948: The fight against cervical and uterine cancer is strengthened when the American Cancer Society advocates for widespread use of the Pap smear, a screening test developed by the physician Georgios Papanikolaou.

1949: The U.S. Food and Drug Administration approves nitrogen mustard for the treatment of Hodgkin’s lymphoma, the first chemotherapeutic treatment approved for cancer.

1950: American researchers Ernst Wynder and Evarts Graham publish a case-control study that shows an association between tobacco smoking and lung cancer.

1951: In the United Kingdom, the Medical Research Council begins the British Doctors Study, which will continue until 2001; among other results, this study provides strong evidence that smoking tobacco is a risk for the development of lung cancer.

1953: At the University of Chicago, the Argonne Cancer Research Hospital begins operation; it is the first facility dedicated to using radioactive isotopes to diagnose and treat disease.

1953: James Watson and Francis Crick discover the helical structure of DNA, a scientific breakthrough for which they are awarded the Nobel Prize in 1962.

1954: Eugene Goldwasser, working at the University of Chicago, explains the basic working principles of erythropoietin; in 1977, he becomes the first person to isolate erythropoietin.

1955: The National Cancer Institute creates the Clinical Trials Cooperative Group Program, a network facilitating cancer research and clinical trials.

1956: Arthur von Hippel, working at the Massachusetts Institute of Technology, coins the term molecular engineering and develops many of the key concepts in the field.

1958: Combination chemotherapy (using multiple drugs together) is demonstrated by scientists at the National Cancer Institute (part of the National Institutes of Health) as a successful approach to treating leukemia; this approach becomes common in chemotherapy in the future.

1959: Physicist Richard Feyman delivers the lecture “There’s Plenty of Room at the Bottom” at an American Physical Society meeting in California; it is considered by many to be the first discussion of technology at the atomic scale.

1960: Discovery of the chromosomal abnormality called the “Philadelphia chromosome” (because it was discovered by Peter Nowell and David Hungerford, researchers working in Philadelphia) that is linked to many leukemias; this abnormality later becomes the focus of one of the first targeted cancer drugs, Gleevec.

1961: The American biologist Rachel Carson publishes Silent Spring, a highly influential book pointing out the health dangers of human exposure to DDT and other toxins; this book plays a key role in coalescing the environmental movement.
1961: The National Cancer Institute establishes a Laboratory of Viral Oncology to investigate the role of viruses in cancer.

1964: In the United States, the Surgeon General publishes a report that concludes that cigarette smoking bears a causal relationship to lung cancer in men, with an effect greater than all other factors combined.

1964: The World Medical Association publishes the Declaration of Helsinki, an influential statement of research ethics in medical research; it has been revised multiple times, with the 2006 revision being the sixth.

1965: Vincent DeVita and colleagues develop the MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) chemotherapy regime, which has a cure rate of around 50 percent, becomes standard treatment until replaced by the ABVD (doxorubicin, belomycin, vinblastine, and darcarbacine) regime in the 1970s.

1966: Peyton Rous is awarded the Nobel Prize for Physiology or Medicine for his work in identifying the role played by viruses in some kinds of cancer.

1966: Henry Beecher publishes an article in the New England Journal of Medicine identifying a number of unethical medical studies and claimed that they showed a systematic pattern of abuse rather than isolated incidents.

1966: Charles Brenton Huggins, a Canadian-born American physician, is awarded the Nobel Prize for Physiology or Medicine for his work demonstrating that hormones could be used to treat some cancers.

1967: The USPHS (U.S. Public Health Service) Hospital is created in Baltimore to conduct integrated laboratory and clinical research on cancer.

1967: The FOBT (fecal occult blood test) is introduced as a simple method to screen patients for colorectal cancer; two more elaborate techniques, colonoscopy and flexible sigmoidoscopy, are also introduced within a few years, and together these methods contributed to a significant reduction in mortality from colorectal cancer.

1968: Elwood V. Jensen develops a test for the presence of estrogen receptors in breast cancer cells, later concluding that about a third of breast cancer cells contain the receptors.

1970s: The use of asbestos in construction decreases as scientific studies demonstrate a link between asbestos exposure and particular cancers.

1971: Judah Folkman and colleagues announce the discovery of a tumor angiogenic factor (TAF) and hypothesize that if TAF activity could be blocked, the growth of malignancies might also be prevented.

1971: Total mastectomy, which involves removing less tissue than radical mastectomy, is demonstrated to be equally effective in treating breast cancer in the early stages.

1971: On December 23, U.S. President Richard Nixon signs the National Cancer Act, authorizing and funding the National Cancer Institute to create new research and treatment facilities, award research grants, and otherwise spur the War on Cancer.

1972: Janet Rowley, working at the University of Chicago, pioneers the recognition of the genetic basis of cancer with her discovery of a chromosomal abnormality in leukemia.

1972: Computerized tomography (CT) scanning is developed by the British engineer Godfrey Hounsfield and South African physicist Allan Comack. CT scans are first used on the head (the first clinical application is used to diagnose a woman with a suspected brain tumor) but are later used for all parts of the body.

1973: A study reveals that mammography is the best tool for finding early-stage breast cancer.

1973: In the United States, eight institutions are recognized as Comprehensive Cancer Centers (CCCs); the number of CCCs increases over the years, to 37 as of 2000.
1973: John Ulmann and Donald Ferguson demonstrate that staging laparotomy, the surgical examination of part of the body, is useful in the evaluation of Hodgkin’s disease.

1974: William Summerlin, a researcher at the Sloan Kettering Cancer Institute, admits fraud in his research on skin grafts; Summerlin claimed to have successfully grafted skin from unrelated animals but in fact had colored the grafts with ink.

1974: The National Cancer Institute awards funds to state health departments to screen low-income women for cervical cancer.

1975: Dr. Bernard Fisher and Dr. Gianni Bonadonna demonstrate that adjuvant chemotherapy—using chemotherapy after surgery—is effective in treating drug cancer.

1975: In the United States, the Cancer Information Service is created to educate health professionals, patients, and the public about cancer.

1975: The Australian philosopher Peter Singer publishes Animal Liberation, arguing against speciesism, the belief that some species (e.g., humans) are more important and should have greater rights than other species (e.g., animals, including those used for lab research).

1976: The first Great American Smokeout is held in California, encouraging smokers to quit for at least one day; the program proves successful and becomes an annual, nationwide event.

1976: The first oncogene, src, is discovered by Harold E. Varmus and J. Michael Bishop.

1977: A clinical trial demonstrates that advanced testicular cancer can be treated by a combination of cisplatin, vinblastine, and bleomycin.

1977: Studies demonstrate that breast-conserving surgery, in which only the tumor but not the entire breast is removed, is as effective in treating early-stage breast cancer as mastectomy (removing the entire breast), if followed by radiation therapy.

1978: The U.S. Food and Drug Administration approves cisplatin as a chemotherapeutic drug for cancer.

1979: The National Commission for the Protection of Human Subject of Biomedical and Behavioral Research publishes the Belmont Report, which sets out principles and guidelines to govern the treatment of human subjects. The core principles of the Belmont Report are beneficence, justice, and respect for the person, while procedures specified include informed consent, risk and benefit assessment, and subject selection.

1980: The U.S. Supreme Court rules, in Diamond v. Chakrabarty, that life forms (in this particular case, a genetically modified bacterium) can be patented.

1981: The U.S. Food and Drug Administration approves a vaccine for hepatitis B, a disease that is strongly associated with liver cancer.

1981: The Centers for Disease Control and Prevention forms a Task Force on Kaposi’s Sarcoma and Opportunistic Infections to investigate a cluster of illnesses caused by what was later determined to be acquired immunodeficiency syndrome (AIDS).

1981: Gerd Binnig and Heinrich Rohrer, working in Zurich, develop the scanning tunneling microscope, an instrument that allows scientists to create images of individual atoms; they are awarded the Nobel Prize in Physics in 1986 for this achievement.

1981: The National Cancer Institute begins the Biological Response Modifiers Program to develop therapeutic agents that may alter biological responses relevant to cancer and to conduct clinical trials of such agents.

1982: Total mesorectal excision provides a new treatment option for patients with rectal cancer;
prior to this time, the standard treatment was colostomy, the removal of the colon, and the use of a colostomy bag for the rest of the patient’s life.

1982: Aline van Pel and Thierry Boon find that mice can be vaccinated against cancer with mutagenized cancer cells, giving them specific immunity to spontaneous tumors.

1983: The National Cancer Institute creates the R. A. Bloch International Cancer Information Center, housing information programs for scientists and health professionals.

1986: Gerd Binnig, Christoph Gerber, and Calvin Quate develop the atomic force microscope, which allows scientists to view and manipulate materials as small as fractions of a nanometer.

1986: The first tumor suppressor gene, Rb, is discovered by Stephen H. Friend and colleagues.

1986: The U.S. Food and Drug Administration approves a PSA (prostate-specific antigen) test for prostate cancer screening, adding a new tool to the fight against the most common type of cancer in men.

1986: The World Health Organization issues guidelines on the adequate treatment of pain for cancer patients, addressing common worries about addiction, tolerance, and abuse connected with opioid drugs.

1986: U.S. cities begin to ban indoor smoking after the U.S. Surgeon General declares that second-hand smoke is a carcinogen.

1986: Tamoxifen, a drug originally produced from the yew tree, is used to treat breast cancer in conjunction with surgery.

1988: The first Consortium Cancer Center in the United States is created by a grant from the National Cancer Institute, supporting research into cancer prevention, control, epidemiology, and clinical trials at three historically black universities: Charles R. Drew University of Medicine and Science, Meharry Medical College, and Morehouse School of Medicine.

1989: Epoetin Alpha is approved to stimulate the production of red blood cells, addressing the problem of anemia that is often a side effect of chemotherapy.

1990: The California Supreme Court rules, in Moore v. Regents of the University of California, that researchers can claim intellectual property rights in a cell line developed from an individual’s tissue but that the individual does not have property rights to the tissue.

1990: Michelle Le Beau and Janet Rowley use fluorescence in situ hybridization (FISH) to map chromosome dislocation, a method now commonly used to diagnose leukemia and lymphoma.

1991: In the United States, childhood vaccination for hepatitis B becomes routine, resulting in a 98 percent decline of acute hepatitis B among children age 15 and under; in the long term, substantial reduction is also expected in liver cancer, a disease strongly associated with hepatitis B.

1991: In the first attempt at treating cancer with human gene therapy, patients with melanoma are treated with tumor-infiltrating lymphocytes modified by the addition of a gene for tumor necrosis.

1991: The U.S. Food and Drug Administration approves Ondansetron to prevent vomiting, a common side effect of chemotherapy and radiation.

1991: The National Cancer Institute and the nonprofit organization Produce for Better Health begin the Five-a-Day program, which is a public health campaign encouraging Americans to eat at least five servings of fruits and vegetables each day.

1992: The technique of sentinel lymph node biopsy, which involves removing the lymph node closest to a primary tumor, offers a method to assess the spread of cancer without invasive surgery.

1992: Paclitaxel is approved by the U.S. Food and Drug Administration to treat advanced ovarian cancer; it is later discovered to be useful for treating breast cancer as well.
1994: Dr. Roger Poisson, a researcher at the University of Montreal and a member of the National Surgical Adjuvant Breast and Bowel Project, is found to have been enrolling ineligible women in breast cancer trials and maintaining false records to cover up the deception.

1994: The BRCA1 gene, implicated in about 25 percent of breast cancers in women under age 30, is discovered by researchers at the National Institute of Environmental Health Sciences.

1994: Victor DeNobel and Paul Mele, who work at the tobacco company Philip Morris, testify before U.S. Congress about suppressed research demonstrating the addictive properties of nicotine; this testimony leads to a $206 billion settlement between 46 states and the tobacco companies; some of the funds are devoted to antismoking campaigns.

1994: Ralph Weichselbaum and Samuel Hellman propose the existence of “oligometastases,” which is an intermediate state in cancer between not having spread at all and having spread extensively.

1995: The Centers for Disease Control and Prevention reports that the cancer death rate in the United States fell by 2.6 percent between 1991 and 1995, the first time cancer mortality rates declined since the 1930s (when recordkeeping began).

1995: Kunio Doi, working at the University of Chicago, pioneers the clinical use of a computer-assisted system to read mammograms.

1995: A group of religious leaders and ethicists protest the patenting of human body tissue, plants, and animals.

1997: The American Cancer Society begins operating a call center, proving information to cancer patients and their families every day, around the clock.

1998: Results from the Breast Cancer Prevention Trial show that the drug tamoxifen can be effective in preventing breast cancer—women taking tamoxifen had 45 percent fewer diagnoses of breast cancer than the women in the control group.

1998: A large-scale prevention trial finds that a moderate dose of Vitamin E reduces the incidence of prostate cancer, as well as prostate cancer deaths, among male smokers.

1998: Tamoxifen is approved for prophylactic use for women at high risk for breast cancer after a clinical trial shows it reduces the risk of breast cancer in women with a family history of breast cancer or with the BRCA1 and BRCA2 genetic mutations that are associated with a higher risk of breast cancer.

1998: The benefits of neoadjuvant therapy, in which chemotherapy is used before surgery to shrink tumors before they are surgically removed, is shown to allow many patients to have breast-conserving surgery (removing only the tumor) rather than mastectomy.

1999: The risks of human subjects research comes to public attention after a research subject, Jessie Gelsinger, dies during an experiment on human gene therapy conducted at the University of Pennsylvania.

2000: Brian Duker develops the first successful molecularly-targeted cancer drug, Gleevec, which is used to treat myelogenous leukemia.

2000: Radon exposure is associated with lung cancer in the Iowa Radon Lung Cancer Study, raising awareness about the risks of long-term exposure to radon in the home.

2000: Research using microarray technology finds that non-Hodgkin’s lymphoma is actually two
diseases, helping to explain why some patients respond to chemotherapy and others do not.

2000: The Special Populations Networks for Cancer Awareness Research and Training program is created in the United States to address the unequal burden of cancer in particular subpopulations.

2001: Gleevec is approved by the U.S. Food and Drug Administration to treat chronic myelogenous leukemia after three months of review, the fastest approval on record. The same year, Gleevec is shown to be effective against gastrointestinal stromal tumor, a rare type of abdominal tumor.

2002: Helen Davies and colleagues publish research in Nature identifying a faulty BRAF gene as present in many cancers, including over half of all malignant melanomas.

2002: In the United Kingdom, the Cancer Research Campaign and the Imperial Cancer Research Fund merge to form Cancer Research UK, the world's largest independent cancer research organization.

2002: John Crispino, working at the University of Chicago, discovers that the development of leukemia in Down syndrome children is linked to a gene defect.

2002: The National Cancer Institute begins the National Lung Screening Trials to test the efficacy of two methods for screening current and former smokers for lung cancer: chest X-rays and spiral computed tomography.

2003: Results from the Million Woman Study indicate that the current use of hormone replacement therapy (HRT) increases the incidence of breast cancer as well as increasing breast cancer mortality.

2003: The Human Genome Project, a 13-year collaboration among researchers in seven countries, announces that they have completed mapping the DNA in the human genome; the results are made freely available to the international scientific community.

2003: Research published in the New England Journal of Medicine shows that taking aspirin daily is associated with a reduction in the risk of colorectal polyps among people at high risk for colorectal cancer.

2003: British researchers publish research demonstrating that combining chemotherapy and radiotherapy improves outcomes in treating the most common type of pediatric brain tumor, medulloblastoma.

2003: Researchers at Rice University develop gold nanoshells that can be used in the discovery, diagnosis, and treatment of breast cancer.

2003: Eugenia E. Calle and colleagues publish research in the New England Journal of Medicine demonstrating a strong relationship between obesity and many types of cancer, and estimates that if Americans maintained a healthy weight, 90,000 cancer-related deaths annually could be avoided.

2004: The Alliance for Nanotechnology in Cancer is created to integrate nanotechnology into basic and applied cancer research, including supporting the development of nanomaterials and nanoscale devices for cancer detection and treatment.

2004: Avastin (bevacizumab) becomes the first approved anti-angiogenic drug, a type of drug that treats cancer by blocking the growth of blood vessels that feed tumors.

2004: University of Chicago researcher Olufunmilayo Olopade, studying women with breast cancer in North America, Nigeria, and Senegal, discovers that women with African ancestry, as compared to women of European ancestry, are more likely to be diagnosed with an aggressive form of breast cancer; in 2005 she receives a MacArthur Foundation “genius grant.”

2004: Results from a large trial funded by Cancer Research UK involving people with operable pancreatic cancer indicate that using chemotherapy after surgery helps delay or prevent recurrence.
2004: The Environmental Protection Agency strengthens its rules regarding human subjects research with children and pregnant women following public criticism of the Children’s Environmental Exposure Research Study (CHEERS).

2004: The 50-year follow-up study of the British Doctors Study finds that prolonged cigarette smoking caused death 10 years earlier than among non-smokers, based on results from men born between 1910 and 1930; the study also shows that cessation of smoking reduces this risk substantially.

2005: In the United States, the National Human Genome Research Institute and the National Cancer Institute announce the Cancer Genome Atlas Project, whose first goal is to create an atlas of the genomes of lung and ovarian cancer and glioblastoma.

2005: Results from the Women’s Health Study finds that supplemental vitamin E does not reduce the incidence of cancer among women.

2005: The National Institutes of Health (NIH) in the United States strengthens its policies intended to prevent conflict of interest, including barring NIH researchers from consulting with or holding stock in pharmaceutical and biotechnology companies.

2005: The National Cancer Institute creates the Community Networks Program to provide education, research, and training aimed at reducing cancer disparities among underserved populations.

2005: The Childhood Cancer Survivors Study reveals that survivors of childhood cancer suffer from many health concerns later in life, including scarring of the lungs, other types of cancer, and heart trouble.

2005: Eric Pohlman, a professor at the University of Vermont, pleads guilty to falsifying results in numerous scientific grants and research articles; in 2006, he becomes the first person in the United States to be sentenced to prison for research fraud.

2006: The U.S. Food and Drug Administration approves Gardasil, a vaccine to prevent infection with human papillomavirus (HPV), associated with cervical cancer; Gardisil is approved for girls and women ages 9 to 26.

2006: In the United Kingdom, the Network of Experimental Cancer Medicine Centres opens, with the goal of moving new treatments into clinical trials and practice quickly.

2006: In the United States, the National Community Cancer Centers Program Pilot begins operation with the goal of improving cancer care in local communities as well as reducing cancer health disparities and increasing access to prevention and screening services.

2007: Results from the United Kingdom (UK) QUASAR clinical trial of chemotherapy for bowel cancer demonstrates that chemotherapy improves survival for people with less advanced cancer.

2008: Greg Karczmar, Suzanne Conzen and colleagues develop a procedure using magnetic resonance image (MRI) to detect very early breast cancer in mice.

2008: Hans Schreiber demonstrates that, in mice, killing nonmalignant cells surrounding a tumor can prevent spread of the tumor.

2009: Early results from the UK Collaborative Trial of Ovarian Cancer Screening finds that screening women with both a blood test and ultrasound produces more accurate results than ultrasound alone, perhaps because the blood test helps to rule out harmless cysts picked up through ultrasound scans.

2009: Ezra Cohen discovers that grapefruit juice enhances the effectiveness of rapamycin, allowing patients to take lower dosages of the drug.

2009: In the United States, the Family Smoking Prevention and Tobacco Control Act allows the Food and Drug Administration to regulate tobacco products, and creates a Tobacco Products Scientific Advisory Committee to advise the Department of Health and Human Services.

2009: Results from the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial casts
doubt on whether routine screening for prostate cancer reduces mortality, and suggests that screening also leads to overdiagnosis and treatment of cancers unlikely to be life threatening.

2009: The Prevent All Cigarette Trafficking Act prohibits tobacco products from being sent through the U.S. mail.

2010: Results from the National Lung Screening Trial indicate that annual screening by computerized tomography (CT) scan of smokers and former smokers reduces the risk of death from lung cancer; this is the first lung cancer screening program successful in reducing mortality.

2011: An international research team identifies a new oncogene, ZNF703, which is believed to accelerate the development of breast cancer.

2011: The Sunbeds Regulation Act in the United Kingdom bars people under the age of 18 from using tanning beds, associated with the development of skin cancer.

2012: The American Cancer Society and the National Cancer Institute report that the number of Americans living with cancer has increased four-fold since 1971, from 3 million to 13.7 million.

2013: On August 23, Song-Yi Park and colleagues announce results from the Multiethnic Cohort Study showing that, for women, increased consumption of fruits and vegetables is associated with a lower incidence of invasive bladder cancer.

2013: In the September issue of the *Texas Public Health Journal*, researchers report that cancer is the most common cause of death for Hispanics living in Texas.

2013: On November 6, Alastair Sutcliffe and colleagues report research based on children born in the United Kingdom as a result of in vitro fertilization, finding that they are no more likely than other children to develop cancer.

2013: On December 20, *Science* announces that cancer immunotherapy has been selected as the breakthrough of the year.

2014: On February 14, Cancer Research UK publishes a report and makes available two online interactive maps allowing the comparison of the incidence and mortality from cancer globally.

2014: On April 17, a clinical trial studying the effectiveness of personalized treatment for lung cancer is announced by Cancer Research UK, AstraZenica, and Pfizer.

2014: On June 26, Martin Widschwendter and colleagues announce the discovery of a genetic marker or “switch” observable in blood samples associated with increased risk for breast cancer, suggesting the possibility that a simple blood test may be available in the future to help predict the likelihood of noninherited breast cancer.

2014: On July 11, Min Yu and colleagues report in *Science* that they successfully isolated breast cancer cells in patients’ bloodstreams, including cells carrying the “seed” of metastasis.

2014: In October, the International Agency for Research on Cancer added several recommendations, including for girls to get the HPV (human papillomavirus) vaccine and for mothers to breastfeed.

2014: In December, Jan Durmanski and colleagues at Uppsala University in Sweden reported research linking smoking with the loss of Y chromosomes from the blood cells in men. In addition, the researchers found that the loss of Y chromosomes from at least one fifth of an individual’s blood cells was associated with almost four times the risk of developing certain cancers.

2015: According to estimates by the American Cancer Society, approximately 1.66 million new cancer cases are expected to occur in the United States in 2015; this estimate does not include noninvasive cancers or basal cell or squamous cell
skin cancers. In addition, about 589,430 Americans are expected to die of cancer in 2015.

2015: In January, England’s National Health Service removed nine cancer drugs from the list of treatments it will pay for, based on the high cost of the drugs relative to the value they provide to patients. At the same time, NHS England reduced the number of conditions for which several other drugs were an approved treatment, reducing the total number of treatment options by 25.

2015: In February, the World Health Organization (WHO) announces that cancers are among the leading worldwide causes of illness and death, with about 14 million new cases of cancer and 8.2 million deaths due to cancer, occurring in 2012. In addition, the WHO reports that the number of new cancer cases per year is expected to rise to 22 million within the next 20 years.

2015: In March, Takaaki Hirotsu and colleagues at Kyushu University report that roundworms were able to correctly identify individuals with cancer, based on urine samples in Petri dishes, with 96 percent accuracy.

Saint Louis University
Abbott Laboratories (United States)

Abbott is a global company specializing in diagnostics, medical devices, nutritionals, and branded generic pharmaceuticals. Its headquarters are in Abbott Park, Illinois, but it operates in more than 130 countries, and the most recent data show revenue in excess of $20 billion. Abbott has products that are designed specifically to help in diagnosis for cancer patients. Abbott’s history goes back to its founder, Wallace Calvin Abbott, who created the Abbott Alkaloidal Company in 1888. The key innovation that propelled Abbott Alkaloidal to success was the development of a technology that allowed the separation of the active principle of a medicinal plant to deliver it in the form of small pills, which in turn allowed more consistent dosages for patients.

As the company very successfully expanded and grew, its core businesses now focuses on branded generic pharmaceuticals, diagnostics, medical devices, and nutritional products, and its business model organizes it along the following divisions: animal health (anesthesia, animal diets, and other veterinary products), diabetes care (monitoring devices for glucose levels as well as therapeutic products), diagnostics (including a significant number of products in hematology, immunodiagnostic, oncology, and clinical chemistry—famously, in 1984, Abbott developed the first human immunodeficiency virus [HIV] blood screening test), branded generic pharmaceuticals (significant presence in markets outside the United States, including developed and developing markets), medical optics (treatments and equipment for cataract surgery and laser eye surgery as well as drops and solutions), molecular medicine (analysis of DNA, RNA, and proteins at the molecular level), human nutrition (products for babies as well as for adults), and finally vascular technologies (endovascular and coronary technologies developed by Abbott include, for example, the first bioresorbable coronary stents and a first-in-class, catheter-based treatment for mitral regurgitation). Both the diagnostics and molecular divisions have significant interest for oncological patients and their care providers.

Abbott produces a variety of medical devices, diagnostics, and nutritional products. Diagnostic products are very relevant to oncologists in addition to some of the nutritional products (such as Ensure) that may find applications with cancer patients who are struggling to get the required nutrition while in therapy.

Abbott’s molecular division has explored many ideas for the development of a variety of diagnostic tests. Of particular interest is work in the oncology area. Abbott’s work in this direction fits within the current push toward personalized medicine, which requires doctors to be in a position to assess the
specific proteomic and genomic characteristics of the patient’s tumor to identify which patients may be eligible for new, targeted therapies. The genetic origin for many tumors (especially solid tumors) can be detected with fluorescence in situ hybridization (FISH) probe technology.

This technology was developed in the early 1980s, and it is used to detect the presence of specific DNA sequences on chromosomes. By using fluorescent probes that bind only to the targeted areas of the chromosomes, doctors can visualize the bound (or detected areas) using fluorescence microscopy. In this way, this technology can help detect appropriate genetic targets in tissues and determine whether specific mutations or genetic alterations exist.

Abbott has developed numerous products that utilize this technology. The first example is the UroVysion Bladder Cancer Kit, which uses urine only to support an initial diagnosis of bladder cancer; the kit and its accessories also can be used to monitor disease progression (or lack of) and detect disease recurrence. Another example, relevant for women diagnosed with breast cancer, is the PathVysion HER-2 DNA probe kit, which accurately assesses the patient’s HER-2 status, thus providing crucial information to help the doctor select the most appropriate therapy, such as Herceptin (trade name for the monoclonal antibody Trastuzumab, which interferes with the HER-2 receptor). Patients with non–small cell lung cancer (NSCLC) may be tested for the Vysis ALK Break Apart FISH Probe Kit, which may help physicians identify those patients who might respond to the kinase inhibitor crizotinib. Crizotinib, under the trade name of Xalkori, is now the standard of care for NSCLC patients whose tumors test positive for the ALK gene rearrangement (ALK+). While ALK+ patients represent a small percentage of all NSCLC patients (3–5 percent), clinical studies have shown many patients on Xalkori experience improved outcomes.

Further Readings
fall into two principle families of polymers—the omopolymere and a copolymer—each offering valuable properties that provide resistance to deteriorating during extreme temperatures.

Acrylic fiber is also produced from a polymer and is a synthetic fiber that commonly resembles the texture of wool in both look and texture. Because acrylic fibers are lightweight and tend to be soft, they can be found commonly in carpets, home furnishings, and some clothing as a less-expensive alternative to more-expensive natural textiles such as cashmere and cotton. These acrylic fibers are popular for the textile industry and consumers because they are resistant to general deterioration and damage caused by pests, such as moths, chemicals, and oils. Acrylic fibers also are very popular for craftspersons who knit or crochet as their properties lend themselves to holding up during washing and fabric dyeing. Many credit the company DuPont with creating the first synthetic, acrylic fibers in the early 1940s, although they were not mass manufactured until a decade later.

The main ingredient in most acrylic fibers is acrylonitrile, also known as vinyl cyanide, which is considered a carcinogen, as classified by the International Agency for Research on Cancer, linked to causing breast cancer—and also brain, lung, and bowel cancers—as well as negatively affecting and targeting the central nervous system. Acrylonitrile is not a naturally occurring chemical and is produced by mixing propylene with ammonia and oxygen (amnomoxidation) in the presence of a catalyst; this is known as the Sohio process. Acrylonitrile is colorless, extremely volatile, and flammable and does not occur naturally. In addition to its use in the manufacture of acrylic fibers, plastics, resins, and synthetic rubbers, acrylonitrile is also used to produce other chemicals, such as acrylamide, adiponitrile, and carbon fiber. Acrylonitrile is a known toxin. Occupational exposure to acrylonitrile over an extended period can cause effects such as headache, chest pains, insomnia, fatigue, a general unwell feeling, and increased irritability.

Without proper protective equipment and measures, acrylonitrile can be absorbed through the skin, ingestion, and inhalation. A carcinogen is defined as any substance that causes cancer in living tissues, and the process of cancer developing in living tissues is referred to as carcinogenesis, oncogenesis, or tumorigenesis. Basically, this process is when a living, normal cell is transformed into a cancerous cell that then divides in an uncontrollable manner and forms a malignant mass, or neoplasm. Researchers and medical professionals typically classify carcinogens by their structure or chemical as a way to differentiate among known carcinogens and the way they behave; however, all chemical carcinogens have the ability to directly or indirectly change the DNA structure of living tissue.

Acrylonitrile is also a mutagen, which is a physical or chemical agent that changes the genetic material, usually DNA, of an organism or living tissue and, therefore, increases the chances and frequency of occurrence of mutations. A carcinogen can be or not be a mutagen.

The following is a list of common chemicals that can be considered carcinogenic that are used in the production of acrylic rubber and fibers:

- Accelerators
- Oils (process and extender)
• Antioxidants
• Organic vulcanizers
• Antiozonants
• Pigment blends
• Anti-tack agents
• Plasticizers
• Chemical by-products
• Reinforcing agents
• Curing fumes
• Resins
• Extenders
• Solvents
• Fillers

Recent research has primarily focused on the occupational exposure people working in these respective industries suffer from coming into contact with solvents and chemicals used in the development of acrylic rubber and fibers, with specific research studies focusing on the potential linkage between exposure and breast cancers and cervical cancers. However, scientific data exist that indicate individuals working in these manufacturing industries have died due to various cancers, such as bladder, stomach, lung, hematopoietic, and others, after being exposed to the solvents and chemicals used to develop acrylic and rubber products. In addition to cancer, other health effects experienced by workers in these manufacturing industries include adverse respiratory, dermatological, and reproductive effects.

The U.S. Occupational Safety and Health Act of 1970 calls for the industry’s need to standardize its protective measures and take action to improve work conditions to limit workers’ exposure to known carcinogens. As a result, the Occupational Safety and Health Administration (OSHA) has reported that the acrylic rubber and fiber industries have not adequately tested the chemicals for carcinogenicity and toxicity, advocates for a need to reexamine the health effects that exposure to these chemicals has on workers, and proposes more research be conducted on ways to prevent exposure to these carcinogens. Specifically, OSHA calls for more research in the following areas in the face of a lack of data:

• Evaluation of hazardous exposures
• Epidemiologic, toxicologic, and industrial hygiene studies

• Assessment of control measures
• Epidemiologic research
• Collection of injury data
• Evaluation of health and safety programs
• Identification of compounds or groups of substances

Adrenocortical Carcinoma

Adrenocortical carcinoma, adrenal cortex cancer, or adrenal cortical carcinoma is a cancer of the cortex of the adrenal gland. The adrenal gland is an endocrine gland near the kidneys, responsible for producing hormones in response to stress and trauma and for assisting kidney function. Humans have two adrenal glands, one proximate to each kidney: The right adrenal gland is triangular, while the left is semilunar, with each located above its respective kidney. They are small, weighing only about four grams each and surrounded by connective and fatty tissues. Their small size accounts for the high probability of metastasis as there is not much tissue for the cancer to consume before it moves beyond the gland. The cortex of the adrenal gland is responsible for the production of corticosteroid and androgen hormones, such as androgens, aldosterone, and cortisol.

Adrenocortical carcinoma is rare, with about one case per million people per year, with patients predominantly in two clusters: children under five and adults in their 30s. The five-year survival rate is between 20 and 35 percent.

Because it affects the adrenal gland, a number of hormonal syndromes can occur in adrenocortical carcinoma patients. Cushing’s syndrome results from excessive cortisol, for instance, resulting in weight gain, especially in the face and trunk, a moon face from excessive fat pads around the face, excessive perspiration, thinning of the skin and mucous membranes due to the rapid weight gain stretching them (and resulting stretch marks on the trunk, buttocks, and legs), dry and brittle hair or hair loss, and increased facial hair growth. In extreme cases, the endocrine system may be thrown off and cause insomnia, impotence, or female infertility. Memory and mood problems are common, and the patient is more prone to acne, fungal infections of the skin, and the development of adult-onset diabetes.

Another possible complication, Conn syndrome, is caused by excessive aldosterones, which can affect almost every kind of cell in the body but especially sodium and potassium channels. As a result, excessive aldosterone can lead to increased intracellular potassium and increased sodium reabsorption throughout the intestines, resulting in constipation, muscle cramps, elevated blood pressure from sodium retention, and headaches from electrolyte imbalances.

Hormonal imbalances can lead even to abnormal virilization, the process by which biological sex differences develop. When virilization occurs in adults, it typically refers to a long-term hormonal imbalance causing the development of characteristics of the opposite sex; in women, this may mean thinning hair, increased facial hair, increased muscle strength, enlargement of the clitoris, deepening of the voice, and fertility problems, while in men, it can include the development of breasts, impotence, and a decrease in body hair. Male patients with adrenocortical carcinoma actually may experience a combination of these symptoms—for instance, an increase in facial and body hair and deepening of the voice but the development of female breasts—as the body converts excess androgen to estrogen and the patient thus suffers from an overabundance of both sex hormones.

Adrenocortical carcinoma tends to present differently in children than adults. Though both are likely to experience Cushing’s syndrome, adults are more likely to experience Cushing’s alone, while children usually experience it in conjunction with virilization. Children also may experience early-onset puberty as a result of the hormonal imbalance, which may be the first sign of something wrong.

The etiology of adrenocortical carcinoma is not well understood. Certain hereditary diseases increase the risk, including Li-Fraumani syndrome (which increases risk for several cancers), Beckwith–Weidemann syndrome (an overgrowth disorder resulting in large babies with large tongues and low blood sugar), and Carney complex (noted by dark spots on the skin and tumors in several organs).

Early symptoms can include a lump, pain, or feeling of fullness in the abdomen, but in more than half of cases, the tumor is a functioning one that impacts hormonal production, resulting in one of the syndromes above. In nonfunctioning tumors, there may be no symptoms until the tumor is late stage.

The tumor is usually discovered and identified through radiology, and blood and urine tests can uncover hormonal imbalances. Biopsies of tumors usually are not performed, but a pathologist will confirm the cancer diagnosis after surgery removing
Adrenocortical Carcinoma, Childhood

Adrenocortical carcinoma (ACC) is a rare but often malignant neoplasm found most commonly in children. These tumors are chiefly identified by the presence of virilization, the excessive production of sex hormones and often are selective for androgens. These adrenocortical hormone secretions that are strongly upregulated above normal baseline values are found most commonly in female pediatric patients under the age of five. The constellation of clinical symptoms may all suggest Cushing’s syndrome or other paraneoplastic processes. The result of excessive hormone production includes physical asymmetry and growth disorders, including precocious puberty. Germ-line mutations in key tumor suppressor genes, such as p53, have been readily associated with ACC.

The classical clinical presentation of ACC is a female, pediatric patient exhibiting poor growth velocity, signs of virilization, accompanied by acne, puberache, and macroclitoris. These patients also may exhibit additional steroid hormone disorders, including glucocorticoid excess. Patients may have a family history of Li-Fraumeni syndrome or Beckwith–Weidemann syndrome. Germ-line mutations in TP53, affecting IGFII growth factor, have been associated with ACC. J. Fraumeni and J. Miller were the first to discover and document the familiar linkage through a nationwide retrospective analysis of children with ACC in 1967 (Else, 2012). Loss of p53 may be correlated to promote further genetic damage such as gain of function mutations in IGF2, for both are seen in malignant neoplasms. Other molecular factors may be at play, including stem and progenitor cells in the adrenals.

Population-based studies have revealed a carrier rate of a distinct mutation associated with ACC. The R337H mutation has been identified in 0.3 percent of the population of Southern Brazil and is found in the majority of pediatric ACC patients in this region. These pediatric patients present with the classical clinical symptoms at an earlier age of onset than those lacking the R337H mutation. Additionally, ACC may have been predicted to occur in one in every 455 live births in the region. R337H is one of the most common inherited mutations in southern and southeastern Brazil, with patients presenting with a constellation of malignant neoplasms. This same frequency of discovery has not been found in northern and northeastern Brazil.

Unlike in adults, histological features do not correlate with clinical outcome in pediatric patients. Nevertheless, compact cells with eosinophilic cytoplasm are common features of ACC tumor cells.
These cell nuclei demonstrate nuclear pleomorphic characteristics. Pathologic analyses reveal tumor masses that are large and browned, possessing cut surfaces and areas of focal necrosis and hemorrhage. Further microscopic evaluation reveals cells that may retain some characteristics of adrenal tissue but are significantly maligned or primary.

The presence of virilization supports evidence that pediatric adrenocortical neoplasms arise from within the fetal zone of the fetal adrenal cortex. The fetal adrenal gland rapidly grows through cell proliferation and angiogenesis at the gland periphery, cell migration, hypertrophy, and apoptosis. In terms of steroidogenesis, the fetal adrenal cortex is characterized by extensive production of dehydroepiandrosterone and its sulfate. After birth, the fetal zone rapidly involutes, followed by a decrease in androgen secretion. Following fetal zone regression, adult definitive zones arise from these definitive zones of the fetal adrenal. Disruption in these processes may promote ACC.

Childhood ACC cannot be distinguished by a specific prognostic indicator, including in R337H carriers. The loss of two functional alleles in the majority of all R337H-positive ACC is expected, however. Less than a quarter survival is predicted in patients with stage III and IV. Low survival is correlated to the R337H mutation as well as low-income status. Most of these children were found to be positive for germ-line R337H. Additionally, low family income status is also a predictor for poor prognosis as cancers are rarely found and options for appropriate treatment may not be available.

ACC diagnoses often precede poor prognosis, which is uncharacteristic of most adrenal cortex tumors. Five-year, disease-free survival for a complete resection of a stage I through III ACC is approximately 30 percent, while the most important prognostic factors are age of the patient and stage of the tumor. Poor prognostic factors include those commonly associated with malignant neoplasms, including high mitotic activity, local and distal invasion, mass of greater than 30 grams, diameter of greater than five centimeters, and failed or mutant p53 activity.

New treatments under investigation include targets to the IGF 1 complex. Figitumumab, an anti-IGF 1R monoclonal antibody has shown promising results; multikinase inhibitors, and growth factor blockers affecting epidermal growth factor and VEGF have also been shown to be effective therapeutic treatment options. These inhibitors retard tumor growth by interfering with processes of angiogenesis and tumor growth. They may also help to slow down the rate of metastasis.

Advertising

New forms of advertising allow cancer centers and pharmaceutical companies to bypass gatekeepers such as physicians and regulatory commissions and appeal directly to consumers regarding cancer drugs and treatment options. The results have been manifold, from awareness and prevention of cancer to detection and diagnosis of its symptoms as well as treatment options and end-of-life decisions. This entry first discusses the nature and origins of cancer drug and treatment center advertisements then outlines responses to and regulations for these advertisements.
Types of Drug and Treatment Center Advertising

While cancer-related advertisements appear across many media outlets including print, radio and the Web, the most common forum for drug and treatment-center advertisements is television commercials. These television spots encourage patients to perform a behavior or express behavioral intent with regard to awareness, prevention, diagnosis, and long-term treatment of cancer. For instance, a recent advertising campaign by Pancreatic Cancer Action encourages people to see their doctor if they display symptoms of pancreatic cancer, one of the least known but most deadly of the common cancers. Also, many companies promote breast cancer awareness with advertisements for mammography or other breast-related services with sexual innuendoes or images of mastectomy scars.

In its first two years from 2001 to 2003, CURE magazine, a publication directed at cancer patients, survivors, and caregivers, published more than 50 advertisements for chemotherapy drugs such as Xeloda and Taxoetere, supportive agents such as Neulasta and Aloxi, hormonal agents such as Arimidex and Femara, and other targeted therapy drugs such as Bexxar and Tarceva. Other examples include a recent campaign by Pancreatic Cancer Action, which emphasized the severity of pancreatic cancer and the importance of early diagnosis by showing patients who wished they had more treatable forms of cancer. Similarly, a campaign for Neulasta, a prescription medication used to reduce the risk of infection in people receiving strong chemotherapy, featured cancer patients saying that, with Neulasta, they are ready to face chemotherapy. Also, a print advertisement that ran in the New York Times showed a man and woman climbing a mountain, with the man extending his arm to the women and helping her to the summit. The slogan read, “Prostate surgery so effective, even women can feel the difference.”

Also, many comprehensive cancer centers advertise the quality of physicians and efficacy of treatment through patient testimonials and emotional appeals. For instance, the MD Anderson Cancer Center’s Making Cancer History and University of Maryland Medical Center’s Life-Saving Mission manage their reputations through advertisements that emphasize comprehensive competence with individual attention, from early diagnosis to end-of-life decisions.

Origins and Efficacy of Advertising

Since the 1700s, when patent medications were first advertised in U.S. newspapers, direct-to-consumer advertisements for medications have formed the majority of newspaper revenues. In 1938, the passage of the Food, Drug, and Cosmetic Act gave the newly created Food and Drug Administration authority over the labeling of drugs and the Federal Trade Commission over the regulation of drug promotion and advertising. In 1962, the passage of the Kefauver–Harris Act required proof that all drugs were safe and effective and transferred the authority for oversight of promotional material to the Food and Drug Administration, which in turn, required that advertisements present both benefits and side effects of advertised drugs. Today, drug advertisers must present only a major statement of risks and provide adequate provision to a brief summary of these risks on the company’s Web site. These summaries include educational advertisements about medical issues, promotional advertisements with the name of a drug, and product-specific advertisements that outline the uses of a product and direct patients to other outlets for supplemental information.

The efficacy of advertising for cancer drugs and treatment centers depends on several factors. Socioeconomic (education, income, and employment), geographic (neighborhood and urbanicity), and sociodemographic (age, sex, race, and ethnicity) determinants, as well as factors such as social networks, social support, social capital, and health insurance, impact exposure and attention to cancer advertisements and external information seeking and processing. These communication inequalities lead to gaps in knowledge of treatment options and may also compromise the doctor–patient relationship and lead to patient dissatisfaction and lack of trust or low health literacy. All of these health communication issues may, in turn, lead to general health issues such as problematic health behaviors and under and overconsumption of health products. Together, all of these factors serve to exacerbate socioeconomic, geographic, and sociodemographic cancer outcomes.

Responses to Advertising

With this in mind, critics of cancer drugs and treatment center advertisements argue that the generalities in cancer drug and treatment center advertisements serve the interests of the pharmaceutical companies, not the patient, by building...
brand recognition among physicians rather than providing understandable information to patients. On one hand, advertisements do not educate patients thoroughly enough, require a high level of medical literacy that most patients lack, and promote overprescription that hampers treatment decisions. On the other, advertisements provide patients with information they would not otherwise have known, empower patients as participants in their own health care, and echo new models of patient-physician relationships centered on patient needs.

Proponents of cancer drug advertisements argue that they empower patients to play more of a role in their own treatment in an increasingly nonpaternal and patient-centered medical environment. Patients can take the general information provided in advertisements and contextualize their own situations so that they can be more knowledgeable and responsive when visiting their physician. For instance, a recent study showed that advertisements for the breast cancer drugs aromatase inhibitors led to a slight increase in total prescriptions for the drugs but only among women who had a medical use for them.

Cancer treatment center advertisements in particular have been criticized because, unlike the drugs themselves, they are not held to the highest levels of scientific scrutiny in their claims. They appeal to the emotions of the patients and fear of the disease with superlatives such as highest cure rate and lowest risk, which are not supported with any scientifically verifiable statistics. For many, these advertisements are evidence of a disconnect between cancer research and advertising of treatment options. While the Food and Drug Administration mandates that any claims in advertisements for cancer medicines must be substantiated with scientific proof, the Federal Trade Commission does not require such substantiation regarding claims for the efficacy of treatment centers. As a result, treatment centers may use superlative language to tell a story of miraculous (yet anomalous) survival through the most technologically advanced treatment options but with no evidentiary support.

For instance, a representative television advertisement for the MD Anderson Cancer Center in Houston, Texas, features cancer patients crossing out the word cancer for their Making Cancer History campaign. The advertisement then displays the company’s slogan, “When Cancer Strikes, We Strike Back,” with a number one ranking for cancer care by U.S. News and World Report. Similarly, the University of Maryland Medical Center’s Life-Saving Mission campaign features action shots of a group of physicians working collaboratively, with the following voiceover: “Good morning, cancer, watch your back. All these people mean you harm.” The advertisement emphasizes the collaborative approach of the center, in which physicians gang up on each person’s cancer individually. The advertisement ends with a group of doctors told to gather round, listen up, and make sure a patient lives to see his daughter’s marriage.

A 2012 study of more than 400 TV and magazine ads from more than 100 U.S. cancer centers in the Annals of Internal Medicine found that advertisements relied mainly on patient testimonials and emotional appeals that elicit hope for survival with few statistics or actual results. Such advertisements have been criticized for several reasons. In the case of breast cancer awareness, advertisements that seek to increase the number of women seeking mammograms may be funded largely by the companies that sell mammography equipment. Other advertisements may capitalize on the emotions of grieving and overwhelmed patients, contradict the relatively little progress made in combating cancer, and rest on the erroneous assumption that the decision about a cancer center will be a deciding factor in the patient’s life or death. For the advertisers, such emotional appeals are meant merely to manage the reputations of the centers and not to promote competition among cancer treatment centers or take advantage of vulnerable consumers.

Aerospace Industry

Employees of the aerospace industry face cancer risks from a variety of occupational sources. Workers who build and repair aircraft are exposed to many carcinogens, including asbestos, industrial solvents, rocket fuels, and rubbers. The pilots, flight crews, and astronauts who operate aircraft at altitude are exposed to ionizing radiation from cosmic rays and the sun. Ionizing radiation degrades genetic material and has been linked to a cancer incidence; however, aerospace employees can reduce their exposure to this radiation by limiting flight times and flying at low altitudes. Both aircraft manufacturers and operators are subject to the potentially carcinogenic effects of shift work, which disrupts the body's natural circadian rhythms.

From the 1940s through the 1980s, aircraft were manufactured using many parts made from asbestos. These included airplane brakes, insulation, glues, and epoxies. During this period, workers who assembled or repaired aircraft, as well as those who manufactured aircraft parts, risked exposure to carcinogenic asbestos. Asbestos was thought to be ideal for aircraft manufacturing because it is lightweight, offers efficient sound insulation, and is highly resistant to damage from friction, heat, and chemicals. However, asbestos releases particles into the air that can cause health problems when inhaled or swallowed. In the 1970s, asbestos was linked to lung cancer, esophageal cancer, and mesothelioma. Asbestos dust can become attached to clothing or other surfaces, causing aerospace workers and their loved ones to be exposed to the carcinogen. Although asbestos is no longer used to manufacture new aircraft, some older aircraft still contain parts made from asbestos. Aerospace workers continue to risk asbestos exposure during aircraft maintenance and retrofitting. When removing or replacing aircraft parts made from asbestos, workers can become exposed to carcinogenic asbestos dust.

Workers in the aerospace industry are exposed to carcinogenic industrial solvents, increasing their overall risk of kidney cancer, liver cancer, cervical cancer, prostate cancer, melanoma and non-Hodgkin's lymphoma. Studies have linked occupational exposure to mineral oil with increased instances of melanoma, stomach cancer, and esophageal cancer in aerospace workers. The aircraft manufacturing and repair industries regularly use the industrial solvent trichloroethylene (TCE) as a metal degreaser. TCE is a colorless, nonflammable liquid that is toxic to humans and believed to be a carcinogen. It was originally used as a general anesthetic in medicine and was also used as an inhaled analgesic during childbirth. Developed countries discontinued medicinal uses of TCE in the 1980s. Economic factors and government regulation have led to a decreasing industrial use of TCE in the United States since the 1970s. Studies show that TCE causes liver and kidney cancers in animals. Studies linking TCE to specific instance of human cancers are less conclusive because occupational TCE exposure tends to occur along with other known carcinogens.

Aerospace workers involved in the manufacture, testing, and repair of aircraft and rocket engines are exposed to cancer-causing substances called hydrazines, which are flammable, colorless liquids commonly used in rocket fuels. Aerospace workers can come in contact with hydrazines in the production of rocket fuels and while testing or repairing rocket engines. Studies have shown that exposure to hydrazines correlates to increased incidence of lung and colorectal cancers.

Manufacturing of rubber products used in the aerospace industry has been associated with increased incidence of lung cancer, bladder cancer, and leukemia. It is difficult to isolate the individual toxic substances that cause these cancers because the production of rubber involves a variety of potentially dangerous chemicals. Furthermore, as workers combine the materials that produce rubber, these substances undergo chemical reactions that can alter their structures and potentially change their carcinogenic qualities.

Airplane pilots, flight crews, and astronauts experience an elevated cancer risk from a number of sources, including interruption of circadian rhythms, radiation produced by airplane cockpit instruments, and ionizing cosmic radiation. Air travelers and airline employees flying at altitude are
exposed to ionizing radiation that penetrates the
Earth's atmosphere from space. Ionizing radiation
refers to high-energy particles emitted by radioac-
tive sources. These consist of subatomic particles
such as neutrons, protons, electrons, positrons, and
photons including both X-rays and gamma rays. The
subatomic particles interact with atoms in the body,
causing them to lose an electron or break apart the
nucleus. Humans become exposed to ionizing radia-
tion through contact with materials in the ground,
inhaled radon, radioactive substances within body
tissues, and galactic cosmic radiation. The Federal
Aviation Administration (FAA) acknowledged in
1994 that aircrews are at risk of cancer and other
health effects due to the effects of ionizing radiation.

Supernovae, or exploding stars, are believed to be
the primary source of ionizing radiation emanat-
ing from outer space. During a supernova event, the
core temperature of a dying compact star suddenly
rises, restarting the nuclear fusion reaction. This
destabilizes the star, resulting in an explosion that
propels radioactive particles through space. Solar
flares and other disturbances in the atmosphere of
the sun also produce radiation particles that reach
the Earth.

The FAA operates the Solar Radiation Alert
system in order to inform airlines about radiation
levels at specific altitudes. Alerts are distributed by
the National Oceanic and Atmospheric Adminis-
tration's Weather Wire Service and report radia-
tion conditions between the altitudes of 20,000 and
80,000 feet. Aircraft are recommended to avoid
prolonged flight times at the affected altitudes in
order to minimize the risk of exposure to ionizing
radiation within the atmosphere. Flying at night is
not an effective way to reduce the risk of radiation
from solar disturbances because the Earth's mag-
netic field disbands radioactive particles more or
less equally around the globe.

Long-distance flights at high altitudes expose
travelers and airline employees to the greatest risk
of negative health effects from ionizing radiation.
Flying shorter distances at lower altitudes reduces
this risk because the increased amount of air above
the aircraft acts as a shield against radiation. Addi-
tionally, flights at lower geographical latitudes
receive more shielding by the Earth's magnetic field.
Thus, the risk of radiation exposure is lowest on
short flights at low altitude close to the equator and
highest on long flights at high altitude nearer the
north or south poles.

Fatal cancers are the most common health effects
caused by exposure to ionizing radiation during
flight. Radiation damages DNA and disrupts cellular
metabolism, which can cause genetic mutations
and cancers. Parents who are exposed to high levels
of ionizing radiation can pass on genetic defects to
their children. Prior to conceiving a child, the par-
ents' reproductive genetic material may be dam-
aged by ionizing radiation. During pregnancy, both
the mother and the fetus are at risk of exposure to
ionizing radiation, which can cause a miscarriage or
lead to fatal cancers in the child.

Despite their increased exposure to ionizing
radiation, a study found that German commer-
cial airline pilots had a lower incidence of cancer
than the general population and a below-average
mortality rate. Researchers attributed these results
to the relatively high socioeconomic status of the
pilots as well as the nonsmoking environment in
which they work. Both of these variables contribute to lower rates of fatal cancers throughout the population. Additionally, pilots must meet stringent physical fitness standards, further contributing to their overall health. This study suggests that, while ionizing radiation can contribute to increased incidence of cancer in flight crews, it may not be the most important factor contributing to their risk of cancer mortality.

The carcinogenic effects of ionizing radiation remain one of the primary obstacles to long-distance space flight within the solar system, including proposed interplanetary missions to Mars or asteroids. Astronauts in low Earth orbit are protected from cosmic radiation by the Earth’s magnetosphere, making their risk of cancer relatively low. Beyond low Earth orbit, however, astronauts would be exposed to higher rates of ionizing radiation, greatly increasing their cancer risks. New shielding materials and propulsion technologies would be required to protect astronauts from ionizing radiation and reduce their time of exposure, but these have not yet been discovered. Researchers at the National Aeronautics and Space Administration (NASA) are investigating biomedical and pharmaceutical treatments that might prevent the cancerous effects of ionizing radiation exposure in astronauts. These could include mapping astronaut genomes to look for known cancer-causing mutations and then administering therapies as a preventative measure. Current research, however, remains limited to animal studies and genetic testing of astronauts is a controversial topic.

Workers in the aerospace manufacturing industry and airline flight crews who work during irregular hours experience disruptions in the sleep–wake cycle. This shift work, or work done outside the typical work day, has been shown to lead to increased incidence of cancers due to the disturbance of physiological cycles known as circadian rhythms. Melatonin produced by the body during the night has been shown to have anticancer effects; however, exposure to artificial light at night suppresses melatonin production. In 2007, the International Agency for Research on Cancer concluded that disruptions to circadian rhythms can increase the risk of cancer in humans. Disrupted circadian rhythms correlate with elevated rates of breast cancer, prostate cancer, and colorectal cancer. Flight crews who cross time zones in the course of their workday are especially affected.

Airport employees and air traffic controllers who work at night are also subject to the deleterious health effects of shift work.

Afghanistan

The Islamic Republic of Afghanistan is a landlocked country in central-southern Asia with an arid to semiarid climate. Afghanistan has been invaded many times, and many great powers have battled for control of this territory, including the Timurids, Persians, Indians, Arabs, and British. In 1919, after three Anglo-Afghan wars, King Amanullah Khan declared Afghanistan a sovereign and independent country and began a modernization program. In 1973, Mohammed Daud seized power in a coup but was overthrown in 1978. The Soviet army invaded Afghanistan in December 1979 and propped up the People's Democratic Party, which had seized power in 1978. As part of the Cold War, the United States and the Soviet Union both funded conflict in Afghanistan with money, weapons, and equipment, and the Soviet invasion and the resulting civil war resulted in more than 1 million deaths and the creation of more than 6 million refugees who fled to the neighboring countries (mostly Iran and Pakistan).

Most of the recent history in Afghanistan saw the rise in power of the political-religious extremist movement of the Taliban, which imposed a brutal Islamic theocracy and committed many crimes against human rights, including systematically massacring civilians, forcing women into segregation, destroying many people's homes, and burning vast areas of fertile land. In 2001, the United States, together with the United Kingdom, launched Operation Enduring Freedom, allegedly in response to the September 11 terrorist attacks. Today, Afghanistan is one of the poorest nations in the entire world.

Decades of civil war and struggle have destroyed much of the Afghan health care system. Poverty, insufficient sanitation, and drought have exacerbated the problem, as has the exodus of health professionals. After Operation Enduring Freedom in 2001, the newly appointed Ministry of Public Health, with the help of foreign nations such as the United States, the United Kingdom, and France, did much to improve the health care system by building new clinics and hospitals, and in 2008, the fees charged for medical services were drastically reduced. However, most of the largest and better equipped medical facilities, many of which are military-controlled hospitals, are located in comparatively wealthy urban settings, such as Kabul, while poor rural communities have access only to lower quality services, often provided by poorly qualified personnel. Some efforts have been made by the government to educate the public about the importance of preventive health care, such as the establishment of a Breast Cancer Day, when volunteers from the Afghan Society Against Cancer distribute leaflets that teach women how to do a breast self-examination.

Afghanistan lacks a national cancer registry system, and specific cancer treatment facilities are not available, so people with the necessary resources often travel to neighboring countries (mostly India and Pakistan) to seek treatment. For these reasons, there are no conclusive statistics on the cancer burden, incidence, or mortality in Afghanistan. However, evidence from older and less comprehensive data sources (e.g., data collected from Afghan refugees in neighboring states or assistance camps, statistics provided by nongovernmental organizations, and research on foreign soldiers) indicates that among women, breast cancer is the most common, while among men, upper gastrointestinal tract (esophagus and stomach) cancer is the most common, followed by skin cancer and prostate cancer. Data on overseas military personnel deployed in Afghanistan show an alarmingly high risk of their developing prostate and breast cancer, possibly due to exposure to toxic substances such as depleted uranium (DU; used in ammunition and bombs).

Both sociocultural and environmental risk factors appear to play an important role in cancer incidence in Afghanistan. For instance, the high incidence of upper gastrointestinal tract cancer may be related to the dietary habits of the local populace, including the consumption of large quantities (up to 1 kilogram per day) of red meat barbecued over a wood fire. The elevated incidence of cancer in foreign soldiers may be related to chronic or continuous exposure to carcinogenic pollutants—from DU to chemicals from burn pits, kerosene-fueled pits used to incinerate all kinds of military waste. Burn pits are known to have released many known carcinogens, such as sodium dichromate, into the air, exposing thousands of
individuals to these toxic materials. The relationship between DU and elevated risk for cancer is controversial, but many peer-reviewed studies have found an elevated incidence of child/infant mortality and cancer in areas with high exposure due to military bombardment (e.g., Fallujah, Iraq). Many field tests performed by the Uranium Medical Research Center on the Afghan population in Jalalabad and Kabul shortly after Operation Enduring Freedom showed DU concentrations 400 to 2,000 percent above normal, and a significant amount of civilians examined suffered from symptoms of acute radiation poisoning.

Age

Cancer incidence shows a clear relationship with age, with the highest rates among older individuals. For instance, according to statistics from the Surveillance, Epidemiology, and End Results (SEER) Program, for the years 2007–2011, age-adjusted cancer incidence rates in the United States for those age 65 and over were 2,095.8 per 100,000, compared to 223.8 per 100,000 for those under age 65. The age-adjusted death rate from cancer is also higher in older individuals: 994.3 per 100,000 for those age 65 and over compared to 55.1 per 100,000 for those under age 65, for the years 2007–2011. Despite this, less is known about this population than about younger populations with cancer. This reflects lower participation in clinical trials and poor understanding of the unique issues in aging and cancer, ability to tolerate treatments, the role of comorbidities and comorbidity management, and perhaps the use of inadequate assessments. Yet with greater longevity, older adults are likely to be survivors with cancer, may benefit from a different approach to both assessment and treatment, and above all, should be treated as individuals rather than as an age group.

Given projections of a United States population by 2030 of approximately 365 million, including 72 million older adults (at or more than 65 years), cancer incidence is expected to increase 45 percent overall to 2.3 million persons with a 67 percent increase in cancers among older adults, according to B. D. Smith and colleagues. This reflects both that tumors occur at a higher proportionate rate for people more than 65 and that, with longer survival rates, T. O. Blank and K. M. Bellizzi report, many of those whose cancer initially occurred at younger age are also present in this older group. These realities require consideration of links between aging and cancer, cancer prevention in older age, challenges for cancer assessment, cancer treatment in older age, survivorship in older age, and palliative and end-of-life care.

Links Between Aging and Cancer

Although rates of cancer increase with age, the nature of this relationship is still unclear, and it
is definitely not established that there is a causal sequence. It does appear that aging is related to greater susceptibility to the promotion of tumors probably because most cancers require time to develop, and molecular changes in tissue attributable to aging both increase readiness to be affected by carcinogens and reduce immunities. V. N. Anisimov advances three hypotheses: (1) higher incidence of cancers in older age reflects longer exposure to carcinogens, (2) age-related physiological change, particularly in the endocrine and immune systems, may create an environment that is increasingly favorable to both the initiation of neoplasms and the emergence and growth of previously latent malignant cells, and (3) higher onset reflects a combination of cumulative mutations, gene silencing, dysfunction in telomeres, and alterations in stromal milieu. Choosing among these hypotheses is further complicated because incremental growth in incidence is not uniform across types of cancer, describes R. A. DePinho.

Cancer Prevention in Older Age
Research on primary prevention, efforts to understand the clinical quality of life, and cost of care implications of health promotion, smoking cessation, and healthy lifestyle interventions for older adults is lacking and therefore is also not a major feature in intervention approaches, S. M. Miller and colleagues state. The long life in the development of many cancers has been an argument for the provision of secondary prevention strategies such as screening particularly, explains L. C. Walter and K. E. Covinsky, because there are likely to be identifiable molecular abnormalities even when cancers appear asymptomatic, and if diagnosed in early or preclinical stages there is a high rate of success in curative surgery. Yet there is less emphasis on screening in older patients, often attributed to responses to shorter life expectancy, concerns about tolerance for screening tests, and beliefs that screenings in younger years were sufficient. However, an increasing older age in populations is now well established, with those more than 90 years being the fastest-growing age group, W. He and M. N. Muenchrath have found. Given this increased longevity, there are recommendations for screenings for breast cancer for women deemed to have life expectancies of five or more years and for prostate cancer for men deemed to have life expectancies of ten or more years (i.e., for the majority of those over age 65) and for additional research to establish similar recommendations for other types of cancers, observe researchers. There are concerns that ageism and poor understanding of the potential to self-manage or be supported in cancer diagnosis and care has encouraged a lack of attention to screening in older adults and indeed to curative treatment, according to R. Yanick.

Challenges for Cancer Assessment
There are issues that traditional cancer assessment may not be sufficiently comprehensive and that standard measures such as the Eastern Cooperative Oncology Group (ECOG) and the Karnofsky performance status (KPS) measures may not be sensitive enough in older age. What is known is that, for older adults, there is a need to both measure and consider depressive symptoms, comorbidities (particularly those that may preclude use of treatment such as a specific chemotherapy drug or that may have a direct or indirect impact on the cancer itself), the accumulation of comorbidities, the level of functional reserve, and potential for toxicity given the likelihood of multiple medications. Reliance on instruments tested for sensitivity for older adults and use of comprehensive geriatric assessment protocols is particularly recommended, states M. Extermann.

Cancer Treatment in Older Age
There are challenges in older age that may mean that cancer treatment is more problematic. Specifically, past disease may influence current onset and readiness for the rigors of treatment, and the progression of cancer may be lower, recovery times may be longer, and there are higher levels of comorbidity which may influence choices in treatment, potential for complications, and likelihood of polypharmacy concerns, describe T. O. Blank and K. M. Bellizzi. Therapy approaches must also consider the potential consequences of reductions in the individual’s cardiovascular and pulmonary reserve, declines in renal function, increased peripheral neuropathy, reduced bone marrow reserve, declines in hormones, and gastrointestinal changes, explain M. Sehl, R. Sawhney, and A. Naeim. However, the biggest challenge for treatment is the lack of older adults in most clinical trials, which means that there is inadequate guidance on appropriate levels of dosing and insufficient
information on potential for intervention effectiveness, according to S. M. Lichtman, L. Balducci, and M. Aapro. For example, in treatment for older women with breast cancer, there is increasing recognition that there have been too few studies of therapy processes, comorbidities, and outcomes. There are also recommendations that trials particularly examine not only the impact of comorbidities but also the cognitive and quality-of-life effects of the treatments themselves. Greater attention is also suggested to physician communication strategies that promote patient choice or that convey ageism and their impact on outcomes as well as attention to the impact of perceived social support on treatment outcomes among a group more likely to live alone, points out M. Tallarico and colleagues. Regardless of research findings, these are areas in practice that require physician and other clinician attention.

There are similar issues with radiation therapy. Older adults are less likely to receive radiation therapy because of quality-of-life concerns or ability to cooperate with the procedures. Their tumors may be identified as less aggressive and therefore not suitable for radiation, and deficiencies in organ function may also be a barrier. Preexisting cardiac issues, devices such as pacemakers, and other comorbidities may be additional barriers. Impaired function and cognitive status and difficulties with transportation may also be construed as reasons why older adults with candidates may not be considered good candidates for radiation, M. K. Mell, L. J. Munt, T. Wasil, and colleagues agree. However, the clinical data available, while recognizing the need to pay attention to comorbidity and quality-of-life barriers, do not support that age in and of itself precludes the use of radiation therapy. What is clear is that more work is needed to better understand the clinical, behavioral, and social support criteria for intervention, whether for radiation therapy or other approaches, report B. Given and C. W. Given.

Survivorship in Older Age
Greater longevity for those with late onset cancers and increased survival of those with earlier onset concerns into older age both mean that cancer survival in old age is a greater reality and must be a feature of cancer responses. The limited data that is available suggests that, in survivorship, older adults may have more psychological issues as compared to those without cancer, but compared to younger cancer survivors, their issues are more likely to be physical with some risks for mobility impairments, which may mean they are no longer able to live independently, explain N. E. Avis and G. T. Deimling.

Palliative and End-of-Life Care
Given the challenges in assessment, the realities of comorbidities, the increased threats to quality of life, and barriers to treatment, treatment options include palliative as well as curative responses. Effective cancer care then requires that clinicians work with patients to better understand their desires and goals. To date, there are concerns that advanced care planning is too rarely undertaken or relies on surrogates who are not sufficiently informed of the patient's wishes, summarizes B. Saraiya and colleagues.

AIDS-Related Cancers

AIDS-related cancers are those that are particularly prevalent in individuals either infected with the human immunodeficiency virus (HIV) or diagnosed with acquired immunodeficiency syndrome (AIDS).

AIDS-Defining Cancer

Three main forms of cancer have been identified as AIDS-defining cancers or malignancies. Kaposi’s sarcoma, non-Hodgkin lymphoma (NHL), and among female patients, cervical cancer are so closely identified with AIDS that the diagnosis of any one of these conditions in an HIV-positive patient signifies the transition from HIV infection to full-blown AIDS.

Kaposi’s sarcoma is rare among the general population; it is several thousand times more common among people infected with HIV. Similarly, NHL is some 70 times more likely to occur in an HIV-positive patient, and among female patients, cervical cancer occurs at least five times more commonly than in HIV-negative individuals.

These cancers occur with high frequency among those infected with HIV due to the oncogenic viruses that cause them. Human herpesvirus 8 is the pathogen responsible for Kaposi’s sarcoma; some subtypes of NHL are caused by Epstein-Barr virus; and human papillomavirus (HPV) is the cause of cervical cancer as well as other genito-urinary cancers.

Kaposi’s sarcoma was, along with pneumocystis pneumonia, one of the rare conditions whose sudden widespread appearance in the 1980s—the first description of AIDS-related Kaposi’s sarcoma appeared in 1981—led to the discovery of HIV and AIDS. While lesions due to Kaposi’s sarcoma can occur on any part of the body, a typical presentation of AIDS-associated Kaposi’s sarcoma includes cutaneous red or purple macules, usually on the upper body and the mucous membranes.
Kaposi’s sarcoma is most commonly transmitted through infected saliva.

NHLs are considered AIDS defining if they are either small noncleaved lymphomas or immunoblastic sarcomas, and they are lymphomas of B-cell or unknown immunologic phenotype; lymphomas of the brain are also deemed AIDS defining. NHLs are caused by, among other pathogens, Epstein-Barr virus; AIDS-related NHLs are the result of a compromised immune system, and a clear correlation exists between the extent of a patient’s immune suppression and the risk of comorbidity.

Cervical cancer among female AIDS patients is a result of infection by human papillomavirus. The risk of cervical intraepithelial neoplasia (CIN) in women with HIV is higher than among the general population; CIN is considered AIDS defining when it escalates into invasive cervical cancer. There is evidence of increased abnormality in Pap tests among HIV-positive women and that screening for cervical cancer by Pap smear is more reliable than by HPV DNA testing.

Because each of the three AIDS-defining cancers is caused primarily by an opportunistic infection, AIDS treatments that address immune suppression will also have an impact on cancers that are a consequence of AIDS—a shrinkage of lesions at the commencement of highly active antiretroviral therapy (HAART) is seen in more than 40 percent of Kaposi’s sarcoma patients, with incidence of NHL in particular among AIDS patients also reducing. HAART works by restoring a degree of immune function, enabling the infected patient to better fight the viruses responsible for these cancers.

Other AIDS-Related Cancers
In addition to the three AIDS-defining cancers, a range of other cancerous conditions are commonly comorbid with HIV and AIDS. Primary among these are cancers of the liver, anus, mouth, throat, lungs, testes, colon and rectum, and skin, as well as Hodgkin lymphoma and angiosarcoma. While these cancers are not caused by viruses opportunistically infecting patients with weakened immune systems, they are typically cancers that are strongly associated with risk factors that are commonly found among AIDS patients. Smoking, for example, is closely linked with cancers of the lungs, throat, and mouth; smoking is more common among HIV-positive patients than in the general population, and smoking, rather than HIV per se, is implicated in the increased incidence of these cancers. Similarly, there is a clear link between cancers of the liver, mouth, and throat and heavy alcohol consumption, which is also more common among patients with AIDS.

There is also evidence that the weakening of the immune system due to infection from HIV leads to a disruption in normal immune responses to very early malignancies.

Anal cancers are more common among AIDS patients; these cancers are primarily caused by human papilomavirus, but the prevalence among AIDS patients would appear to be due to the fact that male anal intercourse is a common means of transmission of both human papilloma and human immunodeficiency viruses.

Since the success of HAART has led to a reduction in the number of patients dying of AIDS at an early age from Kaposi’s sarcoma or non-Hodgkin’s lymphoma, AIDS has become a chronic condition with a significantly longer life expectancy, with the result that non-AIDS-defining cancers such as Hodgkin’s lymphoma and lung cancer have the opportunity to develop.

AIDS and Cancer Treatments
As AIDS is a weakening or failure of the immune system, patients with AIDS have specific considerations in terms of cancer treatments. In particular, chemotherapy and radiation therapy are, even in HIV-negative patients, harmful to the immune system. An additional complication is the interaction between the highly active antiretroviral therapies used to treat AIDS patients and the chemotherapies used to address their cancers. For example, both certain newer antiretroviral drugs and several cancer treatments are associated with long QT syndrome, itself implicated in sudden death from ventricular fibrillation.

Albert Einstein Cancer Center

Affiliated with Yeshiva University, the Albert Einstein Cancer Center is a leader in basic and clinical research related to better understanding cancer and the human body’s response to it. Taking an interdisciplinary approach, the Albert Einstein Cancer Center combines talents from across Yeshiva University to better understand the origins of cancer and how best to detect, prevent, and treat it in patients. The Albert Einstein Cancer Center has also formed partnerships with private concerns to further research related to cancer. With its location in New York City, the Albert Einstein Cancer Center has played a significant role in providing health services to members of low-income groups from that city.

Background

Yeshiva University was founded in 1886 to provide education for Jewish students and to serve as a center for Judaic studies. Over the years, Yeshiva University has evolved into a major research university, with an endowment of more than $1 billion and serving more than 10,000 students. As Yeshiva University has evolved, it has increased its emphasis upon graduate education, adding a medical school and other programs related to the sciences. In order to advance these research efforts, in 1971, Yeshiva University established the Albert Einstein Cancer Center, which is a part of its Albert Einstein School of Medicine. The initial director of the Albert Einstein Cancer Center was Harry Eagle, a pathologist and physician who once was at the National Institutes of Health (NIH). The following year, the Albert Einstein Cancer Center was designated as one of the inaugural academic cancer research centers by the National Cancer Institute, an honor it has held continually since that time.

The Albert Einstein Cancer Center is comprised of more than 150 scientists and researchers who are drawn from 18 academic departments at the Albert Einstein College of Medicine. These researchers seek to foster basic, clinical, population, and translational research regarding a variety of types of cancer. This work is broadly concentrated on five separate but related areas, which include the following:

- Tumor microenvironment and metastasis
- Stem cells, differentiation, and cancer
- Experimental therapeutics
- Cancer epidemiology
- Colon cancer biology

This interdisciplinary research is supported by a series of 14 shared resource facilities that Yeshiva University has developed. These shared resource facilities provide laboratory space, clinical research services, and population technologies.

Research

Each of the Albert Einstein Cancer Center’s programs serves to find better methods to detect, prevent, and treat specific types of cancer. The Tumor Microenvironment and Metastasis program examines the interactions between cancer cells and their microenvironments so that physicians might better understand those determinants of the potential of tumor cells that allow them to invade surrounding tissues, penetrate blood vessels, and enter and grow in distant tissues. This work has focused upon better understanding the contribution of macrophage subpopulations to tumor progression and how growth factors and cytokine action regulate cell migration, dissemination, angiogenesis, and invasion of distant sites. Work has also focused upon how these studies can be translated into therapeutic results. The stem cells, differentiation, and cancer program brings together investigators working on B-cell leukemia and lymphomas with investigators that study myeloid malignancies. These researchers have been joined by scientists who focus on cancer stem cells so that basic science discoveries related to mechanisms of transcription (including histone and chromatin biology), lineage determination and differentiation, and splicing and translation at the biochemical and molecular levels can be made. This
work has led to a series of correlative and clinical therapeutic trials and to the identification of new targets for future drug development.

The Albert Einstein Cancer Center’s Experimental Therapeutics program has focused upon preclinical drug development. This work has concentrated upon examining transition-state inhibitors, novel microtubule-stabilizing agents, targeted drugs, antifolates, and a broad spectrum of biologicals. This work has proven especially beneficial to physicians working with and patients facing breast, gynecological, head and neck, and lung cancers. The cancer and epidemiology program has been organized in three separate areas, including those working on viral issues; hormonal, obesity, and inflammation concerns; and genetic and epigenetic matters. This work has led to new treatment options for patients and increased understanding of how best to direct future research endeavors. Finally, the biology of colon cancer program has used mouse models and strain crosses to increase understandings of genetic and environmental mechanisms that increase the risk for and development of intestinal cancer. This work has examined the role of inflammation on colon cancer and which treatments show the most promise for patients battling this disease.

Outreach
The Albert Einstein Cancer Center often works with the Montefiore Medical Center, a teaching hospital that is part of Yeshiva University. Located in Norwood, a working-class neighborhood in the Bronx, Montefiore Medical Center has established the Montefiore–Einstein Center for Cancer Care. At this center, researchers from the Albert Einstein Cancer Center engage in a variety of clinical research activities. Members of the clinical oncology services teams conduct these activities as part of multidisciplinary disease-focused teams. Phase I, II, and III clinical trials have embraced a wide spectrum of cancers and their specific stages. A clinical trials office has established specific procedures and services that have assisted with protocol development, regulatory affairs administration, and data management. The Albert Einstein Cancer Center provides scientific review and prioritization of all clinical trials before they are evaluated by the Yeshiva University Institutional Review Board (IRB). This extra level of review has helped to streamline the IRB process and to increase the rate at which proposed studies are approved.

The Bronx contains an unusually high concentration of individuals living below the federal poverty line. Indeed, this community has been identified as the poorest urban county in the United States. The Albert Einstein Cancer Center has made a commitment to improving the health and well-being of the Bronx population and has initiated several programs to help assist with this goal. To that end, the Albert Einstein Cancer Center has conducted treatment research that has focused on reaching a high proportion of ethnic and racial minority patients who are often underrepresented in cancer clinical trials. Epidemiological research conducted by the Albert Einstein Cancer Center has thus concentrated on certain factors that can contribute to the excess burden of cancer in low socioeconomic-status and minority communities, including obesity, viral infections, and comorbid illness. Behavioral and social scientists from the Albert Einstein Cancer Center have worked in conjunction with medical care providers and community partners to find ways to improve cancer outcomes in the Bronx and other areas, efforts that have improved the outcomes for those facing cancer.

**Alcohol**

The International Agency for Research into Cancer (IARC), part of the World Health Organization (WHO), has classified alcohol as a Group 1
carcinogen since 1988. It is a known fact that cancer can occur when cells become damaged. In addition, it is known that alcohol can indeed damage cells and DNA. Alcohol also reduces the amount of folate in the blood. Folate is a B vitamin that cells need to create new DNA correctly. Alcohol may increase the risk of cancer by impairing the body’s ability to break down and absorb a variety of nutrients that may be associated with cancer risk. In the colon and rectum, bacteria can convert alcohol into large amounts of acetaldehyde, a chemical that has been shown to cause cancer in lab animals. Alcohol and its by-products can also damage the liver, leading to inflammation and scarring. As liver cells try to repair the damage, they can end up with mistakes in their DNA, which could lead to cancer.

Research shows that, the more a person drinks, the more his or her risk for certain cancers increases. Alcohol is a major contributor to cancer mortality; prevention of cancers associated with alcohol use includes limiting drinking. Education, screening, and brief counseling are ways to help decrease the risks associated with alcohol-related cancers.

Prevalence
According to the British Medical Journal, in Western Europe, a proportion of cases of cancer can be attributed to alcohol consumption, especially consumption higher than the recommended upper limits. Among men and women, 10 percent and 3 percent, respectively, of the incidence of total cancer was attributed to former and current alcohol consumption in selected European countries. A study published in 2013 in the American Journal of Public Health found that an estimated 18,178 to 21,284 alcohol-attributed deaths in the United States during 2009 amounted to 3.2 percent to 3.7 percent of all cancer deaths that year (accounting for an average of up to 19.1 years of potential life lost per death).

According to the WHO, alcohol is estimated to cause between 20 percent and 30 percent of esophageal and liver cancers worldwide. The impact of alcohol-related cancer is highest in North America and Europe and lowest in the Eastern Mediterranean and South East Asian regions. Of all deaths from cancers related to alcohol, approximately 30 percent occurred with a consumption of less than 1.5 drinks per day, thus indicating that there may be no safe consumption level at which there is no cancer risk.

Types of Cancers Associated With Alcohol
A meta-analysis of more than 200 studies assessing the links between alcohol and various types of cancer supports that alcohol consumption has been linked to an increased risk for various types of cancer including oral cavity, pharynx, larynx, esophagus, liver, colon, rectum, and in women, breast. The Lancet supported that evidence of a casual impact of average volume of alcohol consumption was found for these types of cancers.

While cirrhosis and aerodigestive cancers are generally seen with higher amounts, increases in incidence are seen at these low levels. The alcohol attribution rate for esophageal cancer is around 75 percent; lip, oral cavity, pharynx, and larynx cancers are around 45 percent; and liver cancer is around 15 percent. Usually, cirrhosis precedes liver cancer and often tends to shorten one’s life even before cancer sets in. According to the American Cancer Society, alcohol can also be connected to pancreatic cancer.

Alcohol can increase the level of hormones such as estrogen in the body. Unusually high levels of estrogen can be linked to breast cancer. An increase in breast cancer can be detected in women who drink one or more drinks per day.

Smoking and Alcohol Use: Double Trouble
People who smoke and drink multiply the risk for certain cancers because tobacco and alcohol work together to damage the cells of the body. For example, research suggests that alcohol makes it easier for the mouth and throat to absorb the cancer-causing chemicals in tobacco, making the risk of these cancers much larger compared to either drinking or smoking alone.

Alcohol Use and Cancer Treatment
According to the American Cancer Society, alcohol should be avoided during and after cancer treatment. Alcohol—even in very small amounts—can irritate mouth sores caused by some cancer treatments and can even make them worse. Alcohol can also interact with some drugs used during cancer treatment, which might increase the risk of harmful side effects. Although for those who have completed cancer treatment, the effects of alcohol on cancer recurrence risk are largely unknown in theory, it’s possible that alcohol use might raise the risk of recurrence.
Prevention

The study published in 2013 in the *American Journal of Public Health* was the first to quantify alcohol use in cancer death, identifying alcohol consumption as a leading cause of cancer deaths. The World Cancer Research Fund found that, in the United Kingdom, 51 percent of esophagus and 22 percent of breast cancers could have been prevented if everyone stopped drinking alcohol. Abstaining or cutting down on alcohol seem to be the best barriers against alcohol-related cancers and other problems. The American Institute for Cancer Research (AICR) provides the following prevention recommendations:

For cancer prevention, AICR recommends not to drink alcohol. However, our expert report recognizes that modest amounts of alcohol may have a protective effect on coronary heart disease. If you do drink alcohol, limit your consumption to no more than two drinks a day for men and one drink a day for women. The evidence that all types of alcoholic drinks increase the risk of a number of cancers is now stronger than it was in the mid-1990s.

The sooner prevention efforts begin, the better. For example, a pooled analysis of 13 case-control studies of cancer of the oral cavity and pharynx combined found that alcohol-associated cancer risk did not begin to decrease until at least 10 years after stopping alcohol drinking. Even 16 years after they stopped drinking alcohol, the risk of cancer was still higher for ex-drinkers than for nondrinkers.

Recommendations and Interventions

The prevalence and risk associated with alcohol and cancer is not well publicized. This is a problem and therefore an area of opportunity for the media, academia, health care providers, community advocates, and policy makers. Educators can use various platforms to inform students about the dangers of alcohol misuse. Early intervention is ideal as the sooner one hears a preventive message, the better. Health care providers have a perfect opportunity to make a difference in terms of prevention and intervention. Recommendations include integrating brief alcohol screenings such as the Alcohol Use Disorders Identification Test—Consumption (AUDIT-C) in primary care and in other points of entry in the health care system, including urgent care settings. The AUDIT-C, for example, is easy and quick to administer and gives a good indication of alcohol misuse.

Alcohol screening, followed by brief alcohol counseling interventions for patients who screen positive, has been found to decrease drinking. Research has shown that brief intervention is effective and essential. In fact, longer counseling sessions are not necessarily better. Five minutes of advice has been shown to be just as effective as 20 minutes. Brief intervention can be a one-time conversation or series of conversations between an at-risk drinker and a practitioner. The goals are to (1) help the drinker increase awareness of his or her alcohol use and its consequences and (2) encourage the person to create a plan to change his or her drinking behavior to stay within safe limits. The conversations are
typically 5 to 15 minutes, although they can last longer if needed. This is much more manageable for health care providers, who are often very busy with high patient workloads. It is not only time effective but cost-effective. One study of trauma patients in emergency departments and hospitals found a net savings of $89 in health care costs alone per patient screened and $330 for each patient offered an intervention.

Conclusions
Research has found that, the more a person drinks, the more the cancer risk increases. Proportions of cases of cancer can be attributed to alcohol consumption internationally. Alcohol consumption has been linked to an increased risk for various types of cancer including oral cavity, pharynx, larynx, esophagus, liver, colon, rectum, and in women, breast. People who smoke and drink multiply the risk for certain cancers. It’s possible that alcohol use after cancer treatment might raise the risk of recurrence if a person resumes drinking. Alcohol consumption is the number one preventable cause of cancer deaths. Prevention of cancers associated with alcohol use includes limiting drinking to no more, or less, than two drinks per day for men and less than one drink per day for women. Alcohol screening, followed by brief alcohol counseling interventions for patients who screen positive, has been found to decrease drinking and should be integrated into all levels of health care.

Algeria

Cancer in the north African nation of Algeria is one of the country’s leading causes of mortality and morbidity with roughly 30,000 new cases reported annually. The incidence of cancer is increasing due to growth of the population in the country, population aging, and the pervasiveness of tobacco smoking. The World Health Organization (WHO) GloboCan project reported, in 2008, that there were 28,736 cancer cases in Algeria. The GloboCan project predicted that the cases of cancer would
increase nearly 25 percent to 35,628 by 2015. The most common cancers in the nation are lung, breast, and prostate cancer, which together, account for more than 25 percent of new cancer cases annually. Treatment and management of other types of cancers, including Hodgkin’s disease, have seen considerable progress in Algeria, both in improvement in treatment outcomes and in reduction of long-term side effects.

During French colonial rule (1830–1962), Algerian medical practitioners were trained in European techniques, and health care in the nation came to be well regarded abroad. However, at the time of independence in 1962, it is reported that there were only 300 physicians and a faltering health care system. In the decades since independence, there has been discernable progress in enhancing and expanding the health care sector in Algeria to be one of the best across the African continent. Development has included education and training of doctors and other health care practitioners and the establishment of numerous health care facilities, including 13 university hospitals and research centers, 34 specialized hospitals, 460 polyclinics, 1,110 medical centers, and 3,600 small dispensaries and basic health care units, most with adequate practitioner staffing levels to serve the nation’s 34.9 million citizens.

In recent years, the Algerian health care system has continued to achieve a considerable level of development. Health care expenditures have also continued to increase; the WHO, in 2008, reported that the Algerian government spent more than 10 percent of its overall budget on health care. The gross domestic product (GDP) share of health expenditures has increased in the past decade from 4.1 percent in 2003 to 5.6 percent in 2009; however, this level is low given the vast needs of modernizing health care infrastructure and given that the epidemiological profile of Algeria is changing with increases in noncommunicable diseases such as cardiovascular diseases, diabetes, and cancer.

Most health services for Algerian citizens are provided by the public sector, although there does exist a small private sector in which approximately 20 percent of Algerian physicians practice.

The Algerian government established a national plan of information and communication technology use in the health care sector since 2002 to build connectivity and enhanced and expanded information dissemination to health care professionals and patients.

In 2010, the Ministère de l’Al Santé Algérien of the Algerian government launched a medical orientation plan to 2025 and allocated $28.5 billion to improve the health care infrastructure. Most notably, the plan includes the construction of 57 cancer treatment centers and 200 hospitals to increase health care access across the nation. This increase is important considering that Algeria is the largest country on the African continent, covering 919,595 square miles, and comprises vast rural areas populated by nearly one-third of the overall national population, who have been severely lacking in health infrastructure.

In January 2015, Abdelmalek Boudiah, the Algerian Minister of Health, announced several measures intended to improve health care in Algeria, including promotion of the use of generic drugs and the local production of pharmaceuticals, increasing the production of sera and vaccines by the Pasteur Institute of Algiers, and the creation of new centers to treat cancer. In May 2015, the Algerian Council of Ministers announced a new anticancer plan for the years 2015 to 2019, with funding amounting to about DZD 180 billion. Aspects of this plan include improved prevention, screening, and diagnostic services, modernization of existing facilities, and increased funding for oncology units and anticancer centers.

There are three strategic health and medical sites in Algeria, first, the capital city of Algiers, with expertise in heart disease; second, the northwestern city of Oran, specializing in oncology; and third, Blida, specializing in kidney research and care. However, there are several oncology research and treatment specialists in Blida, most notably at Le Centre Anti-Cancer de l'Hôpital Frantz Fanon de Blida, named for political theorist, activist, and social philosopher Frantz Fanon (1925–1961), who served as head of the psychiatric department of l'Hôpital Blida-Joinville from 1953 to 1956.

Along with the growing health care infrastructure, more generally, the cancer-specific health care infrastructure is developing. Noteworthy clinics with specialization in oncology and radiotherapy include the private Clinique Al Azhar in Dely-Ibrahim. In addition, at least 12 private-sector cancer diagnosis and treatment centers are in their planning stages, along with proposals to modernize existing cancer diagnosis and treatment centers.
and a plan to establish a National Cancer Care Institute in Oran. Medical equipment and particular medicines generally and specifically to diagnose and treat cancer may not be the newest available in Europe or the United States, and thus, some of Algeria’s health care network is in need of modernization, particularly in rural and remote areas.

Cancer specialists are members of international organizations such as le Congrès Nationale de la Société Française de Radiothérapie Oncologique (SFRO) in Paris, France, la Société Française de Cancérologie, la Fondation Française de Cancérologie Digestive, l’Association Internationale des Registres du Cancer, la Société Internationale de Chirurgie Hépato-Pancréato-Biliaire, la Fédération Pan-Arabe de Chirurgie, and the Arab Medical Association of Cancer. They have studied abroad at le Centre International de Recherche sur le Cancer in Lyon, France (CIRC—Lyon) and continued research partnerships with the International Agency for Research on Cancer in Lyon.

Relevant organizations within the nation include L’Association “El Fedjr” d’Aide aux Patients Atteints de Cancer, La Fondation Nationale pour la Recherche Médicale, La Société Algérienne d’Hématologie et de Transfusion Sanguine, Le Société Algérienne d’Oncologie Médicale in Blida.

Tobacco use continues to be an important risk factor for lung cancer in Algeria. A WHO study reported that 29 percent of adult men and 0.2 percent of women in Algeria use tobacco. Surgical procedures for lung cancer include lobectomy, bilobectomy, and pneumonectomy. Adjuvant chemotherapy is a standard treatment for patients with non-small cell lung cancer. The three-year survival rate for lung cancer reported in Algerian research is 22 percent. In addition, there is a relatively high risk for nasopharyngeal carcinoma in Algeria; rates of 5.4 in men and 1.9 in women are 10 times higher than incidence in Europe. Standard treatment of locally advanced undifferentiated nasopharyngeal carcinoma is chemotherapy followed by locoregional radiotherapy.

Cancer registries in Algeria, such as Le Registre des Tumeurs d’Alger, Institut National de Santé Publique, Le Pierre & Marie Centre Curie, Dept. of Medical Oncology, Algiers, and the Algeria Anti-Cancer Centre (CPMC) tumor registry; those of neighboring nations—Morocco, Tunisia, Libya, and Egypt—have increased in number from one to nine and cover at least 13 percent of the total regional population. Data from the registries is considered to maintain quality levels from acceptable to good, according to available indicators. The pattern of risk shown by North African cancer registries is exceptional in that the total cancer burden in the region ranges from one-third to one-half of what is observed in Western Europe. The overall incidence rate in men (world age standardized, per 100,000) ranges from 86.3 in Sétif, Algeria, to 156.1 in Garbiah, Egypt. The range is similar in women: 80.3 in Sétif, to 164.0 in the capital city of Algiers. Case mix and level of rates are quite homogeneous across the region. As mentioned, the most frequent cancers—lung, breast, and prostate—are consistent with those in Western Europe. The pattern of consistency between North Africa and Western Europe diverges entirely from that of sub-Saharan Central and Southern African countries, where infection-related cancers are predominant.

Allergan (United States)

Allergan, Inc. is one of the major global pharmaceutical companies in the world, and though its involvement in direct cancer therapy is limited, it has played (and potentially will play again) a role in this arena. The precursor to what would become Allergan was founded in 1948, when Gavin Herbert developed its first antiallergy nose drop product; soon after, Gavin Herbert and his business partner Stanley Bly developed an eyedrop to treat allergic conjunctivitis. As a company, Allergan, Inc. was established in 1950 under the name of Allergan Pharmaceuticals. Beginning in 1957, the company was led first by Mr. Herbert’s son, Gavin Herbert, Jr., and more recently Allergan has been led by David Pyott, who served as president and chief executive officer (CEO) since 1998 and serves as chairman of the board and president as well. Allergan is headquartered in Irvine, California.

Allergan is a multibillion-dollar, global health care company with several lines of product in a variety of areas focused on ophthalmic pharmaceuticals, neurology, medical dermatology, urology, and medical aesthetics. The best-known pharmaceuticals offered by Allergan include Botox, Restasis, Lumigan, Botox Cosmetic, and the family of dermal fillers Juvederm. In addition to pharmaceuticals, Allergan’s products include breast implants, and until recently, the company produced the lap band and the Orbera system (an intragastric balloon designed to be inserted in the stomach and to assist in weight loss).

As part of the company’s focus on the urology therapeutic area, in 2008, Allergan and Spectrum Pharmaceuticals announced a collaborative agreement for the development of Apaziquone (EOquin), which was investigated for the treatment of non-muscle invasive bladder cancer (NIMBC), a form of cancer localized in the surface layers of the bladder and that has not spread to the deeper layers of the bladder muscles. However, at the beginning of 2013, Spectrum Pharmaceuticals reacquired all development and commercialization rights for Apaziquone. At least for the moment, Allergan is therefore not directly involved in cancer therapy, though this might change in the future.

Indirectly, some of Allergan’s products still affect the lives of cancer survivors. For example, Allergan is the producer of breast aesthetics products targeted at women who desire restoration of their breasts following a variety of events, including breast cancer.

Finally, it is worth mentioning that, in 2010, Allergan received the CEO Cancer Gold Standard accreditation, recognizing its commitment to concrete actions aimed to reduce the cancer risk of its employees and their families. This award is given yearly by the CEO Roundtable on Cancer, whose goal is to recognize the way in which companies can use screenings, early detection, and healthy changes in lifestyle as ways to reduce cancer risk.

**Alternative Therapy: Diet and Nutrition**

Good nutrition is significant during cancer treatment. It restores health and prevents malnutrition. Some cancer treatments rely more on diet and nutrition as natural alternatives to help patients recover from cancer rather than conventional medicine, such as radiation therapy. In most cases, the diets and therapies have not been well tested, and the government has not approved them. However, more research has been conducted, and new therapies are being introduced. A few of these therapies have entered the medical mainstream, and doctors and hospitals are adopting the techniques as a result of increasing requests from their patients.

Alternative therapies do not rely on surgery, radiation, and chemotherapy. Their origins extend far back to ancient times, when they were associated with religion and folklore. Some of the therapies have undergone scientific tests but were either found ineffective or unproven. The therapies analyze the pathological conditions that caused the cancer to take over the body and the conditions needed for the healing. The response to the illness includes spiritual, physical, mental, and emotional factors.

Some experts in the past have called the alternative therapy industry a fringe or quackery. They say it is based on theories; some therapies have not received thorough examination and may reduce the quality of life, and their use may delay treatments from medicines that have been proven to work. Researchers have conducted more studies that have improved the understanding of their benefits, hospitals have adopted some forms of alternative therapy due to requests from patients, and more therapies are being developed and presented to the public. Today, complementary medicine, which uses its approach with conventional medicine, and alternative medicine are generally associated with one another, and they are referred to as CAM. CAM has grown in popularity in the United States and throughout the world.

Experts use five categories to define CAM: mind-body medicines, manipulative and body-based practices, energy medicine, whole medical systems, and biologically based practices. Mind-body medicines imply that the mind can affect the body. Its activities include yoga, imagery, and meditation.

Manipulative and body-based practices involve working with one or more parts of the body, such as massage, chiropractic care, and reflexology. Energy medicine suggests the body has energy fields that can influence healing and wellness, such as tai chi, reiki, and therapeutic touch. Biologically based practices focus on dietary supplements and herbal products like vitamins, foods, herbs, and special diets.

Cancer cases are often explained by genetics and dietary factors. The food consumed and an individual’s nutritional status change a person’s risk of obtaining cancer, the types of cancer the person is at risk of getting, and the age when the cancer develops. Experts have indicated that diets high in fat increase cancer risk, while low-fat diets rich in fiber, fresh fruits, veggies, and whole grains ward off the disease. Diet and exercise increases the body’s defenses, helping slow or inhibit the cancer process.

Diet, nutrition, and medicine play significant roles in the quality of life of a cancer patient before, during, and after treatment. They build strength and energy, help maintain weight, and help accelerate the healing process during recovery.

Many cancer patients experience involuntary weight loss and malnutrition. Treatments like chemotherapy and radiotherapy may cause loss of appetite, problems with swallowing, or an upset stomach. The cancer and its treatments alter the way foods are consumed as well as which foods and nutrients the body tolerates. The nutritional needs of a cancer patient vary. The type of cancer, the treatment, and side effects need to be considered. Patients undergo nutritional screenings and assessments prior to treatment. The screening identifies
nutritional risks, and the assessment determines nutritional health. This also gauges how well the patient can handle the cancer treatment. The patient may have to change his or her diet to include food items that are not typically recommended.

A variety of foods can give the body the nutrients it needs to fight off cancer, and a significant number of patients have sought out alternative nutritional therapies as a result. These therapies have focused on changing the consumption of nutrients that could aid healing and detoxification from the cancer and the treatments.

**Asian Diet**

Many people living in Asian countries who follow the traditional diet have had lower rates of heart disease, obesity, cancer, and other chronic diseases. Most Asians live longer when compared to people in the United States. The diets in these countries are associated with religious practices and long-held customs.

Although the geographical base of the diet is broad and people in each country values their unique flavors and cooking styles, their most common food is rice. They also eat high amounts of plant-based foods, vegetables, fruits, beans, legumes, nuts, dairy, and fish.

Consumption of soy products and tea is very high throughout most parts of Asia. Both are considered food staples. Researchers found that hormone-dependent cancers are less prevalent in Asia. Their studies suggest bioactive components found in soybeans and tea have cancer-fighting properties.

Soybean proteins contain phytoestrogens, such as isoflavones which are found in abundance. Their chemical structure and function are similar to mammalian estrogens. Genistein is the major isoflavonoid present in soybeans. It has been shown in studies to inhibit the growth of cancer cells, depending on the dosage and when the soy is consumed. It has also been found to have antioxidant properties.

A growing number of studies show the cancer-preventive effects of teas. They suggest that tea not only slows down cancer progression, but it also changes the characteristics of the factors related to the cancer development. Most studies have focused on green teas. The components of the tea have been linked to stopping tumor growth at certain organ sites and during certain phases of growth. Other teas showing strong cancer-preventive effects include black, oolong, and white tea. Most of their cancer-fighting characteristics have been associated with the strong anti-oxidative activity of polyphenols, a large group of plant chemicals found in high amounts in green tea. Most of the polyphenols are catechins, which is a type of disease-fighting phytochemical compound.

Studies indicate the combination of the soy and tea have been effective at reducing the proliferation of tumors.

Fish and plant-based foods are consumed in high amounts. These foods are rich in phytochemicals and omega-3-fatty acids, which help to lower the risk of cancer. Phytochemicals are plant-based compounds that exhibit either antioxidant or hormone-like activity. They have been shown to block the action of carcinogens that attack organs and tissues, or they stop the development of the cancer. Omega-3 fatty acids have also been found to suppress the formation and growth of cancer.

The Asian diet also limits certain foods with a high glycemic index, like sugars and starches. The index estimates carbohydrate-containing foods’ effect on blood sugar. Recent research has associated a diet with a high glycemic load with an increased risk of cancer.

**Macrobiotic Diet**

The macrobiotic diet has been around for centuries, and it is believed to have originated in Japan. Macrobiotics started off as a cultural movement in the United States. The movement heightened when it was led by Michio Kushi, who founded the Kushi Institute in Boston. It promoted the macrobiotic way of life. The diet is rooted in spirituality. Its dietary principles include simplicity and avoiding toxins, which relates to some aspects of Buddhism. The concepts of yin and yang were woven into the philosophy. The diet’s association with cancer prevention arose when a popular book promoted the diet’s benefits for cancer treatment and prevention. Research has been limited, but the studies that have occurred show that the diet increases the survival rates for cancer patients and improves the quality of their lives. It also has lowered estrogen levels in women possibly because of its high phytoestrogen content.

The macrobiotic diet’s framework is tailored to the individual. Half of the diet consists of organically grown whole grains such as brown rice, barley, millet, oats, and wheat. Studies suggest the
cancer-preventive effects of whole grains come from estrogen metabolism, glucose and insulin metabolism, and oxidative processes. Local and organic fruits and vegetables make up a quarter of the diet, and the rest of the diet includes soups, seaweed, beans, and bean products particularly containing soy like tofu and legumes, such as chickpeas and lentils. The diet avoids meat, poultry, animal fats, potatoes, tomatoes, sugar, coffee, stimulants, aromatic herbs, and genetically modified foods. It also requires the use of specific cooking materials such as wood, glass, stainless steel, and ceramic. The diet should be properly managed to avoid nutritional deficiencies.

**Mediterranean Diet**

The Mediterranean diet derived from some of the cultures and traditional foods found along the Mediterranean basin. Scientists noticed how Mediterranean countries historically have had a lower incidence of all cancers when compared to northern European countries, the United Kingdom, and the United States. They found a connection with food people ate in those countries and began analyzing the food patterns. They found that it perhaps provides a protective role toward cancer in general.

Some scientists consider the Mediterranean diet as a low-fat diet. It consists of consuming high amounts of olive oil, fruits and nuts, potatoes, vegetables, legumes, seeds, cereals; moderate amounts of fish, seafood, and wine; and low amounts animal products like diaries, meat, and meat products. The diet is rich in antioxidants such as vitamin C, vitamin E, carotenoids, phenols, and flavonoids.

The olive oil is the principal source of fat, and the type of fat is monosaturated, which is a low-saturated fat. Researchers believe the monosaturated fat regulates the gene that has the potential to cause cancer. The consumption of red and white wine has shown that its polyphenolic substances like catechins and resveratrol provide an anti-oxidative effect.

Many of the foods associated with the diet have anticancer properties. Scientists have attributed the diet’s cancer-fighting effects to the integration and interaction of the foods. Some of the foods have undetectable health effects, but when working in combination with other foods, their effects become more pronounced.

The diet has also been associated with lowering heart disease and meets the nutritional requirements better when compared to the Western diet.

The diet also protects against heart disease, lowers bad cholesterol levels, and reduces the chances of getting Parkinson’s or Alzheimer’s diseases. Researchers found that people who followed the traditional Mediterranean diet closely had lower mortality rates.

**Vegetarian Diet**

Vegetarianism is the practice of eating a mainly plant-based diet. The plant sources include grains, nuts, fruits, and vegetables. The diet varies. Some common vegetarian diets strictly exclude animal products, such as a vegan diet, while others include some animal products, such as the ovo-vegetarian, lacto-vegetarian, and pesco-vegetarian diets. The vegetarian diet helps to lower the risk of several diseases, like heart disease, diabetes, high blood pressure, and certain types of cancer.

When compared to diets that contain meat, vegetarian diets offer more fiber, vitamins, minerals, antioxidants, and other plant chemicals. Studies show vegetarians have lower incidences of cancer compared to meat eaters; vegetarians receive more essential nutrients and absorb the nutrients more efficiently, and a vegan diet provides mild protection from all cancers, especially female cancers.

Vegetables are a major source of phytochemicals. Phytochemicals generally provide vegetables with their flavor and color. Studies have found phytochemicals may help to prevent the following activities: the formation of tumors, cellular mutations, and the growth of cancer cells. They have also been found to protect against the oxidation of lipids, which is considered a crucial step to the development of a disease, and they adjust immune and inflammatory responses.

Food processing has a major influence on the levels of phytochemicals in vegetables and vegetable products. Heat, washing, peeling, cutting, and drying can degrade phytochemicals, and many of them can be poorly absorbed; therefore, it is important to manage the diet properly to avoid protein and other nutritional deficiencies.

**Wheatgrass Therapy**

Wheatgrass was popularized for therapeutic purposes by Dr. Ann Wigmore. Most people consume wheatgrass as a dietary supplement, but it
Alternative Therapy: Diet and Nutrition

also has been used to treat common ailments like colds, coughs, and fevers. It is rooted in folk medicine, and not many clinical studies have occurred to help support its benefits. Wheatgrass has high amounts of chlorophyll, and supporters claim that the chlorophyll raises the body’s oxygen level, giving cancer patients energy. It also has an alkalizing effect. This and its antioxidant characteristics help it to fight free radicals in the body. Wheatgrass is rich in vitamins A, C, E, K, and B complex as well as minerals like calcium, iron, and magnesium. It is a great source of protein as it contains 17 amino acids, and eight of them are essential. It also has a high amount of enzymes. Supporters claim wheatgrass boosts the immune system, cleans the digestive system of bad bacteria, and detoxifies the body, causing the cancer to decrease. They suggest only a few ounces of the juice is needed on a regular basis to achieve some of its benefits. However, very little clinical data has been conducted to support its use.

Enzyme and Metabolism Therapies

Enzyme supplements are becoming a common form of alternative cancer treatment. Enzymes are natural proteins that activate and speed up biological reactions within the body. For instance, digestive enzymes break down food in the stomach, so nutrients are absorbed in the body, and metabolic enzymes build new cells and repair damaged cells. Some 10,000 enzymes of various types are produced by human cells to keep metabolism normal.

Enzyme supplements come from animal organs and some plants. They are consumed either by pills, capsules, or powders. Proponents claim the supplements strengthen the immune systems, improve circulation, aid weight loss, and relieve rheumatoid arthritis. They suggest the enzymes strip cancer cells of a protective layer, giving white blood cells the opportunity to identify and attack them.

The use of enzymes in mainstream medicine has occurred. They have shown up in chemotherapy drugs and treated digestive problems for patients who had their pancreas removed. Scientific research has yet to support the claims of the enzyme supplements’ effectiveness.

Metabolic therapies often incorporate enzyme therapy in combination with special diets and nutritional supplements. Research does not support this therapy as well, and some practices are considered harmful.

The metabolic therapy rids the body of toxic substances built up in the body from either food or the environment. Proponents believe the toxic substances create a chemical imbalance within the body.

The therapy uses special diets usually consisting of fresh fruits and vegetables, vitamins and mineral supplements, colonic irrigations with coffee or hydrogen peroxide enemas, visualization, and stress-reduction exercises.

The Gerson Therapy, Gonzalez treatment, Kelley’s Metabolic Treatment for Cancers, and the Issels's Whole Body Therapy are among the types of metabolic therapies.

Gerson Therapy

The Gerson Therapy originated from Dr. Max Gerson. When suffering from migraine headaches, he adopted a low-salt, vegetarian diet to help alleviate his pain. He used his diet to help with skin tuberculosis, which showed some success. The Gerson Therapy rids the body of toxins and boosts nutrition with an organic, plant-based diet that includes raw juices, coffee enemas, and natural supplements. It involves hourly consumption of raw juices, three plant-based meals, and fresh fruit for snacks. Between 15 and 20 pounds of nutrients from organically grown fruits and vegetables are delivered to the body each day. The diet stimulates the metabolism with thyroid, potassium, and other supplements. Coffee enemas help to rid the liver of toxins. The diet does not allow sodium, fats, or proteins. The intense detoxification removes waste from the body, reactivates the immune system, increases oxygen, and improves cell metabolism.

No scientific evidence has supported the claims of the therapy, and it has not been approved for use by the U.S. government. The therapy has been considered dangerous. The coffee enemas have been associated with infections and other health issues, and they even have been related to a few deaths.

Gonzalez Therapy

Gonzalez Therapy was derived from the analysis of early studies conducted by Dr. John Beard. Dr. Beard proposed that the early placenta behaved similar to a tumor, as pancreatic enzymes forcefully regulate their growth, and the development the very same enzymes could defend against cancer. Orthodontist William Kelley developed
Beard’s ideas. Dr. Nicholas Gonzalez began working closely with Dr. Kelley, and their combination of work developed Gonzalez’s regimen. The therapy acknowledges that tissue and organ efficiency are improved by diets, vitamins, minerals, and trace elements; however, pancreatic enzymes target and kill cancer cells.

The therapy involves the use of freeze-dried pancreatic enzymes from pigs, nutritional supplements, and special diets that range from vegetarian raw foods to the Atkins approach; coffee enemas are part of the detoxification routines. The therapy has been promoted to treat advanced pancreatic cancer, but it has not received approval from the government. Although Dr. Gonzalez’s program mimics Dr. Kelley’s, it has many differences. Dr. Gonzalez’s program does not employ the spirituality component, and it allows animal proteins in the initial stages of the program.

**Kelley’s Metabolic Treatment for Cancers**

Dr. William Kelley developed a nutritional program during the 1960s after he learned he had pancreatic cancer and only a couple of months to live. He self-administered doses of enzymes, vitamins, and minerals to treat it and recovered. The treatment comprises four components. Large amounts of pancreatic enzymes are administered daily for an antitumor effect. The diet and supplements support the body. The treatment includes carrot juice and a vegetarian diet. Detoxification occurs with coffee enemas. The program forbids animal proteins. The proteins it does allow include grains, glandulars, and eggs, which must be eaten when the body can metabolize them. The regimen was adopted by Nicholas Gonzalez, who began treating his patients with Kelley’s method. He then provided his patients with a variation of Kelley’s approach.

**Issels’s Whole Body Therapy**

The Issels’s Whole Body Therapy attempts to strengthen the entire body. Dr. John Issels, a surgeon, became convinced while treating cancer patients that a whole body approach was needed to treat the disease. Whole body therapies apply various approaches to cancer treatment and prevention, like combing diet and nutrition, herbs, immune enhancement, and detoxification. Dr. Issels perceived cancer as a general disease of the body and created a therapy intended to restore and regenerate the body’s natural defenses. The Issels’s Whole Body Therapy requires the removal of infected teeth to reduce toxic stress on the body. Tobacco, coffee, tea, and alcohol are among the harmful substances avoided.

Organic whole foods are consumed, and *Lactobacillus acidophilus* is taken for proper digestive support. Toxic emotions like stress and anger are released during an informal psychotherapy. Oxygen therapy is administered to sterilize and reanimate the blood for an aggressive immune response. It uses hyperthermia to reenergize the immune system and encourages a fever to increase white blood cells. Vaccines are deployed for different types of cancers.

**Alternative Therapy: Herbs, Vitamins, and Minerals**

The popularity of dietary supplements has increased, driving more people to use the supplements to ward off disease. Recent research has indicated that some high-dose nutrient supplements can either protect against cancer or cause cancer. Dietary supplements include vitamins, herbs, enzymes, amino acids, antioxidants, and other substances. They are generally distributed as pills, powders, drinks, or energy bars.

Some people may need to take supplements to reach recommended nutrient amounts. These people may be on restrictive diets, or they may have an impaired ability to eat certain foods due to allergies or medical conditions.

Supplements are not drugs and do not need approval from the Food and Drug Administration because they neither treat, prevent, nor cure illnesses. If supplements are taken, use caution. In many cases, getting the adequate amount of essential vitamins and minerals is a balancing act. Getting too little leads to dietary deficiencies, while taking too much can become toxic and may lead to unintended consequences.

Some labels for supplemental products can be misleading. The combination of the supplement with certain prescribed medications or radiation or chemotherapy may interfere with the medications’ metabolism. For instance, some herbs may change the way a chemotherapy drug is absorbed, distributed in the body, metabolized, or eliminated; people taking high doses antioxidant supplements may not only protect healthy cells but tumor cells as well. Therefore, it is important to consult with a health care provider about possible side effects.

Experts recommend that people obtain their nutritional needs through diets rich in vegetables, fruits, and plant-based foods rather than through supplements. Meanwhile, researchers are conducting more clinical studies to determine whether the use of certain supplements cause more harm or provide great benefits when it comes to cancer treatment, survival, and quality of life.

**Herbs**

Herbal medicines have played significant roles in many different cultures. The use of herbs dates back to ancient times. Today, millions of adults throughout the United States have indicated that they use herbal products for health purposes.

Herbs are plants or plant parts that are used for their scent, flavor, or health-related properties. Some dietary supplements either contain only the herb, or the herb is combined with a mixture of other ingredients, but scientists are still learning how they may affect the body, so they can evaluate their safety and effectiveness.

Many health attributes of herbs have been linked to their antioxidant properties, but they can induce changes in a number of cellular processes linked to the risk of cancer or tumor behavior, such as cell division, cell death, and the ability for the body to produce an immune response. Herbs are considered natural health aids, but that does
not guarantee their safety. Sometimes the amount of the herbal supplement received may not agree with what is actually in the bottle. Some factors affect the contents, such as manufacturing and storage methods. Metal, unlabeled prescription drugs, microorganisms, and other substances have contaminated some herbal supplements in some instances.

Therefore, it is important to know how an herbal supplement may interact with prescription drugs and over-the-counter medicines and to receive guidance from a medical professional. It is also crucial that women who are pregnant and nursing take extra precautions.

Açaí. The açaí plant is a species of the palm tree found in Central and South America. The natives of the Amazon have used it for medicinal purposes. The plant produces berries, and studies have found that the berries have very high antioxidant activity. This helps ward off chronic disease. They have cited that the berries’ high concentrations of anthocyanins, which give the berries their deep purple color, exhibit anticancer properties. Also, their polysaccharide, a class of carbohydrates, stimulates white blood cells to help the body to ward off infections. Açaí helps support the immune system.

Allspice. In the 1600s the English thought the herb combined the flavors of cinnamon, nutmeg, and cloves. As a tropical plant, it evolved to protect and preserve its nutrients. It is thought to have antimicrobial, antioxidant, anti-inflammatory, and anticancer properties. It is believed to relieve pain, reduce fever, and offset the formation of tumors. Studies have shown that it can inhibit the growth of several cultured cancer cells. The anticancer properties have been associated with its ability to influence certain carcinogen conversions. However, scientists are concerned that excessive consumption of allspice oil can be toxic and promote inflammation, nausea, and vomiting.

Aloe. Aloe’s roots extend back 6,000 years to Egypt, where it was a common household plant. Aloe vera became a popular species of the plant. When used topically, it heals wounds from burns or abrasions. It is also used as a laxative when ingested. When used as an alternative treatment, its proponents believe that it boosts the immune system and acts directly on abnormal cells, either treating or preventing all types of cancers. Aloe vera is used as a remedy for diabetes, asthma, epilepsy, osteoarthritis, and psoriasis. Some concerns regarding its use include developing diarrhea, its glucose-lowering effects, and its potential danger or even lethality. Aloe products have not undergone a significant amount of review for the government to consider it safe and effective.

Basil. Basil comes from Iran, India, and tropical regions of Asia. Basil use includes treating anxiety, stings, headaches, cough, acne, warts, and kidney malfunction. Basil contains a compound called eugenol, which has been effective with breast cancers because it stops the development of tumors. Basil also has antioxidant, antiviral, and antibacterial properties. Studies have shown that it can lower oxidative damage in animal models.
Caraway. Caraway is used mostly in western Asia, Europe, and Africa. Its seeds have made it a medicinal plant to treat health problems like flatulence, colic pain, and bronchitis. It is known for helping with digestive problems such as relieving stomach spasm, upset stomach, ulcers, bloating, and gas. It also helps to regulate the menstrual cycle and increases breast milk production. An animal study has shown that caraway oils help to suppress the progression of colon cancer. Other studies have shown that thymoquinone, a natural component of the volatile oil of black caraway seeds, has caused some cancer cells to either stop growing or die.

Cardamom. Cardamom is commonly found in Indian cooking and various parts of Europe. The spice is added to sweets, baked goods, and coffee. The seed powder has been used to help with digestive problems like stomachaches, and it relieves vomiting and nausea. It acts as a painkiller and relieves muscle spasms. Its oil is believed to have antimicrobial and anti-inflammatory properties. Cardamom is reported to have antioxidant properties. Studies have evaluated some of its bioactive components and found that it can inhibit cancer development.

Chinese Herbal Medicines. Chinese herbal medicines focus on restoring balance and energy and maintaining spiritual health. The herbs have included astragalus, ginkgo, ginseng, green tea, and Siberian ginseng. Some herbs and extracts can aid in cancer prevention and treatment with mainstream treatment, but more research is needed to determine the effectiveness. Many Chinese herbalists believe that the herbs relieve some side effects from standard treatments like radiation therapy and chemotherapy. The herb can help improve the quality of life, boost the immune system, and stop and prevent tumors from spreading and growing.

Cinnamon. Cinnamon is a traditional Chinese medicine. It comes from the bark of trees that originate from China, India, and South East Asia. The components of cinnamon's extracts influence its antioxidant, antimicrobial, anti-inflammation, and antidiabetic activities as well as its anti-tumor activity. Studies have found that cinnamon inhibits tumor growth and suppresses the progression of certain cancers. However, more studies involving humans are needed. Some people may have allergic reactions to cinnamon, and it should not be consumed in large amounts.

Cranberry. Cranberries originated in North America, and these red berries help with a variety of problems such as wounds, urinary disorders, diarrhea, diabetes, and liver problems. They have high-quality antioxidants, such as flavonoids, and a large quantity of them. Their abundant flavonoid content and phenolic acids are believed to stop the oxidative process, and this may contribute to its antitumor activities. The phytochemicals, which are chemical compounds found in plants, have a strong effect on certain types of tumors. They either slow or inhibit tumor development, and they may also help decrease the risk of certain cancers. Take caution not to consume too much cranberry juice because it can cause an upset stomach or diarrhea. Cranberries should not be consumed with medications that affect the liver.

Garlic. Garlic has been used as a medicine for thousands of years. Eaten raw or cooked, this bulb from a plant has been used throughout the world to relieve a variety of ailments such as arthritis, asthma, toothaches, high cholesterol, heart disease, and high blood pressure. Clinically, garlic has been evaluated for a number of conditions including cancer. It is believed that the anticarcinogenic activity is associated with its organosulfur compounds, which contain amino acids, vitamins, and micronutrients. While garlic appears to be safe for most adults, it can thin blood like aspirin; therefore, it should be avoided during or after surgery or when receiving dental work.

Rosemary. Rosemary, commonly found in the Mediterranean, is a household plant in some parts of the world, and its purposes have included flavoring and cosmetic use. It has been used to relieve renal colic, which is stomach pain caused by kidney stones. It has also helped with stomach spasms, respiratory disorders, and the stimulation of hair growth. Rosemary contains compounds with high antioxidant effects. When rosemary is included with balsamic vinegar, it protects against oxidative stress in humans. It’s phenolic properties have provided protective effects from some cancers by inhibiting the growth of cancer cells as well
as related molecular conditions associated in their development.

**Turmeric.** Turmeric gives the cuisines of many Indian and tropical Asian regions their flavor and color. The root and rootstock contain curcumin. This antioxidant and active ingredient has exhibited anti-inflammatory properties and anticancer effects by slowing the growth and spread of some cancer cells. Studies show the active agent may provide benefits to other ailments like arthritis, Alzheimer’s disease, and stomach ulcers. It is also believed to lower bad cholesterol and improve the outcome of kidney transplants.

**Vitamins.** Vitamins are a group of organic compounds needed for the body to support an adequate diet. These natural chemicals aid biochemical and physiological processes, such as growth, development, and metabolic functions. They are needed to maintain overall health. Some vitamins dissolve in water, while others dissolve in fats and oils. An excess of water-soluble vitamins ends up in the urine, while an overabundance of fat-soluble vitamins gets stored in moderate amounts in the body’s fatty tissue.

Many cancer patients and survivors have opted to take vitamin supplements as a way to stave off side effects from cancer treatments and to avoid recurrence of the disease. Studies have not provided a firm conclusion regarding vitamin use, but doctors have raised concerns that the interaction of vitamins with treatments may lead to undesired consequences such as cancer progression.

Not enough proof has demonstrated that vitamins can prevent cancer, but the following have been studied recently.

**Vitamin B6.** Vitamin B6, a water-soluble vitamin, is found in abundance in foods such as whole grains, nuts, vegetables, and bananas, but the body only needs small of amounts of it to stay healthy. It helps to fight off infections, normalize blood sugar levels, and produce red blood cells. It makes sure enzymes function appropriately and keep skin and nerves healthy. Cancer patients often encounter decreased levels of the vitamin, and this deficiency can lead to mouth and tongue sores and a nervous disorder. Scientific observations suggest vitamin B6 metabolism influences cancer development and tumor progression. The vitamin has been studied in the prevention of hand–foot syndrome. The syndrome is provoked by certain anticancer drugs. The hands or feet either feel pain, swell, tingle, or become numb or red.

**Vitamin B12.** Small amounts of Vitamin B12, a water-soluble vitamin, are needed for bodily maintenance. This includes helping to make red blood cells, DNA, RNA energy, and tissues, and they support the health of nerve cells. Liver, meat, eggs, poultry, shellfish, milk, and milk products are good sources. A B12 deficiency can lead to certain types of anemia and neurologic disorders. Researchers have been studying the vitamin along with folate for the prevention of certain cancers. For instance, studies have suggested a deficiency of folate, a type of B vitamin, is related to cancer development. Folate helps to control the stability of DNA. B12 along with folate may be used to help improve the survival of those suffering from gastric cancer.

**Beta-Carotene.** Beta-carotene is a fat-soluble vitamin, and it is the most prominent carotenoid. A carotenoid is a colorful, natural plant pigment. The body makes vitamin A from beta-carotene. Beta-carotenes are found in yellow and orange fruits and dark green leafy vegetables. Studies have found that high dietary intake of fruits and vegetables with an abundance of beta-carotenes helps reduce the risk of several types of cancer. Beta-carotene is a type of antioxidant. Research has also shown that it influences the differentiation of cancer cells and suppresses their growth.

**Vitamin C.** Vitamin C is a water-soluble vitamin found in all fruits and vegetables. It helps to ward off infections and heal wounds. As an antioxidant, it prevents cell damage by free radicals. Studies determining its role of some types of cancer have demonstrated that large doses of vitamin C delivered intravenously help to reduce inflammation in cancer patients, and it supports chemotherapy drugs by increasing the drugs’ abilities to kill off cancers cells while leaving healthy cells intact.

**Vitamin D.** Vitamin D is a fat-soluble vitamin that helps in the creation of strong bones and teeth and is found in fatty fish, egg yolks, and dairy products.
Some experts indicate that vitamin D is a multifunctional prohormone rather than a vitamin. Skin exposure to sunlight also creates vitamin D in adequate amounts; however, many people throughout the world have become deficient because of concerns related to skin cancer, indoor occupations, and other reasons. A vitamin D deficiency can result in rickets, which is the softening or weakening of bones. Studies have suggested that a vitamin D deficiency not only increases the risk of developing cancer, but it can also worsen the disease.

**Vitamin E.** Vitamin E is fat soluble and it is found in seeds, nuts, leafy vegetables, and vegetable oils. It makes up the majority of food consumed in the Mediterranean diet. It helps to elevate the immune system and prevents the formation of blood clots and cell damage from free radicals that destroy cell membranes through lipid oxidation. Its antioxidant qualities have encouraged research in the prevention and treatment of some types of cancers.

**Folic Acid.** Folic acid is a water-soluble vitamin used to make and repair DNA, so it can create new cells. It also may help with turning some genes on or off. Folic acid is found in whole-grain breads and cereals, liver, green vegetables, orange juice, lentils, beans, and yeast. It is the man-made form of folate, and it is in most multivitamins and considered easier to absorb. Folate is found naturally in green vegetables, juices, and beans, and it has a significant role when it comes to cellular survival and proliferation and is needed for cells to divide. Low levels of folic acid are believed to change the chemicals affecting DNA, which may enable cancer growth.

**Minerals**

Minerals help change food to energy; they aid cellular activities and support a healthy immune system. Some minerals participate in the catalytic activity of enzymes. They fall into two categories: major or trace minerals depending on the amount needed in the diet. Food sources for minerals either come from plants or animals. However, the amount of the mineral found in plants depends on the soil and where the plant was found.

Minerals are an essential part of the diet. No food contains all these minerals, and without them, cellular damage, disease, or death can occur. Some of these elements have anticancer properties. Studies have shown that, when selenium, zinc, molybdenum, vanadium, and germanium are taken in the proper amounts, they can help cancer patients to prevent and improve their ability to achieve natural immunological remission of cancer.

The following minerals recently have undergone scientific review.

**Iron.** Iron supports cell replication, metabolism, and growth. It helps create red blood cells, and a deficiency of it results in anemia. Several studies have shown that elevated amounts of iron can lead to cancers. For example, a research team exposed human breast cancer cell cultures to large amounts of iron and discovered an increase in cell growth. Iron participates in free radical formation, which can contribute to both tumor initiation and tumor growth.

**Selenium.** Selenium is an essential trace element. Studies have focused on selenium’s antioxidant properties and its ability to inhibit experimental tumors, especially those in the gastrointestinal tract. Some researchers believe the mineral’s ability to counteract cell growth may be due to some of its activities, such as its effect on DNA stability, cell proliferation, and regulation of oxidative stress.

**Zinc.** Zinc supports the activities of certain enzymes. It is required for cell division and protein synthesis. Cancer patients generally are deficient in this mineral. Researchers have found that deficiencies can change patterns of gene expression, and when the mineral is replenished, it can induce cancer cell death. Its anticancer properties include inhibiting cancer development and improving immune response. Zinc supplements have been considered for the treatment and prevention of prostate cancer.

Alternative Therapy: Manual Healing and Physical Touch

Alternative therapies are known by a number of names: unorthodox, unconventional, unproven, nontraditional, and so on. They have specific meanings in cancer therapy. They are remedies or cures that substitute for standard medical treatments. Nonetheless, most people who use alternative therapies also see physicians and follow standard treatments. This raises questions about physicians treating cancer patients who are also using alternative treatments. This entry discusses alternative cancer therapies and describes their current state and persistence despite the lack of scientific evidence of their effectiveness. Then the most frequently cited alternative therapies involving...
manual healing and physical touch are described and discussed.

**Background**

Medical therapies are a recent arrival; alternative therapies have long histories because they alleviate patients' anxieties concerning a disease that often is overt (openly visible), progressing destructively, and leading to death. The ancient dilemma of the healer is to distinguish a treatment that leads to a cure from the general palliative services provided by a healer. Palliative services are mainly psychological in offering hope in the face of chronic pain, incapacity, and death. But mind and body practices also include evoking a physical response that reduces stress, strengthens the immune system, and alleviates anxiety. This has been called a placebo effect, although it is also physical as the body produces endorphins with physiological effects from touch. This placebo effect can be significant and blurs the line between scientific treatments and other treatments that lack evidence of medical effectiveness.

While this entry focuses on physicians and their unorthodox counterparts, in standard cancer treatment, there are many occupational specialties involved. Their number and variety varies with the kind of cancer and often with the country in which the treatment is located. This entry focuses on the United States, which has a history of conflict between standard medicine and its competitors.

The physician faces a patient who desperately wants to hear more than is medically possible. In cancer, this demand is great, due to the course of the disease, as the patient continues on a downward path, often accompanied by acute suffering. How is this downward course toward eventual death to be managed? There is more to this question than a stark choice between standard and marginal types of treatment.

A third form of treatment appears: palliative care that treats the symptoms. In the competition between standard and alternative treatments, the latter's benefits are often opposed by the medical establishment (and promoted by those marginal to it) by considering only their effectiveness in treating the cancer. This is not the only way to assess their place in cancer care, but it is the way we have come to see the two, not as complementary but as competitors. Considering their potential benefit to the patient, they would be accepted widely if understood to be palliative care.

Competition between medically approved and alternative therapies continues. The former are more likely to prolong life and even effect a cure, while the latter bring hope for a cure through over-promising results.

From a medical point of view, alternative cancer therapies are worthless, and they can cause a patient to forego necessary treatment. Nonstandard treatments can have significant side effects that are harmful or can interfere with the effectiveness of standard treatments. However, there is another side to these therapies, often seen in traditional ones accepted in their native cultures for centuries. They increase the quality of the patient's remaining life by integrating the condition with the patient's culture through giving it meaning that the patient and family can accept.

Unwittingly, both physicians supporting standard cancer treatments and their nonstandard competitors have confused the basic question of how to help a patient in decline from cancer. The two competitors both lay claims to providing a cancer cure. When hope for a cure from standard treatments is small, the nonstandard types gain more traction. Their alternative treatments include those of physicians and others on the borderline between medicine and shamanism. These treatments vary from marginal experimental drugs and therapies to those based solely on wishful thinking that appeal to the desperate.

Open conflict erupted between conventional and alternative cancer treatments over Laetrile, which became the leading unorthodox cancer therapy in the United States during the 1960s and 1970s. Promoters of this unproven drug founded a patient organization, the International Association of Cancer Victims and Friends (IACVF) in 1963, which backed unconventional health approaches, including unproven cancer therapies. This organization founded book stores through their Cancer Book House and arranged transportation across the U.S. border to a Mexican clinic providing Laetrile. In this growing conflict, Laetrile and other nonstandard treatment supporters took to castigating the medical establishment for its opposition to their unproven treatments and characterized standard medicine as inhumane, blocking medical progress, and creating a monopoly.
The John Birch Society supported the Laetrile social movement through its book stores and chapters across the country. Together, they opposed the legal restrictions on unproven cancer treatments. The John Birch Society opposed the federal government in general and promoted opposition in local communities to the fluoridation of water as a communist plot to poison the American people. With support from the John Birch Society and other opponents of government regulation, Laetrile providers sponsored legislation that exempted Laetrile from the Federal Food and Drug Administration's (FDA's) control. Although strongly objected to by state medical societies, these local political movements often were successful in swaying the public and the legislatures of states. Eventually 27 states passed laws favoring unrestricted Laetrile use. However, the FDA remained in control as the federal government forbade the transport of Laetrile across state lines.

Despite efforts of medical practitioners to support education about medical treatment, alternative therapies continue to have public support. In a recent study by Yates and colleagues, 91 percent of cancer patients receiving radiation or chemotherapy admitted to their doctors use of alternative or complementary therapy. In cancer centers across the country, this combination is called integrative medicine. A cancer diagnosis continues to evoke a strong emotional response of fear, anxiety, and dread. Countering this reaction is integrative medicine, supplementing standard treatments with others that offer hope and, for manual methods and physical touch, the human touch.

The question remains of how many cancer patients use complementary and alternative practices. In some studies, patients are counted as using alternative treatments when they are merely using vitamin supplements or praying for good health. The number using specific alternative treatments appear to be rather small, although when the numbers include all forms of these alternative treatments, which are quite numerous, they can appear much larger.

In recent years, although they remain controversial, alternative therapies have been tolerated by many physicians. Their hope is that alternative treatments will supplement, not supplant, conventional cancer treatments. An alternative treatment can become complementary, save for the lingering conflict between standard medicine and supporters of nonstandard treatments who reject science, claim they have a new science that "doctors don't want you to know," or overpromise cures.

By remaining ethical and not offering false hope to needy people, physicians have opened the door to marginal therapies that mainly offer the hope that adept charlatans exploit. However, not all purveyors of alternative and complementary therapies are charlatans; many view themselves service providers or professionals in their craft. Each type of alternative therapy has its own social history and presentation to the client. It is a disservice to view such practitioners as charlatans or opponents of standard medicine. This is especially the case with manual healing and physical touch, which involve specialized occupations with considerable training and certification. They are found today in centers of integrative medicine and in a growing number of hospitals and clinics, alongside conventional medicine.

The unfortunate social history of nonstandard treatments in conflict politically with standard medicine has its echoes in the National Institutes of Health (NIH) today. The NIH has housed the National Center for Complementary and Alternative Medicine (NCCAM) since 1999. However, the center has been controversial within the NIH and medical establishment, especially as it offers grants for the study of certain of these alternatives. Nonetheless, the center has become a respected source of information about nonstandard treatments.

Summary of Manual Healing and Physical Touch

The picture of alternative cancer therapies is complex, filled with a large variety of nostrums and practices. The category of manual healing and physical touch alone includes 32 different therapies, according to the American Cancer Society. Each has its own characteristics of interest, and most will be included here. Unless noted otherwise, all have the following characteristics: (1) they do not have any proven benefit for the treatment of cancer, such as slowing or halting its progression; (2) they are sometimes helpful in providing palliative results in reducing stress, producing relaxation, and increasing tolerance for pain; (3) for some patients, they alleviate certain side effects of cancer treatments, such as nausea, and (4) their physical nature, which
may include forcible and vigorous manipulation of the patient’s body, carries risks. In all cases a cancer patient should consult with a physician before embarking on a course of alternative therapy.

**Acupressure and Shiatsu (Traditional Asian Bodywork)**

These therapies include varieties of traditional Chinese medicine (TCM). As such, they have a different social history from the alternative treatments that are a product of American culture. TCM has a history of being central to Chinese medical practice, while alternative treatments remain marginal in the United States. The benefits of TCM include the integration of the traditional patient and patient’s family into Western medical practice when TCM is used as a complement to standard medical treatments.

Asian bodywork is based on traditional theories of the body, including the pressure points along body axes that are more commonly known through their use in acupuncture. In bodywork, these pressure points are the focus of massage and finger pressure. The techniques include the following: acupressure, shiatsu, tui na, ohashiatsu, and watsu.

There are concerns that bodywork and massage in general can be harmful for cancer patients and should not be carried out in areas that may be affected by tumors. The concern is that cancer cells could be spread by vigorous massage, bones that are weakened by cancer and its attendant therapy could be fractured, and contraindications for specific types of Asian bodywork should be checked before undergoing those treatments for specific cancer conditions. In general, practitioners of Asian bodywork are usually trained and conversant with the limitations of their practice for cancer patients and should be open to discuss them with their clients. The American Cancer Society is a good source of information on all alternative cancer treatments.

**Acupuncture**

The best-known TCM, acupuncture, consists of inserting very thin needles through the skin along the pressure points visualized in TCM. It has the singular quality of being testable in double-blind experiments when the insertion of the needles through a mechanical device can be manipulated without the knowledge of either the patient or practitioner. That is, the needles can be inserted at the assumed proper depth or merely into the surface of the skin. The results show that the same degree of benefit is felt by the patient whether the needles are used traditionally or not. This finding supports the conclusion that these alternative medicine techniques are acting as placebos. Nonetheless, a placebo benefit can be useful and helpful, so it cannot be discounted completely.

Unlike more vigorous physical manipulation, acupuncture is considered safe when the needles are sterile and the acupuncturist is careful and well trained. However, certain health conditions (such as the use of blood thinners, which prolong bleeding) are contraindications for acupuncture. Acupuncture is not recommended for patients with implanted electrical devices such as pacemakers.

**Applied Kinesiology**

Not to be confused with the academic discipline of kinesiology (the study of human body movements), applied kinesiology is based on an archaic theory that organ function can be diagnosed through the pressure testing of an associated muscle. Evidence for these beliefs is absent. Practitioners can include medical professionals as well as trained applied kinesiologists. While mainly diagnostic, some claims of treatment and even cures of cancer have been made by practitioners. Other than the danger of postponing necessary cancer treatment, applied kinesiology is considered safe.

**Bodywork**

Various bodywork practices exist. They are active (through exercise and awareness activity) or passive (another person manipulates the body). In general, most practitioners claim benefits without claiming to prevent or cure cancer, although a few do in the absence of evidence to support such claims.

Bodywork includes Rolfing (a passive form with practitioners using deep pressure), the Feldenkrais Method (an active form following a sequence of movements under guidance), and the Alexander Technique and the Trager Approach (a combination of self-guided motions with practitioner touch).

As with Asian bodywork, cancer patients should avoid manipulation of areas where a tumor is or may be present along with vigorous movements and pressures on affected body areas. Practitioners
skilled in dealing with cancer patients will avoid risky activity.

**Chiropractic**
This alternative medical system has trained professionals who deal mainly with problems related to pain and stiffness in physical movement. The practice is based on a theory that alignment of the spinal vertebrae is the cause of various physical problems. The practice is also called spinal manipulation. A few practitioners also claim that diseases, including cancer, are caused by misalignment of the spine and promote chiropractic as a cure. There is no evidence to support such claims, but there is some that chiropractic alleviates some back pain and other bone and muscle problems. Chiropractic should be avoided in cases of advanced cancer or cancer of the bone. Cancer patients should consult their physicians before undergoing chiropractic.

**Craniosacral Therapy**
Also known as cranial balancing, cranial osteopathy, cranial sacral manipulation, and craniopathy, this is a massage treatment used on the head, back, and pelvic area. The treatment is said to normalize various body systems dependent (in theory) on the bones and fluids in the head, back, and pelvic area. In this theory, many different diseases and conditions are a product of obstructed flow among these areas. Cancer patients should consult their physicians before undertaking any such therapy involving manipulation of muscles and bones, as in acupressure.

**Cupping**
This is a form of TCM that is also found in other world cultures. It consists of inverting a cup or glass full of hot air over the patient's skin. As it cools, the air pressure inside reduces, causing the skin to be pulled into the container, along with what are believed to be poisons and, in some cultures, evil spirits. Sometimes the skin is punctured before cupping, causing blood to be sucked into the device as a kind of purge. While relatively safe, it has no known medical benefits and has been the cause of child abuse reports in the United States.

**Massage**
There are many forms of massage, using pressure, friction, and manipulation on the muscles of the patient's body. The manipulation can be with the hands, other parts of the therapist's body, and with tools. The objective is to enhance circulation and reduce muscle stiffness felt by the therapist and targeted as knots or trigger points. Massage may produce relaxation, reduce pain, and enhance range of movement.

Massage appears in various forms. The most popular in the United States is Swedish massage, or simply massage therapy. It consists of long, deep strokes and uses lotion and oils. Sports massage is designed for relaxing sore muscles and involves stretching as well as massage. Aroma therapy massage adds scented oils to vary the mood of the session. Hot stone massage involves heated stones placed on body areas for relaxation and gentle pressure, less than other massage techniques. Deep tissue massage is more forceful and uses friction techniques. Additional types focus on the target area (back massage), the type of client (pregnancy massage), and more (myotherapy, neuromuscular therapy, Thai massage, and trigger point therapy). Professional massage therapists are trained and certified. They are available in clinics, hospitals, and other venues. Massage has a long history in many cultures. It appears as alternative therapy but lacks evidence that it can treat or cure cancer. Massage has the contraindications of other forms of bodywork, but variations that use injections are more problematic.

**Moxibustion**
Also known as acumoxa or auricular mo, moxibustion consists of applying heat to a body's acupuncture points to stimulate the body's forces for self-healing. In TCM, a small pile of herbs (moxa) is burned on the skin, which may be painful and scarring. Today, the heat is applied through acupuncture needles. This technique is claimed to cure diseases but lacks evidence that it does, as in cupping.

**Myofascial Release**
The theory behind this therapy is that the body's connective tissue becomes rigid and needs stretching and manipulation to relieve pain and restore proper functioning. Practitioners include some chiropractors, massage therapists, osteopathic doctors, and others. The evidence supporting the theory and its resulting claims is lacking. The usual problems
with use for cancer patients are present, and cautions should be observed.

**Osteopathy**

Osteopathic medicine is an alternative medical practice with trained physicians (doctors of osteopathy [DOs]) who practice medicine. Osteopathy involves manually testing the patient’s bones and muscles. If not in balance, they can be brought into balance through physical manipulation. For many osteopathic physicians, their osteopathy practice is integrative medicine. But a few may place unwarranted faith in the efficacy of osteopathy itself to cure disease.

**Polarity Therapy**

A form of massage, polarity therapy (also called polarity balancing or energy balancing) uses a theory of bodily energy flow to direct the application of massage, combined with other forms of treatment. Polarity therapists are trained in this theory, with about 1,000 practitioners in the United States. They combine many alternative and complementary techniques, and no two patients are treated the exact same way. The benefits and cautions are the same as acupressure and massage.

**Psychic Surgery**

Practitioners claim that they can remove cancerous tumors, diseased organs, and toxic materials invisibly by using their fingers and hands pressing against the patient’s body, performing psychic surgery. This is a traditional form of healing practiced among Native Americans and notably in the Philippines. Close observation shows that the shaman produces blood, feathers, cotton, leaves, and other material from a place apart from the patient’s body. There is no evidence that this is effective against cancer or any other disease.

**Reflexology**

Similar to forms of massage and traditional healing, the cluster of therapies oriented to the hands and feet come from a belief in pressure points that affect energy flows through the body. Those points are targeted for massage in reflexology and zone therapy. The same results and cautions for acupressure and massage in general apply here.
Reiki
This is a traditional Japanese form of massage that channels the body’s natural, spiritual energy through the body. By removing obstacles to energy spread by massaging blockages, the body’s ability to heal itself is enhanced. Because only light touch is involved, Reiki is considered safe.

Rosen Method
This is a form of massage combined with counseling. Painful memories and thoughts are believed to be located in tense muscles that can be manipulated to free those negative thoughts for other therapy. As only light touch is involved, the Rosen Method is considered safe.

Rubenfeld Synergy Method
Very similar to the Rosen Method, the Rubenfeld Synergy Method (also called the Listening Hand) incorporates hypnosis and dream analysis with massage and talk. As in the Rosen Method, there is only light touch involved, and it is considered safe.

Therapeutic Touch
There is no actual touch involved in this technique, which is practiced mainly by registered nurses. Therapeutic touch is based on a nonstandard belief in a body’s energy fields; the touch therapist can feel, manipulate, and remove negative energy from the patient. Touch therapy has been tested, and therapists have been unable to distinguish the presence or absence of a human hand behind a screen.

Conclusion
Originating from many different cultures and theories of health and disease, manual healing and physical touch appear greatly varied. But as they move toward being complements to standard treatments and are incorporated into integrative medicine and normal hospitals, they become more similar to each other. They present a theory of the body being out of its natural order and use some kind of physical manipulation and talk to soothe the patient’s fears. They complement standard medicine by serving as a placebo, where standard medicine is constrained in what its practitioners can offer a suffering, even dying, patient.

Further Readings

The art and science of healing that involves mind, body, and spirit, variously called holistic medicine, unconventional medicine, complementary medicine, or integrative medicine, provides a viable system of medicine that focusses on empowering the individual for optimal health conditions. Although in existence for thousands of years, especially in India and China, healing and medical care have in recent years sought to include holistic medicine as providing an alternative care system alongside biomedicine.

More so, of late and also globally, alternative medicine has revealed a significant paradigm shift in the way human body, illness, and illness states have been observed, perceived, and interpreted. Being more akin to a revolutionary approach to dealing with health and disease conditions of the contemporary world, with focus on behavioral, psychosocial, and life-style interventions, alternative medicine understands the human being as a totality of mind, body, and spirit, which calls for understanding disease and health in accordance with the balance of three vital elements.

Needless to say, amid restoring the balance of the constituent elements, the patient occupies a central place in understanding his or her symptoms and eventually manages the treatment plan.
under the guidance of an alternative healer. In other words, owing to the indispensability of the patient’s contributions, empowering patients in a way that would contribute to producing his or her effective mental, physical, social and emotional well-being forms the basis of an individualized treatment philosophy in alternative medicine. It aims to resolve the physical, mental, emotional, spiritual, economic, and social elements of the patient. The ideal of integrated care, thus, entails, according to M. Nadeau and D. Moss, “that the full range of mind–body interventions are included from the first day of any patient’s health care, and remain a part of each successive episode of treatment.”

With a patient or individual-centered focus, a unique dynamic relationship between the physician and the patient becomes imperative. This dynamism builds up patient autonomy in the context of his or her social and physical environment, including the immediate family, peer groups, occupational links, and spiritual elements. Additionally, there develops a desire to know more about various alternative health options, philosophies, and therapies.

Understanding Alternative Medicine in History
In scholarly discussions on health care systems and alternative healing practices, an important issue that comes to the fore is the historical trajectory that has paved the way for the professionalization of contemporary elements of alternative healing practices.

The development of the medical profession has witnessed an interesting trajectory of medical practice and, concomitantly, the visions of medical practitioners. Physicians in the early part of the 19th century, while maintaining “allegiance to traditional drugs doing something active in place of waiting for nature, instilled confidence in patients that the doctor had power and confidence stimulated recovery,” according to James Whorton.

While the traditional knowledge systems have been in existence for almost 3,000 years, the framing of alternative medicine in some parts of the world, such as America, appear to have emerged in the early 1800s, but at the time, alternative medicine included practitioners of folk medicine herb doctors, the purveyors of native American medicine and other informally trained practitioners, who were not, as described by Whorton, “professionalized to any significant degree.”

Ironically, their practices were not termed alternative well until the late 1900s; prior to this, they were said to practice irregular medicine. Elsewhere and in the rest of the world, the early part of the 20th century was significant for the developing medical profession. The rise of the scientific discipline highlighted the professional unity among advocates of Western biomedicine against competition from nonconventional practitioners; besides, the rise of the pharmaceutical industry in the interwar years also added to this differentiation and distancing of Western biomedicine and nonconventional medicine. Although significant advances in the medical sciences were made in the late 19th century, they were regrouped only retrospectively at the turn of the 20th century. The development of the germ theory of disease alongside scientific advances in natural and biological sciences, and the founding of new institutions to study tropical medicine, strengthened the authority of Western biomedicine in the Western world. With these were heightened the nuances and differences between Western biomedicine and indigenous systems.

The global appeal of alternative medicine and its impact on health and wellness concepts have their roots in the early 20th century, when “natural” remedies and focus on physiological balance through diet and controlled personal life style took shape. In Wharton’s words, “‘The best antiseptic’ was not the chemical drugs but the ‘vital force.’” This force was largely responsible for the changes associated with various bodily processes such as metabolism, reproduction, and growth.

While there are several alternative practices of healing involved, Ayurveda exists as one of the oldest systems of medicine practiced in India since ancient times. Believed to have origins in the oldest repositories of Indian knowledge, the vedas, Ayurveda literally means knowledge of life or longevity (ayus = life and veda = knowledge) and was codified almost 3,000 years ago by sages. As an alternative and mind–body medicine, it was first introduced to Europe and North America in the late 1970s and 1980s. Vasant Lad’s Ayurveda: The Science of Healing (1984) was largely successful in bringing Ayurveda to the American audience. Similarly, Deepak Chopra’s reputed works reflect the success in appealing to a large audience through the language of biomedicine with a well-received focus on mind–body medicine; Deepak Chopra is also known for his tireless efforts
in translating the ancient 4,000-year-old healing knowledge into bringing emotional, physical, and spiritual balance in individuals’ lives across the globe; his signature program, Perfect Health, offers a unique blend of meditation, Ayurvedic healing, and yoga for optimizing good health and well-being.

Alongside Ayurveda, Chinese traditional medicine, has been equally successful in drawing a popular appeal for its ability to improve lifestyles and quality of life across the world. In effect, mind–body medicine is premised on the belief that the state of mind can affect bodily functions and symptoms. A healthy state of mind is achieved through meditation, relaxation and yoga, and qi gong. Qi gong refers to traditional Chinese medicine that aims to bring bodily functions into a balance through vital energy, or qi. Similarly, naturopathy guides the special energy that, in turn, guides other bodily functions. Both Ayurveda and traditional Chinese medicine have various specialties that strengthen their professional base and healing capacities. The unique combination of body doshas or bodily humors (vata, pitta, and kapha), which make up a unique mind and body constitution, is expressed through various blends of physical, mental, and emotional states of individuals.

Over the years, the appeal of alternative medicine has also been facilitated through the establishment of various institutions. For instance, the National Ayurvedic Medical Association was founded in the United State in 1998, while the Ayurvedic Practitioners Association was founded in 2005 in the United Kingdom; both have institutionalized alternative practices by providing leadership and a positive vision of a holistic approach to healthy living to promote and preserve the knowledge base of Ayurveda. Ideally, alternative or holistic medicine engages in the use of lifestyle changes aimed at treating the disease. While certain diseases may be easily dealt with, achieving mind–body–spirit balance in special life-threatening diseases can be particular helpful for patients suffering from cancer. Increasing stress owing to the uncertainty in a patient’s life heightens mental and physical stress. It is here that the significance of emotions, family, and social behavior becomes apparent. Finding self-help groups and survivors of cancer have an important role to play in decreasing the stress resulting from the dreadful affliction. Thus, according to Moshe Frenkel, “Where as evidence for the role of psychosocial factors in cancer initiation has been equivocal, support continues to grow for links between psychological factors such as stress, depression, and social isolation and progression of cancer.”

Premised on the crucial principles of innate healing powers and treatment directed toward understanding the cause of the disease rather than just treating it, holistic medicine addresses the nature of a person to enable self-healing and well-being with the eventual aim to enhance the quality of life and overall health. Thus, remark N. Cummings and J. Cummings, “The patient of the future will encounter an integrated system of behavioral and medical care, involving a partnership of behavioral practitioners, physicians and nurses, in ‘one house’ and ‘one system’.”

Alternative Therapy: Pharmacological and Biological Treatment

Alternative therapy for cancer treatment encompasses those treatments not taught in conventional
Alternative Therapy: Pharmacological and Biological Treatment

medical schools and not generally offered at hospitals and cancer centers across North America. Some of these therapies have been used in the past, some use pharmaceutical substances, while some use variations on dietary interventions. It is impossible to review all alternative therapies, so the focus is on those that have been studied and have the most promise, listed here in alphabetical order.

**Alpha Lipoic Acid**

Alpha lipoic acid (ALA), also known as thiotic acid, is an organosulfur compound essential for aerobic metabolism. It is available as a dietary supplement and marketed as an antioxidant. ALA is a cofactor in the pyruvate dehydrogenase complex and at least four other enzyme systems including the production of acetyl-coenzyme A. ALA scavenges reactive oxygen species and reactive nitrogen species. Its therapeutic and antiaging effects may be due to modulation of signal transduction and gene transcription, which thus improve cell antioxidant status. This is likely through Phase II detoxification enzymes. Humans produce less ALA with aging.

ALA is found in foods such as kidney, heart, liver, spinach, broccoli, and various yeasts, but the quantities are extremely small; 10 tons of liver yields 30 milligrams. All ALA used as a supplement is chemically synthesized.

ALA helps cells undergo normal apoptosis, a process absent in cancer cells. ALA induces apoptosis in ovarian and lung cancer. This apoptosis occurs by up regulating the caspase-independent and caspase-dependent apoptotic pathway, which is mediated by intracellular calcium.

In three patients with pancreatic cancer, intra-venous ALA was instrumental in reversing their cancers and leading to survival of more than 78 months. One patient had a history of pancreatic cancer with metastases to his liver and retroperitoneal region as well as a history of B-cell lymphoma and prostate cancer. ALA in these patients reduced oxidative stress, stabilized NF-kappa-B, stimulated pro-oxidant apoptosis and discouraged malignant cell proliferation.

The main side effect of intravenous ALA is a hypoglycemic with nausea, fever, and chills that can develop several hours after treatment. This does not occur in all patients and may be dependent on the source of the synthesized ALA. ALA is sensitive to light, and so it is stored in the dark, and the IV bag is covered during the infusion. Clinical trials are required to confirm the successful case reports.

**Cancer Clinics Abroad**

There are many cancer clinics where patients go for treatment that operate outside of the United States and Canada. The number of clinics and types of therapies offered is too many to list and evaluate. There is no independent rating scheme or agency to evaluate the success of these clinics or the types of cancers they specialize in treating.

Mexico houses a number of these clinics. Some are small hospitals where patients can stay for several weeks; others are clinics where treatment is provided in nonhospital settings. Therapies include diet and fasting, vitamins, and chemotherapy cocktails.

Cuba has a large population of well-trained physicians who offer both conventional and alternative cancer treatments. Diet, fasting, surgery, chemotherapy, and vitamins are given as therapy. Patients from the United States cannot fly directly to Cuba because of embargo policies.

Europe offers numerous small clinics or small hospitals where patients can receive treatment. Diet, fasting, hydrotherapy, botanical medicines, homeopathy, chelation, vitamins, and chemotherapy are the principle treatments.

**Chelation Therapy**

Chelation is derived from the Greek word chele, which means claw, so named because a chelating compound binds with a metal and carries it out of the body in urine or stool. Various chelators have been developed to remove lead, mercury, arsenic, radioactive by-products of the nuclear industry, copper, iron, and other metals.

The first chelator used in a clinical setting was calcium-disodium ethylene diamine tetracetic acid (EDTA). It was infused in the 1950s into workers from a battery factory with high levels of serum lead. A side effect of this intravenous treatment was that several of the patients had improvement of their coronary heart symptoms and were able to walk farther with less pain. Subsequently, many physicians used EDTA as a treatment for coronary heart disease.

Controversy arose because there were no clinical trials, and EDTA had not been compared to the then standard coronary bypass surgery. A large trial
was recently undertaken, conducted in the United States, to assess the clinical effectiveness of EDTA for heart disease. It did not test the hypothesis that EDTA treated or prevented cancer. Anecdotal data published by several physicians noted that patients who had received multiple EDTA treatments had lower incidences of cancer or less-aggressive cancers than nonchelated patients.

Iron is an essential mineral, but iron overload can be a factor in the development and progression of cancer. Iron chelators have been tested for their antitumor effects in cell, animal, and human trials. Most studies use desferrioxamine (DFO), a drug approved for iron overload. DFO has a positive but modest effect on cancer. Newer compounds appear more promising. These compounds will require similar testing to determine their clinical potential.

Copper is an essential mineral but, at high levels, is a promoter of inflammation and tumor growth. Tetrathiomolybdate (TM) is a novel anticancer and antiangiogenic that chelates copper and causes NF-kapp-B inhibition. Cell line, animal, and Phase I and II human clinical trials have shown both efficacy and limited toxicity. Further study is needed to ascertain the place of TM in the treatment of cancer.

Coley Toxins
William Bradley Coley, M.D., was a bone surgeon at New York City Cancer Hospital, later part of Memorial Sloan–Kettering Cancer Center. When an early patient he operated on for sarcoma died, he sought answers. He found references to fevers and cancer going into remission back to the 1700s; the organism was likely Streptococcus pyogenes. Initially, he injected bacteria. The condition was difficult to control, and in 1893, he switched to dead bacteria: Streptococcus pyogens and Serratia marcescens. He injected more than 1,000 patients with at least 13 versions of what became known at Coley's Toxins. He published a case series showing about a 10 percent cure rate, with the greatest effect in ovarian cancer and postmenopausal breast cancer. In 1962 Coley's Toxins were assigned new drug status by the Food and Drug and Administration, meaning they could not be prescribed outside of a clinical trial. They are manufactured today in Canada, Europe, and China and used in Germany, Central America, and China. The bacterial formulae vary, and one company is studying the DNA of the bacteria as a treatment.

Research is limited despite wide clinical use. In a trial of follicular lymphoma, 85 percent had a complete response compared to 44 percent who received only chemotherapy. A study of advanced liver cancer found better results in those treated with Coley's Toxins than those who received liver resection. A retrospective study of surgery and Coley's Toxins to 1960 and conventional therapy in 1983 concluded that his patient survival rates were comparable. Factors at work with Coley's Toxins probably include IL-1, IL-6, GM-CSF, G-CSF, IL-12, interferons, TNF-alpha, and a shift from Th1 to Th2 cytokines.

Coley is known as the father of immunotherapy. His efforts led to the creation of immunology as it relates to medical conditions. In 1953, his daughter founded the Cancer Research Institute in New York to study how immunology can help diagnose and treat cancer. BCG therapy became possible because of the pioneering work of Dr. Coley.

Dichloroacetic Acid
Dichloroacetic acid (DCA) is an analogue of acetic acid (vinegar). DCA occurs in the seaweed Asparagopsis taxiformis, and it is produced in trace amounts by the chlorination of drinking water and by the metabolism of some chlorine-containing medications and chemicals. DCA can reduce the production of lactic acid and thus has been used in trials to treat lactic acidosis and topically to remove warts and skin growths.

Cancer cells express increased glycolysis because they rely on anaerobic respiration in the cytosol for energy. This is the Warburg effect, which occurs as a result of the hypoxia found in tumors and their malfunctioning mitochondria. A mouse study found that DCA restored mitochondrial function; this restored apoptosis and caused cancer cells to naturally self-destruct. Mitochondrial function is restored by inhibition of the enzyme mitochondrial pyruvate dehydrogenase kinase. This shifts metabolism from glycolysis to glucose oxidation, increases mitochondrial hydrogen peroxide, activates potassium channels, and thus activates normal cell death, or apoptosis. DCA induces these changes in cancer cells. Cell line studies found this reaction in glioblastoma multiforme brain tissue but not in healthy brain tissue. In the first trial of patients with glioblastoma who were considered
Alternative Therapy: Pharmacological and Biological Treatment

palliative, 80 percent survived for at least 15 months. Mean survival time at Stage IV without treatment is 3 months.

DCA is given to patients orally or intravenously. Intravenous treatments appear to be more effective, with resolution of glioblastoma multiforme and ovarian cancer in multiple clinical settings. DCA is often combined with intravenous vitamin C and intravenous alpha lipoic acid.

Side effects include reversible peripheral neuropathy, neurotoxicity, and gait disturbances that disappear one to two months after cessation of DCA. Patients are usually given a B-complex vitamin and benfotamine or thiamine orally or intravenously to prevent or reduce the neurologic side effects. The Environmental Protection Agency lists DCA as a cancer-causing agent and a cause of reproductive harm in men. In mice, 77 mg/kg/day for three or more years increases the risk of liver cancer. Downstream metabolites of DCA may cause increased liver cancer risks.

Homeopathy

Homeopathy is the use of minute doses of plant, animal, and mineral substances originally prepared according to the Organon of Samuel Hahnemann, M.D. Hahnemann conducted and published the first recorded blinded medical experiments, testing homeopathic medicines on himself and students. Today, homeopathic medicines are prepared according the Homeopathic Pharmacopeia United States and are regulated in the United States and Canada as drugs. They are also regulated as drugs and produced according to Pharmacopeias of the European Union and India.

The prescription of a homeopathic medicine is based on the patient's most unique mental and emotional symptoms: symptoms that set him or her apart from others with the same condition or diagnosis. Final selection of the medicine is based on repertorization of the patient's symptoms in combination with an understanding of the clinical actions of the medicine.

The first physician to use homeopathy extensively in the treatment of patients with cancer was James Tyler Kent, M.D., but his student Arthur Grimmer, M.D., treated many types of cancer. His best-known medicines include the cadmium salts, which he used especially for gastric cancers, severe abdominal pain, and bleeding.

Homeopathy is a significant part of the medical treatment of millions of people in India. Two clinics that have specialized in treatment of patients with cancer are the Banerji and Ramakrishnan. The Banerji Method is designed to treat thousands of people who cannot afford or access Western-style treatment. The clinic will typically see 1,000 patients a day of whom nearly 200 will be diagnosed with cancer. Patients are given two to three medicines that must be repeated one to three times per day. Some of the medicines are prepared homeopathically, and others are mother tinctures of medicinal plants extracted in a water-alcohol mixture based on the plant's chemical and botanical constituents. Selection of the medicines is based on the type of cancer the patient has. As the patient improves, a homeopathic medicine more closely aligned with the personality of the patient is added to the treatment protocol.

The Ramakrishnan Method uses two different medicines given during alternate weeks using a plussing method of delivery. Their method requires more time with the patient to get to know the patient's personality as well as the symptoms of the cancer. The first medicine will be selected based on the diagnosis of cancer, whether it is a solid tumor, and whether there is a family history of cancer. This medicine will be taken 8 to 10 times per day for one week. The second medicine that will be given based on the type of cancer and the unique symptoms associated with this cancer. This medicine also will be given daily, 8 to 10 times per day, during alternate weeks. Alternation of medicines continues for several months to a year and is changed only as the condition of the patient changes.

Clinical studies at major cancer research centers have shown that homeopathically prepared medicines have negative effects on cancer cells and cancer inoculated into animals. These include breast, prostate, colon, lung, and glioblastoma multiforme. A best-case series found that the Banerji Method improved the quality of life and patient survival in breast, lung, and esophageal cancers. Homeopathic medicines have not been shown to interfere with radiation and chemotherapy and in fact can reduce patient side effects from these treatments as well as the symptoms of menopause induced by conventional treatments. Side effects of homeopathy are limited and relatively minor.
No adverse events have been reported in the published studies.

**Insulin Potentiation Therapy**

Insulin potentiation therapy (IPT) was developed by Donato Perez Garcia, Sr., M.D., in 1930 for chronic disease and several types of cancer. Insulin became available in 1926. Treatment is based on the fact that tumor cells require glucose for metabolism, and insulin enhances the transmembrane transport of nutrients across the gut and blood–brain barrier into cells. The first case treated by Dr. Garcia was advanced tertiary syphilis. In 1947, he treated his first case of cancer with IPT. Insulin is secreted by several cancerous tumors including breast, lung, cervix, kidney, fibrosarcoma, and Hodgkin’s lymphoma. This helps supply the tumor with glucose for its metabolism.

Patients are given a slow, intravenous injection of insulin to decrease the plasma glucose level. A low point is maintained for a brief period and then a mixture of glucose and chemotherapeutic agents are given. Usually, the dose of the chemotherapy is less than that typically given. Both will be rapidly taken up by the tumor, leading to cell death and tumor lysis. Side effects are a profound hypoglycemic state of short duration during which the patient may become weak, sweaty, and disoriented. IPT awaits large clinical trials to determine its safety and the types of cancers that are most effectively treated by this therapy.

**Low Dose Naltrexone**

Low dose naltrexone (LDN) was initially shown to enhance a patient’s response to an infection by the human immunodeficiency virus (HIV). The dose was 3 milligrams. Naltrexone has been approved by the Food and Drug Administration since 1984 in 50 milligram doses for helping heroin and opium addicts by blocking both of these substances. Naltrexone blocks reception of opioid hormones that the brain and adrenal glands produce: beta-endorphin and metenkephalin. Many tissues have receptors for these endorphins and metenkephalins, including most of the body’s immune system. Cellular peptide opioid growth factor (met5-enkephalin)
and opioid growth factor receptor are important in both autoimmune diseases and cancer. If naltrexone is given at 50 milligrams, increased cell proliferation occurs, but if LDN is used, the effect is opposite: a decrease in cell proliferation. LDN is approximately 2 to 5 milligrams.

In the presence of LDN, cancer cells are prevented from proliferating rather than killed by apoptosis. LDN also decreases the tumor blood supply. Angiogenesis is critical to the growth and proliferation of solid tumors including ovarian, pancreatic, and lung cancers. LDN does not interfere with taxol and cisplatin and may actually enhance their effects. If LDN is combined with opioid pain therapy, such as morphine or codeine, its beneficial effects are blocked. LDN is most effective when taken at bedtime. The blocking effect is prominent between 2 and 4 a.m., producing higher levels of beta-endorphins the next day. The use of slow-release or timed-release LDNs prevents the essential therapeutic spike.

Side effects are uncommon. Some patients will have difficulty sleeping, but this rarely persists beyond one week. Patients taking thyroid replacement for Hashimoto thyroiditis hypothyroidism are advised to begin treatment at the lowest dose. Patients with an organ transplant and using immunosuppressant medication are advised not to use LDN.

There is currently a trial of LDN versus placebo in malignant glioma at Duke University. Results are not expected before late 2015.

Melatonin
Melatonin, chemically known as N-acetyl-5-methoxytryptamine, is a hormone found in animals, plants, and microbes. In animals, it plays a role in circadian rhythms, and it is an antioxidant. Melatonin is produced in the pineal gland, but 85 percent of its receptors are in the gut-associated lymph tissue (GALT). Blue light suppresses its nocturnal production. Campfires and incandescent lightbulbs have little effect on its production.

Melatonin is twice as active as vitamin E and scavenges radical oxygen and nitrogen species, including hydroxyls and nitrous oxides. Immunological effects are via the MT1 and MT2 receptors, and they have effects in viral and bacterial infections and cancer. Melatonin production decreases with age, and its production peaks earlier in the elderly, possibly explaining the sleep changes seen with aging.

Melatonin increases the cancer-killing activity of macrophages, monocytes, natural killer cells, T-helper cells, and eosinophils. It inhibits angiogenesis, and it reduces inflammation in the tissue around the tumor. Inflammation can help a cancer grow and spread in the body.

Low melatonin levels have been reported in patients with breast and prostate cancer. In women with breast cancer taking tamoxifen, the addition of melatonin caused tumors to shrink in over a quarter of the women. In another study, the use of melatonin before chemotherapy prevented reduction in platelet counts. Its use in prostate cancer leads to increased survival.

Melatonin’s use in patients with cancer starts at physiological doses and increases to supraphysiological doses over a period of several weeks to months. It has been given concomitantly with chemotherapy to lung cancer patients, yielding longer survival times compared to patients receiving only chemotherapy. Much of the melatonin research has been conducted in one research center. Duplication of clinical trials in various centers is required to confirm its clinical benefits.

Side effects of melatonin use may include increased memory of dreams and drowsiness during the day, but this disappears after a week or two. Melatonin can worsen depression in some individuals; its use should be closely monitored.

Mistletoe
Mistletoe extracts were developed by Rudolph Steiner, Ph.D., the founder of anthroposophy, Waldorf schools, biodynamic farming, and anthroposophical medicine. His system was based on intuitive thinking about the relationships between the human body and plants, minerals, and the cosmos.

Mistletoe is a parasitic plant that eventually kills its host: a parallel to cancer. This led Steiner to test and later use mistletoe in the treatment of patients with cancer. Extracts are prepared according to biodynamic principles and appropriately and serially diluted. They are injected in the abdomen subcutaneously, much like an insulin injection. Nearly 1,000 studies and trials have shown longer survival and better quality of life in patients who receive this therapy. There have been no large trials at major research or cancer centers to date. Mistletoe commonly is used in European cancer clinics and by
Extracts of mistletoe (*Viscum album*) contain alkaloids, lectins, and viscotoxins. Separately and together, these constituents have anticancer effects. Mistletoe found on different trees, both hardwoods and conifers, are selected for the treatment of different cancer types. In the case of breast cancer, whether the woman was pre- or postmenopause at the time of diagnosis will determine the type of mistletoe selected.

A common side effect of the injections is a superficial and subcutaneous inflammation. This is considered desirable as long as it is not too large. Occasionally, a fever will develop. Both of these usually resolve within a few days.

**714-X**

This is a camphor compound modified by the addition of a nitrogen atom. Chemically, it is trimethylbicyclonitramineoheptane chloride. Analysis has shown the presence of nitrogen, ammonium salts, sodium chloride, ethanol, and less than 0.01 percent camphor. 714-X was developed by Gaston Naessens, a Frenchmen who moved to Quebec, Canada, in the 1970s. This compound works by countering somatids, a life form that is neither bacterial or viral or fungal but distinct unto itself.

714-X is injected into the lymphatic system in the groin or may be inhaled by a nebulizer. It is manufactured in Canada and available under the Special Access Programme of Health Canada. 714-X is banned for sale and importation in the United States.

The few animal studies have shown no beneficial effect. There are no published studies on its safety or efficacy. The main side effects are pain in the groin after injection and the risk of infection if not administered using clean techniques.

**Conclusion**

There are a wide variety of alternative cancer treatments. Some have been studied more than others, some are widely used in certain settings or countries, and some have little data or theory to explain their use. Cancer patients may become desperate to find a cure, but they need to do extensive research before seeking alternative treatments.

**American Academy of Pediatrics, Section on Hematology/Oncology**

The belief that children have unique health and developmental needs was a new concept in 1930, the year the American Academy of Pediatrics (AAP) was founded by 35 pediatricians. The AAP’s mission is to care for infants, children, and adolescents to attain the best possible physical, mental, and social health. The general well-being of children is also a part of its mission. There are more than 62,000 primary care pediatricians, subspecialists, and surgical specialists currently in membership.

The AAP’s Section on Hematology/Oncology was first organized in 1975 to improve the care of children with cancer and blood disorders through an educational forum that discusses the problems and treatments related to pediatric hematology (dealing with blood and the organs that produce blood) and oncology (dealing with cancer and tumors). Not only does the Section on Hematology/Oncology aim to increase research in and the teaching of hematology and oncology in academia, it is a resource of knowledge for other medical professionals, the public, and governmental agencies.

There are two memberships granted in the Section on Hematology/Oncology. Section membership is granted to honorary international members, national affiliate members, postresidency training members, residents, emeritus fellows, candidate members, and corresponding fellows. Affiliate members must be under the direct supervision of
a certified pediatric hematologist or oncologist in a pediatric hematology or oncology department that has devoted at least 50 percent of their practice or work to addressing pediatric hematology or oncology. These members are licensed physicians, nurses, and clinical research associates.

The Section on Hematology/Oncology has provided guidelines that address the unique needs of pediatric hematology and oncology patients. Among these is a policy regarding long-term care for pediatric cancer survivors. This has become an increasingly pressing concern since 1970. Prior to 1970, almost all children with cancer died. Currently, almost 80 percent survive. Most of these children are followed by their primary care physicians, thus, the need for guidelines for long-term care.

Because chemotherapy, radiation, and surgery often have complications, long-term concerns can include problems with organs, growth, development, brain function, and academics. There is also the risk for additional cancer. There are also long-term psychosocial concerns that affect the family, peer, and financial domains.

Pediatric cancer survivors require ongoing long-term and comprehensive follow-up care to optimize long-term outcomes by successfully monitoring for and treating the late effects that may occur as a result of previous cancer therapies. The Section on Hematology/Oncology recommends that follow up is tailored based upon the unique age of the patient, type of cancer, type of treatment, and ongoing evaluations. They offer a report that addresses these and is available to pediatricians. They also facilitate working relationships between the pediatrician and pediatric oncology specialists. The Section of Hematology/Oncology believes that the family's pediatrician is in the position to address specific childhood disease and concerns, is family centered, is available in a timely manner, has a continuous relationship, and is comprehensive.

Pediatricians are also in the position to promote healthy lifestyles as survivors of childhood cancer have a high rate of chronic health conditions. Survivors coached to eat a well-balanced diet decrease their risk for obesity, cardiovascular disease, and osteoporosis. The pediatrician should accomplish coaching through appointments, written media, and Web-based material. The Section on Hematology/Oncology also offers these resources.

Further, transitioning from pediatrics to adult health services requires planning prior to the transition due to the additional challenges for survivors into adulthood. By the time survivors reach adulthood, they should be well-educated regarding their history and ongoing risks and concerns. Pediatricians and family members can coach survivors so that they have the knowledge and skills to maintain optimal health while being aware of their health risks and aware of new information as it becomes available.

The Section on Hematology/Oncology guidelines also include pediatric cancer centers. They recommend that care be provided by a board-certified physician whose subspecialty is in pediatric hematology and oncology by the American Board of Pediatrics. The pediatric team may consist of a number of individuals, including surgeons, urologists, pathologists, nurses, social workers, nutritionists, pharmacists, and other allied health professionals. All members should be board certified in their disciplines.

The facility should include a fully staffed, immediately accessible, on-site pediatric intensive care unit. Diagnostic imaging equipment should be state-of-the-art and include radiography, magnetic resonance imaging (MRI), ultrasonography, computed tomography, and other relevant technologies. Radiation equipment must be up-to-date. The laboratory must be capable of cell analysis, chemistry, and molecular diagnosis. Collection and storage of specimens must be easily accessible. The facility should also have a blood bank, a pharmacy, and access to stem cells.

The pediatric cancer center should offer educational and training programs, coordination of services, a multidisciplinary pediatric board that meets regularly, and protocols for follow-up care. They should also have memberships or affiliations with groups that offer information regarding clinical trials, new information, and treatment recommendations.

Programming for families and other health care providers involved with the child needs to be available as well as open communication regarding continuity of services. Parents and appropriate family members should also have access to educational information and supportive programs.

The American Academy of Pediatrics Section on Hematology/Oncology stresses that children
American Association for Cancer Education

The American Association for Cancer Education (AACE) is a multidisciplinary membership organization originally founded in 1947 under the name Coordinators of Cancer Teaching (CCT). Educators from various American medical and dental schools who gathered yearly to discuss common interests related to cancer research, methodology, and other pedagogical concerns for medical schools founded CCT. It was in 1967 that the CCT became the AACE. The AACE seeks to promote high standards for cancer education through evidence-based practices that result in high-level outcomes.

Educating patients, practitioners, politicians, and others is a key strategy to end the burden of cancer both nationally and internationally. As a membership organization, AACE provides an outlet and space for allied health care professionals and others concerned with improving the quality of cancer education at the undergraduate, graduate, continuing professional, and paraprofessional levels. Doctors, genetic counselors, nurses, occupational and physical therapists, patient advocates, patient educators, physicians assistants, radiologists, and social workers are a few of the professional and paraprofessional areas and disciplines represented by the membership who work collectively to exchange information and ideas to improve cancer education. Individuals and institutions interested in membership with AACE must first complete an application, pay the membership fee, and be approved for membership after completing the first two steps.

The AACE, along with the European Association for Cancer Education (EACE), offers two distinct forums for the dissemination of ideas, concepts, research, and pedagogical shifts related to cancer education: The Journal of Cancer Education (JCE), which serves as the official journal for both organizations, and the International Conference on Cancer Education. Both provided vetted participants an opportunity to share their ideas for best practices in cancer education research, pedagogy, and methodology.

JCE is an international, quarterly, peer-reviewed journal and features a varied editorial board made up of M.D.s and Ph.D.s working in the field who see the importance of disseminating information about improving cancer education worldwide. JCE serves as the ideal source to educate physicians, dentists, nurses, students, social workers, as well as other allied health care professionals, patients, and the general public in various aspects of cancer education techniques and contemporary issues. Articles featured include results of original educational research, discussion of current trends, problems, and techniques in cancer education. In addition, book and media reviews, announcements of educational programs, fellowships, and grants are also published.

JCE articles are abstracted and indexed and can be accessed via Academic OneFile, EMBASE, Science Citation Index Expanded (SciSearch), Journal Citation Reports/Science Edition, PubMed/
American Association for Cancer Education

Medline, SCOPUS, PsycINFO, Google Scholar, Cumulative Index to Nursing and Allied Health Literature (CINAHL), CSA Environmental Sciences, Current Contents/Clinical Medicine, Educational Research Abstracts Online (ERA), EMCare, Index to Scientific & Technical Proceedings, OCLC, Scimago, Studies on Women & Gender Abstracts, Summon by ProQuest, and Vocational Education and Training Abstracts.

The AACE and its longtime collaborator the EACE have broadened their cosponsorship of the International Cancer Education Conference to include the Cancer Patient Education Network (CPEN). The aim of the conference is to provide a platform for validated educational models, provide a multidisciplinary forum for the dissemination of cancer education research, facilitate interdisciplinary networking, and enhance the educational and evaluation skills of attendees. The goal of the conference organizers is to expand the cancer education community from which all can learn and share best practices in cancer education, making best use of its educational efforts.

Significant topics for both the journal and the conference include but are not limited to the following: interpersonal communication between doctors and patients; spirituality in cancer education; computer-assisted instruction in cancer education; teaching strategies and delivery methods for patients, practitioners, and students; palliative care; self-care; and oral cancer.

The AACE established two awards to honor excellence in cancer education: the Samuel C. Harvey Memorial Lecture award, established in 1951, and the Margaret Hay Edwards Achievement Medal, established in 1986. The Samuel C. Harvey Memorial Lecture award is named in honor of the CCT’s first chairperson, who also chaired Yale University School of Medicine’s Department of Surgery for 23 years. The first Harvey Lecture was delivered by Ward Darley, M.D., in 1951. Recent lecturers include: (2013) Mary Gospodarowicz M.D., Fellows of the Royal College of Physicians and Surgeons in Canada (FRCPSC), President of Union for International Cancer Control Princess Margaret Cancer Centre University of Toronto, Cancer Care Ontario—Cancer in the World: Addressing the Equity Gap; (2012) Rena J. Pasick, DrPH, Helen Diller Family Comprehensive Cancer Center at the University of California San Francisco—Persistent Cancer Disparities and Health Behavior Theory: Finding Our Way to the Real World; (2011) Katherine Oliveros, Susan G. Komen for the Cure—An Overview of the Susan G. Komen for the Cure: International Programs; and (2010) Betty Ferrell Ph.D., M.A., Fellow of American Academy of Nurses (FAAN), FPCN, Research Scientist and Professor, City of Hope—A Program of Research in Patient, Family and Professional Education.

The Margaret Hay Edwards Award, for whom the award was named, was a member of the National Cancer Institute and was instrumental in establishing peer-reviewed cancer education support mechanisms. The AACE Advisory Committee grants this award annually to individuals who have made noteworthy contributions to cancer education. Each recipient receives a medal and $1,000. Recent honorees include: Joe B. Harford, Ph.D. (2013), Virginia M. Krawiec, MPA (2012), Ajit K. Sachdeva, M.D., FRCPSC, Fellow of the American College of Surgeons (FACS) (2011), and Arthur M. Michalek, Ph.D. (2010). In addition to formal education programs for future allied health care professionals and continuing education or training for current allied health care professionals, AACE focuses on educational programs for those currently diagnosed with cancer, their families, the general public, and populations that are at high risk for cancer. The AACE Web site includes a variety of educational resources available to the general public.

American Association for Cancer Research

The American Association for Cancer Research (AACR) is the world’s oldest and largest professional association related to cancer research. Located in Philadelphia, AACR focuses on basic, clinical, and translational research in etiology, prevention, diagnosis, and treatment of different cancers. It was founded in 1907 by 11 physicians and scientists; the institute now has more than 33,000 members in 97 countries.

Annual Meeting
The AACR annual meeting invites more than 18,000 participants from more than 70 countries and has been defined as the major forum to present and discuss cancer-related research. Attendees meet to discuss more than 5,000 abstracts and more than 300 presentations on substantial discoveries in basic, clinical, and translational cancer research. Scientific award lectures, grant-writing workshops, and educational sessions constitute this widespread program.

Publications
AACR publishes eight peer-reviewed journals: Cancer Discovery, Cancer Immunology Research, Cancer Research, Clinical Cancer Research, Molecular Cancer Therapeutics, Molecular Cancer Research, Cancer Prevention Research, and Cancer Epidemiology. In addition to its print publications, the AACR provides online access to the latest in cancer research, cancer prevention, and cancer reviews with online versions of each of its eight journals. The AACR also publishes Cancer Today, a magazine for cancer patients, survivors, and their families and friends.

AACR also offers monthly editors’ picks from highly-esteemed journal collections. They highlight one article from each issue that has been determined a must read by the editors. All of these research articles have been made freely available for a specific and limited amount of time.

Cancer Research is the most frequently cited cancer journal in the world. The journal publishes significant, original studies, reviews, and perspectives on all areas of basic, clinical, translational, epidemiological, and prevention research in cancer. Some of the topics include biochemistry; chemical, physical, and viral carcinogenesis and mutagenesis; clinical research including clinical trials; endocrinology; epidemiology and prevention; experimental therapeutics, molecular targets, and chemical biology; immunology and immunotherapy molecular biology, pathobiology, and genetics; radiobiology and radiation oncology; cell and tumor biology; tumor microenvironment; systems biology; nanotechnology; and other emerging biomedicine technologies.

The AACR Foundation for the Prevention and Cure of Cancer
The AACR foundation for the prevention and cure of cancer is a public charity that provides financial support for scientific research, education, and communication. The foundation funds programs considered by the AACR to be of the highest priority and effect.

Funding
The AACR foundation for the prevention and cure of cancer directly funds research that holds promise for a cure for cancer. The foundation’s mission to “speed up progress in the conquest of cancer by providing financial support for scientific research, education, and communication” is well-known by its support of scientists at all levels. The AACR offers support to cancer researchers at various steps in their careers, from fellowships to career development awards to key grants for independent investigators. In 1970, the AACR established the Cornelius P. Rhoads Memorial Award in honor of the prominent cancer researcher and administrator who directed Memorial–Sloan Kettering Cancer Center and had a long career in working to cure cancer. It is awarded annually to a promising young researcher. Due to revival in 2002 of a 1932 controversy, in which a racist letter by Rhoads was found and publicized, the AACR stripped his name from the award.

Since 1961, the AACR has presented about 500 prizes, awards, and lectureships to recognize the scientific accomplishments of scientists and physicians who cooperatively have made significant contributions to the understanding, diagnosis, prevention, and treatment of cancer. Details about the eligibility criteria and nomination process for each of these honors may be viewed on the AACR Web site.
Vibrant interactions and exciting science characterize all of the AACR's meetings, conferences, and educational workshops. The AACR annual meeting, the largest of its kind in the world for cancer researchers, attracts about 20,000 researchers from more than 50 countries each spring.

In addition to the annual meeting, the AACR holds several large conferences with 1,000 to 5,000 participants that focus on the latest breakthroughs in molecular targets and cancer therapeutics, frontiers in cancer prevention research, cancer health disparities, and frontiers in basic cancer research.

Several special conferences of 200 to 1,000 attendees are held each year that focus on demanding areas of cancer research and specific disease sites. The same conferences are also held overseas in collaboration with international cancer research organizations.

AACR’s educational workshops and special courses provide early-career investigators with opportunities to develop skills in clinical trial design, pathobiology, and related fields. Many programs enhance the educational aspects with mentoring, networking, and career development opportunities. Combined with a broad range of educational and career development sessions at the annual meeting and year-round Associate Member Council (AMC) programs and activities, younger researchers are prepared for the next critical steps in their careers.

Membership
New members join more than 34,000 investigators from around the world who depend on the association’s programs and activities for the exchange of appropriate scientific information. Moreover, members have the opportunity to take advantage of the many benefits of membership, including substantially reduced fees for meeting registrations and journal subscriptions as well as excellent opportunities to bolster important relationships and collaborations with cancer scientists internationally. These are just a few of the benefits that are offered to a member of AACR.

AACR offers seven categories of membership to support each aspect of members’ professional development and enhancement in cancer research.

Candidates applying for membership should be aware of the responsibilities of membership prior to submitting the membership application form.

AACR Membership Application

Applications for membership may be submitted at any time during the year. One may either submit the official AACR membership application online or download the application and submit it to the AACR office with the required documents. It takes 30 days for application review and approval notification.

American Brain Tumor Association

The American Brain Tumor Association (ABTA) is a 501(3)(c) nonprofit organization headquartered in Chicago, Illinois. The organization is dedicated to advancing the understanding and treatment of brain tumors through education and information. Created in 1973 by two mothers—Susan Netchin Kramer and Linda Gene Goldstein—who both suffered the loss of a child due to a brain tumor, the ABTA’s mission is focused on not only improving the lives of patients suffering from a brain tumor diagnosis but also funding critical medical research that could lead to methods that would extend and save the lives of these patients.

As a result of their shared tragedy and with the help of medical professionals and experts in the field of brain tumor treatment and research, Kramer and Goldstein embarked on building the
first U.S. nonprofit organization dedicated solely to the research of brain tumors and potential treatments. Since 1973, the ABTA has built a comprehensive program focused on engaging with brain tumor patients and their caregivers, collaborating with other similar nonprofit organizations and medical professionals, and funding related research efforts.

In addition to the educational mission that provides information to patients on a variety of topics, including but not limited to symptoms, tumor types, treatments, and associated risks, the organization also funds major research initiatives out of its Brain Tumor Research Center. As of 2014, a majority of the center’s funding focused on research dealing with drug research—including development of new drugs and research into how existing drugs can be used in treatment of brain tumors. Other research efforts focus on improved diagnostics, vaccines, immunotherapies, and rehabilitative services for recovering brain tumor patients.

In addition to educational materials and funding of research, the following list outlines some of the other services provided by the ABTA:

- Phone and email-based supportive care provided by licensed health care professionals
- Online support community
- A free clinical trial matching service, TrialConnect
- An online caregiver support tool
- National and regional meetings for patients and caregivers

While the ABTA’s overall program and research can be applicable to both adults and children, the organization’s program for adolescent and pediatric patients is extensive and focuses on the complexities that can arise from dealing with young patients. As a result, the ABTA’s adolescent and pediatric program provides patients and their families with information and support services in the following areas: treatment methods, the long-term effects of treatment, impacts on families and caregivers, and tips on returning to school, to name a few.

While the ABTA does not conduct its own research, it provides a major source of funding for brain tumor research in the United States by providing grants to scientists and researchers working across the United States and Canada. ABTA’s program is highly competitive and is based on an application process. Funding decisions are based on ABTA’s research priorities that demonstrate the greatest potential for advancing the treatment and care of patients diagnosed with brain tumors. The funding decisions are carried out, in part, by the ABTA’s Scientific Advisory Council, which is made up of experts who volunteer their time and services to identify trends and new areas of research and make research funding recommendations to the organization’s board of directors. Researchers who are near the end of their research grant periods present their findings at ABTA’s annual Patients and Families Conference.

The three main research funding areas for the ABTA are: (1) career development initiatives, (2) exploration of innovative research, and (3) collaborative funding opportunities. The career development initiatives look to provide research opportunities for scientists and researchers at the early stages of their careers and are looking to begin research projects in the field of brain tumor research or are looking to remain in this field of research.

While the career development initiatives look to support young researchers, the exploration of innovative research areas focuses on research proposals that look at how brain tumors are diagnosed and treated and challenges the current processes with innovative improvements.

Last, the collaborative funding research projects provide a way for the ABTA to collaborate with other similar research institutions or nonprofit organizations in order to leverage the resources, expertise, and methods of multiple organizations for the good of a common goal. Programs that fall under ABTA’s research funding purview include the following:

- Basic research fellowships
- Translational grants
- Discovery grants
- Medical student summer fellowships
- Survivorship
- Brain Tumor Funders Collaborative
- ABTA/American Association of Neurological Surgeons (AANS)/Congress
of Neurological Surgeons (CNS) Young Investigator awards
- International Outreach Fellowship
- Brain Tumor Epidemiology Consortium (BTEC) Junior Investigator awards
- Central Brain Tumor Registry of the United States (CBTRUS) grant
- Spore Collaborative Funding Project

A majority of the research funded by ABTA focuses on glioblastoma and malignant gliomas, which are tumors that arise from the brain's supportive tissue, or glia, that helps keep the brain's neurons in place and functioning. These tumors are commonly found in the cerebral hemispheres of the brain but can also be found in other brain areas or the spinal cord. Additionally, the connective, supportive characteristics of the glia mean that tumors in this area of the brain are typically highly cancerous, with cancer cells rapidly reproducing due to access to the brain's large network of blood vessels found in the glia.

The ABTA also funds current research into pediatric brain stem tumors and studies focused on finding biomarkers or indicators of childhood brain tumors. Since its inception in 1973, the ABTA has become a driving force in brain tumor patient advocacy, education, and research and is currently the only U.S. nonprofit solely dedicated to advancing brain tumor treatments and research.

American Cancer Society

Founded in 1913, the American Cancer Society is a voluntary health advocacy group that is committed to eliminating cancer. Throughout its history, the American Cancer Society has lobbied for legislation that has served to increase research spending on cancer and to limit the availability of certain products believed to increase the public’s risk of contracting this disease.

The American Cancer Society is one of the best-funded charities in the United States, and it spends heavily on research initiatives, public awareness campaigns, and efforts to reduce risk-enhancing behaviors on the part of the public. Some have criticized the American Cancer Society for spending too much of the donations it receives on overhead and other expenditures, criticisms that have caused certain reforms within the organization.

Background
Originally named the American Society for the Control of Cancer, the organization that became known as the American Cancer Society has, since the beginning, sought to increase awareness of cancer, its causes, and possible treatment options. At the time of the American Cancer Society’s formation, few patients diagnosed with cancer discussed their condition with family or friends. Fear and denial meant the disease was not discussed, and this lack of knowledge contributed to an environment where those with cancer almost certainly died as a result.

To deal with this, the physicians and business leaders who founded the American Cancer Society wrote a variety of articles, published in both the popular press and professional journals, that raised public awareness of cancer and possible cures for the condition. The Sword of Hope symbol, frequently used in the American Cancer Society’s publications, was developed during the 1920s as the result of a poster contest submission.

During the 1930s, women volunteers created the Women’s Field Army, a group that wore uniforms, had rank and insignia, and went door to door to raise money for cancer research. Whereas there had been approximately 15,000 volunteers involved in cancer control in 1935, the year before the Women’s
Field Army’s birth, by 1938, this number exceeded 150,000. In the aftermath of World War II, Mary Lasker and other supporters of the American Cancer Society raised more than $5 million for the organization, with 25 percent of that targeted at funding a research initiative. In conjunction with efforts to educate the public about the signs of cancer, this research effort would be the focus of the organization for decades to come.

Research
From the beginning, researchers who received funding from the American Cancer Society made discoveries that assisted patients facing cancer. Sidney Farber, one of the first American Cancer Society grant recipients, administered aminopterin to a child with acute leukemia, achieving the first temporary cancer remission in a child. Other major breakthroughs also resulted from studies funded by the American Cancer Society. These included studies that established the link between cancer and smoking, confirmed the Pap test’s effectiveness, developed cancer-fighting drugs and biological response modifiers, noticeably increased childhood leukemia’s cure rate, and established mammography’s safety and effectiveness of mammography. To date, more than $4 billion has been provided to researchers by the American Cancer Society, and scientists who have received these grants have been awarded more than 45 Nobel Prizes for their efforts.

Leaders of the American Cancer Society used this research to advocate for legal and policy changes that aligned with these studies’ findings. For example, during the 1960s, the American Cancer Society supported the surgeon general’s report that established the link between smoking and cancer. This report was given added credibility with the public and press when early American Cancer Society-sponsored studies confirmed the connection between tobacco use and cancer. The surgeon general’s report laid the groundwork for changes in how tobacco is treated and controlled, changes that continue today.

The American Cancer Society supported the passage of the National Cancer Act in 1971, which changed the society’s role in cancer research. The National Cancer Act provided the government both the funds and authority to expand the National Cancer Institute (NCI). As such, the act radically changed the war on cancer, making research funding a consistent source of support for those scientists engaged in this activity. The NCI’s development also changed the role of the American Cancer Society with regard to such research by changing from providing primary funding for such studies to that of strategically funding those areas that fall outside of the federal government’s chief areas of focus. Since the establishment of the NCI, the American Cancer Society’s funding has focused chiefly upon cancer prevention and education. Recently, as National Institutes of Health funding for young investigators has decreased, the American Cancer Society has allocated more funds to that generation, maintaining its role in advancing cancer research.

Outreach
Raising approximately $1 billion each year to support its programs, the American Cancer Society is one of the largest charities in the United States. The American Cancer Society has more than 3,400 offices across the United States, and each year more than 2 million volunteers work in these. Because it views public health advertising
as important to its mission, the American Cancer Society sponsors a variety of events designed to promote public interest in cancer, its causes, and lifestyle changes that might decrease one's chance of getting cancer. These events include the Relay for Life, a multiday, outdoor public gathering held in multiple locations, and the Great American Smokeout, a day where those who smoke are encouraged to quit. The American Cancer Society also operates thrift stores that are used to generate income for its projects.

Criticized by some as spending too much on overhead and other expenses, the American Cancer Society has in recent years worked to ensure that as much money as possible is spent on research and direct services to cancer patients. Approximately 72 percent of the American Cancer Society's budget is spent on program services, which includes 28 percent on patient support, 16 percent on prevention, 16 percent on research, and 12 percent on detection and treatment. The remaining 28 percent of the American Cancer Society’s budget is spent on fund-raising (21 percent) and administration (7 percent). Although spending 7 percent on administration is in keeping with other large charities, the American Cancer Society has been criticized for the compensation provided its executive director, which has ranged from $850,000 to more than $2.5 million per year. Despite this controversy, the number of cancer patients surviving has increased dramatically over the lifespan of the American Cancer Society, as its efforts have been largely successful.

American College of Gastroenterology

Founded in 1932, there are greater than 12,500 doctors, representing 86 countries, who are members of the American College of Gastroenterology. Members stay informed through a variety of measures, including meetings, postgraduate training, research, and the American Journal of Gastroenterology. They have 22 committees that gather and exchange information regarding the most effective care for patients.

Gastroenterology studies the diseases of the liver, bile ducts, pancreas, rectum, large intestine, small intestine, stomach, and esophagus. It is a detailed examination of normal function, disease, the movement of nutrients through the stomach and intestines, digestion and absorption of these nutrients, waste removal, and the function of the liver. Gastroenterologists are physicians who have dedicated training and experience in the management of the digestion system. Gastroenterologists study any number of these diseases: colon polyps, cancer, reflux, ulcers, colitis, irritable bowel syndrome, Crohn’s disease, pancreatitis, and nutritional absorption issues.

Gastroenterologists must first complete medical school. They then go on to three years in an internal medicine residency. Finally, there is a fellowship, which is an additional two to three years. The fellowship is a rigorous program that involves learning from nationally recognized experts to develop further skills in evaluating patients, caring for conditions, and providing recommendations for better health and to prevent disease. It is monitored by national groups that include the American Society for Gastrointestinal Endoscopy, the American Board of Internal Medicine, the American Gastroenterological Association, and the American College of Gastroenterology. Once training is complete, the fellows are board eligible. Once they have successfully passed the gastroenterology board certification test (administered by the American Board of Internal Medicine), they are board certified.

Endoscopy (upper endoscopy, sigmoidoscopy, and colonoscopy) is a diagnostic and treatment tool often used by gastroenterologists. It is a narrow, flexible, lighted tube with built-in video cameras. Training by expert instructors advises gastroenterologists
when and how to perform endoscopy, methods for safety and effectiveness, and use of sedation for comfort and safety for patients. A number of general procedures can be accomplished with the use of endoscopy, including removal of colon polyps, stretching of narrowed areas of the esophagus and intestines, stopping bleeding, and biopsy when cancer is suspected. Gastroenterologists learn to interpret the biopsy results and make recommendations regarding treatment. Some gastroenterologists take advantage of advanced training using endoscopes. Advanced procedures can include biliary examinations, removal of tumors, internal drainage tubes, and endoscopic ultrasound. These advanced procedures are not considered surgical but minimally invasive alternatives to surgery. Yet, the gastroenterologists can utilize them to remove stones in the bile ducts and evaluate and treat tumors.

The American College of Gastroenterology advocates a thoroughly comprehensive knowledge of the entire gastrointestinal tract as the best way to provide quality care in consulting and endoscopy services. Gastroenterologists should therefore be highly trained specialists with a unique skills set, broad medical knowledge, specific internal medicine training, and the best skills set in the utilization of endoscopy.

More than 250,000 people are diagnosed with gastrointestinal cancer in the United States every year. Gastrointestinal cancer consists of malignant cells that form in the digestive tract. Stomach cancer forms in the lining of the stomach. Of the 250,000 gastrointestinal cancers diagnosed each year, 21,000 are stomach cancer. There are a variety of risk factors, which include family history, H-pylori infection, long-term stomach inflammation, obesity, and poor diet. Small intestine cancer, which accounts for 7,000 new cases in the United States each year, has several common types: adenocarcinoma (cells that make and release mucus and other fluids); carcinoid (neuroendocrine cells); stromal tumor (wall of the intestine); lymphoma (lymph tissues); and sarcoma (connective supportive tissues). The risk factors for small intestine cancer include age, alcohol use, tobacco use, high-fat diet, family history, gender, and conditions where the small intestine is inflamed (celiac disease, Crohn's disease, etc.). Colorectal (colon or rectum) cancer accounts for 40,340 cancers diagnosed each year in the United States. Risk factors include age, family history, personal history of cancer, history of polyps in the colon, history of ulcers in the lining of the large intestine, and Crohn's disease. There are two types of esophageal cancer, squamous cell carcinoma (cancer in the flat cells lining the esophagus) and adenocarcinoma (cancer in the cells that make and release mucus and other fluids). There are more than 17,990 new cases diagnosed in the United States each year. Risk factors include age, gender, reflux disease, Barrett's esophagus, smoking, and obesity. Pancreatic cancer is diagnosed in the United States more than 46,420 times each year. The most common type is exocrine pancreatic cancer (cancer in the ducts that carry pancreatic fluids). Risk factors include diabetes, family history, obesity, inflammation of the pancreas, and smoking.

The American Journal of Gastroenterology is the official publication of the American College of Gastroenterology. It is published monthly and ranked first among clinical journals that cover gastroenterology. The journal provides both practical and professional support for gastroenterologists and most often covers common gastroenterological disorders. They organize their content by topics such as colon, small bowel, endoscopy, esophagus, inflammatory bowel disease, liver, pathology, stomach, and pediatrics. The American Journal of Gastroenterology includes a red section that summarizes important matters included in the journal, original research, editorials, clinical reviews, practice guidelines, and continuing educational opportunities. The journal is available online and in print.

The American College of Gastroenterology also sponsors an institute whose primary goal is to advance the field through education and research. They promote research, educate physicians and the general public, and provide resources for the further study of gastroenterology. It was founded in 1994 and is officially referred to as the ACG Institute for Clinical Research and Education. It serves as a major funder for patient care that falls within gastroenterology research.

American College of Radiation Oncology

The American College of Radiation Oncology (ACRO) is a nonprofit corporation whose goals include the advancement of radiation oncology science, improved patient care, improved education, and the study of the socioeconomic aspects of radiation oncology practice.

ACRO’s mission statement outlines its desire to provide high-quality care for patients receiving radiation therapy. They also wish to promote success for practitioners by integrating science and technology, responsible socioeconomic advocacy, and education. ACRO adopted its mission statement and vision statement in 2005, and essentially describes itself as the professional society for success in the practice of radiation oncology.

ACRO is managed by a board of chancellors who are volunteers. They are elected by the members and follow ACRO bylaws. The board has 17 elected members: chair, president; vice president; secretary–treasurer; the immediate past chair; four committee members; seven general members; two liaisons; and two nonvoting members. The entire board meets twice per year. However, the executive committee meets monthly through telephone conference. Elections are held annually. Each member serves a three-year term but not more than two terms. ACRO’s CEO is the president of ACRO, who automatically assumes the position of chair.

Committees in charge of programming are appointed by the board. Committee members rotate as per ACRO guidelines. A management company (PAI Management Corporation) assists the board with management direction, conference management, financial management, committee support, administrative services, publications, and membership administration. The board carefully appoints committees and supports participation of all members in educational activities.

There are four membership categories in ACRO. Initially, members are considered regular members. After 10 years of membership (continuous), regular members can apply for fellowship, which allows them to use the acronym FACRO. Regular members who also serve in the military or are in their first year of practice have reduced annual dues. Military members’ dues are $175 annually. First-year practitioners pay $275 annually. All others in this category pay $375 annually.

Associate members are practitioners engaged in radiation–oncology practice. These may be radiation therapists, radiology technologists, or administrators. Annual dues are $255. Associate members receive a number of publications as part of their membership: quarterly newsletters, the American Journal of Clinical Oncology, and the ACRO Practice Management Guide (at a discounted price). Associate members can be appointed to committees but cannot vote nor hold elective office. Any physician who has not been a member of ACRO but holds a residency position in radiation–oncology are resident members. They do not pay any dues. They also can be appointed to committees but cannot vote or hold elective office either.

Corresponding members are physicians who have been active members or associate members for greater than five years but are not employed more than 10 percent of their time in a field related to radiation–oncology. Practitioners who are not physicians but who have a major interest in ACRO and can prove involvement in the field or have worked to improve the field are also eligible to be corresponding members. As with associate members and resident members, they can be appointed to committees but cannot hold office or vote. Corresponding members’ dues are $100 annually.

ACRO developed an accreditation program in 1995. It is voluntary and consists of agreed-upon practice standards for quality practice. Audits are conducted to ensure these standards are followed. Since 1995, the accreditation program has been revised to include scientific advances. The most recent review, in 2010, included major changes to address online submission of cases, faster turnaround for applications for accreditation, and onsite visits (to include physics and administrative professionals).
ACRO has also created a code of ethics that aids in maintaining standards of service and ethical conduct. It is a set of standards radiation oncologists can utilize to monitor their own conduct in their relationships with colleagues, the public, patients, and other allied professionals. The ACRO code of ethics is divided into two primary categories: principle of ethics and rules of ethics. The principles of ethics are intended to be an exemplary code of conduct for all ACRO members. They are goals for all members. The principles of ethics are not subject to disciplinary action and are not enforceable. The primary objective is to provide medical care with a full respect for dignity. ACRO members should also continuously improve upon their knowledge and skills. ACRO members should protect the general public (and itself) from incompetence or physicians who do not hold a high moral character. All laws related to radiation oncology should be upheld, and violations of laws or ethics should be immediately exposed. ACRO members should focus not only on the health of their patients but also on the well-being of their communities. Patient confidentiality is upheld unless revealing information is required by law or to protect the public. Services should always be in the best interest of the patient, and the decision to accept or decline services is the patient’s.

The second part of ACRO’s code of ethics includes the rules of ethics. These are mandatory and specific regarding minimal standards of conduct. These are enforceable by disciplinary actions. ACRO members should offer only consultative opinions in settings where they participate in the quality of patient care, and utilization reviews are a matter of policy. ACRO members may not participate in misleading billing arrangements. ACRO members may never divide fees. Before practicing in hospital settings, ACRO members must apply and be accepted as a member of the hospital staff in the same way other medical staff have applied and been accepted.

When an ACRO member violates the code of ethics he or she may be disciplined, expelled, suspended, or censured. Complaints are filed with the president, who may initiate an investigation. If the complaint requires further attention, the president refers it on to the executive committee.

American Joint Committee on Cancer

The American Joint Committee on Cancer (AJCC) created the guide for staging cancer, titled The Cancer Staging Manual. Physicians and the community rely on this manual as it is the most comprehensive guide available. Anatomic staging that is evidence based is one of the critical factors in understanding cancer and when treating patients. New science in oncology, radiology, pathology, and molecular science are routinely utilized to precisely define, assist with treatment planning, and offer prognosis during treatment. Cancer science is continually evolving, and the AJCC’s role continues to be crucial clinically in research and in patient advocacy communities.

The AJCC defines its mission to be providers of worldwide leadership in the classification and management of cancer through the development, maintenance, and promotion of evidence-based practices. The mission is multidisciplinary and dedicated to monitoring cancer and to improve care. The five key objectives include: a timely and rigorous, evidence-based, and biologically relevant system for classification and prognosis; proactive education of the oncology community (including program development and delivery to guide patient care); support of research and dissemination of predictive tools, prognosis factors, and other indicators that predict or classify cancer; collaboration and fostering relationships among
member organizations and organizations with similar objectives; and support and response to public or private efforts to predict outcomes or improve care.

Twenty member organizations comprise the AJCC. Member organizations have consistent or complimentary missions and goals to the AJCC. In general, the member organizations are involved in one (or more) of these areas: biostatistics, research, cancer epidemiology, cancer registration, patient care, cancer control, or professional education. Membership in the AJCC is derived from representatives from the member organizations. The executive committee makes decisions and sets the strategic direction of the organization.

The member organizations include: American Association of Pathologists’ Assistants; American Cancer Society; American College of Physicians; American College of Radiology; American College of Surgeons; American Head and Neck Society; American Society for Radiation Oncology; American Society of Clinical Oncology; American Society of Colon and Rectal Surgeons; American Urological Association; Canadian Partnership Against Cancer; Centers for Disease Control and Prevention; College of American Pathologists; National Cancer Institute; National Cancer Registrars Association; National Comprehensive Cancer Network; North American Association of Central Cancer Registries; Society of Gynecologic Oncology; Society of Surgical Oncology; and Society of Urologic Oncology.

The AJCC has four committees that individuals and member organizations can volunteer for. The Finance Committee monitors funds, reviews and advises on budgets, and identifies strategies for funding. The Membership and Bylaws Committee identifies new members who can add to the expertise that supports the mission and objectives of AJCC. These committee members also review the bylaws and make recommendations for any appropriate amendments. The Informatics Committee initiates dialogue with the National Cancer Institute to maintain AJCC’s Web site, explore vendor relationships, and develop electronic products. Short- and long-term goals to promote the staging system and related products, presentations, and journal articles are the responsibility of the Education and Promotions Committee.

Cancer staging, the primary function of the AJCC, describes how much cancer is present and where. Physicians use staging to develop treatment plans and offer prognoses. Understanding the cancer stage is also critical in determining if any clinical trials may be appropriate for patients. There are four types of staging: clinical staging (how much cancer based on exam, tests, or biopsies); pathologic staging (a combination of clinical staging and surgical interventions as with tumor extraction or biopsy); post-therapy staging (how much of the cancer remains after treatment); and restaging (extent of cancer if it reoccurs).

Staging is based on the knowledge of how cancer develops and spreads. Typically, there are four main factors: location of the original tumor, size and number of tumors, whether the cancer has spread to lymph nodes, and whether the cancer has spread to a distant site in the body (not adjacent to the original tumor). The T category, which describes the primary (original) tumor, has three classifications: TX (tumor can’t be evaluated), T0 (no evidence of primary tumor), and Tis (cancer is early and has not spread to surrounding tissues). The T1 through T4 ratings describe the size of the primary tumor. The N category describes whether the cancer has reached lymph nodes that are nearby: NX (cannot be evaluated), N0 (no involvement), and N1 through N3 (number and extent of lymph nodes involved). The M category describes the spread of the cancer: M0 (no spread) and M1 (cancer has spread).

Some forms of cancer (i.e., breast and prostate) further subdivide. On the other hand, some cancers do not follow the above system at all, though this is uncommon. Spinal cord and brain cancers, for example, are described by their grade and cell type. Certain bone marrow and blood cancers also use other staging systems.

There are a variety of tests that assist physicians with staging. Physical examination may be utilized to locate and size a tumor and whether lymph nodes or other organs are involved. Imaging, magnetic resonance imaging (MRI), computed tomography (CT), and X-rays can identify the location and size of the tumor and whether it has spread. Laboratory tests provide information on fluids, in particular blood and urine, which may have indicators of type and severity of the cancer. Pathology reports are often used to confirm diagnosis and type of the cancer and determine size, if invasion of other tissues has occurred, and the grade of the tumor. Surgical reports (tumor removal or biopsy)
can indicate the size and appearance of the tumor and offer additional information about other tissue or lymph node involvement.

American Lung Association

With more than a 100-year history, the American Lung Association (ALA) is the oldest health-related organization of its type in the United States. The association, originally named the National Association for the Study and Prevention of Tuberculosis (NASPT), began in 1904 and was dedicated to the fight against tuberculosis, the most feared and deadly disease at that time. In 1918, continuing its central thrust on tuberculosis, its name changed to the National Tuberculosis Association (NTA). As tuberculosis declined and was controlled across the United States and other serious lung diseases commanded attention, the focus of the organization grew. Expanding its mission to improve the health of lungs and to prevent diseases of the lungs, the organization was renamed the American Lung Association in the early 1970s. Today, it continues work on this expanded mission, and its efforts center in three main areas: (1) ending consumption of tobacco products and thus eradicating lung disease linked to tobacco use, (2) improving air quality overall to ensure that it does not harm the lungs, and (3) assisting patients and families affected by lung disease. Along with its community, state, and regional affiliates, the ALA, headquartered in the national's capitol, Washington, D.C., is at the forefront of ensuring the health of our lungs and the quality of the air that we breathe.

The ALA engages in a three-pronged effort—research, education, and advocacy—to achieve these goals. Endeavors address a variety of respiratory issues, including lung cancer, emphysema, asthma, chronic conditions (bronchitis, sinusitis, and hay fever), respiratory distress, sudden infant death syndromes (RDS and SIDS), influenza (flu), and pneumonia. Research efforts address topics ranging from asthma to lung cancer and seek to prevent or slow illness development, alleviate patient suffering, and discover new treatments or cures. Educational efforts include assisting patients in better managing illness as well as well-respected smoking cessation programs. The ALA also works to educate the public on the dangers of using tobacco products, with a goal of preventing tobacco use by nonusers as well as on the environmental and workplace dangers of air pollution. Advocacy efforts include lobbying for legislation to ensure clean air. Recently, the ALA was instrumental in securing passage of a bill allowing the Food and Drug Administration to oversee the manufacturing, marketing, and selling of tobacco products. The organization also produces a number of reports, such as the yearly State of the Air report and the State of Tobacco Control report, that are useful to policy makers, researchers, educators, and citizens.

Given the heavy toll of lung disease on the U.S. population, the ALA is advancing important health initiatives. Lung cancer is the most frequent cancer across the globe, and it kills more people (both men and women) in the United States each year than any other cancer. Further, lung disease ranks as the third-highest cause of death in the U.S. population, and millions of additional people suffer from the effects of chronic lung conditions. The ALA has played a leading role in addressing the negative health effects caused by using tobacco products and working to eliminate these preventable risks as well as focusing attention on the role of air pollution in lung disease.

Much information and many resources are chronicled on the organization's Web site. Users
American Lung Association

can easily access information on topics such as lung function and health, air quality, research, and smoking cessation as well as discover ways to get involved in the association’s efforts or to donate to the cause. The Web site also houses publications and reports, features news stories and a link to register for the electronic newsletter, and facilitates connections with activities in one’s community.

Christmas Seals

Perhaps the most widely recognized effort of the ALA is its Christmas Seal Campaign. This initiative began in 1907 and continues today as an illustration of the key role that volunteers play. Emily Bissell created Christmas Seals to generate funds for tuberculosis care and subsequently headed the popular fund-raising initiative for several years. Commemorating her pioneering health efforts, Bissell was recognized with a U.S. postal stamp in 1980. Since its inception, the Christmas Seal campaign has raised millions of dollars.

Building on an idea employed in Denmark for fund-raising for tuberculosis, Bissell borrowed money to print the first Christmas Seals and began selling them for 1 cent apiece. To combat slow sales, she enlisted the help of a popular newspaper, which ran a Stamp Out Tuberculosis campaign. With the newspaper support and an endorsement from President Roosevelt, Bissell raised 10 times her initial fund-raising target. In 1908, the Christmas Seal campaign became a national effort in partnership with the American Red Cross. By 1920, the National Tuberculosis Association, which later became the ALA, began managing the fund-raiser on its own, and its symbol, the double-barred cross, began appearing on Christmas Seals. This double-barred cross, or modified Lorraine Cross, had long been the symbol for antituberculosis efforts. The organization had been using this cross since shortly after it was founded and, in 1920, registered the cross as its official trademark.

Over the years, several celebrities have acted as chair of the annual Christmas Seal Campaign, and the seals, especially early ones, have become popular items for stamp collectors. Each year the fund-raiser significantly contributes to ALA initiatives.
and raises awareness of the importance of clean air and the prevention and cure of lung disease.

American Psychosocial Oncology Society

The American Psychosocial Oncology Society (APOS) represents the only organization primarily devoted to the psychosocial aspects of cancer. The society offers a strong, two-prong approach by providing both professionals and nonprofessionals a forum for the psychological, social, behavioral, and spiritual characteristics of cancer.

The mission of APOS encompasses elevating awareness about the psychosocial realms of care for patients with cancer. The organization develops and implements education programs for professionals and nonprofessionals. By developing a research agenda, the organization helps guide scientific priorities in the psychosocial aspects of cancer and cancer care for the nation.

The APOS core values comprise five statements aimed at the care of individuals with cancer. The significance of the values is paraphrased as follows:

Psychosocial care improves quality of life and lowers the stress of cancer. The distinct profession of psychosocial oncology is integral to the science of caring for cancer patients by using evidence-based knowledge. Interdisciplinary research, education, and networking teach the science and practice of psychosocial oncology. Integrity, honesty, and accountability to professional ethics and standards of care provide the backbone to APOS. Because a diversity of experiences transpire in individuals with cancer, APOS maintains intense respect for the rights of the individual to choose their desired courses of action in state-of-the-art treatment.

Members benefit from an online subscription to the journal Psycho-Oncology. APOS provides subscriptions to three other professional journals at reduced rates. Palliative and Supportive Care, Journal of Cancer Survivorship, and the Journal of Psychosocial Oncology comprise the three journals offered to members. APOS hosts special-interest groups to join, including Bereavement, Genetics, Health Disparities, Pediatrics, Sexual and Reproductive Health, Spirituality, and Survivorship. Belonging to these special groups provides a venue for networking and opportunities to build bridges to complementary organizations and other professions. The society maintains a list of care providers for online referrals though a toll-free number. This directory of sorts gives professionals the unique ability to contact specialists in difficult or unusual cancer cases.

APOS maintains a store of products. A “Quick Reference for Oncology Clinicians” and a “Quick Reference for Pediatric Oncology Clinicians” refer to pocket-size handbooks on essential information about the psychosocial needs of oncology patients, available in the online store. The store sells DVDs like the History of Psychosocial Oncology. This DVD commemorates interviews with past presidents of the APOS and tells stories of previous challenges present in APOS. Many webinars can be purchased online with titles such as “Acceptance and Commitment Therapy,” “Bright IDEAS Problem-Solving Skills,” and “Evidence-Based Psychosocial Interventions.”

APOS represents an extremely active organization at the forefront of implementing programs to assist both oncology professionals and cancer patients. In 2014, at the APOS annual conference, APOS announced funding by the National Cancer
Institute (NCI) and initiation of a Screening for Psychosocial Distress Program as a joint venture between APOS and the Yale University School of Nursing. The NCI is providing funding for this five-year initiative beginning in 2014.

The Psychosocial Distress Program initiative financially supports cancer care professionals’ attendance at a one-day workshop at the beginning of each year, followed by webinars every three months for two years. The program aims to educate select professionals to attend the program, learn about a comprehensive distress-screening instrument, acquire knowledge about cancer patients’ distress or depression and assist cancer patients’ movement to appropriate psychosocial health care services. A total of 39 oncology professionals represent cancer care organizations nationwide. Two people from a facility representing the disciplines of oncologists, nurses, chaplains, psychiatrists, psychologists, and social workers attend the program.

The APOS held their 11th Annual Conference on February 13 to 15, 2014, in Tampa, Florida. The focus of the conference centered on executing quality-of-care standards for psychosocial oncology and compassionate care of cancer patients. The conference aimed to raise awareness about the Commission on Cancer’s Cancer Program Standards 2012 to Ensure Patient Centered Care and to identify gaps in psychosocial cancer care through research or policy analysis. The conference program emphasized all age groups by highlighting pediatric, adolescent, young adult, and adult populations in psychosocial oncology during the education sessions.

APOS supports many links via social media to other organization sharing similar goals to improve access for cancer patients to useful information. APOS shared a link via Facebook to the Center for Advancing Health for an app developed for patients receiving negative health news (e.g., diagnosis of cancer, failure of treatment, and side effects of medications).

Publications in the professional literature represent another area that APOS endorses to diffuse information to the variety of health care professions caring for cancer patients. Researchers provided up-to-date information on significant cancer standards and reviewed the distinctive role of the APOS Referral Helpline to help oncology staff and patients find appropriate psychosocial care for cancer patients.

In conclusion, APOS arose to fill a gap in cancer care regarding the psychosocial aspects of cancer patients. The APOS actively pursues issues related to psychosocial issues and engages a variety of existing agencies to achieve its mission.

American Society for Radiation Oncology

The American Society for Radiation Oncology (ASTRO) is a professional association of doctors, scientists, and researchers who utilize various radiation therapies to treat cancer.

The society presently has more than 10,000 members worldwide and is headquartered in Fairfax, Virginia. ASTRO’s internationally recognized facility accreditation program, APEx, offers an
international standard for radiation oncology care team, policies, and procedures.

The organization's annual meeting is attended by thousands of health care professionals from various countries and is the premier radiation oncology-based scientific event in the world.

History
ASTRO was founded in Chicago, Illinois, in November 1958 under its original name, the American Club of Therapeutic Radiologists. The society sprung from three other major radiological organizations functioning at that time, namely the American College of Radiology (ACR), the Radiological Society of North American (RSNA), and the American Roentgen Ray Society (ARSS).

In 1966, the society officially changed its name to American Society for Therapeutic Radiologists. ASTRO's first officially sponsored scientific journal, the *International Journal of Radiation Oncology, Biology, Physics* (IJROBP), also referred to as the Red Journal, was published in 1976.

ASTRO was pivotal in the fostering of new technological breakthroughs in radiation oncological care throughout the 1970s and 1980s, centered on the emergences of its annual meeting as one of the world's premier stages for the introduction and popularization of new technologies related to treating cancer with radiation treatments.

Throughout the 1990s, ASTRO's membership nearly doubled as the organization continued efforts to establish itself as an international organization and one that would become instrumental in legislative and regulatory arenas related to radiation oncology care.

ASTRO's administrative team moved to its new headquarters in Fairfax, Virginia, in 1998. The society's latest initiatives, member profiles, and available course work are published in its quarterly magazine *ASTRONews*.

ASTRO's administrative affairs and governance are operated under the direction of a 15-member board of directors. Elections for chair of the board, treasurer, and vice chair of Clinical Affairs and Quality Control are held annually.

Clinical Efforts
Among ASTRO's major initiatives is its frequent publication of evaluations of emerging trends in the field of radiation oncology as well as the construction and adaptation of recommended patient guidelines for use by member and nonmember physicians and oncologists. In addition to its ongoing list of active treatment guidelines, ASTRO also invited members to suggest topics and offer treatment guideline endorsements.

ASTRO's office of Clinical Affairs and Quality Control oversees the organization's treatment guidelines under the oversight of the group's Guidelines Subcommittee. ASTRO guidelines are outlined for varying radiation treatments for a wide variety of cancer types, including genitourinary cancers, brain tumors, and thoracic malignancies.

Grants and Funding
ASTRO operates an evolving database of funding options for member clinicians and researchers to apply for aid from varying organizations and government agencies. ASTRO also offers a variety of annual research awards to foster new clinical trials and research initiatives surrounding radiation treatments and their effects on cancer biology. Annual grants include the ASTRO Junior Faculty Career Research Training Award, a two-year grant award to new students involved in radiation oncology, and the ASTRO/ROI Comparative Effectiveness Research Award, a two-year grant granted to established researchers conducting experiments exploring developments in the effectiveness of radiation oncology.

The organization also offers several grants each year to members to defray travel costs related to attendance to the annual meeting as well as a series of travel grants for member students to attend specialty meetings related to their specific disciplines within radiation oncology.

Accreditation Programs
ASTRO's newly implemented accreditation program, known as APEx, debuted in 2014 and was created to assess the radiation oncology policies and procedures at cancer treatment facilities worldwide. The accreditation system's five-phase application process evaluates facilities in all phases of patient care. In addition to an evaluation care processes, APEx evaluators also review each facility’s radiation oncology team, safety practices, quality control management, and quality of patient-centered care. The APEx accreditation is
one of the most advanced accreditation programs of excellence ever offered to radiation oncology treatment centers.

**Member Education Resources**

ASTRO is the world’s leading provider of professional and educational development for physicians and nonmedical professionals working in the radiation oncology community. In addition to hosting a rotating schedule of webinars, virtual meetings, and certification maintenance seminars, ASTRO members are also granted access to a variety of self-assessment models where they can evaluate treatment techniques and learn of new developments in radiation oncology care.

The organization also offers a series of online seminars dedicated to ethical and professional issues, which educate member physicians and physicists about the nonmedical and policy nuances related to the practice of diagnostic radiology and radiation oncology.

**Publications**

ASTRO’s official peer-edited scientific journal is published 15 times a year and is considered the premier source for research related to radiation oncology treatments and research developments.

The journal publishes both laboratory and clinical investigations related to radiation oncology in addition to works related to health policy relevant to radiation care. Articles covered in the journal include: prospective clinical trials, outcomes research, and evaluations of large statistical databases on cancer treatment statistics. Emerging technical advances related to radiation treatment are also frequently featured in addition to ongoing investigations related to tumor physiology and molecular biology and their effects on cancer’s response to radiation treatments.

ASTRO also publishes the *Journal of Practical Radiation Oncology*, which is comprised of studies and evaluations related to specific radiation treatment techniques, and is published six times per year.

In addition to its annual meeting, ASTRO also operates an annual symposium dedicated to the discussion, evaluation, and dissemination of information related specifically to emerging technologies in radiation treatment. The State of the Art Radiation Therapy Symposium includes seminars on the latest developments in practical treatment, biology, and imaging techniques that utilize radiation technology.

**American Society of Clinical Oncology**

The American Society of Clinical Oncology (ASCO) is a professional organization for oncologists of all specialties. Founded in 1964 by doctors Fred Ansfield, Harry Bisel, Herman Freckman, Arnoldus Gouldsmit, Robert Talley, William Wilson, and Jane Wright, it is headquartered in Alexandria, Virginia, with a membership of about 35,000. The ASCO founders are widely credited with the organization and development of the modern clinical oncology field. Bisel, the Mayo Clinic’s first oncologist and founder of its Section of Medical Oncology, served as the first president of ASCO as well as consulted with the National Cancer Institute; he also founded the American Society of Preventive Oncology and the American Association for Cancer Education. ASCO
cofounder Jane Wright was one of the first African American female oncologists and the granddaughter of William Fletcher Penn, the first African American graduate of Yale’s medical school; she was a pioneer in chemotherapy, the first to identify methotrexate's usefulness in destroying cancer cells and to develop tested and proven chemotherapy regimens that minimized side effects while maximizing efficacy.

ASCO publishes the peer-reviewed journals *Journal of Clinical Oncology* (JCO) and the *Journal of Oncology Practice* (JOP) as well as a number of newsletters, books, smaller journals, and educational curricula for oncology. JCO was founded in 1983 and is published three times a month, with open access to online articles provided with a one-year delay. ASCO’s first official journal, JCO was proposed by Emil Frei III, former director and physician in chief of the Dana-Farber Cancer Institute. Recent articles have included an ASCO statement on obesity and cancer, a special series of articles on radiation oncology, and a study of the effect of vitamin D deficiency on rituximab patients. JOP was founded in 2005, with a slightly different focus, covering day-to-day issues of oncology practice. Its premier issue, for instance, covered the effects of recent Medicare changes on oncology; recent issues similarly covered the effects of the Affordable Care Act and related state laws.

The Quality Oncology Practice Initiative was launched by ASCO in 2003 to 2006. In response to the Institute of Medicine’s National Cancer Policy Board’s 1999 report on the state of cancer care in the United States, ASCO launched a five-year study, the National Initiative on Cancer Care Quality (NICCQ). Among its goals were not only assessing the quality of care (specifically of breast and colorectal cancer patients, in five specific geographical areas, for the purposes of the study) but a methodology of quality monitoring in order to investigate the feasibility of ongoing accurate and useful national quality monitoring of cancer care. Pediatric oncologist Joseph Simone proposed a quality assessment program with a national infrastructure provided by ASCO but local implementation by the medical oncology community. At the time, most nationwide reporting programs collected information from hospitals and medical centers, pertaining to brief episodes of care, specifically surgeries and other interventions and their short-term (30-day or less) outcomes. What Simone called for would focus on a broader array of practice settings and would thus survey the bulk of cancer care settings and scenarios. He presented a pilot plan for this initiative—Quality Oncology Practice Initiative (QOPI)—while the NICCQ was still ongoing, in 2002, and meetings began in 2003 to formulate QOPI’s methodology. Pilot programs were operated until 2006, when QOPI was officially opened nationwide to the oncology community. The waiting list of practices waiting to join was nearly 100 names long.

Under QOPI, practices collect patient-level data, which is reported to the national leadership at six-month intervals and returned at the following interval with an anonymous comparison of the practice’s performance compared to other practices. Participation is both voluntary and free: In return for its practice-level data and the work required to collect it, each practice receives access to nationwide data and recommendations of cancer-specific measures. Simone guided the initiative as the senior-most oncologist associated at the national level. Face-to-face meetings were limited to the annual ASCO meeting, and ASCO provided staff resources at the national level. Other meetings were held by telephone, designed to be efficient and make the best use of time.

By 2014, when ASCO celebrated its 50th anniversary, QOPI included 450 participating practices and about 4,000 oncologists. In 2010, QOPI launched its certification program in response to requests by participants as a way of demonstrating a certified practice’s commitment to quality assessment, safety standards, and QOPI measures.

ASCO operates Cancer.Net, a patient information Web site. It includes information ranging from types of cancer and coping with cancer to survivorship, 120 guides to different diseases, and tips for finding a cancer clinical trial. A mobile app has been developed for both English and Spanish speakers.

ASCO University is ASCO’s educational program, providing an e-learning center for oncology professionals. Topic-specific courses are offered as well as oncology training programs, maintenance of certification (MOC) courses, and both a printed and e-book version of ASCO-SEP, a self-assessment continuing medical education (CME) program.
The Conquer Cancer Foundation is ASCO’s 501(c)(3) registered charity, funding initiatives in clinical research, patient education, and patient advocacy. Since 1984, it has awarded 800 research grants as well as a number of specific research awards like the Merit Award, the Cancer Development Award, and the Young Investigator Award.

American Society of Hematology

The American Society of Hematology (ASH) is a global professional society of hematologists, researchers, and clinicians headquartered in Washington, D.C., founded in April of 1958, when it held its first official meeting in Atlantic City, New Jersey. Since that first meeting, the ASH has been a critical organization in helping develop hematology as a specialized discipline and advancing the understanding and treatment of blood diseases.

Currently, the ASH focuses its efforts and resources on three main areas of interest in the area of hematology: research, education, and advocacy. Under the umbrella of these three focus areas, the organization aims to help the global community of hematologists become poised to better develop research efforts focusing on various blood diseases in order to provide effective treatments and cures.

Hematology is the study of the physiology of the blood and the diseases that can affect its health, and hematologists are a specialized group of doctors, researchers, scientists, and clinicians focused on treating patients afflicted with these conditions and finding cures for the world’s population. Blood diseases most commonly under the ASH's hematologists’ purview include various blood conditions and blood cancers, such as anemia, sickle-cell anemia, hemophilia, blood clots, leukemia, lymphoma, and myeloma.

ASH reports that the organization has more than 14,000 members spanning almost 100 countries. This membership count places ASH as one of the largest professional societies committed to helping researchers, scientists, and clinicians who specialize in hematology focus on researching and curing blood diseases on a global scale.

Governance and Structure
The governance of ASH is carried out by a member-elected executive committee, which is made up of 13 representatives. The committee’s membership includes a president, a president elect, a vice president, secretary, treasurer, and eight councilors. In addition to the executive committee, ASH has 14 standing committees and 18 scientific committees. The standing committees are charged with carrying out the overall operations of the society and recommending policies, programs, and actions to the executive committee, and the scientific committees are charged with developing the agendas and topics for ASH’s annual meeting as well as identifying new areas of research and advising the organization on scientific policy priorities.

ASH's standing committees include the following: ASH Foundation and Development Committee, the Awards Committee, the Committee on Communications, Committee on Educational Affairs, Committee on Government Affairs, International Members Committee, Committee on Investment & Audit, Nominating Committee, Committee on Practice, Committee on Promoting Diversity, Publications Committee, Committee on Quality, Committee on Scientific Affairs, and Committee on Training, which also includes a subcommittee called the Trainee Council.

In addition to focusing on their specific scientific areas, the ASH’s scientific committees routinely collaborate and work with ASH's standing committees
in order to carry out their functions and are active participants in the organization’s advocacy mission. The ASH’s 18 scientific committees include the following:

- Ad Hoc Scientific Committee on Epigenetics and Genomics
- Scientific Committee on Blood Disorders in Childhood
- Scientific Committee on Bone Marrow Failure
- Scientific Committee on Hematopathology and Clinical Laboratory Hematology
- Scientific Committee on Hematopoiesis
- Scientific Committee on Hemostasis
- Scientific Committee on Immunology and Host Defense
- Scientific Committee on Iron and Heme
- Scientific Committee on Lymphoid Neoplasia
- Scientific Committee on Myeloid Biology
- Scientific Committee on Myeloid Neoplasia
- Scientific Committee on Plasma Cell Neoplasia
- Scientific Committee on Platelets
- Scientific Committee on Red Cell Biology
- Scientific Committee on Stem Cells and Regenerative Medicine
- Scientific Committee on Thrombosis & Vascular Biology
- Scientific Committee on Transfusion Medicine
- Scientific Committee on Transplantation Biology and Cellular Therapies

**Current Research**

ASH’s research agenda is focused on areas that will produce the greatest impact on critical need areas. To carry out that agenda, ASH lobbies and advises federal agencies to develop funding methods that focus funding on hematology research on efforts that would produce the greatest impact in those critical need areas while leveraging and coordinating with other funding resources. ASH’s research is outlined in a three-year strategic plan titled the “ASH Agenda for Hematology Research.” The 2012 to 2014 edition of the plan, which is collaboratively developed by ASH’s scientific committees, represents the third instantiation of ASH’s strategy. The ASH Agenda for Hematology Research 2012–2014 plan not only outlines significant contributions of international hematologists and related research fields but also prioritizes the top hematology areas ASH believes should be funding in the near and long term.

**Membership in the ASH**

Membership in the ASH consists of the following types: (1) active membership, which is available to persons residing in the United States, Canada, or Mexico who hold a doctoral degree or an equivalent degree and work in a field or discipline directly involved in or related to hematology; (2) international membership, which is available to persons fitting the same professional description as active members but who reside outside of the United States, Canada, or Mexico; (3) associate membership, which is reserved for individuals who are either classified as postdoctoral fellows with a medical degree or equivalent, who reside in the United States, Canada, and Mexico, and who are enrolled in an approved hematology or oncology-related training program, or those trainees who have earned their degrees from programs in the United States, Canada, or Mexico and are in a postdoctoral position or training program in a hematology- or oncology-related field; (4) resident members include persons who reside in the United States, Canada, or Mexico and are enrolled in an
accredited hematology-related residency program; and
(5) graduate and medical student memberships, which are granted to graduate or medical students in the United States, Canada, or Mexico who are enrolled in either a postdoctoral or doctoral North American biomedical program or enrolled in an accredited medical school and working toward a medical degree or equivalent doctoral degree.

Publications
As part of its overall education efforts, the ASH produces four main publications that include clinical and scientific research and education on current efforts in the field of hematology. These publications include

Blood—ASH’s official scientific journal dedicated to publishing peer-reviewed articles on hematology research and clinical treatment efforts;

Hematology, ASH Education Program—providing in-depth overviews of the scientific sessions that take place during the ASH annual meeting;

ASH Self-Assessment Program (ASH-SAP)—an educational product that provides current information on the field of hematology with a target audience of internists, hematologists, pediatricians, and fellows in the hematology or oncology fields of study;

The Hematologist: ASH News and Reports—serves as the organization’s newsletter for its members; and

How I Treat—A Compendium for the Practicing Hematologist—which takes 33 “How I Treat” articles from the editions of ASH’s magazine Blood and republishes the article along with updates that might have occurred since the initial publication date.

Further Readings

American Society of Pediatric Hematology/Oncology

The American Society of Pediatric Hematology/Oncology (ASPHO) is a multidisciplinary organization dedicated to the best care of children and adolescents with blood disorders and cancer. Creating premier education opportunities for hematology/oncology fellows and continuing education for pediatric oncologists is also a central goal of the organization. ASPHO was initiated in 1974 by pediatricians who had a commitment to pediatric cancer and who approached the American Society of Pediatrics and the Society of Pediatric Research for sponsorship. In large part creating a new specialty, their early meetings took place at the Blood Club, held in conjunction with the annual meetings of the American Society of Pediatrics/Society for Pediatric Research. At the Blood Club meeting in 1977, Carl Pochelly first proposed a society for pediatric hematologists and oncologists. Bill Krivit was also a leader in the Blood Club and, with others, began to plan the incorporation of a separate society devoted to pediatric hematology and cancer.

ASPHO was incorporated in Illinois in April 1981. In 1987, Carl Pochelly advocated for a freestanding meeting of ASPHO, and that first meeting was held in Chicago in 1988.
The new society was publicized through the *American Journal of Pediatric Hematology/Oncology,* first published in 1979. Although closely identified with ASPHO, the journal predated it by two years. After ASPHO's incorporation, the journal's front cover identified it as “The Official Journal of the American Society of Pediatric Hematology/Oncology.” The name of the journal was changed in 1995 to the *Journal of Pediatric Hematology/Oncology* to reflect the increasingly international nature of the contributors and subscribers. Today, *Pediatric Blood and Cancer* is the official publication of ASPHO.

The core purpose of the society is to serve the membership in their goal to improve the health and well-being of children with blood disorders and cancers. Its values are compassion for patients and their families, dedication to the health and well-being of children and adolescents with cancer and blood disorders, commitment to excellent service to members, promotion of high standards of quality and safety, the practice of absolute integrity, fostering of innovation, dedication to professional development, an fostering of collegiality and cooperation. The society wishes to be the premier organization for pediatric hematology and oncology worldwide. A key focus of ASPHO is the educational opportunities for its members, particularly fellows. The annual meeting is the center of these opportunities as well as the annual review course, workshops, and webinars. Certification for the pediatric hematology and oncology specialty is provided in these courses.

In recent years, ASPHO has created the ASPHO Advocacy Alliance With the American Academy of Pediatrics (AAP). The purpose of this alliance is to create a subspecialty-specific advocacy agendas for the pediatric hematology and oncology community as well as unite and combine to promote better outcomes for children. The ASPHO Advocacy Committee works closely with the AAP Department of Federal Affairs, leading advocacy efforts on behalf of children with cancer and blood disorders. Advocacy activities include educating ASPHO members about policy issues in frequent communications, encouraging members to contact their legislators when important issues arise, planning advocacy programming at the annual meeting, and bringing ASPHO representatives to Washington, D.C., to meet directly with policy makers.

The Advocacy Committee has several priorities and important issues that it shares with pediatric hematology and oncology physicians. These are the current goals and objectives: (1) guaranteeing a sufficient supply of existing drugs for children with hematologic or oncology disease and decreasing or ending the number of drug shortages in the United States; (2) making sure every child with sickle cell disease has a medical home with access to primary and subspecialty care; (3) educating policy makers about coordinated care, delivery system reform, and payment barriers; (4) ensuring needed access to subspecialists for children with cancer and improving Medicaid payments; (5) increasing the number of pediatricians going into the hematology and oncology fields to guarantee a sufficient number of these physicians in the future.

---

**Amgen (United States)**

Amgen, Inc. is considered to be one of the first biotech pharmaceutical companies and is currently the largest independent biotechnology organization in the world. In 2013, Amgen reported revenues of $18.7 billion, with total product sales of $18.2 billion and a research and development budget of $5.2 million. This represents an increase of product sales of $16.8 billion in 2012 and $16.3 in 2011 and in research and development budgets of $3.4 billion in 2012 and $3.2 billion in 2011. Further, seven of
Amgen’s pharmaceutical products are on the list of the top 100 drugs in the United States.

Pharmaceutical products manufactured and marketed by Amgen focus on the therapeutic areas of hematology, oncology, inflammation, bone health, nephrology, cardiovascular, and general medicine. Names of the products and marketing agreements with other countries (e.g., Pfizer markets Embrel outside of the United States and Canada) vary across countries, but in the United States, their primary products are as follows:

- **Aranesp**, generic name: darbepoetin alpha; indications/marketed for: treatment of anemia associated with chronic kidney disease (CKD) and the treatment of anemia due to concomitant myelosuppressive chemotherapy in patients with nonmyeloid malignancies (indicated for patients both on dialysis and not on dialysis)
- **Enbrel**, generic name: etanercept; indications/marketed for: moderate to severe rheumatoid arthritis, chronic moderate to severe plaque psoriasis, and active psoriatic arthritis
- **Epogen**, generic name: epoetin alpha; indications/marketed for: treatment of anemia associated with CKD for patients on dialysis
- **Neopogen**, generic name: filgrastim; indications/marketed for: reducing incidence of infection associated with febrile neutropenia in patients with nonmyeloid malignancies who are undergoing myelosuppressive chemotherapy
- **Neulasta**, generic name: pegfilgrastim; indications/marketed for: to decrease incidence of infection associated with chemotherapy-induced febrile neutropenia in cancer patients with nonmyeloid malignancies
- **Sensipar/Mimpara**, generic name (note: marketed in the United States as Sensipar): cinacalcet; indications/marketed for: treatment of secondary hyperparathyroidism in CKD patients on dialysis
- **Xgeva/Prolia**, generic name (note: same product, different indications for different names of product): denosumab; indications/marketed for: Xgeva is indicated for the prevention of skeletal-related events in adults with bone metastases from solid tumors, and Prolia has four indications all related to the treatment of osteoporosis

As previously indicated, Amgen, Inc. invests a significant amount of its revenue in research and development, resulting in up to 10 innovative molecules of which, according to the letter to shareholders in their 2013 annual report, six have the potential to be introduced and marketed beginning in 2017. Products in the Phase 3 clinical trials include a human monoclonal antibody to be used in the treatment of dyslipidemia; a product for the treatment of unresected stage IIIB, IIIC, or IV melanoma; and a drug for the treatment of ovarian cancer. Other products under development focus treatment of heart failure and angina.

Thus far, this description of Amgen depicts a large organization, one with a presence in more than 75 countries, yet it was an organization with a meager start and many years of profit losses. The company, originally called Applied Molecular Genetics, was founded in 1980 by William Bowes, who came from Centus Corporation, one of the first biotechnology companies. Bowes established Amgen in Thousand Oaks, California, within reach of three research universities and hired Winston Salser, a scientist from the University of California, Los Angeles (UCLA), and George Rathmann, the former chief of Abbot Laboratories’ diagnostics division. Rathmann was hired as CEO, and his original office was in a trailer so that the scientists whom were hired would have enough lab space.

Amgen was far from an immediate success as, for the first five years, they suffered losses and did not break even until 1986. In 1986, research grants from other pharmaceutical companies were a crucial source of income. The company was also in fierce competition and legal disputes regarding alleged patent infringements with another biotechnology organization, Genetics Institute (GI). Amgen also underwent a long legal conflict with Johnson and Johnson’s Ortho Pharmaceutical Division regarding sales of EPO in the United States and other countries.

The product involved in the lawsuits was EPO, a synthetically produced hormone that stimulates the production of red blood cells. The small target
market for EPO was patients on dialysis as dialysis lowers the kidneys’ capacity to produce natural EPO. EPO was not approved for use by either GI or Amgen until 1987, when an article on the use of EPO on 25 dialysis patients was published in the *New England Journal of Medicine*. In the article, Eschbach and colleagues reported encouraging results with the use of Amgen’s EPO in that it demonstrated reduction of transfusions and increased hematocrit levels to normal in these high-risk patients. The Food and Drug Administration (FDA) then granted orphan drug status to Amgen’s EPO because the market for the drug was small, yet soon, EPO was found to be a product that could be used for anemia that was related to cancer, arthritis, and other treatments.

Amgen applied for new drug status in 1987 for its EPO, Epogen. Epogen was the first FDA-approved EPO, and when it was approved on June 1, 1989, Amgen shipped out the first batch the next day. At the end of the first month of sales, Epogen had brought in close to $17 million. The company followed with Neopogen and other products previously listed. Amgen also established successful partnerships with companies like Kirin Brewery, which could help in the manufacture of its products.

The company continues to demonstrate a focus on research and development but also currently has focused efforts on sustainability. In particular, it reports that, in 2013, they recycled 74 percent of wastewater generated at its largest manufacturing plant. Further, since 2008, it states that the company has also reduced energy costs by $20 million due to conservation projects that were put in place.

Finally, Amgen has demonstrated a commitment to philanthropy. The company provides research grants that help in promoting patient care and science as well as science-related (e.g., lab equipment) donations to assist public schools and nonprofit organizations. They also provide Embrel and other medications free to patients based on need and provide health care and nonhealth care donations that are related to education or have literary or scientific purposes.

**Anal Cancer**

The term *anal cancer* refers to any form of cancer associated with the anus. There are many types of malignant and benign cancers as well as precancerous conditions that can be found in the anal canal (a canal approximately an inch and a half long, connected to the rectum).

Some of the earliest signs of anal cancer include bleeding from the anus or rectum, pain around the anus, itching or discharge from the anus, and a lump near the rectum. Currently, there are no national screening guidelines for anal cancer.

Tests that may indicate the presence of anal cancer include a physical examination, a digital rectal examination, an anoscopy or proctoscopy, an ultrasound procedure in the anus or rectum, and a biopsy.

Many benign tumors occur in the anus. Some of these include polyps, warts, fibroid tumors (leiomyomas), granular cell myoblastoma (large cells filled
with fine granules), hemangiomas (extra blood vessels in the skin that look like strawberry-colored birthmarks), lipomas (growths of fat under the skin), and schwannomas (tumors originating in the peripheral nerve fibers). Sometimes, benign tumors in the anus can turn malignant. These tumors are known as precancerous conditions, and those associated with anal cancer are specifically called anal intraepithelial neoplasia. Some anal warts are examples of anal intraepithelial neoplasia.

The prognosis for anal cancer depends on a number of factors, including the size and location of the tumor and whether it has spread to the lymph nodes.

In terms of malignant (or cancerous) tumors, the most common type of anal cancer is squamous cell carcinoma, which can be found in the tissues that line the anal canal and the anal margin. When these carcinomas have not spread from the original cancerous site, they are called carcinoma in situ. Another type of cancer occurs in the cloaca, which is located between the rectum and the anal canal. A specific type of scaly, cancerous tumor can occur there, known as cloacogenic carcinoma. Adenocarcinomas are another form of anal cancer involving tumors that grow in the glands under the anal epithelium and discharge cancerous secretions into the anal canal. Those forms of cancer that form under the rectum are called rectal carcinomas. Basal cell carcinomas are another form of cancer that can develop in the skin outside the anus.

Anal cancer is usually curable, and there are many treatment options. Treatment options for people with anal cancer include surgery (which may completely remove the cancerous site), radiation therapy, chemotherapy, or a combination of all of these treatments. However, treatment options depend on a number of factors, including the stage of the cancer, its location, whether this is a recurrence of cancer, and whether the person has the human immunodeficiency virus (HIV). People who have primary tumors that are less than 2 centimeters in size have better prognoses.

For Stage 0 anal cancer (carcinoma in situ), the primary treatment for lesions of the perianal area, not involving the anal sphincter, is surgical resection. For Stages I, II, and IIIA anal cancers, small tumors of the perianal skin or anal margin are usually excised, and chemoradiation is often necessary for cancers of the anal canal. Follow ups, including rectal examination every three months for the first two years are important, and doctors may also perform endoscopy with biopsies or endorectal or endoanal ultrasound in certain cases.

Patients with Stage IIIA cancer receive the same treatment as those with Stage I and II, including radiation plus chemotherapy, but they may also receive a radial resection.

For those with Stage IIIB cancer, treatment includes radiation therapy plus chemotherapy as well as surgery and inguinal node dissection for residual or recurrent tumor. Cure of this stage of the disease is still possible. However, the presence of inguinal nodes associated with metastatic disease is a poor prognostic sign. As a result, patients should be included in clinical trials whenever possible. For patients with Stage IV anal cancer, palliative care is vital. Such palliative care might include surgery, radiation therapy, combined chemotherapy and radiation therapy, and the inclusion of the patient in clinical trials.

Overall, the incidence of anal cancer is increasing in the United States. According to the National Cancer Institute, there were 7,210 new cases of anal cancer in the United States in 2014, and 950 deaths were expected. Approximately 0.2 percent of the U.S. population will be diagnosed with anal cancer at some point. The five-year survival rate for anal cancer is 65 percent, according to the National Cancer Institute.

Anal cancer is one of the most common forms of cancer for people in high-risk sexual categories, such as those who have HIV and men who have sex with men (MSM). It affects people with HIV at a much higher rate than people who do not have HIV.

Some of the risk factors for anal cancer include having HIV, age (it is more prevalent among people over 50), being infected with human papilloma virus (HPV), smoking (smokers have a higher rate of anal cancer), having many sexual partners, and having receptive anal sex. Organ transplant recipients and people with chronic immunosuppressive states are at much higher risk of getting anal cancer.

Anal cancer affects men and women differently. Men tend to get anal cancer outside the anus, whereas women tend to get anal cancer inside the anus. Although most forms of anal cancer can be cured, women experience a mortality rate from anal cancer that is approximately twice the rate experienced by men. Women who have a history of cervical, vaginal, and vulvar cancer are at higher risk of developing anal cancer.

One preventive intervention, the quadrivalent HPV vaccine, has been approved for use by the Food and Drug Administration (FDA) since 2010.
for the prevention of anal cancer. The Centers for Disease Control and Prevention (CDC) recommends routine vaccination of males ages 11 and 12 and vaccination of those 13 to 21 who have not been vaccinated previously.

Angola

Angola is situated in Southern Africa. The People’s Republic of Angola, as it was formally called, is bordered on the north by the Democratic Republic of the Congo, on the east by Zambia, south by Namibia, and west by the Atlantic Ocean. It is the seventh-largest country by area in Africa and 31st-largest globally. It is the 15th-most populous country in Africa and 59th in the world, with a population of more than 18 million. There are many different ethnic groups in Angola, each of which has its own cultural traditions, including traditional medicine and ethnopharmacological practices. Although Portuguese is the official national language, there are 38 other indigenous languages still spoken by respective ethnic groups in Angola; the most widely used languages include Cokwe, Kikongo, Kimbundu, Oshiwambo, and Umbundu.

There are many traditional medicinal preparations used in the Angola. Most of these traditional medicines incorporate use of myriad local plant materials, many of which have been shown to have medicinal properties in laboratory studies. For example, extracts of *Euphorbia tirucalli* and *Vernonia ambigua*, both of which are used for traditional healing, demonstrated antitumor activities. Research also suggests that use of certain plants may help protect against cancer by reducing oxidative stress and stimulating enzymes and other processes that help the body fight carcinogens. For example, an extract from *Cochlospermum angolensis*, locally referred to as *borututu*, demonstrated substantial antioxidant potential, as did an extract from *Nymphaea lotus*, referred to as *mbandu* in Kimbundu.

Medicinal plants are used in Angola to treat many health problems commonly associated with cancers. For example, the powdered bark of *Canarium schweinfurthii*, which the Chokwe call *mubafo* or *mupaxi*, is eaten with millet to treat coughs. A bark infusion of *Cochlospermum angolensis*, locally referred to as *borututu*, demonstrated substantial antioxidant potential, as did an extract from *Nymphaea lotus*, referred to as *mbandu* in Kimbundu.

The average number of cancer cases annually in Angola are 95.7 per 100,000 population. Cancers account for a substantial amount of disability and suffering among impacted populations. According to the World Health Organization’s “Disease and Injury Country Estimates,” the age-standardized disability adjusted life-year estimates for 2004, the 10 most prevalent cancers in Angola were led by stomach cancer at 289 per 100,000 population; cervical and uterine cancers at 226 per 100,000 population; breast cancer at 218 per 100,000 population; lymphomas at 178 per 100,000 population; mouth and oropharynx cancers at 172 per 100,000 population; trachea, bronchial, and lung cancers at 134 per 100,000 population; liver cancer at 118 per 100,000 population; esophageal cancer at 89 per 100,000 population; colon and rectal cancers at 71 per 100,000 population; prostate cancer at 70 per 100,000 population.

There are serious deficiencies of modern pharmaceutical supplies, as opposed to traditional preparations, and in modern medical services for cancer and similar conditions. Angola, for instance, is among the countries with the lowest morphine consumption rates in the world; it is ranked 152nd of all nations at 0.0005 milligrams per capita. In 2010, the annual prevalence of use of all opiates as a percentage of the population age 15 to 64 years in Angola was 0.25 percent, which ranks it as the 61st-highest country. These factors make access to appropriate palliative care highly problematic. A 2012 report by Lopes and colleagues found that the National Oncology Center in Luanda provided chemotherapy for cancer treatment, and
also had radiotherapy equipment supplied by Varian, but that the latter was not yet in operation.

Ten cancers are among the 50 leading causes of death in Angola. Breast cancer is the 23rd leading cause of death; the age-standardized death rate for breast cancer in Angola is 13.04 per 100,000 population, which ranks Angola as the 139th-highest country in the world for breast cancer deaths. Cervical cancer is the 24th-leading cause of death; the age-standardized death rate for cervical cancer in Angola is 12.52 per 100,000 population, which ranks it 28th in the world. Liver cancer is the 27th-leading cause of death; the age-standardized death rate for liver cancer in Angola is 9.57 per 100,000 population, which ranks it 56th globally. Prostate cancer is the 31st-leading cause of death; the age-standardized death rate for prostate cancer in Angola is 8.55 per 100,000 population, which ranks it 54th. Lymphomas are the 41st-leading cause of death; the age-standardized death rate for lymphomas in Angola is 4.68 per 100,000 population, which ranks it 112th.

Stomach cancer is the 42nd-leading cause of death; the age-standardized death rate for stomach cancer in Angola is 4.50 per 100,000 population, which ranks it 136th. Esophageal cancer is the 44th-leading cause of death; the age-standardized death rate in Angola is 3.98 per 100,000 population, which ranks it 65th. Oral cancer is the 46th-leading cause of death; the age-standardized death rate is 3.56 per 100,000 population, which ranks it 73rd. Colon and rectal cancers are the 47th-leading cause of death; the age-standardized death rate is 3.51 per 100,000 population, which ranks it 168th. Lung cancer is the 50th-leading cause of death; the age-standardized death rate for lung cancer in Angola is 2.33 per 100,000 population, which ranks it 168th in the world.

Furthermore, according to the World Health Organization’s “Global Health Observatory Data Repository,” in 2008, the age-standardized estimates of deaths from all cancers was 88 per 100,000 population for males and 83 per 100,000 population for females in Angola. As a consequence, life expectancy as of 2011 for males is 50.0 years and that for females is 52.9 years, which gives an average life expectancy of 51.5 years, ranking Angola as the 168th highest globally. There is a clear and urgent need for improved cancer awareness, early detection programs, and health services infrastructure in Angola.

Antibiotics

Antibiotics (also called antimicrobials) are a category of medications (living organisms and synthetic antimicrobials) that target, terminate, or inhibit the multiplication of microorganisms. Originally, antibiotics were used to describe antibacterials but have been broadened to include fungi, viruses, and parasites. Antibiotics are classified by the microorganism...
they target, such as antibacterials (bacteria), antifungals (fungi), antivirals (viruses), and antiparasitic (parasites). Antiseptics can terminate microorganisms that live on the skin or in the mucous membranes and also aid in reducing infection associated with surgical operations. There are also a number of mostly nonmedical disinfectants that terminate or reduce microorganisms from medical instruments, work surfaces, and so on, and prevent the spread of bacteria, fungi, viruses, and parasites.

Antibiotics are considered one of the most significant advances in medicine in combating microbes to date. Yet, the modern medical community struggle continues as the microbe evolves and the medical community seeks to gain the upper hand.

**History of Antibiotics**

Throughout history, the healers as well as the modern medical community have been in a constant struggle to develop treatments that inhibit and terminate microbes. The early use of antimicrobials dates back at least 2,000 years to early Egyptian, Chinese, and Greek civilizations as well as indigenous groups of Central America. The ancient civilizations were known to use molds, soils, and plant extracts for the treatment and management of infections. For example, ancient civilizations used mold from bread and other molds to prevent infections from serious cuts. Other groups used molds to treat rashes. Infections and other diseases were thought at the time to be the product of evil spirits and the molds, soils, and plant extracts expelled the evil spirit from the body.

In 1877, Louis Pasteur (1822–95) demonstrated that microorganisms were causative agents of diseases (e.g., the germ theory of disease). Pasteur also verified that anthrax (a bacterial disease) could be rendered innocuous by injecting the animal with bacteria from soil. His work on chicken cholera (also called avian pasteurellosis) discovered that introducing weakened bacteria (similar to the treatment of smallpox) to the chickens resulted in them becoming ill and subsequently becoming immune to the disease. In 1888, building on the germ theory, E. de Freudenreich by chance discovered the blue pigment from *Bacillus pyocyaneus* could inhibit bacterium from growing in cell cultures.

In 1899, Rudolf Emmerich and Oscar Low conducted an experiment where they took germs from infected bandages and grew them in cultures. The bacteria (i.e., *Bacillus pyocyaneus*) that caused green infections in open wounds was isolated and placed into test tubes with other bacteria, such as cholera, typhoid, diphtheria, and anthrax. Their experiment demonstrated that germs that cause one disease were a possible cure for others. From this experiment, the first antibiotic drug, called pyocyanase, was created. However, pyocyanase was potentially toxic to humans, and its effectiveness in patients was inconsistent and thus was considered clinically unusable. In 1910, Paul Ehrlich was investigating possible agents that would kill specific microorganisms, or a “magic bullet.” He discovered the first modern chemotherapeutic agent, known as arsphenamine (e.g., compound 606 or Salvarsan). Arsphenamine was the first effective treatment for syphilis and valuable in treating the parasitic disease trypanosomiasis.

In 1928, Alexander Fleming (1881–1955) discovered (apparently by chance) a natural antimicrobial fungus that could treat *Streptococcus aureus* (which earlier and little-known work by Andre Gratia and Sara Dath had done). Fleming’s discovery was known as *penicillium*. Harold Raistrick grew Fleming’s *penicillium* in cultures but was not able to isolate the mold producing penicillin. Charles Thom helped Raistrick correctly identify the responsible organism as *Penicillium notatum*.

In 1930, Cecil George Paine used *penicillium* to cure several infants with a gonococcal infection. Building on the work of others, Ernst Boris Chain and Howard Florey made it possible for mass production of antibiotics. Florey, Chain, and Fleming won the Nobel Prize in Physiology or Medicine in 1945. *Penicillium* was renamed penicillin in 1942, and it proved successful in treating a host of infectious diseases, in particular gram-positive bacteria, such as genera bacillus, clostridium, streptococcus, and staphylococcus. Penicillin is used to treat conditions such as gangrene, leptospirosis, Lyme disease, pneumonia, sexually transmitted infections (e.g., chlamydia, gonorrhea, and syphilis), strep throat, and typhoid fever.

**Antimicrobial Treatments for Bacteria, Viruses, Fungi, and Parasites**

Antimicrobial treatments are categorized broadly into two types: microbiostatic or microbicidal. Microbiostatic antimicrobials operate by hindering or inhibiting the replication of the pathogen,
Antibiotics are a category of medications that target, terminate, or inhibit the multiplication of microorganisms. Although microbes have acquired or developed resistance to antimicrobials in antibiotics, the drugs are still considered one of the most significant advances in medicine in combating microbes to date. (Flickr/Angela Doss)
schizont of the malaria parasite include combinations of chloroquine, quinine sulfate, and artemisinin. Treatments to reduce symptoms are a combination therapy of blood schizonticidal medications (e.g., attack and kill the schizonts) such as chloroquine, quinine sulfate, and artemisinin. To prevent relapses of \textit{P. vivax} and \textit{P. ovale}, a schizonticidal medication called primaquine is used to kill parasites residing in the liver. Gametocytocidal medications are used to prevent spread by killing the gametocysts include primaquine (for \textit{P. falciparum}) and chloroquine for all other parasite species.

\textbf{Antibiotic Resistance}

Antimicrobial resistance is a natural phenomenon because microbes have always exchanged genetic material rapidly and mutated often. Although antibiotics are still effective, over the years, microbes have acquired or developed resistance to antimicrobials, and their ability to evolve rapidly is aided by the misuse and overuse antimicrobials. Antibiotic resistance is the microbe itself rather than humans becoming resistant to the antimicrobial medicines. For example, in the late 1940s and throughout the 1950s, penicillin was the standard medical treatment for \textit{Staphylococcus aureus}.

Staph infections were primarily viewed as a manageable nuisance; however, during this time, staph began to show signs of being penicillin resistant. The main problem with antibiotic resistance is that, once a microbe becomes antibiotic resistant, humans can become infected with the evolved, antibiotic-resistant microbe and transmit it to others. The new infectious disease strains make it more expensive and require more advanced treatments as well as those infected experiencing longer illnesses, disability, and higher mortality. Antibiotic resistance is more common in bacteria than in fungi, viruses, and parasites. Other infections that have become antibiotic resistant include: \textit{Mycobacterium tuberculosis} (TB), HIV/acquired immune deficiency syndrome (AIDS), \textit{Enterococci}, \textit{plasmodium parasite} (malaria), and various gram-negative bacteria, such as \textit{E. coli}, \textit{Acinetobacter baumanii}, \textit{Pseudomonas aeruginosa}, \textit{Klebsiella pneumonia}, and \textit{Neisseria gonorrhoeae}.

Some significant public health examples of antibiotic resistance conditions are: methicillin-resistant \textit{Staphylococcus aureus} (MRSA), TB, and malaria. After staph infections started showing penicillin resistance, the medical community developed a semisynthetic penicillin called methicillin. Methicillin became a standard medical treatment for \textit{staphylococcus aureus} until the early 1960s. In 1961, scientists in Britain documented the first MRSA. There are drug-resistant TB strains, and if infected with one, it can still be treated with up to two years of chemotherapy in combination the second-line anti-TB drugs. If left untreated, active TB can result in the infection spreading to other body parts via the bloodstream, such as the bones (spinal pain, rib and joint destruction), inflammation of the brain (meningitis), liver or kidneys failure (inability to detox blood), and heart (pericardial tamponade), or be lethal. Treatment for these conditions requires extensive medical treatment and intervention. In certain areas, such as select areas of Africa, the plasmodium species have become resistant to antimalarial drugs. Globally, three of the five malaria species known to affect humans—\textit{P. falciparum}, \textit{P. vivax}, and \textit{P. malariae}—are resistant to treatments. The emergence of artemisinin-resistant \textit{P. falciparum} is of considerable concern to global public health efforts to eradicate malaria. As a result, antibiotic resistance is no longer simply a manageable nuisance, but is a growing global public health concern. Another emerging issue is the superinfection, which is when new bacteria, virus, fungal, or parasite infection occurs, or a coinfection develops during antimicrobial treatment.

Anticancer Drugs

Anticancer drugs are those used to treat or target cancerous cells or growths detected in living tissue and have been used frequently to treat cancer patients since the late 1940s. Medical knowledge and research over the past 50 years has significantly advanced the therapies and treatments—the most common being chemo- and radiation therapies—used by doctors and oncologists to treat their patients. As such, chemotherapy and radiation treatments have benefitted patients’ life expectancies by significantly increasing the overall survival rates for many types of cancers. However, secondary carcinogenicity, which is when anticancer drugs cause secondary cancer, is a serious medical issue for cancer patients undergoing long-term chemotherapy or radiation as part of their treatment regimens.

A carcinogen is defined as any substance that causes cancer in living tissues, and the process of cancer developing in living tissues is referred to as carcinogenesis, oncogenesis, or tumorigenesis. Basically, this process is when a living, normal cell is transformed into a cancerous cell that then divides in an uncontrollable manner and forms a malignant mass, or neoplasm. Researchers and medical professionals typically classify carcinogens by their structure or chemical as a way to differentiate among known carcinogens and the ways they behave; however, all chemical carcinogens have the ability to directly or indirectly change the DNA structure of a living tissue. This effect is caused by the fact that many anticancer drugs used in treatments today are themselves classified as carcinogens. Many researchers, doctors, and cancer patients have reported acute, toxic side effects that occurred after patients underwent prolonged treatment. These treatments then unduly caused additional damage or cancers to occur in a patient’s vital organs and tissues. Additionally, the use of anticancer drugs that are classified as carcinogens have been seen to cause neoplasm, or the growth of tumors in living tissue. Neoplasms are classified into four categories: benign neoplasms, in situ neoplasms, malignant neoplasms, and unknown or uncertain neoplasms. The malignant neoplasm is classified as cancer.

This cell division is a physiological process that can occur for a variety of reasons. However, carcinogenesis mutates the normal cells and throws off the cells’ natural balance, resulting in uncontrolled and rapid cell division. This can lead to the benign tumors that are not typically a threat to a patient as they most often do not invade other tissues or to malignant tumors that do spread to other areas of a patient’s body and are life threatening.

In general, anticancer drugs target cancerous cells that are identified by their ability to multiply rapidly. In chemotherapy regimens, a patient’s normal cells also can be damaged as a direct result of the drug’s ability to cause or induce mutations. A few other anticancer drugs are also proven to generate free radicals that harm the DNA of a patient’s normal cells.

Despite the fact that studies of second carcinogenicity have been ongoing since the late 1940s, today’s researchers better understand how and why anticancer drugs may contribute to second cancers in patients. As such, the medical and research community recently has started spending a significant amount of time researching preventative measures that would lessen the carcinogenic effects of common anticancer drugs used in treatment therapies and programs.

Today’s chemotherapy and radiation treatments have progressed significantly since first being developed, with studies focusing on various types of new anticancer drugs or combinations of drugs that reduce the carcinogenic effects of common products used in treatments, including the addition of various compounds or molecules that would negate the carcinogenicity of the main drug used to treat the cancer. This includes recent success demonstrated with a compound called metallothionein that works as a suppressant of the cancer-inducing properties found in carcinogenic anticancer drugs. Additionally, researchers and medical professionals have published studies that show a standard, minimum dose of anticancer drugs given to patients can reduce the risk of patients being diagnosed with a second cancer due to treatment. However, researchers agree that second cancers can occur in
patients randomly without any indication that anticancer drugs played a role in the cause.

Research shows that anticancer drugs that work through binding to the DNA, or alkylation, are carcinogenic in humans and are shown to cause long-term damage to a patient, to include damage to bone marrow and, although rare, acute leukemia. This risk has been shown to be dose dependent, so researchers advocate for as minimal a dose as possible to avoid the carcinogenic effects of the drug or treatment being used. In many cases, patients who experience secondary carcinogenicity do so several years—possibly five to ten years or two to three decades later—after receiving treatment for their initial diagnoses. Furthermore, research has shown that some patients may be more susceptible to secondary carcinogenicity than others. These factors can include age and genetic predisposition. This indicates that children may be more susceptible to the carcinogenic effects of treatment therapies verses adults. Regardless, cancer patients who have survived their initial prognoses and treatment regimens are closely followed throughout the remainder of their natural lives.

Those anticancer drugs used in chemotherapy that are alkylating agents are believed to increase the risk secondary cancers, especially leukemia, in patients who have been diagnosed with Hodgkin's disease, non-Hodgkin's lymphoma, ovarian cancer, lung cancer, or breast cancers. All in all, 37 anticancer drugs have been determined to be carcinogenic. However, several of these drugs have links to causing leukemia in cancer patients and survivors years after their initial treatments end. These drugs include, but are not limited to, the following:

- Mechlorethamine
- Chlorambucil
- Cyclophosphamide (Cytoxan)
- Melphalan
- Semustine
- Lomustine (CCNU)
- Carmustine (BCNU)
- Prednimustine
- Busulfan
- Dihydroxybusulfan

Additionally, researchers do not yet have data that indicates the possibility of anticancer drugs causing carcinogenic effects to those that handle these products in occupational settings, especially those working in hospital environments, although this topic is a research area of interest to many in the medical community. The limited research data available suggests that there might be a link between anticancer drugs and a slight increase in the risk of abnormalities in pregnancy, to include miscarriages, malformations in children, and difficulty in getting pregnant in women who work closely with anticancer drugs in hospital environments.

Overall, researchers, medical professionals, and oncologists do not believe the potential risk of secondary cancers caused by some anticancer drugs and agents should not dissuade cancer patients from seeking chemotherapy and radiation therapies as treatment options to their current diagnoses. While the risks are evident, today's researchers and medical professionals' awareness of the potential risks have led to numerous studies to proactively mitigate any risk factors in their patients. In short, patients are more likely to experience more short-term negative side effects as a result of their treatment options than experiencing the risk of secondary cancer caused by these treatments.

Argentina

Argentina is a Latin American country located in the southern cone of South America with a current population of approximately 42 million people. Cancer is a leading cause of death in this region of the world. Between 2012 and 2030, cancer deaths in the Americas will increase from 1.3 million to 2.1 million.

Argentina has an incidence rate of 206 per 100,000 inhabitants and a mortality rate of 148 in men and 97 in women. The most common cause of cancer mortality is breast cancer in women and prostate and lung cancer in men. Common risk factors include: alcohol consumption, tobacco use, low level of physical activity, and obesity. Leukemia is the most common type of cancer in children. The incidence rate in children and adolescents under 15 years of age is 128.5 per million, while the mortality rate is 43.8 per million. These rates are similar to those in other Latin American countries, with the exception of leukemia, where mortality rates are lower.

Several programs for cancer prevention and early detection have been created for breast, colorectal, and cervical cancer, as well as the control of tobacco use. These programs have resulted in the training of provincial medical teams, the dissemination of information to the general population about the lifestyle risk factors related to cancer, and the introduction of cancer prevention and control in the political agenda. In 2011, the Plan Nacional de Tumores Familiares y Hereditarios (National Plan of Hereditary and Family Tumors) was created to improve early detection and treatment in high-risk groups. February 15 has been established as the Day Against Childhood Cancers to increase awareness of the early signs of cancer in children and promote prompt diagnoses. There are also future plans to develop a national program for the coordination of palliative care.

Argentina spends 8.1 percent of its gross domestic product (GDP) on health. The country has a complex health care system that is divided into three main sectors: a public health system based on a universal care model, different private insurance companies, and a system of social security linked to employment and managed by unions. It is estimated that 37 percent of the population rely on public coverage, 51 percent on social security, and 12 percent on private insurers. The Programa Médico Obligatorio (Obligatory Medical Program) guarantees all of the population free access to medical attention, regardless of residency status or nationality. There are specific health policies that guarantee equal access to medical treatment for cancer.

Argentina has a national cancer registry at the hospital level and 13 population-based registries. Cancer cases in patients under 15 years of age are recorded under the Registro Oncopediátrico Hospitalario Argentino (Argentinian Oncopediaiatric Hospital Registry).

The Instituto Nacional de Cáncer (National Cancer Institute) was created in 2010 to coordinate national strategies aimed at preventing and controlling cancer. Its main responsibilities include: the development of prevention campaigns, the establishment of early detection and screening programs, the training of health professionals, the design of guidelines for patient care, the identification of risk factors, the reduction of cancer incidence and mortality, epidemiological surveillance, and the promotion and funding of research.
Cancer research is funded and directed by the Consejo Nacional de Investigaciones Científicas y Técnicas (National Council of Scientific and Technical Research). There are also private institutions, such as the Instituto Leloir, with extensive experience in applied research and clinical trials. Four of the main hospitals leading cancer research in the country are: Instituto de Oncología Angel H. Roffo, Universidad Católica de Cordoba, Hospital Eva Peron, and Hospital Municipal de Oncología Marie Curie.

Despite policies establishing the provision of medical services to all diagnosed cancer patients, the Argentine health care system currently is dealing with inappropriate screening and diagnosis processes, the interruption or suspension of treatment protocols, and inadequate follow-up care. Oncology services are concentrated in major cities, leaving large areas of the country, usually rural, without trained personnel and equipped facilities. This leads to delays in the diagnosis of cancer and the treatment of the disease in advanced stages, a factor that is linked to higher rates of mortality. Furthermore, this centralized distribution of services forces patients to travel long distances to access care or relocate to distant cities. The need to leave the place of origin to access medical treatment puts pressure on the families of patients as they must find ways to deal with travel costs and the effects of family separation.

There is a national shortage of medical equipment required for screening, diagnosis, and treatment such as magnetic resonance imagings (MRIs), computerized tomography (CT) scans, positron emission tomography (PET) scans, and radiotherapy units. Furthermore, despite the establishment of national and regional oncology drug banks, there have been documented shortages of anticancer medicines.

Nongovernmental organizations are currently working with state institutions to improve oncology services across the country. These organizations provide assistance in the form of improving the training of medical professionals, preparing campaigns on cancer prevention, carrying out research on the design of new medical protocols, and delivering medical and support services to patients and their families (medication, psychosocial support, and housing and travel allowances).

Asbestos

Asbestos is a set of six naturally occurring silicate minerals used primarily for its insulation properties. While many countries have banned the use of this material in most applications, it is still mined, manufactured, and used around the world today.
Asbestos despite the known carcinogenic hazards. Human exposure increased as demand increased in the 20th century, which included both occupational and public exposure. Due to the unique size ratio of asbestos, this long but very thin material may penetrate into the deep lung tissues, causing permanent health problems. Those exposed to asbestos most commonly see repercussions later in life through the form of lung cancer, asbestosis, or mesothelioma among other irreversible diseases.

**Type of Asbestos and Uses**
Each of the six types of asbestos comes from different types of rock, depending on the location of the mine. The mining of asbestos has been taking place for thousands of years and continues to be mined today. The small crystalline fibers that can be extracted from asbestos mines have many practical uses, and its popularity exploded in the mid-20th century. The six types of asbestos include actinolite, tremolite, crocidolite, anthophyllite, amosite, and chrysotile (most commonly used); they are further categorized by their fiber characteristics as serpentine (long, flexible fibers) and amphibole (brittle, straight fibers). The only type of asbestos categorized under serpentine is the commonly used chrysotile asbestos, while the remaining five are classified under amphibole. These fibers were and are still today valued and utilized for their specific qualities in many applications, such as insulation products, roofing and flooring materials, fire-resistant clothing, car parts, piping, cement, and countless other products. Asbestos can be used across an extremely wide array of products, and this, along with its relative abundance, efficacy, and low cost, has proliferated its usage even further.

Most uses of asbestos are banned in the United States and many other countries, although there are still products in which it is not banned, such as cement piping, vinyl floor tile, and disk brake pads, among other applications, where the asbestos is suspended in a solid matrix like plastic or cement with little to no chance of fibers becoming airborne. Since the discovery of asbestos’ carcinogenic nature, government regulations have been set up to phase out and remove applications that pose a risk to public health. Exposure occurrences range from residential homes to shipyards and can lead to seriously harmful long-term health effects.

**Types of Exposures**
Exposure to asbestos can occur by inhalation and subsequent lodging of the material in the delicate lung tissues, or alveoli, used for exchange of oxygen to red blood cells. Once these fibers are lodged in the tissues, they are stuck there permanently, causing the lung tissue to scar over, thus reducing the number of alveoli and making it harder to breathe. Also, once the fibers are lodged, it can migrate or cause the cells that it comes in contact with to mutate, leading to cancer and other asbestos-related diseases later in life.

Occupational exposure has been one of most clear links in determining the carcinogenicity of asbestos. Asbestos fibers are released into the environment from the use and deterioration of more than 5,000 asbestos products, including roofing and electrical insulation, cement pipe and sheet, flooring, plastics, and textile and paper products. Workers in asbestos insulation, brake maintenance and repair, and building demolition jobs are exposed to high levels of asbestos. The fibers can subsequently stick to the clothing and other personal items of the workers, who may then carry them home to contaminate their families. After the links were made between lung disease and asbestos fibers, it was already too late for many exposed individuals who would go on to develop asbestosis, mesothelioma, or lung cancer later in life. Because of the clear link and tens of thousands of people who have died from occupational asbestos-exposure-related diseases, there was no denial in the carcinogenicity of this substance, and it remains today as one of the most notorious, causative cancer agents, even though its exact cancer-causing mechanism is not wholly understood.

Although occupational exposure has had a devastating toll, the public was also being exposed to smaller, but still concerning, amounts of asbestos from the countless products and buildings in which asbestos products were used. After new legislation concerning asbestos, removal projects started around the country, and the business of asbestos removal now presented the public and workers with possibly more hazardous exposures. Most of the asbestos used in insulation or other products was sealed and presented little risk of inhalation hazards, although once the removal process started, it was easily made airborne. Places like schools, homes, and other public buildings began to remove
and replace their asbestos insulation, and this process is still going on today with great precautions.

**Types of Cancer and Asbestos-Related Diseases**

Asbestos has been classified as a known human carcinogen by the U.S. Department of Health and Human Services, the Environmental Protection Agency (EPA), and the International Agency for Research on Cancer. Increased rates of mesothelioma and cancer of the lung have been consistently observed in a variety of occupations involving asbestos exposure. Mesothelioma is an incurable tumor that develops inside the abdominal cavity on the pleural tissue leading to trouble breathing, chest pains, and death. This disease has a relatively long delay period from initial exposure and onset, about 20 to 40 years. In addition to lung cancer and mesothelioma, asbestos exposure has been linked with gastrointestinal and colorectal cancers as well as an elevated risk for cancers of the throat, kidney, esophagus, and gallbladder; however, evidence is inconclusive.

Asbestos exposure may also lead to asbestosis, which is an inflammatory condition that causes shortness of breath, coughing, permanent lung damage, and pleural (tissue surrounding the lungs) disorders, specifically pleural plaques. Pleural disorders can induce changes in the pleural, or tissue membrane, surrounding the lungs, causing the tissue to collect fluid abnormally between its thin layers. Although pleural plaques are not precursors to lung cancer, evidence suggests that people with pleural disease caused by exposure to asbestos may be at increased risk for lung cancer. Through unknown mechanisms, asbestos is able to migrate out of the lung tissue and into the pleural tissue surrounding the lungs, which can lead to pleural plaques and mesothelioma.

Asbestos exposures account for the largest percent of occupational cancer, with the greatest risks among workers who smoke. The entire population may have been exposed to some degree because asbestos has been so widely used in the past. Exposure to the general population has decreased due to restricted use in the United States. Nonetheless, workers employed in construction trades, as electricians and carpenters, can still experience high levels of asbestos exposures through renovations, repairs, and demolitions. Several factors are useful to determine how asbestos exposure can and will affect the health of an individual, including size, shape, chemical composition of the asbestos fibers, dose (how much asbestos exposure an individual incurred), duration (how long an individual was exposed), and individual risk factors (e.g., smoking and preexisting lung disease). Although the exact mechanism as to how asbestos causes cancer is not certain, there are a few theories. The simplest is direct mutagenic contact between asbestos fibers and host cells; other theories suggest that the immune system response to asbestos causes a reactive oxygen species (molecule) to be formed, which is in turn carcinogenic to lung cells, while others link inflammation mechanisms as a cause of the carcinogenic effects. However the mechanism works, asbestos is a known carcinogen and mutagen that affects cells on a molecular level to change and erase DNA, which can lead to malignant tumors, cancer, and respiratory illnesses.

**U.S. Legislation**

Government action on asbestos is still ongoing, and although asbestos products are not completely banned, most products that pose a serious threat of airborne fibers are banned. Under authority granted by various laws, governmental agencies, like the EPA and Occupational Health and Safety Administration (OSHA), issue and enforce different regulations, which include: the Clean Air Act (CAA), Toxic Substance Control Act (TSCA) and the Consumer Product Safety Act (CSPA). The TSCA, enforced by the EPA, has banned the manufacture, importation, and distribution of certain materials like asbestos corrugated paper, roll board, and flooring felt due to its affinity to release airborne fibers. The CAA has enabled the banning of certain uses of asbestos for uses such as piping insulation and as a spray-applied surface coating. The CSPA has prohibited asbestos products from being used in household fireplaces for insulation purposes. These regulations are designed to protect the public and industrial workers, phase out the use of hazardous asbestos, and encourage awareness about the dangers associated with certain asbestos materials.

**Conclusion**

Asbestos is a well-known and well-documented carcinogen, and even though certain uses of the
product have stopped in the United States, there is still risk of exposure in older buildings and removal situations. Exposure occurs by inhaling small, crystalline asbestos fibers, which get lodged permanently in the delicate lung tissues, causing serious health effects and even death. Government regulations have excluded many uses of the product and continue to support removal and the cleanup of sites like schools and other public buildings. Even though many people have been affected by the deadly diseases caused by asbestos, it is still mined and used today. The mechanism by which asbestos causes cancer is not completely understood, although it is a known mutagen and carcinogen that affects the lung and pleural cells, with possible links to other cancers. Although asbestos is a natural, abundant, and useful product under certain conditions, its carcinogenicity makes it a notoriously deadly substance.

Asian Diet

Unlike the traditional Western diet that is high in fats, Asian diets consist mainly of healthier foods including fish, rice, noodles, soy, fruits, vegetables, and tea. The Asian diet contains greater amounts of fiber, antioxidants, vitamins and minerals, protein, iron, and calcium than does the typical Western diet, which is heavily reliant on foods of animal origin, such as dairy products and meat, especially red meat. Asian diets are viewed by many as a way to reduce the risk of cancer as the cancer incidence of those who choose such a diet over the traditional Western one is much lower.

Background

Asia is the largest continent, and the diets consumed by its various peoples vary widely. In addition to Chinese and Indian cuisine, the major categories include East Asian, southeast Asian, south Asian, as well as central Asian and Middle Eastern cuisine. East Asian cuisine includes that of Japan and Korea and is heavily influenced by the Chinese cooking tradition. Southeast Asian encompasses Brunei, Cambodia, Indonesia, Laos, Malaysia, the Philippines, Singapore, and Vietnam. South Asian cuisine includes Bangladesh, Burma, Pakistan, and Sri Lanka and has been inspired by Indian cooking. Central Asian and Middle Eastern cuisines usually are not included when referring to the Asian diet. A cuisine that constitutes the Asian diet has greater amounts of healthy elements than Western diets. Asian diets typically include approximately five times the amount of cruciferous vegetables as the diet most Americans consume. This difference has been suggested as leading to the health benefits, including reduced cancer rates, of the individuals who consume it.

The most common cruciferous vegetables are those that come from the cabbage family. These include broccoli, Brussels sprouts, cabbage, cauliflower, Chinese cabbage, kale, and watercress. In addition to these, however, some root vegetables such as kohlrabi, parsnips, radishes, rutabaga, and turnips are also included in this category. Cruciferous vegetables make a valuable contribution to good health, insofar that they contain natural substances called glucosinolates. Glucosinolates break down in the body to form indoles and other compounds that are believed to fight the incidence of the development of cancer in a variety of different ways.

Indoles and other anticancer compounds that are derived from cruciferous vegetables slow down enzymes that can activate carcinogenic substances. Indoles and these other anticancer compounds are
also believed to accelerate other enzymes that serve to detoxify carcinogens in the body. These compounds are seen as beneficial to reducing the risk of cancer because they increase the self-destruction of cancer cells and stop or slow down the growth of cells that might become cancerous. Certain studies that have investigated cruciferous vegetables suggest that the protective compounds they contain may also alter how the body metabolizes estrogen, which might decrease the risk of hormone-related cancers.

Most of the studies that have examined the effectiveness of the Asian diet have been population studies. Population studies show the link between the increased consumption of certain foods, such as cruciferous vegetables, and a decreased risk for a variety of cancers for those who consume this diet. Breast cancer is one form of the disease that has shown a decreased incidence of the condition when an Asian diet is followed, although recent studies suggest that the benefits of eating cruciferous vegetables are greater for premenopausal women than they are for older females. Other cancers have also shown a decreased incidence when an Asian diet is followed. These cancers include that of the colon, lung, and ovaries. While some studies have indicated that consumption of an Asian diet results in no reduction in prostate cancer risk, others suggest that consumption of cruciferous vegetables exhibits a protective influence on patients during the early stages of prostate cancer development.

As an Asian diet also tends to be higher in foods derived from soy beans, many are also interested in the effects of soy consumption on humans, especially as it relates to cancer. Soy-based foods include edamame, miso, tempeh, tofu, and many products derived from soy flour, such as veggie burgers. These soy-derived foods contain isoflavones, which are chemically similar to estrogens.
Two major types of isoflavones, genistein and daidzein, can emulate estrogen in the body, although this occurs at a very small fraction of the potency of circulating free estrogen in women. These effects of this can be good or bad. While certain animal studies suggested a link between soy and breast cancer, epidemiological studies that have followed large populations of healthy women, who reported details about their diets for many years, have either shown no association between soy and breast cancer or suggested that soy has a protective association, meaning that women who ate more soy-based products had lower incidences of breast cancer.

Studies regarding the effects of soy in the diet have shown contradictory results, with those focusing on Asian women finding women who eat more soy having a lower risk of breast cancer, while those concentrating on women in the United States have not found a relation between the amount of soy consumed and the risk of breast cancer. A meta-analysis of 14 epidemiologic studies found that, in Asian countries, women who consumed more soy isoflavones had a 24 percent lower risk of developing breast cancer than women who consumed the link, while there was no statistically significant difference between the two groups in Western nations. A major difference between the two cultures, however, includes the great difference in the amount of soy consumed, with Asian women typically consuming up to four servings of soy isoflavones daily, while those in the United States consuming less than half a serving.

Embracing the Asian Diet
Those seeking to enjoy the benefits associated with the Asian diet often look to increase their consumption of vegetables and soy-based foods. For those doing so, it is important to cook vegetables only until tender. This is because this is how Asians consume vegetables, and also, overcooking them tends to produce bitterness. While many in the United States traditionally have boiled vegetables in lots of water, this method should be avoided because this leaches essential vitamins from the cooked vegetables. By contrast, briefly steaming or stir-frying vegetables produces a cooked product that has much better flavor and texture. Some vegetables, such as parsnips and Brussels sprouts, are excellent when roasted in the oven.

During the winter months, fewer vegetables are available in many parts of the United States. At times like these, when salad vegetables are more scarce, using more raw broccoli, cabbage, and cauliflower can assist those striving to maintain an Asian diet. The assertive taste of these vegetables are too strong for many, but this can be countered by the use of equally assertive flavorings, such as extra virgin olive oil or soy sauce, which smooth out the flavor of the vegetables. A variety of groups, such as the American Cancer Society and the American Institute for Cancer Research, provide a variety of recipes that utilize cruciferous recipes through a variety of cookbooks on their Web sites and via CD-ROMs and other databases. Using these sources can provide those interested in following an Asian diet with a variety of suggestions and tips.

Soy-based products can also be used by those seeking to reduce their risk of certain cancers. Recently, three studies examined women's soy consumption. The inclusion of soy was examined in the diets of more than 9,000 breast cancer survivors. The studies examined three groups of women, all of whom were breast cancer survivors, and examined these women's eating habits and other lifestyle decisions after breast cancer. Two of the groups studied were from the United States, and the other was from China. Women from both the United States and China who consumed 10 milligrams per day or more of soy-based foods were found to have a 25 percent lower risk of breast cancer recurrence than those women who did not. Those interested in achieving these results might include more edamame, miso, tempeh, tofu, and other soy-based foods in their diets.

Soy is an especially rich source of protein. While many do not care for meat-substitute soy-based products, there are many more options than these. Soy is found in a variety of foods, such as tofu, that can be used in many ways to prepare meals. Rich in protein but low in fat, soy offers a better choice than many animal-based proteins. Soy milk has become more popular in recent years, especially among the lactose intolerant, but can be used as a substitute for many milk products. Soybeans themselves are becoming more popular, and their use will likely increase.

Aspirin

Evidence from clinical studies continues to show that aspirin serves as a possible agent in the prevention and treatment of cancer. The natural form of aspirin has been used since antiquity. Scientists created a tablet form that's easier to digest, and it has been used for more than 100 years. Aspirin's two main actions in the body are to function as an antiprostaglandin and an antiplatelet agent. These actions result from aspirin's effect on an enzyme in the body. However, scientists discovered more benefits of its use during the last few decades. Research has found that the same daily dose of aspirin used to prevent heart disease may also help prevent some cancers. Public health organizations, like the American Cancer Society, need more evidence demonstrating that daily aspirin can work as a cancer preventive agent and that its benefits outweigh the side effects before they can make a recommendation to the public.

What Is Aspirin?
Acetylsalicylic acid is aspirin's active ingredient. It is a man-made derivative of the compound salicin. Salicin is naturally found in willow trees. Extracts from the willow tree's bark were boiled to make an early form of aspirin, and it has been around for thousands of years. For example, the Egyptians used willow bark and myrtle to reduce pain and fever; the Greek physician Hippocrates in 400 B.C.E. suggested willow to be brewed to relieve labor pains; and, Greek and Roman physicians in 30 C.E. used willow leaf to treat inflammation.

Scientific observations of the natural form of aspirin occurred in the 18th century by an English clergyman known as Reverend Edward Stone. Stone noticed that the bitter taste was similar to chin-chona bark that was used to treat malaria at that time. He pulverized the willow bark, dried it, and administered it to his parishioners suffering from malarial symptoms. He noticed that his patients soon found relief.

The initial attempt to change salicin to salicylic acid was not well received. It tasted bitter and awful, it was hard to swallow, it irritated the lining of the mouth and stomach, and it led to upset stomachs and vomiting.

Scientist Charles Fredric Gerhardt attempted to prepare acetyl salicylic acid in 1853. He tried to prepare it by adding an acetyl chemical to natural salicylic acid, but he chose not to market it.

During the fall of 1897, chemist Felix Hoffman of the German dye manufacturer Fredrich Bayer & Co. in Elberfeld concentrated on developing a process that synthesized the acetylsalicylic acid. His efforts worked. His attempt was personal. Hoffman was trying to help his rheumatic father, who had taken the salicylic acid for his arthritis, but he could no longer take it because it made him vomit. The chemical process he used produced a more chemically pure, stable, and palatable aspirin. It received its trademark under the Imperial Office of Berlin in 1899, and it was marketed.

For centuries, no one really understood how aspirin worked. It was not until the 1970s that British scientist Sir John Vane determined that aspirin blocks an enzyme called prostaglandins. This enzyme is a natural hormone that participates in several processes in the body. Vane later received a Nobel Prize in 1982 for his work.

The derivation of aspirin's name acknowledges its origins. The a is associated with the use of acetyl in its preparation, the spir relates to the plant Spiraea ulmaria, from which salicylic acid was extracted, and the in is the suffix.

How Aspirin Works
Today, aspirin is widely used. Billions of tablets are swallowed throughout the world each year. It generally is purchased over the counter, and it usually contains about 325 milligrams per tablet.
In the world of chemistry, aspirin goes by the name of acetylsalicylic. Acetylation, a chemical reaction, transforms salicylic acid into the compound with the help of acetic anhydride, which is a colorless liquid with a sharp odor.

Acetylsalicylic acid inhibits the production of prostaglandins in the human body by inhibiting the enzyme that produces it, and this provides relief from pain, fever, and inflammation. Prostaglandins are found in the body and increase the perception of pain, fever, and redness and inflammation that occurs with injuries that result from issues, such as excessive stress, poor posture, or force. They send strong pain signals through nerves to the brain. They also cause the area where the pain is perceived to swell or inflame. Inflammation is part of the healing process, and it occurs with the help of enzymes. The enzyme known as cyclooxygenase 2 is a protein that takes chemicals floating around in bodily tissues and converts them into prostaglandins. When aspirin is consumed, it dissolves in the stomach or small intestine and travels throughout the body by way of the bloodstream. It latches onto cyclooxygenase-2, making it difficult for the enzyme to do its job. Ultimately, the aspirin does not stop the problem causing the pain; it lowers the intensity of the signals.

For nearly half a century, scientists have discovered how aspirin can play a much larger role within the human body. For instance, doctors’ observations in the 1940s noticed how some children given aspirin-laced chewing gum to relieve pain after a tonsillectomy bled more than those who did not receive the gum. This led the doctors to question and analyze aspirin’s role at preventing blood clots and heart attacks. Some studies were done, but they did not receive too much attention due to how they were published. Later, the 1970s controlled trials demonstrated aspirin’s helpful effects in preventing blood clots.

When blood clots occur, certain prostaglandins cause platelets to stick together to form the clots, such as those that clog the blood vessels that transport oxygen to the heart. The heart pumps blood throughout the body, and these types of clots can lead to heart attacks. Taking aspirin can slow the process of clot production. Researchers began suggesting that an aspirin a day may help prevent heart disease. In addition, scientists have discovered that aspirin can also help with cataracts, gum disease, dementia, and high blood pressure during pregnancy and cancer. Some side effects can occur from taking aspirin. This can include upper abdominal pain from gastric irritation and gastrointestinal bleeding. The risks of these side effects are influenced by dosage. Also, prostaglandins are produced in the lining of the stomach. They exist there to protect against the acid. Aspirin has the potential of depleting the protective barrier, and this can cause stomach ulcers.

The Chemopreventive Effects of Aspirin
Researchers have analyzed the use of aspirin as a prevention agent since a large number of studies conducted over recent years that demonstrated definitive evidence that taking aspirin daily may reduce the risk of cancer and prevent it from spreading. Regular aspirin has been shown to help to prevent colorectal, esophageal, stomach, prostate, ovarian, breast, and certain skin cancers. In addition, it has helped keep cancer from spreading once it has been diagnosed. Studies have found the following benefits:

- **Breast cancer**: Women who swallowed aspirin or ibuprofen at least biweekly for five years or more had reduced their chance of getting breast cancer.
- **Colorectal cancer**: Regular aspirin intake can reduce the risk of polyps and colon cancer.
- **Esophageal cancer**: People with the most aggressive forms of Barrett’s esophageal cancer have benefited from aspirin, ibuprofen, and other nonsteroidal anti-inflammatory drugs.
- **Ovarian cancer**: Daily intake of aspirin reduces risk by 20 percent.
- **Prostate cancer**: Longtime use of aspirin has helped lower risk of developing prostate cancer by about 30 percent.
- **Stomach cancer**: Gastric cancer risk dropped with the increasing frequency of aspirin use.
- **Skin cancer**: Women between 50 and 79 years old who consumed aspirin on a regular basis reduced their risk of melanoma by 21 percent.

While other methods have been proposed, most studies have suggested that the direct inhibition
Aspirin is proposed to stop the development of certain cancers. Despite these findings, scientists want to help health professionals and patients make well-informed decisions about aspirin use. Currently, the evidence is not clear enough to fully confirm the potential benefits; therefore, public health organizations have not recommended aspirin as a sole cancer prevention agent. The results for many clinical studies have been mixed for reasons that include different study strategies, uneven use of aspirin and the long periods of time and large patient numbers needed to collect statistically significant results.

Researchers have expressed another concern. The evidence is not strong enough to prevail over harmful side effects like internal bleeding and hemorrhagic stroke, which is caused by the rupture of a blood vessel in the brain. Another issue is how soon the benefits of aspirin begin. For instance, researchers suggest a delay of several years occurs between when a person starts an aspirin regimen and when the risk of developing colorectal cancer is reduced.

The American Cancer Society learned different types of studies that can help clarify the confusion and provide the evidence showing aspirin benefits as a cancer-preventive agent. Ongoing studies like randomized trials designed to study the effects of aspirin on heart disease and high-quality observational studies that track large numbers of people for decades requesting detailed information from time to time are considered effective. An ideal study is a randomized trial involving tens of thousands of people. The participants would be assigned randomly to take an aspirin or a placebo pill daily for at least 10 years. In the meantime, researchers continue to collect evidence about the preventative effects of aspirin to determine what other types of cancers it prevents. Consult with a health care professional before starting an aspirin regimen to account for the effects the aspirin will have regarding your medical history and the other medications that are taken.

**How Aspirin Differs From Some Other Nonsteroidal, Anti-Inflammatory Drugs**

Aspirin is an NSAID. NSAIDs are considered safer than steroids like cortisone. Steroids were liberally prescribed for all sorts of conditions during the 1950s, but over a period of time, a number of serious side effects occurred, such as cataracts and osteoporosis. NSAIDs became more popular as a result. The health issues, which were ulcers and heartburn, were not frequent. Aspirin and other NSAIDs aim for the same molecular targets. The difference is how aspirin stops cyclooxygenase isozymes. Isozymes are enzymes that have a different sequence of amino acids but activate a chemical reaction the same way. For instance, cycloxgenase-1 appears in most tissues. Its main role is platelet aggregation and gastric cytoprotection.

This isozyme is found in mature platelets. It is a source for a major metabolite, a substance produced during metabolism. The metabolite supports the activation and aggregation of platelets, vasoconstriction, and the proliferation of vascular smooth muscle cells. Cycloxygenase-2 is found in vascular endothelium, kidney, and brain tissues as well as others. It occurs in other tissues during inflammation, healing of a wound, and the formation of tumors. It is the main source of prostacyclin, a prostaglandin found in the vascular endothelium. Both cyclooxygenases 1 and 2 are irreversibly inactivated in the presence of aspirin.
Assisted Suicide

Assisted Suicide

Assisted suicide or physician-assisted suicide refers to the ending of life, usually for terminally ill patients, through voluntary self-administration of lethal medications expressly prescribed by a physician for that purpose. This is seen as morally distinct from euthanasia because the physician does not cause the patient’s death but offers the patient the choice of the time and circumstances of his or her own death.

The ethical basis for assisted suicide is derived from the doctrine of double effect, which states that, if the conduct of a morally good act (here, relief of pain) has a morally bad side effect (namely, death), it is ethically permissible provided the bad side effect was not intended. The check for the intention is based on the Sulmasy test, where physicians are supposed to ponder whether they would feel a sense of failure if the patient were not to die after the prescription.

Terminologies Used
Euthanasia, from the Greek eu (good) and thanatos (death), is the intentional premature termination of another person’s life either by direct intervention (active euthanasia) or by withholding life-prolonging measures and resources (passive euthanasia), either at the express or implied consent of that person (voluntary euthanasia) or in the absence of such approval (nonvoluntary euthanasia). Physician-assisted suicide is where doctors provide a prescription for a terminally ill patient to hasten his or her death. This term has been replaced with physician-assisted dying in the state of Oregon to describe the action of its Death With Dignity Act. This act legalizes physician-assisted suicide but prohibits euthanasia.

Assisted suicide should not be confused with death after treatment is stopped on the instructions of the patient, either directly or through a do
not resuscitate (DNR) order. The latter is a written order based on an advance directive from a person, or from someone entitled to make decisions on his or her behalf, that resuscitation should not be attempted if the person suffers cardiac or respiratory arrest. Enforcing a DNR order is not considered legally assisted suicide or suicide of any kind. However, in any cases of doubt, emergency medical technicians, paramedics, and other medical workers are required to function as if a DNR order does not exist.

Regional and National Legislations
As of 2009, places that legally permit active assistance in dying of patients include the following:

1. The U.S. states of Oregon, Vermont, Washington, and Montana (physician-assisted suicide only)
2. Switzerland (physician and nonphysician-assisted suicide only)
3. Belgium (permits euthanasia but does not define method)
4. Netherlands (voluntary euthanasia and physician-assisted suicide)
5. Luxembourg (permits euthanasia for the terminally ill)

Two doctors must be involved in most cases, plus a psychologist if there are doubts on the patient’s competency. This is not stipulated in Switzerland, although at least one doctor is usually necessary as right-to-die societies insist on medical certification of a terminal condition before giving lethal drugs. United States and Switzerland prohibit death by injection. Switzerland alone does not bar foreigners, but careful watch is kept to ascertain that the reasons for assisting are altruistic.

Since 1980, right-to-die groups have tried to change the laws in Washington, California, Michigan, Maine, Hawaii, and Vermont, so far without success. In Australia’s Northern Territory, euthanasia was legalized by the Rights of the Terminally Ill Act (1995). Soon after, the law was voided by an amendment by the Commonwealth to the Northern Territory (Self-Government) Act 1978. However, before this amendment was made, three people had already been legally euthanized.

The Netherlands passed the Termination of Life on Request and Assisted Suicide (Review Procedures) Act on April 1, 2002, that permits assisted suicide when all of the following conditions are met:

1. The patient’s suffering is unbearable with no prospect of improvement
2. The patient’s request for euthanasia is voluntary, given in a state of mental competence, and persists over time
3. The patient is fully aware of his or her condition, prospects, and options
4. Consultation with at least one other independent doctor is obtained who confirms the conditions mentioned above
5. The death is carried out in a medically appropriate fashion
6. The patient is at least 12 years old (patients between 12 and 16 years of age require parental consent)

Death is usually effected by intravenous administration of the sedative sodium thiopental to induce a coma. Once ascertained that the patient is in a deep coma, typically after some minutes, a muscle relaxant is administered to stop the breathing and cause death. An alternative method is the oral administration of a strong barbiturate potion. By far, most reported cases in the Netherlands concerned cancer patients.

Oregon Ballot Measure 16 in 1994 established Oregon’s Death with Dignity Act (DWDA), which legalized physician-assisted suicide for capable adult Oregon residents who were diagnosed with a terminal illness. Under the law, a patient can request a physician for a prescription for a lethal dose of medication for the purpose of ending his or her life. The request must be confirmed by two witnesses, one of whom cannot be related to the patient, be entitled to any portion of the patient’s estate, be the patient’s physician, or be an employee of a health care facility caring for the patient.

Once the request is made, another physician must confirm the patient’s initial diagnosis. If the request is authorized, the patient must wait at least 15 days to make a second oral request before the prescription is given. The patient has a right to rescind the request at any time. The 2005 Death with Dignity Act Annual Report notes that assisted-suicide participants were more likely to have malignant neoplasms, be younger, and have more formal education compared to all Oregon decedents.
In 2013, 121 individuals received prescriptions under the DWDA, and 73 died from ingesting prescription drugs received under the DWDA; in 2014, 155 received prescriptions and 105 died.

Public Perceptions
According to a 2013 Gallup Poll, 70 percent of Americans were in favor of allowing doctors to hasten a terminally ill patient’s death when the matter was described as allowing doctors to “end the patient’s life by some painless means.” However, only 51 percent supported it when the process was described as doctors helping a patient “commit suicide.” In the United States, significant differences in perceptions toward assisted suicide are also encountered between religious and ethnic groups. Among Christians, conservative Protestants are usually more opposed to euthanasia than nonaffiliates and the other religious groups. Moderate Protestants and Catholics show mixed views concerning end-of-life decisions in general, while liberal Protestants are the most supportive of the groups. In general, Buddhists view termination of life, no matter under what circumstances, as amounting to destruction of human life. In Jewish law, nearly every other consideration is put second to saving a life. The premature ending of a person’s life is against this perspective, and thus, suicide and euthanasia are unequivocally rejected in modern Judaism. Conversely, Hinduism refers to death as the ultimate truth and as one of the stages in human life. While Hinduism does not explicitly disapprove of euthanasia, an alternate perspective philosophizes that euthanasia interrupts the timing of the cycle of rebirth and both the physician and patient will take on bad karma as a result.

Opinions also have varied between various ethnic groups on this issue. Recent studies have shown that European Americans are more accepting than African Americans regarding euthanasia. They are also more likely to have advance directives and to use other end-of-life measures. Among African Americans, those without a four-year degree were twice as likely to oppose euthanasia as those with at least that much education.

Ethical Concerns
Advocates of voluntary euthanasia contend that, if a person is terminally ill; is unlikely to benefit from the discovery of a cure for the illness during what remains of his or her life expectancy; is as a direct result of the illness suffering intolerable pain or only has available a life that is unacceptably burdensome because the treatment entails the person being unacceptably dependent on others or on technological means of life support; has an enduring, voluntary, and competent wish to die (or has, prior to losing the competence to do so, expressed a wish to die in the event that the first three conditions are satisfied); and is unable without assistance to commit suicide, then there should be legal and medical provisions to enable him or her to be allowed to die or assisted to die.

However, despite the growing support for right-to-die activist groups, there is still strong opposition to assisted suicide. Objections commonly stem from the increased availability of palliative and hospice care and the fear that one never can have adequate evidence of the genuineness and competence of a dying person’s request. Most importantly, people fear that a society that legally permits voluntary euthanasia will have set off on a slippery slope that will lead to supporting other forms of euthanasia, including nonvoluntary euthanasia.

Modern society will continue to debate on legalization of euthanasia, but physician-assisted suicide is now legal in some parts of the world with increasing popularity elsewhere, although opposition for it is also based on genuinely grave concerns.

Association for the Cure of Cancer of the Prostate

The Association for the Cure of Cancer of the Prostate (CaP CURE) or the Prostate Cancer Foundation (PCF) started with a personal crusade that aimed to find cures for prostate cancer by raising public awareness, providing funding for breakthrough research, accelerating the pace of discovery, and broadening the knowledge of the disease. Today, PCF is the leading philanthropic organization committed to curing prostate cancer in the United States and worldwide.

Prostate Cancer

Prostate cancer is the most common cancer among men. According to Centers for Disease Control and Prevention, the three most common cancers among men from 1999 to 2010 were prostate cancer, lung cancer, and colorectal cancer (ranked by rate of incidence from high to low). Prostate cancer was first among men of all races and Hispanic origin populations. In cancer-related deaths, prostate cancer was the second-leading cause among white, black, American Indian and Alaska Native, and Hispanic men and fourth among Asian and Pacific Islander men. Among the ethnic groups, African American men are at high risk of being affected by prostate cancer and are more likely to die of the disease. Their incidence rate is two-thirds higher than whites, and the mortality rate is at least twice higher than men of other racial and ethnic groups (note: Hispanic origin is not mutually exclusive from races).

The National Cancer Institute estimates that, in 2014, 233,000 men will be diagnosed with prostate cancer, and 29,480 will die of it in the United States. Compared with the 2010 estimate that 217,730 were diagnosed with the disease and 32,050 die of it, it is safe to infer that cases of prostate cancer have increased (due to population growth), while the number of deaths has decreased. Between 2004 and 2010, the five-year survival rate of prostate cancer survivors was 98.9 percent.

Prostate cancer is nicknamed the silent killer because it develops slowly and shows few, if any, signs in its early stage. In the late 1980s, the prostate-specific antigen (PSA) test for screening prostate cancer was introduced and used widely. It caused a rapid increase of incidence rates in the United States. In the subsequent decade, both the incidence and mortality rates were declining. The trend continues to this date. In a sense, the decline represents a personal crusade as well as collective efforts in advancing prostate cancer research and treatment.

Mission and Commitment

When CaP CURE was first established in 1993, prostate cancer was the second-leading cause of cancer deaths among men, yet there was little knowledge about the disease. In fact, the common belief was prostate cancer was a disease of elderly men. In addition to the age factor, prostate cancer was a sexual symbolic taboo to men just like breast cancer to women.

CaP CURE’s founder, Michael Milken was diagnosed with advanced prostate cancer at the age of 46 (in 1993); his case broke the myth that men would not get prostate cancer until older. Because of the progressive condition of his cancer, at one time, he was informed of 12 to 18 months’ life expectancy and advised to do arrangements. During his search for all possible treatment and wellness approaches (including diet, yoga, and meditation), Milken found critical gaps particularly in prostate cancer treatment and research with very limited government funding to fill the gap. He founded CaP CURE, later renamed as the PCF, with a specific mission—“Firmly committed to curing prostate cancer.”

At its establishment, PCF originated a groundbreaking awards process that limits applications to no more than five pages in length, selection is made in 60 days, and grants are disbursed within 90 days (from application) to awardees. The length of funding is for one year; however, prostate cancer researchers can apply multiple times to continue their promising research projects. This process is drastically different from seeking government funding that involves much paperwork. It allows prostate cancer researchers to focus their valuable time on innovative research leading to better diagnostics
or treatments. As Milken reaffirmed, it was for “cutting red tape and encouraging collaboration to speed breakthroughs.” The awards PCF offers include Recognition Awards, Young Investigator Awards, the Creativity Award, Challenge Awards, and other programs (including the clinical scholar A. David Mazzone Awards Program Funding Opportunities, Team Science Partnership Award, translational cancer research, and so on) with a purpose of encouraging and supporting innovative scientific research, translational research, and new drugs for effective treatments for stomach cancer (institutional overhead or other indirect costs are not covered in the awards).

Achievements
PCF has been engaged actively in raising public awareness and education, financially supporting research, advocating for increased federal funding specifically for prostate cancer research, conducting fund-raising to benefit prostate cancer research, building support networks for cancer survivors and their families, and sharing resources. It is worth mentioning that funds raised by PCF are strictly used for research purposes; PCF’s administrative expenses are covered by an annual grant from the Milken Family Foundation independent from PCF (the Milken Family Foundation was cofounded by Michael Milken and his brother in 1982).

Conclusion
For two decades (1993–2013), PCF raised more than $575 million and provided funding to more than 1,600 research projects at nearly 200 institutions in 15 countries in the world. In 2001, the Safeway Foundation has paired with PCF, participating in the annual Safeway campaign that raised a total of $81 million for PCF between 2001 and 2013 ($6.2 million in 2013). Also, the amount of federal funding for prostate cancer research was ranked third in 2012. These are significant achievements of PCF since its establishment in 1993, when Milken was diagnosed with advanced prostate cancer under the age of 50. It was a time when prostate cancer was deadly, yet there was little funding support for breakthrough research, clinical programs, and effective treatments of the disease.

Association of Cancer Online Resources

The Association of Cancer Online Resources (ACOR.org) is an organization providing support and information to patients and friends and family of patients who are fighting cancer. It is a 501(c)(3) organization founded in 1995 and is run by volunteers whose lives have been touched by cancer.

It is one of the first social networks dedicated to health and to bringing together individuals and
organizations with information on more than 142 types of cancer, including rare forms.

The mission of ACOR.org is to provide support and information through Internet mailing lists and Web sites. ACOR.org is dedicated to improving communication among those diagnosed with cancer and health care professionals. Advocacy through providing information and support, according to ACOR.org, is key to survival of patients.

ACOR.org maintains a Web site with links to more than 142 online cancer communities as well as mailing lists where patients and their families and friends can connect to others struggling with cancer to learn about research and experimental or Phase III clinical trials of medications and receive support and encouragement from others. The online communities focus on forms of cancer—some rare, some more common. As information is crucial to understanding treatment options, the ACOR.org Web site serves as a means of providing information through connection between individuals struggling with cancer.

Several of the sites are maintained by ACOR, and these include the following: Cancer-pain, Oncochat.org, Steve Dunn's CancerGuide, Patty Feists' Ped Onc site, Leiomyosarcoma Is a Rare Cancer, GrannBarb & Art Flatau's Leukemia Links, the CMPD Foundation Information Web site, Doug Bank's Testicular Cancer Resource Center, Colon Cancer Alliance, The CLL Foundation, and the Association of Oncology Social Work. Each of these sites provides information on cancer as well as advice on areas that may be of concern for families, friends, and patients. ACOR.org maintains these sites through volunteers, which include patients, caregivers, and family and friends of those afflicted with cancer. All information provided through ACOR.org is free to the public.

An example of one of the sponsored Web sites is Steve Dunn's CancerGuide. The Web site was started by Steve Dunn, who passed away in 2005, and is still maintained. He started the Web site when he found that it was difficult to get information he needed on the Stage IV kidney cancer with which he was diagnosed. The site he created includes a wealth of information that could be used for those struggling with any cancer as it focuses on cancer basics, the mind and attitude, experimental treatments, financial issues, and other practical and supportive information. ACOR.org also provides links to other Web sites that are maintained by other respected organizations and foundations. Examples of other Web sites include the following: The Sarcoma Alliance, the Cutaneous Lymphoma Foundation, and the Carcinoid Foundation. Similar to the ACOR.org supported sites, these too are free.

Another of the sponsored Web sites is the Association for Oncology Social Work. This professional association's Web site includes information on addressing health disparities, joining the organization, and a guide to shopping for insurance. The site, like the others discussed here, is updated regularly, but the focus of the Web site is on supporting those affected by cancer as well as individuals looking at becoming an oncology social worker.

Not just any site is accepted and promoted by ACOR.org; it has to be supported by a reputable individual or organization and has to provide privacy and protection to those who use the Web site, mailing list, or chatroom. For example, on one of the ACOR.org-sponsored sites, Oncochat.org, it discourages using online discussions for research purposes, and religious conversations are also discouraged as religion is a sensitive topic for those who may be facing the end of their lives. Researchers and lurkers are also discouraged from entering Oncochat.org.

It is important to note that the Web sites and mailing lists with which one can connect to through ACOR.org do not promote any form of treatment. Instead, they encourage communication among patients, their caregivers, and health care professionals. Information on multiple treatment options, pain management, and other individuals’ experiences can be found through searching sites specific to common and even rare forms of cancer.

When searching for information on diseases online, it is crucial that patients, family members, and friends be able to access reliable and factual information. Yet, there are many sites that will promote products or treatments. Those searching for information and support should look for Web sites that are sponsored by nonprofit organizations, information provided by universities, or U.S.-supported government organizations. Those looking for health information should consider who is sponsoring a Web site to be sure information is credible. ACOR.org is considered to be one of the top-rated resources with regard to cancer as it is a nonprofit run by volunteers without a focus on promoting products or treatments. It is particularly useful for
individuals with rare forms of cancer who find it difficult to find the information and support they need.

**Association of Community Cancer Centers**

The Association of Community Cancer Centers (ACCC) was formed in 1974 by a group of community cancer physicians. The group focuses on clinical protocols and standards of care, funding community care, treatment innovation, and information and lobbying and advocacy. The ACCC advocates for affordable patient care, access to clinical trials, and the advancement of cancer care standards. ACCC's membership currently includes medical and radiation oncologists, oncology nurses and pharmacists, administrators, medical directors, radiation therapists, social workers, and others employed in various settings. Given the diverse membership, interdisciplinary collaboration is important as are educational programs and publications. The organization's 40th anniversary occurred in 2014.

ACCC was formed in 1974 by a group of community cancer physicians but has since grown into a national organization that advocates for the entire cancer oncology team. In the early years, ACCC was active in lobbying the U.S. government on issues related to community-based cancer care. Subsequently, the National Cancer Act, passed by Congress in 1978, was amended to emphasize community care and community representation on the National Cancer Advisory Board (NCAB). ACCC's membership quadrupled by 1991 as community-based oncology programs increased in popularity.

The mission of the ACCC is to be the leading education and advocacy organization for the multidisciplinary cancer team while adhering to its set of core values (i.e., integrity, collaboration, stewardship, knowledge, service, innovation, excellence, and compassion). At the heart of this mission, the organization seeks to serve the community-based oncology team by leveling the playing field between community-based oncology, which can have fewer resources and less support compared to their colleagues at medical research universities. This is despite the fact that community-based care is estimated to care for up to 60 percent of cancer patients. ACCC, as of 2014, seeks to fulfill its three- to five-year goals, including meeting financial objectives, developing collaborations and partnerships, expanding its influence and advocacy, examining its leadership and structure, and using its resources for knowledge exchange, education, and networking.

The rising cost of cancer care has led the ACCC to advocate for the cancer patient's financial well-being. The ACCC recommends that community oncology teams employ a financial counselor to advise patients on financial issues. The ACCC provides support on how to judge the cancer benefits provided by your insurance and navigating insurance rules, for instance, helping Medicare recipients get coverage for oral anticancer drugs. ACCC has been critical of changes to Medicare in 2006 that changed the drug reimbursement guidelines for hospitals because of the potential impact to patient care. ACCC has also taken an active role in other financial issues related to cancer care, such as getting Food and Drug Administration (FDA)
approval for and insurance to pay for clinical trials and experimental cancer drugs and treatments including off-label uses of drugs. Off-labels use is when a drug was developed to treat one disease while evidence suggests that the drug might have cancer-fighting properties. For instance, the drug Clodronate (clodronic acid) was approved by the FDA to fight osteoporosis and is marketed under brand names like Bonefos, but it is also believed to be effective in fighting breast cancer.

As a knowledge exchange and educator, ACCC created its Standards for Cancer Programs (now called Cancer Program Guidelines) in 1988, which they continue to revise and update. The Cancer Program Guidelines inform the standards of community cancer care across the United States through ACCC’s member programs. ACCC additionally has collaborated with publications such as Physician’s Weekly (PW) to produce two special issues for oncologists and cancer care professionals focusing on legislative changes, care costs, and clinical approaches. PW is estimated to reach 1,500 leading hospitals and academic centers. Online communication is an interest of the ACCC to the extent that it can serve as a platform for building electronic information exchanges for the use of oncology team members, patients, their families, advocates, and others.

The ACCC’s governing structure includes the House of Delegates or the policy body with representatives of each member program, the Board of Trustees, the governing body (i.e., finance and administration) with 15 elected members (e.g., president, president elect, immediate past president, secretary, treasurer, and 10 trustees). The organization is headed by an executive director, currently Christian G. Downs, M.H.A. (health administration), J.D. (regulatory and administrative law), who previously worked for the American Society of Clinical Oncology (ASCO), the Education and Health Committee of the Virginia State Senate. Downs is affiliated with Centers for Medicare & Medicaid Services (CMS), Patient Advocate Foundation, and C–Change.

ACCC sponsors several awards, including the Innovator Award for members who innovate to improve the access, quality, and cost-effectiveness of cancer care. Award winners present their innovation at the ACCC’s annual National Oncology Conference. ACCC’s Annual Achievement Award recognizes an individual with outstanding contributions to community cancer care and cancer patients. The organization’s Clinical Research Award recognizes an individual or individuals producing cancer research with a significant and positive impact. Finally, ACCC’s David King Community Clinical Scientist Award recognizes individuals who have demonstrated leadership in the development, participation, and evaluation of clinical studies or are active in the development of new screening, risk assessment, treatment, or supportive care programs for cancer patients.

Many ACCC functions are managed by committees, and the organization also has liaisons to other national organizations. Several national U.S. cancer organizations exist to serve various exigencies. The ACCC exists alongside cancer organizations such as the National Cancer Institute, American Cancer Society, and the American Association for Cancer Education. The ACCC has more than 700 member cancer programs.

Association of Community Cancer Centers (ACCC).
that was founded in 1987 and is based in the United States. AFROC aims to bring advancements in cancer treatment closer to individuals who need care but has faced difficulties in recent years due to changes to the Medicare and Medicaid payment system and other bills that resulted in significant losses.

Michael J. Katin, MD, and president of AFROC, stated that AFROC represents a fraction of oncology professionals. Oncology itself is a fraction of the greater medical community, so it has been difficult for them to lobby for changes to these bills. Still, Katin issues a message of hope while recognizing the struggles AFROC’s members are facing. Prominent on the official Web site of AFROC is the president’s message with themes of educating members and promises to continue lobbying for this profession.

The Centers for Medicare & Medicaid Services (CMS) released a 2014 Hospital Outpatient Prospective Payment System (HOPPS) that sets the rates at which Medicare and Medicaid will make payments. As of 2014, hospitals will charge for all clinical visits at a flat rate. Formerly, patients’ visits were labeled between levels one and five, where one was lowest and five was highest. For oncology programs, usually patients are on the higher end of the spectrum. The 2014 HOPPS rates were actually higher than the 2013 payment rates.

The changes that concern oncologists most are changes to the relative value units (RVU). RVUs are a breakdown of charges by service and are made from a formula of payment that includes the doctor’s labor, practice expense, and malpractice expense. It is these formulas for specific services that have been cut, sometimes by more than 50 percent. This means that freestanding radiation oncology centers will suffer as they will now have to accept much lower reimbursement from Medicare.

Freestanding radiation oncology centers are able to keep patient costs down because their overhead is a fraction of that for an entire hospital. The reimbursement changes that the government is making will significantly lower imaging revenue for independent radiologists. On the opposite side, it increases the reimbursements that hospitals will receive. Private practice radiologists already charge less per service than hospitals do.

Radiation is a tool physicians use to treat many different types of cancer. Radiation therapy uses doses of high-energy radiation to shrink tumors and eradicate cancerous cells in the body. There are three main specialties in cancer treatment: surgical, medical, and radiation. Radiation can be used alone or in tandem with other techniques. In radiation treatment, the cancer cells are destroyed by damaging their DNA with high-energy radiation. Treatment has to be very careful, though, as radiation will damage healthy cells as well.

Radiation may come from a machine outside of the body, or radioactive material can be placed in the body near cancerous cells. It also can be injected into the patient’s bloodstream. Radiation is not used only with a curative intent, however. Radiation also can be used to relieve a patient’s suffering. If an inoperable tumor is causing pain, for example, radiation may be used in hopes that it can shrink the growth and ease the discomfort of the individual.

The radiation oncologist begins by planning the treatment. Computed tomography (CT) scans are generally used in order to plan the therapy. The oncologist has to make sure the patient will be able to lie completely still in order to target the cancer, even to the point of using body molds or other tools to prevent the patient from moving. The tool used to keep the patient still differs depending on the body part being treated and sometimes includes masks or other restraints.

All of these services are expensive, which means that the lower revenues for freestanding imaging centers are going to cause many of these centers to join into partnership with a hospital. The workers will likely have to become employees of a hospital, and some of these centers will simply have to close their doors.

AFROC is attempting to reverse the bills that will cause so much harm to freestanding radiation centers. They represent and lobby on behalf of many independent radiation oncology centers. With the recent Medicare- and Medicaid-related changes to the fee and reimbursement schedules, the group AFROC represents is facing an alarming future for many of its members. Its Web site, afroc.org, states their mission as the following:

The Association of Freestanding Radiation Oncology Centers have helped to support the needs of people who offer cancer care solutions to patients in many parts around the United States. These physicians, physicists, professional support personnel, and administrators are the key to the current and ideal system that allows most cancer patients
to be treated with advanced techniques within a reasonable distance from their homes. Now more than ever, this is being threatened by policy makers who do not recognize the potential results of their actions. Help AFROC continue to monitor and intervene to maximize our standing before irreversible changes occur.

Only time will tell whether this organization will be able to reverse the decisions that are currently harming their professionals. They will certainly continue to try on behalf of their members.

Association of Oncology Social Work

While researchers have made gains in the early detection of and treatment of cancer, it continues to be the second-leading cause of death in the United States. The psychosocial factors associated with cancer and the impacts on those affected and their families are vast. Social workers in oncological social work provide care to those at risk, affected by, and diagnosed with cancer. The Association of Oncology Social Work (AOSW) is a nonprofit professional organization of social workers headquartered in Deerfield, Illinois. It was founded in 1984 by a group of oncological social workers. The organization’s mission is the enhancement of psychosocial services to those affected by cancer and their families. Members do this through networking, education, research, resource development, and advocacy.

Oncology social workers provide counseling, support, education, and resources to persons dealing with cancer and their families. They provide care in many settings including hospitals, hospices, outpatient clinics, and community-based programs. They promote the field of oncological social work through publishing position papers and providing grants, scholarships, and awards to those practicing in the field. The AOSW news blog is another way the organization communicates with others to promote their efforts.

AOSW members network by participating in various online and face-to-face networking groups and special issues groups. AOSW provides many opportunities to expand members’ knowledge bases and gather new information on practice and research. Research is a core part of AOSW’s commitment to excellence in oncology. The organization supports research that informs practice and policy. Research often addresses clinical, policy, and theoretical approaches that benefit AOSW members and the public at large. AOSW believes knowledge is power, therefore, it provide links, contacts, and information on resources for practitioners working with and families dealing with cancer. Advocacy is at the center of oncological social workers.

AOSW envisions a global vision of cancer care that meets the needs of the whole person and his or her family. The goals of the AOSW are widespread, including to increase awareness of the psychosocial effects of cancer; advance the practice of psychosocial interventions that enhance quality of life and recovery of persons with cancer and their families; foster communication and support among psychosocial oncology caregivers; further the study
The psychosocial factors associated with cancer and the impacts on those affected and their families are vast. of psychological and social effects of cancer through research and continuing education; advocate for programs and policies to meet the psychological needs of oncological patients and their families; promote liaison activities with psychosocial oncology groups and professional oncology organizations; and promote the highest professional standards and ethics in the practice of oncology social work.

AOSW partners with corporate affiliates to provide professional development through various outlets including the AOSW annual conference, research publication, oncology social work certificate, and development of standards of practice. The conference is an opportunity for oncology professionals to network, educate, and present the latest research in their respective areas of cancer research and treatment. AOSW promotes the field of oncological social work through its publications The Journal of Psychosocial Oncology and the Social Work Toolbox.

To further their mission, AOSW supports special projects such as clinical trials, special events, and research that furthers our knowledge about cancer prevention and treatment. The AOSW is a voluntary membership organization of oncology social workers. Members receive benefits that include access to member-only resources, voting privileges, and opportunities to serve on the board of directors and committees. The board of directors includes the president, the president elect, and treasurer. The organization has recently restructured and reduced the number of U.S. regions from five to two. Currently, there are three regions.

Association of Pediatric Hematology/Oncology Nurses

The Association of Pediatric Hematology/Oncology Nurses (APHON) is an organization for nurses and other health care professionals who specialize in pediatric hematology and oncology. APHON promotes and provides expert practice to its members and the public. Members are dedicated to the best nursing care for young adults, adolescents, and children who have cancer or blood disorders. APHON defines and promotes the best standards of practice.

In 1973, four pediatric oncology nurses recognized the need to share information, successes, and concerns that are unique to pediatric nurses. At that time, pediatric cancer was just beginning to be recognized as a specialty. The original four planned a special interest session at the Association for Care of Children’s Health (ACCH) conference in 1974. Forty nurses attended and concluded they needed a professional organization. On November 3, 1974, the Association of Pediatric Oncology Nurses (APON) was created. They incorporated in 1976. The association grew quickly, began an annual conference, and began to develop educational materials. The primary members were registered nurses, although a few allied health care practitioners (social workers, child life specialists, and pastoral care providers) with similar career interests and experience were also members. In 2006, the association recognized that most of their members also cared for hematology patients, and the association voted to change its name to the Association of Pediatric Hematology/Oncology Nurses. The association has grown to 3,100 members in the United States, Canada, and around the world.

APHON is run by a board of directors who are elected by the association members: president, vice president, secretary, treasurer, and six other association members. All serve three-year terms. Six committees are appointed by the board: Nominating Committee, Education Provider Unit, Steering Council, Local Chapter Committee, Chemotherapy/Biotherapy Provider Program, and the Journal of the Association of Pediatric Hematology/Oncology Nursing (JOPON) Continuing Education Committee.

APHON developed the Pediatric Chemotherapy/Biotherapy Provider Program. It is a two-day course that teaches theoretical knowledge and the key principles to consistently, competently, and safely administer biotherapy and chemotherapy. Successful completion earns certification as a Pediatric Chemotherapy and Biotherapy Provider. Renewal is required every two years.

JOPON is the official journal of APHON. It is published six times per year. It consists of peer-reviewed original research and definitive reviews on the entire spectrum of nursing care of childhood cancers. JOPON encompasses the entire disease process from diagnosis to end-of-life care and is distributed to APHON members free of charge. *APHON Counts* is a quarterly newsletter shared with members that features new trends in treatment and best practices as well as in-depth, personal accounts regarding pediatric hematology or oncology. *APHON Counts* is only available to members. Other benefits to membership include discounts on products and educational conferences, grants, awards, and networking opportunities.

APHON’s core purpose is to support and advance nurses and their practices to optimize the care and outcomes for pediatric patients with cancer or blood disorders and their families. Core values include: pride in the profession, commitment to professional and organizational excellence, collaboration as an effective strategy, visionary leadership embracing innovation, continuous professional development.
Astellas Pharma (Japan)

Astellas Pharma is a Japanese pharmaceutical corporation with 17,649 employees worldwide, including subsidiaries as of early 2014. Astellas Pharma came out as number two in Japan and as number 18 on a global basis in the Almanac 2013 Medical Care & the Pharmaceutical Industry 2013 overview of pharmaceutical corporations’ 2011 sales. Astellas Pharma considers itself to be a global category leader (GCL) within urology and has in extension a focus on kidney diseases as well as diabetes complications, immunology and infectious diseases, oncology, and neuroscience. The top-selling urology-related products Vesicare and Mirabegron sold globally for approximately ¥100 billion (about US $1.21 billion) in fiscal year (FY) 2011 (April 2011–March 2012) and ¥117 billion in FY 2012 (April 2012–March 2013).

Astellas Pharma is aiming at establishing itself as a GCL when it comes to oncology related to urology and transplantation. Thus, new products through lifelong learning, absolute integrity and high ethical standards, and gratifying experience through involvement. APHON’s primary vision is to be recognized as the leader in hematology and oncology nursing in pediatrics.

APHON and the Pediatric Nursing Certification Board (PNCB) recognize five issues as important to pediatric health care and where pediatric nurses could make contributions: schools used as points of access for health care; a focus on lifelong learning; coordination of care, including in the home; an advocacy presence whenever children’s groups meet; and quality, evidence-based, safe practice.

Membership in APHON includes the following: active membership (registered nurses who are practicing or interested in pediatric hematology or oncology); associate membership (nonregistered nurses who practice pediatric hematology or oncology and are interested in APHON’s mission); graduate nursing student membership (enrolled full time in a graduate nursing program); and National Student Nurses’ Association (NSNA) membership.

There are 40 local chapters in APHON throughout the United States and Canada. Each chapter engages in community outreach that has included: grocery store gift cards to family members of patients, food donations to homeless shelters, food and toiletry donations to the Ronald McDonald House, diaper and clothing drives, and collection of school supplies. Community outreach occurs most often during the holidays, but chapters are highly encouraged to participate year-round. Community outreach offers an opportunity to network and make a difference in local communities.

APHON has a mentoring program that links members who are interested in the following areas: clinical and project development, teaching and education, research, higher education pursuit, leadership, role integration, and professional and career development. The program matches mentors and mentees with the goal of the mentees’ growth in their careers and to support leadership development in the mentors. The relationships officially last two years and can continue after on an informal basis. Learning materials and manuals are provided, and progress is reviewed every six months through self-report.

APHON also offers its members an enhanced career center. Members can post a résumé or job announcement, browse and search available jobs, and create a personal search agent that e-mails matches according to criteria set by the member. Through the career center, members also can access the National Healthcare Career Network, which consists of more than 200 associations and organizations, tens of thousands of résumés, and more than 1,500 job postings.

Astellas Pharma (Japan)
from 2012 such as Xtandi and Gonax are used in connection with the treatment of prostate cancer. Xtandi (enzalutamide) is marketed for prostate cancer worldwide and is considered as the corporation’s driving force within oncology. It is as of 2013 also in Phase 2 clinical trials for breast cancer in Europe and in the United States. Gonax (degarelix) is also for prostate cancer and is marketed in Japan. The oncology portfolio includes still another prostate cancer-related product, Eligard, and some treatments of other types, including Tarceva, used under some specific conditions such as first-line treatment of people with metastatic non-small cell lung cancer. The oncology segment sold combined for ¥46.4 and ¥47.5 billion in FY2011 and FY2012.

History of Astellas Pharma
Astellas Pharma was formed from the 2005 merger between Yamanouchi Pharmaceutical Co., Ltd. and Fujisawa Pharmaceutical Co., Ltd. These two corporations had before the merger some shared research areas, such as diabetes, urology, and the central nervous system. Yamanouchi had, however, cardiovascular, gastrointestinal, and locomotorium areas of specialization, in contrast to Fujisawa’s immunology, inflammation, and infectious diseases. Fujisawa had been noted for a focus on patented prescription drugs, whereas Yamanouchi had been more comprehensive. The Yamanouchi part was founded in Osaka in 1923, whereas the Fujisawa part had been founded in Osaka already in 1894. The two former corporations had somewhat separate profiles as for strengths overseas, with Fujisawa being focused on North America and Yamanouchi on Europe. Fujisawa acquired Lyphomed Inc. based in Illinois in 1990 and established a research and development (R&D) center there. Yamanouchi acquired the Royal Gist Brocades’ pharmaceutical division in the Netherlands in 1991, and a European R&D location was thereafter developed there.

In addition to these premerger acquisitions, Astellas Pharma acquired the U.S. firms Agensys (2007), a California-based firm specializing in antibodies, and OSI Pharmaceuticals (2011), a biopharmaceutical firm specializing in oncology based in Long Island, New York. Another U.S. acquisition was attempted in 2009, the biotechnology firm CV Therapeutics Inc., but it was acquired by Gilead Sciences instead. On the other hand, Perseid Therapeutics was founded in California in September 2009 as a joint venture with Maxygen, Inc. In 2006, a subsidiary focusing on over-the-counter drugs, and so on, Zepharma, was sold to Daichi Sankyo.

Corporate Philosophy and Recent Strategy
The name of the corporation, Astellas, is based on Latin astella (star) and Greek aster (forward), and the meaning is hence a forward-moving star. The corporation also wants to reflect this momentum in its slogan “Changing Tomorrow.” R&D expenditures as relative to sales were 18.1 percent in FY 2012, a decline from 22.8 percent in 2011 and 19.6 percent in 2010. Astellas Pharma has in recent years undergone reforms of its R&D structure. A Disease Frontier Research Laboratory was established in April 2012, aimed at exploring new potential activity areas. One aim was stated as embarking onto full-scale research into cell therapies. Then, in May 2013 Astellas Pharma announced plans regarding a more comprehensive reshaping of its R&D framework, including new initiatives aiming at, first, utilizing external capabilities and resources to a greater extent; second, initiatives toward new therapeutic areas and innovative technologies such as regenerative medicine and vaccines; third, acceleration of the development speed when it comes to its preclinical pipeline; and fourth, ensuring that there is sufficient investment in its late-stage pipeline. At the same time, Astellas announced the establishment of Astellas Innovation Management in order to strengthen innovation during the preclinical development stage. Overall Astellas has reorganized toward a sequential pattern when it comes to its research functions and structures. As a part of the reorganization, the corporation also announced the closure of OSI Pharmaceuticals and Perseid Therapeutics subsidiaries as well as a scaled-back Astellas Research Institute of America in the United States, abandonment of in-house fermentation research, and a transfer of functions between research sites in Japan. Also in May 2013, Astellas entered into a strategic alliance with Amgen, Inc., concerning co-development and co-commercialization in Japan of five Amgen pipeline medicines, including three treatments for cancer and the establishment of a joint venture, Amgen Astellas BioPharma, for the purpose of developing these five drug candidates. In April 2014, Astellas Pharma and Daiichi Sankyo announced that they planned to form a joint compound library-sharing partnership for approximately 400,000
selected compounds. Such a collaboration would enable them to promote their R&D efforts. This was the first occasion of such a collaboration between Japanese pharmaceutical corporations.

Astellas Pharma has implemented a corporate social responsibility (CSR) program and strives to conduct CSR-based management consisting of five fields: society, environment, employees, economy, and compliance. Societal activities include, for example, the Changing Tomorrow Day, where Astellas Pharma employees may volunteer activities as contributions to the local communities where they work.

AstraZeneca (United Kingdom)

Headquartered in London, the multinational company AstraZeneca is the seventh-largest pharmaceutical company in the world by prescription drug sales. The sixth-largest company with a primary listing on the London Stock Exchange, it has a secondary listing on the New York Stock Exchange and is part of the Financial Times Stock Exchange (FTSE) 100 Index. The company was formed in 1999 through the merger of the Zeneca Group, a UK company spun off in 1993 from Imperial Chemical Industries, and the Swedish pharmaceutical company Astra AB. While Astra, the largest Swedish pharmaceutical company at the time, was focused mainly on pain control and medications for gastrointestinal, cardiovascular, and respiratory disorders, the largest part of Zeneca’s portfolio was devoted to oncology. Recent corporate acquisitions have included Cambridge Antibody Technology, makers of Humira; antiviral company Arrow Therapeutics; Spirogen, a biotech oncology firm; and MedImmune, makers of FluMist. MedImmune and CAT have been combined into the wholly owned subsidiary MedImmune LLC. AstraZeneca’s American headquarters is in North Wilmington, Delaware. In 2014, amid speculation of an attempted takeover by Pfizer, AstraZeneca expanded its commitment to varied cancer treatments.

AstraZeneca’s product portfolio has been reorganized to focus on three major areas: respiratory, inflammation, and autoimmunity; cardiovascular and metabolic disease; and oncology. Among the Zeneca portfolio the company began with are the cancer drugs Casodex, Nolvadex, and Zoladex. Casodex is bicalutamide, a nonsteroidal antiandrogen used in combination with castration to treat advanced prostate cancer and clinically trialed for ovarian cancer. Zoladex is the trade name for Goserelin acetate, a luteinizing, hormone-releasing hormone agonist that supresses sex hormones (testosterone and estrogen) as part of the treatment of breast or prostate cancer. In prostate cancer treatment, this can lead to a temporary increase of symptoms, particularly bone pain, in the first weeks of treatment, a phenomenon known as the tumor flare effect, preceding the desensitization of hormone receptors.

Nolvadex is the original trade name of tamoxifen, one of the most important breast cancer drugs and listed by the World Health Organization (WHO) as one of the medications constituting a basic health system. Tamoxifen was originally developed by Zeneca when it was part of Imperial Chemical Industries and targets the estrogen receptors in breast tissue. In premenopausal women whose cancer is hormone-receptor positive, tamoxifen is one of the standard
and most successful treatments (and is common for postmenopausal women as well). Because these cancers require estrogen to grow, tamoxifen prevents growth by binding to estrogen receptors without activating them. Tamoxifen is also approved for the prevention of breast cancer in high-risk women and is the most common hormone treatment for men with breast cancer. It can also be used to treat some causes of infertility and gynecomastia, premature puberty as a result of McCune–Albright syndrome, and manic episodes in bipolar patients. Despite initial fears that tamoxifen would contribute to osteoporosis, it actually has had the opposite effect, preventing the development of osteoporosis by inhibiting osteoclasts. It has been linked to an increased risk of endometrial cancer and uterine cancer and so is listed as a carcinogen by the American Cancer Society. It also causes some unpleasant side effects, notably reduced cognition, memory, and libido.

In addition to the above drugs, today, AstraZeneca manufactures Arimidex, Faslodex, Iressa, Tomudex, and Caprelsa. Arimidex is the trade name for anastrozole, an aromatase-inhibiting breast cancer treatment used postsurgery or to treat metastasis. Faslodex is the trade name for fulvestrant, a metastatic breast cancer treatment for postmenopausal women designed to follow antiestrogen therapy, administered through monthly injections. Though AstraZeneca's patent on Faslodex has expired, there is no generic available, perhaps in part because it has been less successful than the also off-patent anastrozole. Iressa is the trade name for gefitinib, an epidermal growth factor receptor (EGFR) inhibitor used to block the growth of certain cancers with overactive EGFR, usually breast or lung cancers. Tomudex is the trade name for the antimetabolite raltitrexed, used as part of chemotherapy regimens for colorectal cancer or mesothelioma. Calpresa is the trade name for vandetanib, used in the treatment of some thyroid cancers.

It is also developing cediranib, currently under the trade name Recentin, a vascular endothelial growth factor inhibitor that began clinical trials for non-small cell lung cancer, kidney cancer, and colorectal cancer in adults, and central nervous system tumors in children, in 2007. Trials for non-small cell lung cancer and metastatic colorectal cancer failed, but development continues in other areas.

AstraZeneca's MEDI-4736, the working name for a drug designed to help the immune system fight cancer, entered phase II clinical trials for colorectal cancer, head and neck cancer, and lung cancer in 2014, with phase III trials fast-tracked later in the year. MEDI-4736 is a human monoclonal antibody and shows potential for treating some of the deadliest cancers. It was this and other experimental cancer drugs that provided part of the motivation for Pfizer's attempted, but ultimately unsuccessful, takeover bid of AstraZeneca in the same year.

AstraZeneca's wholly owned subsidiary MedImmune LLC includes the portfolio and assets of the former Cambridge Antibody Technology, which developed a number of human monoclonal antibodies or mabs, a category of biological treatment that is sometimes used in cancer treatments. MedImmune is also developing CAT-5001, acquired from Enzon Pharmaceuticals, an immunotoxin that targets mesothelin in the treatment of some mesotheliomas as well as ovarian and pancreatic cancer.

Australia

Cancer control is one of Australia's nine National Health Priority Areas (NHPA). Initially driven by the World Health Organization's Global Strategy for Health for All by the Year 2000, the purpose of the NHPA is to support collaborative action between all levels of government, policy makers, clinicians, and health professionals. Cancer control is a priority due to the significant contribution of cancer to Australia's burden of illness. By 2032, Australian
health care costs of cancer are projected to increase from $AU3.8 billion dollars to more than $AU10 billion dollars per annum. However, it is estimated that one-third of Australia’s current cancer cases could be prevented through lifestyle change, with a resultant major reduction in health care costs.

As Australia’s largest disease burden, cancer accounts for approximately 16 percent of the total burden of disease. Of a total Australian population of 22.68 million, estimates indicate that 128,290 Australians will be diagnosed with cancer in 2014, with approximately 57 percent of the total attributed to males. In 2012, the most commonly diagnosed cancers in Australia were prostate cancer (18,560 people), bowel cancer (15,840 people), breast cancer (14,680 people), melanoma of the skin (12,510 people), and lung cancer (11,280 people).

Australia has the highest rate of melanoma in the world, accounting for approximately 10 percent of all cancers. While melanoma only accounts for 2.3 percent of all skin cancers, it is responsible for 75 percent of skin cancer deaths. Among young Australians age 20 to 34, melanoma accounts for more cancer deaths than any other single cancer. Given Australia’s geography and climate, national campaigns focusing on reduced exposure to direct sunlight, protective clothing, sunscreen, wide-brimmed hats, and sunglasses are addressed as reductions in melanoma incidence. These programs are particularly prevalent in schools as an attempt to reduce the incidence of melanoma among young people.

Age-standardized rates indicate the incidence of cancer is higher for those living in areas of lower socioeconomic status and in inner regional Australia. The incidence among Aboriginal and Torres Strait Islander Australians is 461 per 100,000 compared to 434 per 100,000 for the nonindigenous population.

Cancer diagnosis in Australia is expected to rise, with cancer diagnosis rates rising significantly between 1982 and 2010. In 1982, 47,388 Australians were diagnosed; by 2010, the figure was 116,850. Projections indicate that, by 2020, 149,990 Australians will receive a cancer diagnosis. In 2009, the average age of diagnosis was 65.4 years, with the risk of developing cancer before 85 being one in two for men and one in three for women. Cancer rates rise sharply across the age gradient, with new cases most common in men age 60 years and over.

In 2012, it was estimated that cancer accounted for 551,300 disability adjusted life years (DALYs), with 457,400 DALYs lost through premature death. In 2011, there were 43,221 Australian deaths attributed to cancer. When standardized for age, male deaths per 100,000 males were 219.1 compared to 136.7 deaths per 100,000 women.

On a landmass of 7.692 million square kilometers, approximately 84 percent of Australia’s population resides in the most densely populated 1 percent of the country, largely around the coastal perimeter. Approximately 32 percent of Australia’s population resides in rural and regional areas. Delays in diagnosis of cancer in rural areas can result in more advanced disease than urban counterparts, with resultant poorer survival rates. The ramifications of a geographically dispersed population, geographic isolation, large distances to urban centers, lack of access to services, lack of access to health professionals, and the impact of relocation for treatment have major impacts on rural people with cancer.

While rates of cancer diagnosis are rising, five-year survival rates for all cancers in Australia rose between the period of 2006 to 2010. Over a 20-year period, these rates have increased from 46.9 percent to 66.1 percent across combined cancer groups. These figures have created significant numbers of people who enter the cancer survivor phase. Initiatives such as the Olivia Newton John Cancer and Wellness Centers are integrating research, cancer treatment, and evidence-based wellness programs to support people across the cancer trajectory.

Australia’s National Cancer Prevention Policy focuses on recommendations for action by government and nongovernment organizations. The policy includes primary prevention, screening and immunization. Chapters of the policy on preventable risk factors include tobacco, being overweight or obese, physical inactivity and nutrition, ultraviolet radiation, alcohol, and occupation. Action on screening is directed at melanoma, colorectal, cervical, breast, and prostate cancer. In 2007, Australia introduced a national human papillomavirus (HPV) vaccination program. The incidences of cervical cancer and mortality rates have fallen by approximately 50 percent since the introduction of a national cervical screening program in 1991. It is expected that the combination of HPV vaccination, HPV testing for secondary prevention, and cervical screening will have major impacts on the incidence of cervical cancer into the future.

The Cancer Council Australia has played a leading role in the development of clinical practice guidelines
to support the delivery of optimal care. Using a wiki platform, the aim is to improve consistency and standards of clinical practice with the Web-based approach enabling constant updates and to incorporate new scientific evidence and changes to evidence that influence contemporary clinical practice.

Austria

Cancer statistics in Austria (population 8.46 million) mirror those of other high-income nations. Cancer in Austria is thus a costly and serious public health issue. Austria faces various hurdles to cancer care and prevention due to unhealthy lifestyle factors. The Austrian Ministry of Health (MOH) has brought forth new initiatives to promote the prevention and early detection of various forms of cancer. Although these initiatives are still in their early stages, they have only had limited participation. Moreover, initiatives in cancer control must also contend with persistent stigmatization and the taboo nature of cancer in Austrian society.

Epidemiology of Cancer in Austria
In 2012, prevalence for all cancers (404.4 per 100,000) was slightly lower than the average among other high-income nations, while the age-standardized mortality rate (157.8 per 100,000) is equivalent. Cancer accounts for 27 percent of all deaths, which is superseded only by mortality from heart disease. Five-year cancer survival rates have increased since the mid-1990s in part due to improvements in treatment.

Both cancer prevalence and mortality are higher among men. The most commonly diagnosed cancers among women are breast, lung, and colon cancer. For men, prostate, lung, and colon cancer are the most common. While rates of lung cancer for men have flattened out, rates among women are on the rise, which is in part due to the later onset and persistent popularity of smoking among women.

Differences in the quality and methods of provincial cancer registries limits comparisons across Austria’s nine provinces, but data from 2009 to 2011 suggest that the urban province of Vienna has the highest cancer mortality rates, and the Alpine province of Carinthia has the highest incidence rates.

Primary and Secondary Cancer Prevention
Health policy scholars have suggested that preventive health measures are not a high priority for Austrians, thereby making cancer prevention a challenging task. Primary cancer prevention in Austria is hindered by the high rates of tobacco and alcohol use. The World Health Organization (WHO) estimates that around 40 percent of Austrians currently use tobacco. Smoking rates of women continue to increase, whereas smoking rates for men have decreased throughout the 1970s and since leveled off. Considering that tobacco-free legislation in Austria is virtually nonexistent and smoking is not a social taboo, tobacco use is likely to remain high. At more than 13.5 liters per capita per year, consumption of alcohol is fairly high, and drinking is considered a cultural norm.

Being overweight or obese is also implicated in cancer risk. The prevalence of both factors is rising, with just over half of adult men and over 40 percent
of adult women classified as overweight or obese. Incidence rates are also increasing among children. As is the case with other high-income nations, those in lower socioeconomic groups have a higher risk of being of overweight and obese.

Given the difficulty of primary prevention strategies, the MOH in conjunction with the Austrian Cancer Society (ACS) has focused its efforts in cancer control on secondary cancer prevention. One exception is the recent introduction of the human papilloma virus (HPV) vaccine free of charge for all children nine years of age. Another is the availability of genetic testing for breast cancer (BRCA) mutations, followed by optional mastectomy and reconstruction. In regard to secondary prevention, the MOH restructured Vorsorge Neu, a program to promote various cancer screening tests including Pap smears, colonoscopy and fecal-occult tests, mammography, and the prostate-specific antigen (PSA) test in 2005. Despite universal access, participation in screening programs is low, and is even more reduced in lower socioeconomic groups and among those with an immigrant background. In January 2014, the MOH enacted a breast cancer screening program whereby women between 45 and 69 are invited to receive a mammogram by a program-certified radiologist every two years, and women between 40 and 44 and 70 and 74 can opt in. Due to very low participation and political pressure, in summer 2014, an invitation is no longer required, and women over 75 can continue to attend screening.

Cancer Therapy and Additional Services

Biomedical cancer care in Austria is excellent, although access is not equally distributed. Austria has a two-tiered health care system, consisting of mandatory government health insurance and the option to enroll in privatized health insurance at an increased cost. Those with private health insurance have shorter wait times for therapy and more time with medical practitioners. There are no cancer-specific hospitals and only four university hospitals with cancer centers. Patients can participate in clinical studies sponsored by groups such as the Austrian Breast and Colorectal Cancer Study Group. In an effort to increase overall access to care for those in rural regions, cancer patients can obtain a free taxi service to attend treatment. Patients have a right to psychological therapy, a stay in a health resort (Kur), oncologic rehabilitation, a wig, prostheses, and certain forms of complementary medicine.

The ACS, subdivided into the nine Austrian provinces, offers informational materials and events, consultation, and psychological therapy. The ACS recently unveiled a computer application to help organize a patient’s individual therapy. Psychosocial support is available through regional cancer self-help groups, but patients do not readily utilize them. The ACS also sponsors Pink Ribbon Austria as part of international breast cancer awareness. The Europa Donna Coalition for breast cancer advocacy is also active in Austria. In addition, there are multiple state and privately sponsored cancer informational events in urban regions.

Cultural Perceptions of Cancer

Despite well-established efforts in cancer care, cancer still remains a stigmatized condition. Qualitative research demonstrates that many with cancer do not readily speak openly about their disease. One reason for this may be the cultural belief that a cancer diagnosis should be accepted as one’s fate, which can lead to an attitude of resignation and a feeling of hopelessness. Since the early 2000s, this stigma has gradually been lifted in part due to better treatment options, the presence of cancer in the media, and celebrities and politicians speaking out about their personal diagnoses. It is clear that the MOH will have to work together with medical practitioners and community leaders in order to mobilize cancer control and remove the stigmatization of cancer.

Automobiles

Automobiles are responsible for a number of carcinogens, made more serious by the prevalence of these vehicles in American life and their necessity to most Americans. Though automobile exhaust and the exhaust of factories manufacturing automobiles are the most obvious sources of carcinogens, they are not the only ones.

The clearest link between automobiles and cancer is the contribution of traffic-related air pollution from muffler exhaust to cancer risks. A University of California, Los Angeles (UCLA) study in 2013 found a link between traffic-related air pollution and several rare childhood cancers, for instance: retinoblastoma (eye cancer), acute lymphoblastic leukemia, and germ-cell tumors. About 4,000 California children diagnosed with cancer were studied, with their pollution exposure during their mother’s pregnancy and their own first year of life examined based on traffic volume, weather, vehicle emission rates, and roadway geometry. Pollution exposure turned out to be highly correlated to cancer risk, especially these particular cancers.

Diesel emissions specifically have been positively correlated with lung cancer, according to studies by the National Cancer Institute and National Institute for Occupational Safety. Though the highest risk is faced by miners and others who are exposed to diesel exhaust in poorly ventilated conditions—a group that faces a lung cancer risk five times higher than Americans who are not exposed to diesel exhaust in the course of their work—many Americans are regularly exposed to diesel exhaust fumes from commercial trucks and public transportation vehicles. In general—though local weather conditions have considerable impact on how quickly exhaust is dispersed—more densely populated, urban areas see greater exposure to exhaust fumes. This is true not only as a result of population density—more people means a greater number of goods to transport to them—but because the largest cities tend also to be transportation and freight hubs, through which a disproportionately high number of commercial trucks, freight and passenger trains, and passenger buses will pass.

Although diesel is generally considered more polluting than the gasoline mixtures used in passenger cars, a National Oceanic and Atmospheric Administration Earth System Research Laboratory study of the Los Angeles area found that diesel traffic did not contribute as great a share of secondary organic aerosols (SOAs)—carcinogenic particles formed in the air as pollutants and precursors oxidize into them—as was expected, and that as much as 80 percent of the SOAs in the air were contributed by gasoline engines.

Automobile exhaust, which contains carbon monoxide, nitrogen dioxide, sulfur dioxide, polycyclic hydrocarbons, benzene, formaldehyde, and a vast array of particulate matter and compounds created through combustion, has long been known to be carcinogenic, especially posing a risk of lung and bladder cancer. A 2010 Canadian study found a positive link between automobile exhaust and breast cancer.

Lung cancer risk analyses have been difficult because of the number of different exposures faced by the same population and contributing similar risk—even apart from smoking and occupational exposure, it is difficult to sort out the different factors contributing to air pollution (traffic exhaust, air traffic, factory exhaust, wood and leaf burning, and other minor factors) and to divide cancer risks among them. That automobile exhaust contributes to cancer risk is certain; exactly how much is less clear. A 2014 study hinted at just how much there is left to learn. Oregon State University (OSU) toxicology professor Staci Simonich’s team published an environmental science and technology report on the mutagenicity of various compounds that result from automobile exhaust and other forms of combustion. Almost every form of combustion generates polycyclic aromatic hydrocarbons (PAH); in the air, these PAHs, many of which are already carcinogenic, become nitrated as they interact with nitrogen, which can increase their mutagenicity by a factor from six to 467, according to the OSU study. These estimates imply that the toxicity of exhaust has actually been understated in the past. An earlier 2008 report published in Science News found that carcinogens’ interactions with nanoparticles could result in their lingering far longer than had previously been realized, making them as harmful as cigarette smoke.
Benzene is a known carcinogen and is strongly linked to leukemia and other cancers of blood cells, with possible links to multiple myeloma and non-Hodgkin’s lymphoma. Claims are made periodically by consumer safety and public health advocates—especially in less-formal and discerning settings like daytime talk shows—that dangerous levels of benzene are released from the plastic surfaces of automobile interiors, which can build up on warm days when the windows are closed in a parked car. The American Cancer Society’s investigation of these claims found that, although drivers and passengers of some moving cars may be exposed to benzene levels that exceed the chronic exposure recommendations for workplaces, this is the result of a poorly maintained car rather than the default condition of every automobile. Most benzene exposure, other than by factory workers, actually comes from cigarette smoke, whether first- or secondhand.

However, some automobile-related activities do involve benzene exposure—gasoline, for instance, contains benzene (as does automobile exhaust), and pumping gas at a gas station without vapor recovery systems to limit fume exposure will expose the customer to some amount of benzene. Modern gasoline pumps and intakes are fairly efficient at limiting drips and fumes.

Many automobile parts, including the brakes, hood liners, gaskets, clutches, and heat seals are used to contain asbestos due to their heat-insulating abilities. While less common today, asbestos linings are still used in some models and in aftermarket parts. Ordinarily the asbestos exposure to the passenger as a result is negligible; mechanics, on the other hand, and those in repair shops may well be exposed to considerable asbestos dust, especially as a result of cleaning out brake surfaces. Automobile repair shops tend to be poorly ventilated, and asbestos particles can accumulate over time. One study by the Seattle Post-Intelligencer in 10 cities has found that one in 10 mechanics is at risk for developing asbestos-related cancer, that many repair shops contain dust that exceeds by as much as 60 times the level of asbestos at which the Environmental Protection Agency (EPA) recommends the use of respirators, and that two-thirds of brake jobs involve dangerous asbestos exposure for the mechanic.

In 2005, an asbestos compensation fund was proposed by a bipartisan group of senators, in part for automobile workers and mechanics who had developed mesothelioma as a result of asbestos exposure. It was endorsed by the United Auto Workers, but the relevant bills died in committee.

Hybrid vehicles offer many advantages, including reduced emissions of carcinogens resulting from the burning of fossil fuels. However, they also have raised new health concerns, most of which are equally applicable to fully electric cars. For instance, the flow of electrical current to the motor produces magnetic fields. While the link is not clearly established, some studies suggest prolonged exposure to magnetic fields—such as over the course of a commute or a road trip as opposed to the brief exposure from using a hair dryer or electric razor—is linked to several health concerns, including a heightened leukemia risk for children. Because of the construction of the car, in which the batteries and power cables are close to both the driver and the passengers, this risk is faced whether one is driving the car or not. Both the National Institutes of Health and the National Cancer Institute have expressed concerns about magnetic field exposure in the past, notably in multiple studies of the cancer risks associated with living near high-voltage power lines and the use of electric blankets. Unlike chemical exposure, however, there is no federal or industry standard defining acceptable exposure levels.

Azerbaijan

The Republic of Azerbaijan is located in the Caucasus region, which is situated at the crossroads
of western Asia and eastern Europe. The country has an ancient and historic cultural heritage and is known to be one of the first Muslim-majority countries to host theaters. Until October 1991, when the country proclaimed its independence, Azerbaijan was a part of the Soviet Union.

Though Azerbaijan claimed its independence at this time, its health care system still bears many of the same key elements as the Soviet model, the Semashiko system. Some reforms have been put in place, but changes have been slow and incremental.

Unfortunately, the government of Azerbaijan does not invest much capital in its health care system, and in 2007, out-of-pocket payments accounted for more than 60 percent of total health expenditures. This leads to financial barriers and burdens for many of the country's citizens. The private health care system is growing in the country, and parallel services provided by other state enterprises and ministries continue to count for a large portion of health care in Azerbaijan.

Recently, due to a boom in the oil industry, the government has invested in projects such as the building of new hospitals with the latest technologies and equipment. Future plans for health care in the country include introducing mandatory health insurance and strengthening primary care.

The number of cancer cases increased by 6 percent from 2009 to 2010, as reported by the cabinet of ministers, revealing a frightening trend that shows an increase of the disease over the next several years. In 2010, more than 8,000 tumors were discovered in the population of Azerbaijan. Cancer deaths were around 5,000 the same year. According to the U.S. National Cancer Institute, in 2012 an estimated 42.7 percent of patients with newly diagnosed cancer in Azerbaijan required surgery (5,609 patients), 71.1 percent required chemotherapy (9,333 patients), and 56.0 percent required radiation therapy (7,346 patients).

**Cancer Incidence and Mortality**

According to the International Agency for Research on Cancer, a specialized agency of the World Health Organization, the age-adjusted standardized incidence rate of all cancers except non-melanoma skin cancer in Azerbaijan in 2012 was estimated at 141.9 per 100,000 population, with a mortality rate of 93.2 per 100,000. The five most common types of cancer in Azerbaijan are breast cancer (incidence of 25.4 per 100,000, mortality of 8.6 per 100,000), stomach cancer (incidence of 13.0 per 100,000, mortality of 11.2 per 100,000), lung cancer (incidence of 11.5 per 100,000, mortality of 10.5 per 100,000), cervix uteri cancer (incidence of 9.8 per 100,000, mortality of 3.9 per 100,000), and prostate cancer (incidence of 8.5 per 100,000, mortality of 4.5 per 100,000). However, incidence and mortality, as well as the most common types of cancer, differed between men and women.

For men, overall cancer incidence (excluding non-melanoma skin cancer) was 165.8 per 100,000 population, and mortality was 118.7 per 100,000. The most common type of cancer was lung cancer (incidence of 20.2 per 100,000, mortality of 18.6 per 100,000), followed by stomach cancer (incidence of 18.2 per 100,000, mortality of 16.0 per 100,000), prostate cancer (incidence of 8.5 per 100,000, mortality of 4.5 per 100,000), brain and nervous system cancer (incidence of 7.8 per 100,000, mortality of 5.0 per 100,000), and colorectum cancer (incidence of 7.1 per 100,000, mortality of 4.3 per 100,000). A man had a 13.6 percent risk of dying from cancer before age 75.

For women, overall cancer incidence (excluding non-melanoma skin cancer) was 124.0 per 100,000 population, and mortality was 73.3 per 100,000. Breast cancer was the most common type, with an age-adjusted standardized incidence rate of 25.4 per 100,000, and a mortality rate of 8.6 per 100,000. Second most common was cervix uteri cancer (incidence of 9.8 per 100,000, mortality of 3.9 per 100,000), followed by stomach cancer (incidence of 8.8 per 100,000, mortality of 7.5 per 100,000), colorectum cancer (incidence of 6.4 per 100,000, mortality of 4.0 per 100,000), and lung cancer (incidence of 4.3 per 100,000, mortality of 3.9 per 100,000). A woman had an 8.1 percent risk of dying of cancer before age 75.

Epidermoid cancer is the most common histological type of skin cancer in all regions of Azerbaijan. The highest rate of epidermoid cancer, with 230 individuals (55.56 percent) was revealed in industrial regions and industrial cities such as Baku and Sumgait. The lowest rate of lung cancer was found in the country's mountain region, with 12 individuals (3.76 percent). Skin cancer was also most common in regions with more sunny days. Smoking and drinking alcohol increases the risk of epidermoid cancer, and almost half of the patients with lung cancer in the country use these substances. The highest morbidity (13.55 per 100,000 population)
and mortality (0.11) rates from lung cancer have been observed in the country’s industrial regions. Other endogenous and exogenous factors are also associated with the disease.

Environmental Effects
A recent environmental study done for the years 1980 to 2000 in Azerbaijan shows that residents in its industrial city of Sumgayit have an increased likelihood of developing cancer due to intense environmental and occupational pollution from industry.

Poisson regression analysis of age- and sex-specific data from these years shows an increased risk for selected cancers in Sumgayit when compared to the rest of the country, as measured by adjusted rate ratios (aRR [95 percent confidence interval, or CI]): lung 1.67 (1.44, 1.92), larynx 1.39 (1.04, 1.85), bladder 2.49 (1.93, 3.22), and all sites 1.51 (1.43, 1.58).

Sumgayit appears to suffer from an increased cancer burden, suspected underreporting, and poor data quality. These prevent accurate estimates of incidence or mortality rates, and estimates indicate that pollution may have an even larger impact on the population than statistics indicate.

Cancer Care
In 2012, the International Agency for Research on Cancer estimated that there were 13,916 new cases of cancer in Azerbaijan, and 8,947 cancer deaths. Both measures were higher for men (7,154 new cases, 4,983 deaths) than for women (6,762 new cases, 3,964 deaths). These estimates are much higher than those reported by official government statistics. For instance, in 2011, the Cabinet of Ministers of Azerbaijan reported that malignant tumors were covered in 8,119 people.

Cancer care for Azerbaijan patients starts with a visit to the oncological outpatient clinics in their hometowns. For an official diagnosis, a patient first applies to the District Oncology Dispensary, where he or she is examined and treated by specialists. Treatment and diagnoses are also available in the department of Onco-Hematology of Azerbaijan Medical University and at the country’s Scientific Oncology Center.

About half of cancer patients in the country consult their doctors for the first time when they are at Stage III or IV in the disease. Radical treatments for these patients often prove ineffective, and there is a distinct need for early diagnosis and prevention campaigns across the country.

Conclusion
Azerbaijan still has much work to do in terms of cancer care. Though some governmental programs have been put in place, there is a need for greater education and awareness surrounding cancer screenings and prevention. Because of the way that the country’s health care system is set up, these changes must be perpetuated by the government, and the country must take pains to branch out from its old Soviet model to address changing trends in cancer and the lifestyle factors that are associated with it. A formal cancer/cancer control plan must be established to ensure that quality of life is preserved for all citizens.

Bangladesh

Bangladesh, officially named the People’s Republic of Bangladesh, is a country located in south Asia. It is bordered by India and Burma and faces the Bay of Bengal to the south. Bangladesh is the eighth-most populous country in the world, with more than 160 million people.

Education and health levels remain relatively low across the country, though poverty levels have decreased slightly over the last few years. Most Bangladesh residents live on subsistence farming in rural villages, and village doctors with very little formal training compose 62 percent of the country’s health care practitioners. Formally trained providers are occupying a mere 4 percent of the total health workforce in the country. About 70 percent of residents consult only village doctors for their health care needs. This leads to an abundance of health problems, including issues from infectious diseases and water contamination. Common diseases include dengue, leptospirosis, tuberculosis, and malaria.

Bangladesh’s poor health conditions stem from the lack of professional medical training and services provision by the government. In 2009, the government spent only 3.35 percent of its gross domestic product (GDP) on health care, according to a World Bank report. There are reportedly four hospital beds per 10,000 citizens, and a large majority of citizens pay their health care bills as out-of-pocket expenditures. This problem is further exacerbated by the fact that 26 percent of Bangladesh’s dense population of 150 million people lives below the national poverty line of US $2 per day.

Cancer in Bangladesh

Cancer is an increasingly important cause of morbidity and death in Bangladesh. In 2012, there were 122,700 new cancer cases diagnosed in Bangladesh. According to the Bangladesh Bureau of Statistics, cancer is the sixth-leading cause of death. The International Agency for Research on Cancer has estimated cancer-related death rates in Bangladesh to be 7.5 percent in 2005. This number is expected to almost double to 13 percent in 2030. In Bangladesh, there are 17 radiotherapy centers in public and private sectors, only one of which is in a rural area. There are only 15 linear accelerators installed across the country, along with 12 cobalt-60 machines and 12 brachytherapy machines.

The two leading types of cancer in Bangladeshi males are oral and lung cancer, and the leading cancers for women and cervical and breast cancer. Currently, Bangladesh is in severe shortage of hospital beds, trained oncologists, radiation therapy machines, physicists and technologists.

Many Bangladeshi are affected by cancers caused by smoking and smokeless tobacco use. The human papillomavirus (HPV) infection is also a concern, as are hepatitis B and C infections, arsenic-contaminated
waters, chemical carcinogens in fruit, *H. pylori* infections, and chromium contamination.

**Antitobacco Campaigns**
According to the World Health Organization, the annual cost of illnesses in Bangladesh attributable to tobacco usage is $500 million, and the total annual benefit from the tobacco sector is $305 million as tax revenue. The National Institute of Cancer Research and Hospital (NICRH) and Bangabandhu Sheikh Mujib Medical University (BSMMU) cancer registry data revealed that 60 percent of the cancers in males and 5 percent of the cancers in females in Bangladesh are tobacco related and hence entirely avoidable. Because tobacco is major contributor to several types of cancer, Bangladesh has developed a National Cancer Control Strategy and Action Plan with the aim of delivering a universal, timely, and quality-based service. The campaign focuses on cancer prevention through tobacco control, promoting health and vaccination programs, and early breast, cervix, and oral cancer detection. Some efforts are being made to develop more cancer research throughout the country as well as create additional cancer detection and diagnostic facilities.

**Age-Related Cancer Statistics**
According to the BSMMU and NICRH, more than 66 percent of the cancers in Bangladesh occur in the age group of 30 to 65 years. About 20 to 25 percent of cancers in the country are diagnosed in a localized stage. Two-thirds of cases are diagnosed when the disease is regional. Disease with distant metastasis at the time of diagnosis is greater than 15 percent.

Childhood cancers in the country make up only 1 percent of the overall incidences, and cancer treatment for children has been considered successful over the past several years. Seventy percent of childhood cancers are curable, with the top five kinds of childhood cancer in the country being soft tissue sarcomas and renal tumors, lymphomas, leukemia, and central nervous tumors.

**National Institute of Cancer Research and Hospital**
The NICRH in Bangladesh is the only tertiary-level center of the country that works within multidisciplinary cancer patient management. The hospital was created in 1982 and moved to its present location in 1986. The hospital is currently composed of 300 hospital beds and is the most comprehensive cancer center in the country.

**Improving Cancer Care**
Currently, in Bangladesh, researchers are striving to build a model program to improve the care of women who have breast cancer and do not have the funds to care for themselves or their families. Researchers across Bangladesh have collaborated with *Amader Gram* (Our Village), a rural information technology organization to build four breast cancer clinics, one specialty treatment, and outpatient diagnostic center.

Radiation therapy is standard for many instances of breast cancer, and the organization’s next step is to create a radiation therapy center that will also provide education for patients and training for new oncologists. No facilities for this kind of treatment currently exist anywhere in the Khulna region of Bangladesh, and right now, there are 18 operational radiation therapy facilities throughout the country. Approximately 300 of these centers are needed.

The current proposal estimates for the next new center include a plan to offer radiation treatments for $125, compared with thousands of dollars in the United States. The total start-up costs for the center would be approximately $1.3 million.

In addition to financial issues, researchers are facing challenges in recruiting women for clinical trials. Many women in Bangladesh believe that they cannot act on their inclinations to seek help with their cancer because of their place in the family. Researchers are attempting to develop a team of social scientists to investigate the complex issues that may explain this behavior and to find solutions to address them. For now, the country’s first free walk-in breast care clinic has been developed. Women are attended by all female doctors, and serious issues are referred to doctors at Khulna Medical College.

**Conclusion**
The cancer burden in Bangladesh is worrisome, but there are some solutions being developed to treat additional patients in the country. To effectively treat this burden, the government must invest in cancer care; private institutions cannot address all of the health care issues in the country alone.

Barbara Ann Karmanos Cancer Institute

Detroit, Michigan, is a city that has endured many vicissitudes in recent years. Between the 2000 and 2010 census, the city suffered a 25 percent population decline and had declined 60 percent since the 1950 census. Between 2000 and 2010, the city’s ranking among the largest municipalities in the United States declined from 10th to 18th. The associated decline in economic status resulted in the city filing the largest municipal bankruptcy case in U.S. history in 2013.

The resultant judgment cited Detroit’s $18.5 billion debt and declared that negotiations with its thousands of creditors were unfeasible. The city has suffered from the blight of urban decay, with thousands of abandoned homes, apartment buildings, and commercial structures. Certain areas have become so sparsely populated that municipal services are sporadic or entirely unavailable. Rampant unemployment and high crime rates in many parts of the city have exacerbated the problems faced by this municipality. Yet with all of the troubles, bright spots remain. Three of these are located in midtown: Wayne State University, the Detroit Medical Center, and the Barbara Ann Karmanos Cancer Institute.

Located in Detroit's Midtown Cultural Center Historic District, Wayne State University (WSU) occupies 203 acres and more than 100 education and research buildings. Wayne State was founded in 1868 as the Detroit Medical College, now the School of Medicine. The university now provides more than 370 academic programs through 13 schools and colleges to approximately 28,000 students. Among the student body are more than 1,600 international students from 70 countries. WSU's comprehensive academic offerings are divided among their schools and colleges: the School of Business Administration; the College of Education; the College of Engineering; the College of Fine, Performing, and Communication Arts; the Graduate School; the Law School; the College of Liberal Arts and Sciences; the College of Library and Information Science; the School of Medicine; the College of Nursing; the Eugene Applebaum College of Pharmacy and Health Sciences; the Irvin D. Reid Honors College; and the School of Social Work. The institution is a leading contributor to the cultural life of Detroit.

The WSU School of Medicine is the nation's largest single campus medical school. The school enrolls more than 1,000 medical students in undergraduate medical education, master’s degrees, Ph.D.s, and M.D.–Ph.D. programs. Fourteen areas of basic science are taught along with graduate programs, including their M.D.–Ph.D. and 10 doctor of philosophy programs, eight master of science programs, and three certification programs. WSU School of Medicine is the academic affiliate of the Barbara Ann Karmanos Cancer Institute. The physicians at Karmanos are appointed as faculty members of the School of Medicine.

The Detroit Medical Center was established in 1985 as a union among several hospitals: Harper University Hospital, Grace Hospital, Hutzel Women's Hospital, and Children's Hospital of Michigan. It is a hospital with more than 2,000 beds, 3,000 affiliated physicians, and more than 12,000 employees. As such, it is the largest single employer in Detroit. The center is affiliated with the medical schools of WSU and Michigan State University. The center operates eight general and specialty hospitals in southeast Michigan. The Barbara Ann Karmanos Cancer Institute is closely affiliated with the Detroit Medical Center but operates as a separate not-for-profit entity.

The Karmanos Institute began in 1943 as the Detroit Institute for Cancer Research. Later, it became the Michigan Cancer Foundation, which included the Meyer L. Prentis Comprehensive Cancer Center of Metropolitan Detroit and the
cancer programs of the Detroit Medical Center and WSU. In 1995, the institute was named after Barbara Ann Karmanos, the late wife of Peter Karmanos Jr., chairman and chief executive officer of Compuware Corporation. Barbara Ann Karmanos died of breast cancer at the age of 46, after an eight-year battle with that malignancy. The institute is one of 41 National Cancer Institute-designated comprehensive cancer centers in the United States with 1,200 staff members, including 300 physicians. Approximately 12,000 patients are treated each year. In addition, 700 cancer-related scientific investigations and clinical trials are conducted each year.

The lofty stated mission of the Karmanos Cancer Institute is the ultimate prevention and cure of cancer. To this end, its programs are directed toward the prevention, early detection, or treatment of malignancy. The institute primarily is based upon laboratory, clinical, and population research. This research is centered upon five programs:

The Breast Cancer Biology Program is dedicated to the study of breast cancer progression, mechanisms of tumor growth and control, the genetic aberrations of the disease, possible dietary prevention, and the improvement of therapy. The Developmental Therapeutics Program focuses on a better understanding of drug pathways and finding ways to improve the prediction of response, including a strong medical imaging initiative. The Molecular Biology and Genetics Program concentrates on mechanisms of genomic instability, encompassing studies of chromatin structure, cell cycle checkpoint control, transcriptional regulation of signal transduction, and posttranslational control mechanisms.

The Proteases and Cancer Program is directed toward determining the functions of proteolytic enzymes in malignant cancer progression. The Population Studies and Prevention Research Program has as a goal to increase the understanding of the causes of cancer in the diverse population of metropolitan Detroit. This is an effort to decrease racial and ethnic disparities. Key features of this program include measurement of cancer incidence, morbidity, survival, and mortality in this population. Measurements also include assessment of genetic predisposition, environmental and behavioral risk factors, screening practices, and quality of care. The center’s Metropolitan Detroit Cancer Surveillance System was a founding participant in the NCI’s national Surveillance, Epidemiology and End Results (SEER) program. This system facilitates investigations into race-related disparities in cancer incidence and survival.

While an important objective of the Karmanos Institute is clinical programs with community outreach activities to local populations in Detroit, the center is directed toward not only patient care but research. More than 300 clinical trials of modalities to improve cancer treatment and cure are ongoing, including one of the country’s leading phase I trial programs of new treatments for the scourge of malignancy. Research as always is the foundation upon which the future of cancer treatment is based.

Battery Acid

Battery acid, commonly known by its scientific name sulfuric acid, poses little if any risk of cancer to people who use batteries in their cars and appliances. In other words, people can buy, install, and change batteries, including car batteries, in relative safety. The risk of cancer is greater for people who work in production facilities where battery acid is used and may form mists that can be inhaled. Intensive and long-term exposure to such mists has been linked to lung cancer and gastric cancer but
more conclusively to laryngeal cancer. Those at risk include workers in the production of lead acid batteries; metals, especially steel; soap; and phosphate fertilizers. Studies in small mammals suggest a correlation between cancer and sulfuric acid exposure; however, studies in humans are less conclusive because of the difficulty in screening for lifestyle behaviors that also result in cancer. Sulfuric acid can also contaminate water.

Battery acid is not a recent discovery. It was referred to by the ancients as *vitriol*. A Sumerian text dating back to 600 B.C.E. refers to a substance that is likely to be battery acid and categorizes the substance by color. Dioscorides, a Greek medical doctor of the 1st century C.E., referred to vitriol production in Cyprus in the neighborhood of copper ore deposits.

Battery acid is a highly corrosive liquid mineral. It is an active ingredient not only in batteries but also in drain cleaners and other cleaning agents. It is the active ingredient in Debacterol, an ointment used to treat mouth sores or cankers. This acid is also used in the production of illegal narcotics and psychotropic drugs.

As a consequence, it is listed in Table II of the United Nation's Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances. In the United States, the Drug Enforcement Administration controls the sale, import, export, and transportation of battery acid.

Battery acid is generally colorless or a very pale yellow. Like any acid, it can quickly destroy many substances with which it comes in direct contact. The greatest health and safety hazard associated with battery acid occurs when it comes in direct contact with the skin, in which case it can lead to severe burns. If direct contact occurs with the eyes, blindness is the worst possible outcome. There is no known correlation, however, between such burns and the development of cancer.

Battery acid can become airborne in industries where it is used. It poses the greatest risk of cancer when it forms a mist that can remain suspended in air for varying amounts of time. In the present day, the people most often exposed to dangerous quantities of battery acid usually work in the lead acid battery production industry, though people are also exposed to sulfuric acid if they work in phosphate fertilizer production, metal pickling, glue production, explosives production, petroleum purification, printing, photography, production of other acids, and soap manufacture. Sulfuric acid has been linked to lung and gastric cancer, but the greatest risk from exposure to battery acid is the development of laryngeal cancer, that is, cancer of the voice box. Treatment for such cancer, if it is detected early, is usually successful. However, the overall outlook for patients with this type of cancer is a 62 percent chance of survival over 10 years.

Several studies of workers in lead acid battery production plants have been conducted with mixed results. A higher-than-average mortality was found in the workers, but causes of death included hypertension (high blood pressure) and nephritis (kidney disease). Deaths associated with lung and gastric cancer among the battery plant workers was 5 percent higher than normal in one study, but the same study concluded that such increased risk was not statistically significant. Studies of battery plant workers have been flawed because the studies could not factor out other causes of cancer such as smoking, diet, and alcohol consumption. Five studies conducted in the late 1980s among deceased steel workers exposed to battery acid more conclusively point to an increased risk of laryngeal cancer. These studies screened for smoking and alcohol consumption and found that the incidence of laryngeal cancer in the studied workers was higher than that in the larger population. One study in particular observed that the occurrence of laryngeal cancer in a group of 879 U.S. steelworkers was more than two times higher than expected. It is worth noting that the use of battery acid in the three plants in the study was phased out by 1980.

A similar study was conducted among workers in a large chemical plant and refinery in Baton Rouge, Louisiana. Fifty workers who contracted upper respiratory cancer were the subject of study. Thirty-four of them had cancer of the larynx. They were compared to three control groups who were like the first group in age, gender, and race. The study suggests that the chemical plant and refinery workers were four times more likely to contract upper respiratory cancer.

On the basis of these studies, the International Agency for Research on Cancer (IARC) determined that battery acid (sulfuric acid) is a known human carcinogen. The World Health Organization, too, has pronounced that there is sufficient evidence that prolonged exposure to sulfuric acid is carcinogenic.
However, in the United Kingdom, the Industrial Injuries Advisory Council concluded that the cancer risks associated with exposure to battery acid would not make people eligible for the Industrial Injuries Disablement Benefit. The council made this decision after looking at several studies of cancer risks among workers exposed to battery acid.

The U.S. Environmental Protection Agency limits the amount of sulfuric acid that can be legally released into the air. The Occupational Safety and Health Administration and the National Institute of Occupational Safety and Health have limited the amount of battery acid that can be released legally within the workplace to one milligram per cubic meter of air. Individual states in the United States have the authority to enact further protections for people who live near facilities using battery acid. For example, in California, the Toxic Hot Spots Program (AB2588) mandates that businesses that produce toxic air pollutants perform assessments to measure health risks. If the calculated risk of cancer is 10 in 1 million or more, the business must inform the community of the risk. The link between battery acid and lung cancer is more tenuous than the link to laryngeal cancer. One study, published in 1987, looked at 1,165 workers in the metal picking industry. As in the aforementioned studies, the workers were exposed to aerosolized chemicals including battery acid. The study concluded that these workers were approximately a third more likely to develop lung cancer than people not working in metals. However, the same study found other acid mists, especially hydrochloric acid, to represent a greater cancer risk than battery acid. Another study found a significant increase in death among pensioners who were former employees of four lead acid battery factories from 1925 to 1976. But the most of those deaths were found to be caused by cerebrovascular accidents, not from cancer. The risk of developing cancer caused by battery acid for people not working in industries that employ it is minimal, though battery (sulfuric) acid can be released into the atmosphere by burning coal, oil, or gas. Children may be at an elevated risk because of their smaller airways and the fact that they inhale more air per body kilogram than adults.
How airborne battery acid causes cancer is unknown. It may irritate epithelial cells—the cells found in glands and skin—or it may lower the body’s pH, that is, the body’s natural acids, causing acidosis and leading to gene mutation and chromosome aberration. Currently, no medical test exists to discover whether someone has been exposed to battery acid. Inhalation of battery acid mist can be extremely toxic. Someone who has inhaled a substantial quantity of such mist should be removed from the environment where the threat is posed and exposed to fresh air. If the patient’s breathing is difficult, he or she should be given oxygen.

A poison center should be consulted, and the patient should go to a hospital. To minimize the cancer risks and other health risks of people working with batteries, the work environment should be well ventilated with a corrosion-resistant exhaust ventilation system. Process enclosure should be implemented to prevent escape of acid mists into the workplace. Those workers who work directly with the acid should wear chemical safety goggles and face shields as well as protective clothing made from butyl rubber. Depending on the level of their exposure, they may need to use air-purifying respirators. Battery acid in the workplace has to be carefully stored in a container that will not deteriorate over time from contact with the acid. Glass, for instance, is nonreactive with battery acid and makes a suitable storage container.

People who use batteries domestically should exercise common sense in handling them. If a battery’s seal is breached, the acid can leak out, in which case the battery should be handled with gloves and immediately discarded. Dead batteries should be deposited at an appropriate recycling facility, not placed in landfills. Improperly discarded batteries can contaminate the soil, though such contamination results more from the release of lead into the soil than from the release of acid. Improperly discarded batteries can also leak acid into waterways. This happens most frequently when batteries are disposed of improperly in landfills. If the landfill is unlined or if the lining has ruptured, the acid from a battery can find its way directly into the groundwater and endanger the quality of drinking water.

Battery acid is commonly referred to by its scientific name, sulfuric acid. Historically, it was called oil of vitriol. It also goes by the names vitriol brown oil, mattling acid, dipping acid, electrolyte acid, dihydrogen sulfate, and hydrogen sulfate.

Further Readings

Belarus
The Republic of Belarus is a landlocked country in eastern Europe that is bordered by Poland, Russia, the Ukraine, Lithuania, and Latvia. Since the country’s independence in 1991, the organizational structure of Belarus has remained relatively the same. Regulated by the state, the health care system is primarily public, with about 7 percent of medical services being provided by the private health sector. The government strives to create conditions so that everyone has a right to health on the basis of state guarantees.

Of special consideration to the government are maternity and childhood protection services. Free medical care is offered during and after childbirth, and observation of newborns is guaranteed to all pregnant women. In Belarus, 100 percent of births are attended by skilled health professionals. This has led to a large decrease in the country’s infant mortality rate and an increase in life expectancy at birth.
In relation to cancer, programs to develop early detection of precancer diseases for the female reproductive system in patients with hormone-dependent neoplasms have been developed. Treatment methods of patients with cancer of the liver have been developed. These involve chemoembolization of the hepatic artery. Treatment for patients with superficial cancer of the urinary bladder and patients with mesothelioma of pleura of I through IIIA stage without remote metastases and local cervical carcinoma have also been developed.

**The Chernobyl Catastrophe**

The Chernobyl disaster, or Chernobyl accident, was a catastrophic nuclear accident that occurred in April of 1986 at the Chernobyl Nuclear Power Plant in Ukraine, under the authority of the Soviet Union. Deemed the worst nuclear power plant disaster in history, the explosion and fire released huge quantities of radioactive particles into the air, spreading all over the western Union of Soviet Socialist Republics and Europe.

Unfortunately, all of this radioactive matter led to a large increase in cancer incidences—about a 40 percent increase in all cancers across the country overall. Increases in cancer are apparent in all regions, with the highest concentration being apparent in the Minsk (49 percent increase) and Gomel (52 percent increase) regions. The 40 percent estimate shows this increase between the years in 1990 and 2000, with findings by the *Swiss Medical Weekly*. Today, it is expected that those rates are even higher.

Some governmental agencies (such as a United Nations committee in the year 2000) have stated that there is no evidence of a major public health impact related to the Chernobyl catastrophe, apart from the increase in thyroid cancers for children following exposure. This comment predominately focused on the disease leukemia and nonmalignant disorders, along with the statement saying that these radiation levels would be comparable or a few times higher than the country’s natural background levels. These results have been proven inaccurate in the years since.

**Thyroid Cancer**

Thyroid cancer is one cancer type that has been well researched by various groups and studies. One such study invested age-adjusted thyroid cancer incidence rates (adjusted to the World Health Organization [WHO] 2000 world population) and showed that they have increased between 1970 and 2001 from 0.4 per 100,000 to 3.5 per 100,000 among males and from 0.8 per 100,000 to 16.2 per 100,000 among females in the country. These estimates mark an increase of more than 700 percent and 1900 percent, respectively. High exposure areas showed an increase of 1,020 in males and 3,286 in females, quite a large difference between increases in lower-exposure areas of Belarus, with a 571 percent increase in males and 250 percent increase in females in these areas. Increases in thyroid cancer are noted among both females and males in all age groups. The highest ratios are shown among those from higher exposure areas age 0 to 14 at the time of diagnosis. The greatest increases have been shown among children across the board. This suggests that a high prevalence of preexisting iodine deficiency in combination with unique susceptibility among younger people might have contributed to potential carcinogenic exposures to the thyroid.

In comparison to areas of Ukraine and other regions of the Russian Federation, there have been many more incidences of childhood thyroid cancers in Belarus. At the time of the accident, many children were heavily contaminated by iodine isotopes. This peaked in the year 1996, while the peak of incidence in the Russian Federation Region was highest in 1998, at 12.6 cases per 100,000 residents.

In sum, on the whole, observations in the Chernobyl childhood thyroid cancer series show that the majority of patients live proximally to the Chernobyl power plant. The highest risk for thyroid cancer has been found in patients 0 to 4 years old at the time of exposure. Papillary thyroid carcinoma was the prevalent pathological type (94 to 98 percent), and most patients have an advanced stage of disease when their conditions are discovered.

**Kidney Cancer**

Kidney cancer is the 12th-most common cancer in the world and the 11th-most common cancer in Belarus. The most common type of kidney cancer is renal parenchyma cancer, which makes up 80 to 90 percent of cases. Smoking is a major cause for kidney cancer, as is dialysis, which occurs through the development of acquired renal cystic disease. Body fat and alcohol can also be factors for kidney
cancer. Many of these cases could be prevented with prevention campaigns throughout Belarus.

Belarus Cancer Treatment
Despite its own cancer troubles, Belarus is known for providing health care services to foreigners due to its excellent resources and the number of specialists. The following treatment methods are available in the country: transplantation of hematopoietic stem cells, photodynamic therapy of patients with cervical dysplasia, and thermo-chemotherapy for patients with advanced lung cancer.

The Children's Oncology and Hematology National Center has an excellent reputation for treating malignant tumors: The efficiency of treatment of lymphoblastic leukemia is 75 percent, and of Hodgkin's lymphoma is more than 90 percent. Medical tourism is becoming increasingly popular in Belarus. Foreign tourists can combine recreational travel with excellent health care. Further adding to its appeal, Belarus is centrally located in Europe and has a well-developed mass transit system. Its mild climate also promotes faster rehabilitation. In 2012, 130,000 foreigners received cancer treatment in Belarus.

Further Readings

Belgium
Belgium, or the Kingdom of Belgium, officially, is a federal monarchy in western Europe that plays host to the European Union. Belgium has a population of about 11 million people. Health care in Belgium is provided by a mixture of nonprofit and public hospitals.

Seventeen percent of the Belgian population is 65 or older, and about 5 percent is 80 or older. Life expectancy continues to increase, meaning the elderly population is expected to increase threefold by the year 2060.

Cancer in Belgium: The Stats
In terms of cancer, in 2008, 59,043 new invasive tumors were discovered in Belgians, with 54 percent of these found in males and 46 percent in females. The mean age at diagnosis was 67 and 65, respectively. In 2008, 26,647 Belgians died from cancer, composed of more males (57 percent) than females (43 percent). Five-year relative survival for all tumors diagnosed between 2004 and 2008 shows a poorer outcome in males than in females (59.5 percent vs. 67.8 percent). This female survival advantage reflects the fact that, for most cancers, females have a better prognosis than males, and males tend to be afflicted by cancers with worse prognoses.

In both genders, survival rate is largely rated to the age at diagnosis, with a younger diagnosis improving the chances of survival. In males, five-year relative survival is 67.6 percent for patients age 15 to 29 and 57.4 percent for patients 65 years and older. In females, the numbers are even more pronounced, with five-year relative survival rates at 84.4 percent for females age 15 to 49 and only 57.3 percent for those who are 65 and older. The almost equal prognosis for both sexes in seniors suggests that female survival benefits disappear at older ages, possibly due to the fact that sex-hormone patterns have a role in women's superior ability to cope with cancer.
Belgium

The Belgian Cancer Registry Foundation
Many of the statistics in this piece can be attributed to the Belgian Cancer Registry Foundation, which collects data on all new cancer diagnoses in the country and how they are followed up to accurately represent the burden of cancer in the country. The most recent data are to be found in Cancer Incidence in Belgium 2008. In addition, the Belgian Cancer Registry also collects all anatomic pathological test results for the purposes of early detection of particular cancers (colon, cervical, and breast).

To aid in the prevention and treatment of cervical cancer, a central cytohistopathological registry for cervical samples (CERVIBASE) is currently being created on the organization’s Web site. This registry collects patients’ comprehensive data to enable the compilation of records.

Colorectal Cancer
In Belgium, colorectal cancer is the third-most frequent cancer in males and the second-most frequent in females. The disease also ranks as the second-most frequent cause of death by cancer in males and the third in females in Belgium.

Colorectal cancer predominately affects males and occurs most commonly in patients age 65 and older. Given the aging of the population, colorectal cancer is expected to remain an important health issue for Belgium in the coming years. This fact is reinforced by the increasing incidence rates of colorectal cancer for both males and females over the last 10 years in the Flemish region. When diagnosed early, colorectal cancers have a high survival rate (above 90 percent when diagnosed during stage I), so education surrounding this cancer is a necessity for Belgium.

Corpus Uteri Cancer
Corpus uteri cancer is the fourth-most frequent tumor in females and the most frequent gynecological cancer across Belgium, with a mean diagnosis age at 68 years old. It is also the gynecological cancer with the best prognosis, with a one-year relative survival rate above 92 percent and the five-year relative survival rate at 79.6 percent. Relative survival rates are marginally better in the Flemish and the Walloon regions (five-year survival rate: 80.1 percent and 79.5 percent, respectively) than in the capital of Brussels.

Breast Cancer
In Belgium, breast cancer is the most frequent cancer in females (around 35 percent of all cancer cases), and it occurs at a mean age of 62 years. Breast cancer also causes the most cancer death in Belgium females, at more than 20 percent. Males have a very low chance of having breast cancer in Belgium—around 0.2 percent—and death is very uncommon.

Breast cancer has a relatively good prognosis, with five-year relative survival rates of 88.0 percent in females and 78.2 percent in Belgian males, according to studies done between 2004 and 2008. Due to late relapses and their related deaths, 10-year survival decreases by about 10 points for both males and females.

Five-year relative survival rates for breast cancer in females show no difference among the three Belgian regions. There is a markedly poorer survival rate for those age 70 and older.

In 2004, breast cancer incidences for Belgium amounted to 110 per 100,000 person-years for all ages and 172, 390, and 345 per 100,000 person-years for those age 35 to 49, 50 to 69, and 70 and over, respectively. Mortality rates for breast cancer increased until the late 1980s and afterward decreased in all Belgian regions for those less than 70 years old.

The burden of breast cancer in Belgium is very high. In 2004, Belgium women ranked first in Europe for all ages combined and in the 35 to 49 and 50 to 69 age groups; however, survival rates are favorable. Mammogram screenings should continue to be encouraged across the country.

Lung Cancer
Around 1.6 million new cases of lung cancer were diagnosed across the world in the year 2008, making it the most common type of cancer in the world. Due to its high mortality rate, it is also the most frequent cause of death by cancer.

Tobacco smoking is well-known as the most important cause of lung cancer, and though the incidence rate for this type of cancer is decreasing in males in Belgium and across the world, it is rising steeply in females.

In Belgium, this cancer is the second-most frequent type of cancer in males and the third-most frequent in females. It is also the leading cause of cancer deaths in males and second in females.
More than half of lung cancer patients die within the first year.

Benin

The Republic of Benin (shortened to Benin) is a country in west Africa that is bordered by Togo to the west, Burkina Faso and Niger to the north, and Nigeria to the east. A large portion of the Benin population lives on its small southern coastline on the Bight of Benin.

In Benin, most serious epidemic diseases have been brought under control through the spread of mobile health units, but there are still many major health issues facing the country. The government of Benin has set goals of upgrading the quality of referrals, expanding its health care system overall, improving care in the public sector and promoting private sector care.

The five most common cancers in Benin are gynecological (including cervix uteri, ovary, and corpus uteri), breast, liver, urological (including bladder, testis, prostate, and kidney), and hematological malignancies (including Hodgkin’s lymphoma, leukemia, non-Hodgkin’s lymphoma, and multiple myeloma).

Breast Cancer
Breast cancer is one of the leading causes of death for women around the world and the principal cause of deaths from cancer. African women, in particular, in comparison with their low incidence of cancer, bear a disproportionately high cancer mortality rate.

It has been estimated that, by the year 2020, approximately 70 percent of new cancer cases will occur among individuals in developing countries and among groups that have previously experienced only low incidences of the disease, with a large fraction of these incidences being breast cancer related.

According to the latest World Health Organization (WHO) data published in April 2011, breast cancer deaths in Benin reached 449 individuals this year, or 0.55 percent of total deaths for the country. The age-adjusted death rate for Benin women with breast cancer is 18.41 per 100,000 individuals, ranking it number 71 in the world in terms of breast cancer. However, as this does not seem like a large percentage, it is a real problem because of the previously mentioned high mortality rate.

Late breast cancer diagnosis is a real problem for African women, with about 70 to 90 percent of cases being diagnosed in late stages and often leading to death that could have been prevented had the disease been recognized sooner.

Breast cancer awareness and attitude are common denominators to several factors determining the stage at which patients with breast cancer arrive at the hospital for treatment. Many of these factors are related to women’s knowledge and beliefs about breast cancer and how to treat the disease. One important strategy in reducing breast cancer mortality in Benin and other parts of Africa is encouraging mammogram screening to achieve earlier detection of cancer. Early diagnosis leads to a greater survival rate and better management of the disease.

Prostate Cancer
According to the GLOBOCAN 2002 database, there are about 255 new cases of prostate cancer diagnosed in men in Benin each year. Though this number may not seem high, death rates from the disease are quite elevated. The estimated age-standardized rate of new cases per year is 19.3 per 100,000 in the country, and the number of deaths
each year is 210, making the estimated age-standardized number of deaths each year 16.0 per 100,000. Estimated one-year prevalence for the disease in Benin is 203, and the estimated five-year prevalence is 677.

Interestingly enough, there seems to be a decrease in incidences of prostate cancer for Benin men. In 2002, the estimated age-standardized incidence was 77 per 100,000, and the estimated age-standardized death rate in 2005 was 60 per 100,000. These increases may be due to greater education surrounding risk factors and early detection of the disease.

Challenges to Cancer Care in Benin
In addition to a lack of funds, Benin faces a number of issues in terms of cancer care. In Benin, cancer treatment capacity cannot meet demand. The same situation is true of many developing countries, and hundreds and thousands of cancer sufferers face a lack of accessibility for care.

For patients in Benin, the cancer treatment capacity cannot meet demand—a tragic reality that is repeated throughout the developing world where cancer has reached epidemic proportions. Hundreds of thousands of cancer sufferers in developing countries face an uncertain fate.

To help find a solution, the Beninese Health Ministry recently requested the International Atomic Energy Agency’s (IAEA’s) Program of Action for Cancer Therapy (PACT) conduct an imPACT review mission. This mission would review all current cancer information, including care, diagnosis, and early detection. The imPACT mission learned that, currently, Benin does not have specialized cancer treatment services or oncology doctors, meaning that many patients must be shipped abroad to receive proper treatment.

With approximately 8.66 million Benin residents and an estimated cancer incident rate of about 5,300 new cases in the year 2008, it is imperative that Benin get the cancer support it needs. Newly diagnosed cancer patients are in need of radiation, chemotherapy, and pathology.

In 2008, it was estimated that Benin is in need of at least seven surgical oncologists, 31 radiation oncologists, 13 pathologists, and several other specialists, amounting to about 45 cancer specialists needed for the country. For developing countries, the IAEA recommends training radiation and clinical oncologists who can prescribe both radiation and chemotherapy for common solid cancers instead of separate specialists for each segment.

To aid in the prevention, diagnosis, and treatment of cancer, Benin (along with other African countries) must put a reliable cancer registration system in place. Many countries do not have this, and the fear is that cancer incidences may be higher in Africa than is actually reported. There is a distinct need to assess accurately the total burden of cancer in each country and to correctly document mortality rates.

Conclusion
Like many other countries in Africa, Benin deals with a lack of funding, education, treatment centers, and prevention tactics surrounding cancer. Breast cancer, for example, can be identified in its early stages, greatly increasing the likelihood that the patient will survive the disease. However, because African women have little access to medical attention and screenings, they are often diagnosed in the late stages of the diseases, leading to high mortality rates. The same is true of several other types of cancer in the country not mentioned here, including lung cancer. The African government must take the threat of cancer seriously, or as studies have proved, incidences of the disease will continue to rise.

Bereavement Issues

The American Cancer Society estimated that 585,720 Americans were expected to die of cancer in 2014, almost 1,600 people per day. Cancer is the second-most common cause of death in the United States exceeded only by heart disease. For each person who dies of cancer, there are primary and secondary survivors—caregivers, family members, and friends who have felt a caring bond with the dying person. All survivors will experience a grief and bereavement experience that in many respects is unique based on the characteristics of the illness and treatments used to care for cancer patients.

Cancer Illness Trajectory

Cancer is characterized by uncontrolled cell growth and is usually classified according to the body organ or body system in which it occurs. Upon detection and depending on staging and other factors, treatments include surgery, radiation, and chemotherapy or some combination of these approaches. Alternative and experimental treatments abound, and many patients will opt for these approaches as well.

The impact of the cancer diagnosis is far-reaching and touches the patient’s functional life (the ability to work, be an active participant in family life, etc.) and emotional and spiritual life. Initially, in the midst of making serious decisions regarding treatment, the patient and those close to him or her are dealing with reactions and fears as they try to chart the best course of care. Once the needed medical decisions are made and a course of treatment decided, ongoing care for the patient must be addressed.

The physical side effects of treatment define the cancer experience and carry a strong emotional impact. Hair loss, extreme fatigue, and weight loss are common, especially with many of the chemotherapies. These symptoms often impact family, social, and work roles. It is not uncommon for issues of self-esteem and control to surface as the debilitating impact of treatment ensues.

The emotional swings of treatment must be noted as factors in the bereavement experience. Upon diagnosis, most patients and those close to him or her will experience both shock and hope, assuming the medical prognosis is favorable; that is, the cancer has been diagnosed at a stage that is responsive to intervention. Assuming treatment is successful, the patient and those close to him or her will ultimately move on and are able to put the illness experience in perspective although never without anguish about the potential for recurrence. For those less fortunate, for those for whom the treatment is not successful, the dashing of the initial optimism about the success of treatment is crushing.

The emotional distress can be intense if more surgery is needed or if more chemotherapy or radiation is required. This often can be an emotional turning point as initial optimism about cure or a return to normal life is dispelled. As treatments extend and the patient becomes more debilitated, optimism fades, and the patient may become more emotionally and physically compromised; all involved may have to accept the prospects of death and loss. It has been noted that families undergo a very stressful time when a family member is diagnosed as they must stand by during the period of the illness and intrusive and often harsh treatments followed by a period of terminal illness and death. Factors in a Cancer Death

At various junctures during the illness trajectory, family members may question the care of the patient as they question themselves and their role in the care—did they act quickly enough to get medical treatment for the patient, should they have gotten varied opinions regarding treatment, did they take the patient to the best cancer care centers or hospitals, were they loving enough as the patient’s condition worsened, could they have done more or done it better, were they patient and loving as the struggles mounted?

To complicate some situations, certain types of cancers, especially lung cancer, are often related to behaviors and their link to a cancer diagnosis. Many people believe that there is a cause-and-effect connection between behavior and cancer, that is,
smoking and lung cancer and diet and stomach cancers. This results in bereavement issues that can surely linger and provoke self-blame and anger toward the deceased in the bereaved person.

Cancer is often associated with mutilation of the body, such as that which occurs with mastectomy. Was the adaptation to the surgery handled lovingly, accepted by the caregiver in a way that eased the patient?

In addition, the unknown etiology of cancer has given rise to speculation about the causes of cancer with no clear-cut research that helps explain its cause. This ambiguity can extend bereavement as existential questions about life and how it should be lived abound.

Initially, people with cancer and their families hope for cure or as much quality time as possible; as the disease progresses and becomes terminal, hope is transformed into a statement about dying with dignity and without pain. Suffering due to pain can be one of the pivots complicating the bereavement experience. Was the patient in great pain, were surgeries especially debilitating, was there emotional turmoil and suffering beyond what one should have to endure? These questions may haunt the bereaved person for some time.

In sum, the unique aspects of cancer diagnosis and treatment create difficult and often protracted bereavement issues. In some cases, bereavement can be made even more complex depending on the precancer relationship between the griever and the deceased. In all cases, the demands of care for the cancer patient, the fluctuations of hope and periods of despair when treatment has not succeeded, and the potential for pain and mutilation of the body all combine to make the bereavement due to cancer death a complex experience. Loss of a loved one is never easy. In cancer deaths, bearing witness to extended decline and suffering can create a bereavement of deep anguish and questioning.

Beta-Carotene

Beta-carotene is a pigment that occurs naturally in many photosynthetic plants and organisms and is one of the most abundant carotenoids found in human blood. The richest dietary sources of beta-carotene are yellow, orange, and leafy green fruits and vegetables, such as carrots, spinach, sweet potatoes, and cantaloupe.

There are several mechanisms by which beta-carotene may be able to offer protection against cancer. Beta-carotene acts as a fat-soluble antioxidant to protect plants and animals against free radical-induced oxidative damage to DNA, lipids, and other molecules. Beta-carotene also serves as a precursor to vitamin A and represents the major dietary source of vitamin A for much of the world's population. Through vitamin A action, beta-carotene can exert effects on cellular proliferation and differentiation, immune function, and cell-to-cell communication. Epidemiological studies suggest that a higher dietary intake of carotenoids, including beta-carotene, may offer protection against the development of certain cancers (e.g., lung, prostate, cervix, bladder, gastrointestinal tract, and breast) as well as other health conditions linked to oxidative damage (e.g., heart disease, macular degeneration, and cataracts). However, two large, double-blind clinical trials have shown that supplementation with high doses of beta-carotene do not reduce the risk of lung cancer and may even increase that risk in smokers. These findings have led to an increased effort over the last decade to better understand the mechanisms behind the conversion of beta-carotene to vitamin A and the role of beta-carotene and its metabolites in the process of carcinogenesis.

Beta-Carotene and Cancer

Observational studies have consistently shown that high intakes of fruits and vegetables rich in carotenoids, including beta-carotene, are associated with a decreased risk of cancer at several sites.
A meta-analysis of case-control and prospective studies reported a significant inverse correlation between an increase in fruit intake of 100 grams per day and the risk of lung, bladder, stomach, colorectal, and head and neck cancers, with estimated odds ratios ranging from 0.53 for mouth and pharynx cancers to 0.93 for colon and rectum cancers. There is also a significant inverse correlation between an increase in vegetable intake of 100 grams per day and the risk of cancers of the breast, lung, stomach, colon and rectum, and esophagus. Estimated ratios range from 0.78 for stomach cancer to 0.89 for esophageal cancer. It appears that diets high in fruits and vegetables may offer significant protection against a variety of cancers, and these diets are known to be high in beta-carotene, lycopene, lutein, and other carotenoids. However, it is still unclear whether these carotenoids are conferring this protection or whether they simply are markers for consumption of fruits and vegetables that may contain other chemopreventive agents. Prospective studies provide weaker evidence for chemopreventive effects than do case-control studies, and results from clinical supplementation trials studying the effects of isolated carotenoids on the prevention of primary or secondary tumors have been much less convincing.

Dietary intakes of total vitamin A and beta-carotene, as well as circulating concentrations of beta-carotene, have been strongly and inversely associated with the risk of lung cancer. These relationships were the rationale behind the large, placebo-controlled clinical trials testing the effects of beta-carotene supplementation on lung cancer incidence in high-risk populations. In the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (ATBC), 29,133 Finnish male smokers age 50 to 69 were randomized into four groups who received either 20 milligrams beta-carotene per day, 50 milligrams alpha-tocopherol per day, a combination of 20 milligrams beta-carotene plus 50 milligrams alpha-tocopherol per day, or a placebo. After five to eight years of follow-up, groups receiving beta-carotene had an 18 percent higher incidence of lung cancer and an 8 percent higher rate of total mortality, while alpha-tocopherol supplementation had no effect on lung cancer. Beta-carotene had little or no effect on the incidence of cancer other than lung cancer. These unexpected results were substantiated when the results from the Beta-Carotene and Retinol Efficacy Trial (CARET) were reported.

In this study, 18,314 male and female smokers, former smokers, and asbestos-exposed workers were randomized to receive either 30 milligrams beta-carotene plus 25,000 international units (IU) retinol per day or a placebo. After four years of follow-up, the trial was stopped early when researchers reported the incidence of lung cancer in the treatment group was 28 percent higher, lung cancer mortality 46 percent higher, and total mortality 17 percent higher than the control group. While these studies did confirm an inverse relationship between baseline dietary and serum beta-carotene and the risk of lung cancer, they also reported a small but significant increase in the incidence of lung cancer in response to beta-carotene supplementation, with this adverse effect more likely to occur in smokers and in those reporting higher alcohol consumption.

A third large study, the Physician’s Health Study (PHS), examined supplementation of 22,071 U.S. male physicians age 40 to 84 with 50 milligrams
beta-carotene every other day. After approximately 12 years duration, this study reported no overall effect of beta-carotene supplementation on total cancer, overall mortality, lung cancer, or lung cancer mortality. Finally, the Women's Health Study (WHS) investigated supplementation with this same 50 milligram dose of beta-carotene on alternate days in 39,876 U.S. female health professionals age 45 and older. After two years of follow-up, there were no significant differences between treatment and placebo groups in overall incidence of cancer, site-specific cancer incidence, or total mortality.

**Study Contrasts**

Two clear differences between the PHS and WHS studies and the earlier ATBC and CARET trials were the serum beta-carotene levels reached in the treatment groups and the environmental exposures of the populations examined. Serum beta-carotene levels in the treatment groups of the ATBC and CARET studies reached 210 to 300 μg/dL, while serum levels in the PHS and WHS treatment groups averaged 120 μg/dL. For comparison, serum beta-carotene levels in the U.S. population generally range from 5 to 50 μg/dL. Second, ATBC researchers studied beta-carotene supplementation in smokers, and CARET researchers studied current and former smokers and asbestos-exposed workers, while the U.S. physicians in the PHS study consisted of only 11 percent current smokers and 39 percent former smokers, and the WHS population consisted of only 13 percent current smokers. Based on these results, beta-carotene supplementation is currently not recommended for the general population, and smokers are especially cautioned to avoid high-dose beta-carotene supplements. Rather, increasing consumption of food sources of beta-carotene and other carotenoids is recommended for reducing the risk of lung cancer in populations. On the other hand, the Linxian (Chinese) Cancer Prevention Study found that supplementation with beta-carotene, vitamin E, and selenium led to a 13 percent reduction in cancer incidence (particularly stomach cancer) and a 9 percent decrease in total mortality. This suggests that correction of preexisting nutrient deficiencies may be important in cancer prevention and that the right combinations of beta-carotene and other antioxidants, through a healthy diet or nutrient repletion efforts, may provide protection against cancer. In addition, recent studies have shown that carotenoids other than beta-carotene (beta-cryptoxanthin and lycopene) can contribute to protection against cancer.

Results from epidemiological studies investigating the intake of beta-carotene on breast cancer outcomes have been inconsistent, with some evidence suggesting that beta-carotene intake and serum beta-carotene may have a protective effect against the development of primary breast cancer and a positive effect on overall survival rate after a breast cancer diagnosis.

With relation to prostate cancer, a beneficial effect of beta-carotene supplementation was observed in a large clinical trial; however, observational epidemiological studies report everything from protection to null effects to a positive association between carotenoid intake and prostate cancer risk. Continued efforts attempt to determine the effectiveness of beta-carotene supplementation against prostate cancer and whether effects are dependent on the dose of beta-carotene administered. Carotenoid intake and serum carotenoid concentrations have been shown to be associated with a lower risk of colorectal cancer in many studies.

However, this effect did not reach statistical significance in two large studies, including a prospective study on fruit and vegetable intake and incidence of colorectal cancer and a case-control study of carotenoid intake and colon cancer risk, where lutein was the only carotenoid studied that was statistically associated with reduced risk of colon cancer. Studies specifically investigating beta-carotene supplementation on risk of adenomatous polyps and other biomarkers of colon cancer showed no significant beneficial effect of supplementation. Therefore, supplementation with beta-carotene is not currently recommended as a strategy to prevent primary or secondary colorectal cancer. Whether intake of other carotenoids or total fruit and vegetable intake can influence colon and rectum cancer risk remains to be seen.

Observational epidemiological studies have also shown inverse relationships between dietary carotenoids, dietary vegetables, and fruits and serum beta-carotene and incidence of cancers of the head and neck, esophagus, stomach, and skin. However, placebo-controlled studies have failed to show consistent protective effects of beta-carotene supplementation against these cancers. Epidemiological
studies suggest a beneficial role for consumption of diets high in carotenoids on the risk and progression of cervical cancer; however, supplemental beta-carotene has failed to show any effects on regression of cervical dysplasia. Results are mixed for studies investigating the role of carotenoids in ovarian cancer. Case-control studies suggest an association between dietary carotenoid intake and reduced risk of this cancer, with alpha-carotene, beta-carotene, and lycopene specifically implicated in these protective effects. While prospective studies have failed to show a significant relationship between dietary or serum carotenoids and risk of ovarian cancer, there is some evidence to suggest that carotenoid intake might be protective in certain subgroups, including adolescents and smokers. Supplementation with beta-carotene or other carotenoids has not yet been studied with relation to risk and progression of ovarian cancer.

**Beta-Carotene Metabolism**

Beta-carotene (C\textsubscript{40}H\textsubscript{56}) has a chemical structure characterized by a large carbon chain with alternating double and single bonds, terminated at each end by a ring structure. In addition to conferring antioxidant properties, these alternating double bonds, called conjugated double bonds, are susceptible to oxidative cleavage and isomerization from trans to cis forms. Cleavage of these double bonds in beta-carotene can result in the formation of potentially bioactive metabolites, including retinoids (vitamin A and its derivatives). While beta-carotene is probably the most well-known of the provitamin A carotenoids and results in the highest beta-carotene yield per molecule, other carotenoids with similar chemical structures can also give rise to vitamin A (e.g., alpha-carotene and beta-cryptoxanthin). In addition to the many functions of vitamin A in vision, reproduction, growth, and immune function, an active form of vitamin A called retinoic acid can serve as a ligand for nuclear retinoid receptors (retinoic acid receptors and retinoid X receptors), ligand-dependent transcription factors that are involved in control of gene expression and cellular differentiation. The molecular mode of action of beta-carotene against cancer can be explained, in part, by the transcriptional activation of genes with distinct antiproliferative activity and by induction of apoptosis by retinoic acid, eliminating cells with unreparable alterations in the genome or killing neoplastic cells.

Two pathways exist for conversion of provitamin A carotenoids to vitamin A, and they are known as the central cleavage pathway and the eccentric cleavage pathway. Central cleavage, or symmetric cleavage, is a major pathway leading to vitamin A formation. In this pathway, the enzyme carotene 15,15'-oxygenase cleaves carotenoids at their central 15,15'-double bond. An alternative pathway for carotenoid metabolism into vitamin A in mammals is the eccentric cleavage pathway, characterized by asymmetric cleavage of beta-carotene at a position outside its central double bond. Recent identification and biochemical characterization of carotene 9,10'-oxygenase demonstrates that this enzyme can catalyze the eccentric cleavage of both provitamin A carotenoids (beta-carotene) and non-provitamin A carotenoids (lycopene). Understanding the actions of carotenoid oxidative metabolites may yield insights into both physiological and pathophysiological processes in human health and disease, particularly the potential for beneficial effects of small quantities of beta-carotene and harmful effects of large quantities of beta-carotene metabolites.

The dosages of beta-carotene used in the ATBC and CARET studies were 20 to 30 milligrams per day for two to eight years, over tenfold higher than the average intake of beta-carotene in the typical American diet (2 to 5 milligrams per day). This pharmacological dose of beta-carotene in humans is believed to result in the accumulation of relatively high levels of beta-carotene and its oxidative eccentric cleavage metabolites in lung tissue, especially after long periods of supplementation. Studies in animal models of lung cancer suggest that beta-carotene is unstable in the free radical-rich environment of lungs exposed to cigarette smoke and that such an environment alters beta-carotene metabolism, increasing eccentric cleavage and producing undesirable eccentric cleavage metabolites. These metabolites have been shown to facilitate a number of changes associated with the carcinogenic process, including induction of carcinogen-activating enzymes, binding of carcinogen metabolites to DNA, interference with vitamin A metabolism, down-regulation of tumor-suppressor genes, upregulation of oncogenes, induction of oxidative stress, and enhanced induction of cell transformation by carcinogens. To better understand the beneficial and detrimental potential for
Beta-carotene in cancer prevention, research is now being conducted to elucidate the mechanistic basis for the bioactivity of carotenoid metabolites. Studies are examining dose effects and the combination of carotenoids with other antioxidants to determine what combinations provide optimal protection against cancer without increasing the formation of undesirable metabolic by-products in smokers and chronic alcohol consumers.

**Tobacco and Alcohol Consumption**

The observation in clinical trials that heavy smokers and drinkers were at an increased risk for lung cancer in response to high doses and high tissue concentrations of beta-carotene has led to an increased effort to understand the mechanisms underlying the relationship between carotenoids and cancer. Studies in animal models of lung cancer, particularly in the smoke-exposed ferret model, have confirmed detrimental effects of pharmacological (supplemental) doses and beneficial effects of physiological (dietary) levels of beta-carotene. Cigarette smoking is associated with substantially decreased plasma levels of beta-carotene despite only slightly lower dietary intakes of carotenoids in smokers compared to nonsmokers.

This suggests that lower levels of β-carotene among smokers may not be due to dietary differences alone. Studies have found that smoke exposure results in decreased cellular antioxidants (e.g., vitamin C and vitamin E) that normally serve to stabilize the reduced form of beta-carotene. The metabolites produced by excessive oxidative cleavage of the beta-carotene in the smoke-exposed lung can interfere with normal vitamin A action and regulation of cellular growth and proliferation. High-dose beta-carotene supplementation, while increasing tissue levels of beta-carotene, has been shown to result in lower levels of lung retinoic acid due to the induction of degradative enzymes (e.g., certain cytochrome P450 enzymes) in animal studies. Furthermore, animals receiving high-dose beta-carotene also show detrimental effects in biomarkers related to cellular proliferation and apoptosis, and these effects are accompanied by precancerous lung lesions when high-dose beta-carotene is combined with exposure to cigarette smoke. On the other hand, animals receiving low-dose beta-carotene, equivalent to the amount contained in five to nine servings of fruits and vegetables, had no evidence of precancerous lung lesions and no changes in molecular biomarkers associated with carcinogenesis, and this level of supplementation was associated with protection against smoke-induced changes in lung retinoic acid levels.

Alcohol also can have a detrimental effect on beta-carotene metabolism and vitamin A action. Interference with vitamin A nutritional status and metabolism is one of the major alterations caused by chronic alcohol intake, and daily consumption of alcohol is related to reduced beta-carotene levels independent of smoking status. Alcohol and vitamin A metabolism involve a similar two-step oxidation process, and these compounds share some of the same metabolic enzymes. Alcohol can interfere with vitamin A metabolism by competing for specific dehydrogenase enzymes, and the hepatotoxicity of alcohol consumption can be exacerbated by high beta-carotene intake.

Chronic and excessive alcohol consumption, especially when coupled with carotenoid oxidative metabolites, can induce the expression of cytochrome P enzymes. These enzymes activate procarcinogens present in alcoholic beverages, tobacco smoke, and diet, leading to increased formation of carcinogen-DNA adducts. The covalent modification of DNA bases by chemicals can alter the structure and biological processing of the DNA by cellular proteins governing replication, transcription, and repair. If not repaired or repaired incorrectly, these modifications may eventually lead to mutations and ultimately cancer, especially if the adduct is located in an oncogene or tumor suppressor gene. In addition, cytochrome P enzymes can break down vitamin A and lead to significantly decreased liver vitamin A stores.

**Antioxidant and Pro-Oxidant Activity**

Beta-carotene has been shown to be an effective antioxidant in vitro, and evidence suggests that this may be one mechanism behind its chemopreventive effects in vivo. Oxidative damage to DNA by free radical species is thought to be a major factor in the initiation and propagation of cancer, and beta-carotene has been shown to reduce DNA damage in vitro, often in combination with vitamins E and C or other carotenoids. However, the antioxidant role of beta-carotene in vivo is more difficult to characterize. Attempts to study this have been complicated by the methodological issues involved in designing
Beta-Carotene

a system to evaluate antioxidant efficiency in living systems. Therefore, while carotenoids have been shown to demonstrate antioxidant activity in certain animal models, beta-carotene from diet and food sources has yet to be clearly shown to act as in vivo antioxidant in human studies.

There exists some evidence that carotenoids might behave as pro-oxidants under certain circumstances. At very high oxygen tension, high concentrations of beta-carotene can have decreased antioxidant activity or possibly even pro-oxidant effects. Based on the evidence presented earlier from the large clinical trials of beta-carotene supplementation in people at increased risk of developing lung cancer, it appears that beta-carotene may act as a protective antioxidant against cancer at physiological levels but may lose its effectiveness or even exert pro-oxidant effects at pharmacological levels, especially in highly oxidative body compartments (e.g., the lungs of a smoker or the liver of a chronic alcohol drinker).

Epidemiological evidence suggests associations between high levels of dietary and circulating beta-carotene and a reduced risk of cancer at multiple sites. However, clinical trials have returned null findings or even evidence of harmful effects of beta-carotene supplementation in certain populations. Studies in animal models of lung cancer have provided possible mechanistic explanations for this discordance. Disruption in vitamin A metabolism and signaling may play a key role in the process of carcinogenesis, and the restoration of vitamin A homeostasis by treatment with beta-carotene could help to maintain normal cell proliferation and apoptosis and may be useful in the prevention and treatment of neoplastic transformations. However, there appear to be detrimental interactions among beta-carotene, cigarette smoke, and alcohol, and the molecular mechanisms that underlie these interactions need to be understood before beta-carotene can be further pursued in the prevention of carcinogenesis in humans.

Recent observations highlight the emerging role of beta-carotene and carotenoid cleavage in vertebrate metabolism and health. The almost ubiquitous expression of carotenoid cleavage enzymes indicates that many tissues may contribute to their own vitamin A homeostasis by endogenous retinoid formation. It appears that, while small quantities of beta-carotene can offer protection against certain cancers and chronic diseases related to free radical oxidation, larger amounts of beta-carotene metabolites may actually be harmful, especially when coupled with a highly oxidative environment, such as the lungs of a cigarette smoker or liver of an excessive alcohol drinker. Oxidative destruction of beta-carotene results in the formation of metabolites that may facilitate the carcinogenic process. Strong interactions among beta-carotene, vitamin E, and vitamin C, and the capability of these compounds to recycle each other, acting as an antioxidant network to regenerate efficient antioxidants from their radical cations, have led researchers to speculate about the potential utility of combined antioxidant therapy in vivo. It is possible that this additional protection against oxidative degradation may increase the utility of nutritional interventions targeting lung cancer in smoke-exposed models, surpassing effects seen in single-agent intervention studies.

The mechanisms behind the chemopreventive effects of carotenoids are not completely known. In addition to antioxidant activity, beta-carotene and other carotenoids may exert biological activity through stimulation of gap junction intercellular communication, induction of detoxifying enzymes, interaction with hormonal growth factors, and inhibition of cellular proliferation. As we await better scientific understanding of carotenoid metabolism and mechanisms of action, a prudent strategy to reduce the risk of cancer incidence and mortality would include increased consumption of vegetables and fruits as part of a healthy, balanced diet. Experts recommend eating between five to nine servings of fruits and vegetables every day.

Given that beta-carotene found in the diet is around six times less bioavailable than supplemental beta-carotene, there is currently no evidence of any dangers associated with high levels of dietary beta-carotene from natural food sources, aside from the occasional appearance of carotenodermia, an accumulation of beta-carotene in the skin that gives it a yellow or orange tint. At this time, supplemental doses of beta-carotene beyond the recommended dietary intake to meet vitamin A needs (700–900 μg retinol activity equivalents per day) are not advisable for the general population. Beta-carotene supplements seem to offer no protection against cancer, heart disease, or mortality in healthy populations of nonsmokers. Smokers and other populations with exposure to high levels of environmental oxidants, as well as those who drink more than one
alcoholic drink per day, are especially encouraged to avoid high doses of supplemental beta-carotene.

**Bicycles**

In its simplest form, a bicycle is a lightweight frame with two wheels designed to be propelled by pedaling. Credit for the invention is generally given to Baron von Drais, who invented a walking machine in 1817. The user straddled the wooden frame and rolled forward by pushing off with alternating feet against the ground. Obviously, several iterations were required before the modern bicycle assumed its final form.

Some have described the bicycle as the most efficient form of transportation ever devised. It is particularly well adapted to commuting short distances, and in many parts of the world, substantial numbers of people use bicycles as their primary means of everyday transportation. It is particularly when people choose to bicycle rather than to drive that the benefits of this alternative means of transportation become apparent from the medical standpoint.

**Potential Adverse Effects and Benefits**

There are, unfortunately, some potential adverse effects as well. One researcher mapped the distribution of ultraviolet exposure on various anatomic sites of cyclists during a seven-day bicycle ride in Australia. Substantial exposure of even vertically oriented areas such as the lower leg were documented. Thus cyclists, as any other participants in outdoor activities, may be at increased risk of developing skin cancers unless adequate precautions are taken. Another research team documented that individuals who cycled in traffic were exposed to increased levels of carbon monoxide, nitrous oxide, nitrogen dioxide, and ultrafine particles, all of which may have an adverse effect on health. And, the cyclist must observe safe cycling behavior to avoid accidental injury. However, the preponderance of evidence suggests that increased use of bicycles as alternative means of transportation (as opposed to motor vehicles) provides several advantages. First, the bicycle commuter automatically gets a certain amount of outdoor exercise every day that he or she chooses the bike over the automobile. Second, when large segments of the population choose alternative means of transportation, including bicycles, the levels of airborne pollutants may decrease, with attendant health benefits to the population. Similar benefits occur when individuals choose to walk or jog rather than use motor vehicles; however, because the bicycle is a more efficient means of covering moderate distances, most of the effort has concentrated on bicycling as an alternative.

**Benefits to the Cyclist and Community**

The most direct evidence for potential benefit to the individual comes from epidemiologic studies that demonstrate that increased physical activity and decreased obesity (both characteristic of the use of alternative transportation such as bicycling) are associated with decreased incidence of carcinoma. For example, a rapid increase in colon cancer incidence has been noted in Shanghai, China, over recent decades. Researchers examined the effects of physical activity (primarily commuting by alternative transportation) in a case-control study and noted that colon cancer risk was significantly reduced among subjects with high commuting
physical activity. In San Francisco, breast cancer risk was noted to be decreased in women with high lifetime levels of physical activities (including bicycling). Similar results were noted in studies from Finland and Norway.

The decreased risk of obesity associated with increased physical activity may account for some of these observations, and there is clear evidence for a link between obesity and increased risk of some malignancies. For example, the Nurses’ Health Study Research Group documented an association with increased metabolic equivalent (MET)-hours per week of physical activity and decreased risk of colon cancer and supported the concept that obesity was detrimental. Similar effects have been noted with non-Hodgkin’s lymphoma and breast cancer.

Recently, data have emerged suggesting that vitamin D may help to protect against cancer development. It is tempting to speculate that daily outdoor exercise (avoiding excessive sun exposure as already noted) might provide additional vitamin D; however, data to support this hypothesis are at present lacking.

When large percentages of a population use alternative means of transportation, congestion on roads is decreased, and airborne pollutants diminished. In 1999, the city of Vancouver did a study and found that individuals who chose to commute to work or school by bicycle did so on a daily basis.

A similar study in California found that the potential length of a commute did not appear to adversely affect the likelihood of opting to bicycle rather than drive. Other studies have shown that bicycle commuters in areas where networks of trails are available may travel as much as an average of seven miles in their commutes; clearly, this is a greater distance than most people would be willing to walk or jog, but it is a bikeable distance.

Communities can encourage the use of alternative means of transportation by developing networks of trails and providing information such as trail maps. Employers can provide bicycle racks and areas where employees can change clothes if necessary. Other strategies include urban planning, which clusters housing, employment, and stores within bikeable or walkable distances. Communities can also encourage cycling by providing bike-sharing programs. In recognition of the importance of these activities, May 18 has been designated Bike to Work Day.

The use of alternative means of transportation such as bicycles provides individuals with an easy way to obtain daily exercise. In addition, by decreasing reliance on internal combustion engines (cars), urban pollution and congestion may be decreased.

Bile Duct Cancer, Extrahepatic

Extrahepatic bile duct cancer is considered a rare form of cancer that creates malignant cells that settle in the ducts that are located outside the liver. However, there are more than 22,000 cases of cancer involving the liver and bile ducts reported every year. There are two different parts of the bile duct that are associated with the extrahepatic bile duct:

- Common hepatic duct, which is also referred to as the perihilar part of the extrahepatic duct
- Common bile duct, which is also referred to as the distal part of the extrahepatic duct

The common bile duct and the common hepatic duct are part of the major connections in the gastrointestinal tract, which include the liver, gallbladder, and small intestine. Part of the digestive process in the body, the liver is the reservoir for the bile. Bile is the liquid that is responsible for destructing fats during the digestive process. Bile moves through the extrahepatic duct to the gallbladder that houses the bile.

Risk Factors
Because the extrahepatic duct has a major involvement in the digestion process of the gastrointestinal tract, there are several risks that could predispose an individual to the possible development of extrahepatic bile duct cancer:

- History of colitis that affects the movement of bile through the ducts
- Primary sclerosing cholangitis, which involves the scarring of the bile ducts that can lead to the formation of cancer cells in the bile ducts
- Development of chronic ulcerative colitis, which causes a disturbance in the gastrointestinal tract that can weaken the bile ducts
- Formation of choledochal cysts, which are congenital deficiencies within the bile ducts that can cause the development of cysts to block the ducts
- Development of an infection that involves contracting a Chinese liver fluke parasite

Symptoms of Extrahepatic Bile Duct Cancer
Some of the symptoms or characteristics of extrahepatic bile duct cancer can mimic those that are associated with other diseases and conditions that affect the gastrointestinal tract. Because of these similarities with the symptoms, individuals should report these symptoms to medical professionals to ensure proper treatment is given. Possible symptoms of extrahepatic bile duct cancer include the following:

- Yellowing of the skin, also known as jaundice
- Chronic abdominal pain
- Fever
- Urticaria or intense itching of the skin—hives will appear on the skin with the intensity of the itching

Staging of Extrahepatic Bile Duct Cancer
Like with any type of cancer, extrahepatic bile duct cancer is classified in various stages. There are five different stages of extrahepatic cancer that deal with the early stages of the conditions to the hardest stage, where the cancer has spread to other parts of the body and requires more invasive treatment. In addition to the stages, there are different
subcategories that break further down how to stage extrahepatic bile duct cancer.

**Tests or Diagnostic Tools for Extrahepatic Bile Duct Cancer**

There are several tests or diagnostic tools that medical professionals use to diagnose and treat extrahepatic bile duct cancer. Most of the testing that is done for extrahepatic bile duct cancer is also used to test and treat for diseases and conditions that affect the liver and the rest of the gastrointestinal system. One examination includes getting a detailed history that pertains to the individual’s symptoms or characteristics of problems with the gastrointestinal process.

An ultrasound employs the use of intense energy waves that surround the organs and tissues to detect any abnormalities—once the test is completed, a sonogram is printed out to review for any problems or abnormalities. A medical professional may order a computed tomography (CT) scan or magnetic resonance imaging (MRI) that is able to highlight and identify any areas that could be affected by any diseases or conditions. A more detailed test such as a positron emission tomography (PET) scan is used widely to identify cancerous cells in the body; this test involves using glucose that can be picked up in the tissues in the body—more glucose will be absorbed in the areas where the cancerous cells are found.

A biopsy may be performed to extract suspect cells from the body through a fine needle aspiration (FNA)—diseased tissues and cells can be taken out during this procedure. A doctor may order endoscopic retrograde cholangiopancreatography (ERCP) to take film of the ducts that transport bile from the liver to the gallbladder and from the gallbladder to the small intestine to detect any abnormalities with the ducts; there is a chance that extrahepatic bile duct cancer can develop when a narrowing of the bile duct occurs, causing a slow movement of bile, which in turn causes jaundice—this test involves using an endoscope and catheter to view the pancreas and smaller ducts; during the procedure, tissue samples can be obtained as well as the stones in the bile duct possible being removed. A specialized test, percutaneous transhepatic cholangiography (PTC), is ordered to take film of the liver and bile ducts—a thin tube injected with dye can detect abnormalities with the liver and bile ducts.

Tests that include monitoring liver function can aid in detecting problems with the liver, gallbladder, and gastrointestinal tract.

A tumor marker test can be performed to detect two antigens that identify extrahepatic bile duct cancer—these two antigens, carcinoembryonic antigen (CEA) and CA 19-9, become increased in the body to alert medical professionals to rule out extrahepatic bile duct cancer—this test involves samples from urine, blood, and tissue that are monitored to assess the presence of cancer cells in the body, including the gastrointestinal tract.

**Treatments for Extrahepatic Bile Duct Cancer**

With respect to the staging of extrahepatic bile duct cancer, this helps medical professionals develop treatments to help individuals with their battles with cancer. There are several treatment options for extrahepatic bile duct cancer:

- Surgical treatment that includes removing the malignant cells from the bile ducts—this is the first treatment option
that is explored if the cancer is in the early stages or when the cancer is not that advanced
• Therapy that involves radiation
• Chemotherapy that also can be combined with radiation
• Palliative therapy—this includes alternative therapy to handle and help manage the effects the disease has on the patient and caregivers both physically and mentally—this treatment is aimed at approving the quality of life for everyone involved in taking care of the person who is dealing with the aftermath of treatment for cancer.

Biologic Therapy

Biological or biologic therapy is the use of living organisms, the substances derived from them, or laboratory-produced synthetic formulations of those substances in order to treat illness, including cancer. Common biological therapy strategies are using such therapeutic substances either to attack cancer cells or to assist the body’s immune system in doing so. Types of biological therapies include cell-based therapies like vaccines, monoclonal antibody therapies, cytokine therapies, and experimental approaches like gene therapy.

There are numerous Food and Drug Administration (FDA)-approved biological therapies and more in the development stage sometimes available to cancer patients as part of clinical trials. Related terms are immunotherapy or biological response modifier therapy—therapies that stimulate the immune system—and targeted therapies, those therapies that target and eliminate cancer cells. Biological therapies may also treat the side effects of other cancer treatments, such as chemotherapy. Increasingly, the term *biologic* (as a noun, as in “Ask your doctor about taking a biologic”) is used to refer to biological therapy products.

The immune system’s ability to fight infection and disease is predicated on its ability to distinguish between foreign and host (self) tissue, which is precisely why cancer is difficult for it: Tumor cells are the patient’s own cells, not a foreign infection. However, tumor cells also display antigens that would normally not be found in that environment or that cell type, which makes it possible to target them, such as through monoclonal antibodies, the first technique developed in immunotherapy.

One of the earliest biological treatments for cancer was Coley’s toxins or Coley’s vaccine—a mixture of dead *Streptococcus pyogenes* (responsible for many strep infections) and *Serratia marcescens* (responsible for many hospital-acquired infections) bacteria, with the intention of provoking an immune response that would work against tumor cells.

It is named for its developer, William Bradley Coley, who first prepared it in 1893. Radiation therapy overtook Coley’s toxins as the preferred treatment, and from 1923 until 1962, the preparation was available only from Parke-Davis. The new FDA regime following the passage of the Kefauver Harris amendment of 1962 (in response to the thalidomide disaster) effectively took Coley’s toxins off the market by classifying them as a new drug requiring clinical trials. Today, they are part of cancer research and clinical trials conducted by Pfizer and Sanofi-Aventis and are available as a treatment from specialists in Germany.
Monoclonal Antibodies

Monoclonal antibodies are a type of monospecific antibody, antibodies with the affinity for the same antigen (any substance that provokes a response from the immune system, which in the case of cancers is usually but not always a protein), produced by cloning a parent immune cell. The generic name of monoclonal antibody therapies ends in -mab by convention, and doctors sometimes refer to them collectively as “mabs.” (Other naming conventions include -tumu- for fully human mabs like panitumumab; -tumo-, -govo-, -pro-, or -colo- for those derived from mice; -tuxi- for chimeric mabs; and -tuzu- for humanized mabs.) Monoclonal antibody therapies were first proposed in the early 20th century by Paul Ehrlich’s description of a “magic bullet” treatment; this work led to the first treatment for syphilis and the beginning of chemotherapy. The first real mab treatments for cancer were developed in the 1970s by Georges Kohler, Cesar Milstein, and Niels Kaj Jerne, who shared the 1984 Nobel Prize in Medicine for their work. Initially cloned from the cells of nonhuman animals, these therapies could result in side effects even after processes were pioneered in the 1980s to humanize the antibodies. A number of commercial technologies have been developed using transgenic mice to produce fully human antibodies.

Monoclonal antibodies used as cancer treatments include mabs designed to induce an immunological response against the cancer cell or to deliver a substance to attack the cancer. Mabs are given intravenously, usually every two weeks; a typical course of treatment can cost around $30,000. Mabs may also be designed as bispecific monoclonal antibodies, which combine fragments of multiple mabs in order to bind to multiple antigens. This is an approach almost entirely unique to cancer treatments. Bispecific mabs have a higher cytotoxicity; that is, they are deadlier to the cells they target.

Bevacizumab is a humanized mab derived from mice, used to treat colorectal, lung, breast (until revoked for this use in 2011), renal, and brain cancer by slowing angiogenesis (the growth of new blood vessels). It was the first angiogenesis inhibitor approved in the United States and was used first in combination with chemotherapy for metastatic colon cancer in 2004. Side effects include hypertension and a possible worsening of artery diseases.

Cetuximab is an epidermal growth factor receptor inhibitor, a chimeric (mouse and human) mab used to treat some colorectal, lung, and head and neck cancers. In the United States, it is marketed under the trade name Erbitux (manufactured by Eli Lilly). Side effects can include a pimple-like rash, fevers, chills, rigo, dizziness, photosensitivity, and respiratory difficulties. In 2013, it was one of the 10 top-selling cancer drugs.

Panitumumab is a newer fully human mab, an epidermal growth factor receptor inhibitor used in the treatment of colorectal cancer. Because it is fully human (developed from the XenoMouse transgenic mice platform), it inflicts fewer side effects than cetuximab while operating with a similar mechanism of action.

Trastuzumab is a humanized mab used mainly to treat breast cancers by interfering with HER2/neu receptors. It has been shown to increase survival in metastatic breast cancer by several months and to reduce the risk of cancer recurring after surgery in early-stage breast cancer by almost 10 percent. Side effects include flu-like symptoms and, in less than 8 percent of cases, cardiac dysfunction that prevents it from being taken by patients with preexisting heart problems.

Ipilimumab, marketed as Yervoy, is a mab developed by Bristol-Myers Squibb to treat melanoma. It is also undergoing trials as a treatment for non-small cell lung carcinoma, small cell lung cancer, bladder cancer, and metastatic hormone-refractory prostate cancer. It is expensive even by mab standards, costing about $120,000 for a course of treatment.

Ofatumumab is a fully human mab sold under the trade name Arzerra to treat chronic lymphocytic leukemia, follicular non-Hodgkin’s lymphoma, diffuse large B cell lymphoma, and rheumatoid arthritis.

Ibritumomab tiuxetan, sold under the trade name Zevalin, is a mab radioimmunotherapy treatment that utilizes ibritumomab in conjunction with a radioactive isotope in order to treat non-Hodgkin’s lymphoma. Non-Hodgkin’s lymphoma can also be treated with tositumomab (trade name Bexxar), though tositumomab was discontinued in 2014 due to a decline in prescriptions being written for it.

Hodgkin’s lymphoma and systemic anaplastic large-cell lymphoma can be treated with Adcetris,
Biologic Therapy

the trade name for brentuximab vedotin, which was approved by the FDA in 2011. Though clinical trials were largely promising, it has been linked with two cases of progressive multifocal leukoencephalopathy, a fatal viral disease causing progressive damage of the brain's white matter, seen almost exclusively in patients receiving certain kinds of chemotherapy or mabs and in acquired immune deficiency syndrome (AIDS) patients.

Acute myelogenous leukemia was once treated with gemtuzumab ozogamicin, a humanized antibody marketed as Mylotarg from 2000 to 2010, but it was removed from the market after a clinical trial showed that there was no benefit over conventional therapies and that patient death actually increased. Several leukemias, as well as transplant rejection and many lymphomas, can be treated with the chimeric mab rituximab, marketed as Rituxan, MabThera, and Zytux. Rituximab was developed in 1998, and the patent will expire in 2015, making it one of the few mabs available as a generic. Chronic lymphocytic leukemia, cutaneous T-cell lymphoma, and T-cell lymphoma can be treated with alemtuzumab under the trade names Campath, MabCampath, and Campath-1H. It also is sometimes used in kidney or bone marrow transplants and for treatment of steroid-resistant, graft-versus-host disease after bone marrow transplant. Its most significant side effect is the increased risk of opportunistic infections, with other side effects including flu-like symptoms, rash, arrhythmia, and respiratory arrest.

Humanizing with respect to mabs means that, after antibodies have been harvested from mice, genetic engineering is used to replace as many mouse portions of the antibody with human portions as possible. Without this process, the antibody itself can provoke an immune response. Fully human mabs are still derived from mice, but transgenic—that is, genetically modified—mice that can carry human tissue, much like the mice on which human ears are grown for transplant purposes. Human immunoglobulin genes are transferred to these mice, which are then vaccinated against the antigen in order to stimulate production of mabs.

Recent work has focused on developing immunoliposomes, liposomes that can carry drugs and are conjugated with mabs in order to target cancer cells. Tissue-specific tests have been successful with brain and breast cancer tissue, and clinical trials are presumed to lie in the near future.

Monoclonal antibodies also are used to treat autoimmune diseases like Crohn’s disease, asthma, and viral infections to prevent coagulation during angioplasty and in kidney transplant patients.

Cancer Vaccines

A number of vaccines have been developed to treat existing cancer; none has yet been shown to function as a general immunization against cancer, though cancers caused by viruses can be prevented by the administration of vaccines like the human papillomavirus (HPV) vaccine and hepatitis B vaccine. The HPV vaccine prevents infection by human papillomavirus, the most common sexually transmitted disease in the world, which is responsible for the development of 70 percent of cervical cancers, 80 percent of anal cancers, 60 percent of vaginal cancers, and 40 percent of vulvar cancers. The World Health Organization recommends universal HPV vaccination for young women, specifically to prevent cancer. Men are at risk principally if they have sex with men, but vaccination helps protect their partners. The hepatitis B vaccine, which has been routinely recommended for infants since 1991, also prevents liver cancer because it had been demonstrated for years that liver cancer is caused by hepatitis B. Despite this, liver cancer remains one of the most common cancers in the world, principally in China and Africa.

Bacillus Calmette-Guerin (BCG) vaccine is a tuberculosis (TB) vaccine that is one of the most basic medications in modern medicine. In addition to its use as a vaccine in parts of the world where TB is endemic, it is used for leprosy, for type 1 diabetes, and as a cancer treatment. Injecting BCG into the bladder, for instance, is an effective immunotherapy for bladder cancer, though the mechanism is not well understood. It has since been used for colorectal and lung cancers as well as melanoma.

BCG is the only cancer vaccine approved worldwide for clinical use, but there are more than two dozen in various stages of development, including GlaxoSmithKline’s melanoma vaccine and Merck’s vaccine for breast cancer. Merck’s vaccine, Tecomotide, formerly known as Stimuvax, was developed in collaboration with Canadian biotech company Biomira. A study of tecemotide as a treatment for non–small lung cancer ended in 2014.
after no improvement was shown, but trials continue as a breast cancer therapy.

In the United States, Supluecel-T, marketed by Dendreon under the trade name Provenge, is an FDA-approved, cell-based therapy for prostate cancer, costing about $100,000 per patient. An autologous cancer vaccine treatment, it uses the patient’s own white blood cells, which are treated and incubated with a prostate cancer antigen and granulocyte-macrophage colony-stimulating factor before being reinjected into the patient. Clinical trials, which began in 2001, showed consistent survival benefits. Side effects include flu-like symptoms. Dendreon is also developing Neuvenge, a modification of Provenge for treating bladder and breast cancers.

In Cuba, the first lung cancer vaccine was released in 2011. CimaVax-EGF was developed at Cuba’s Center of Molecular Immunology.

In Brazil, HybriCell was released, a cancer vaccine for the treatment of late-stage melanoma or kidney cancer. It uses autologous leukocytes to attack the tumor cells and showed an improvement rate of 80 percent in clinical trials.

Cytokines

Cytokines are a group of proteins that are released by cells for cell signaling purposes and influence the behavior of other cells. They are important parts of the immune system, helping to regulate immune responses as well as responses to inflammation, trauma, infection, and cancer. Genetically engineered cytokines have been used as therapies for various conditions, including hepatitis, multiple sclerosis, anemia, and both cancer and side effects of cancer or cancer treatments. Interleukins, for instance, are cytokines released by white blood cells (leukocytes). Interleukin 2, which is key in the body’s ability to discriminate between host and foreign tissue, has been adapted for the treatment of renal cell cancer and malignant melanoma under the trade name Proleukin. Proleukin has also been used in conjunction with the Gp100:209-217(210M) cancer vaccine, using amino acid residues of melanoma antigen. Interleukin 11, derived from marrow stromal cells, is marketed as oprelvekin to treat thrombocytopenia (the decrease in blood platelets) in cancer patients. Granulocyte-macrophage, colony-stimulating factor and granulocyte-colony stimulating factor are cytokines used to treat chemotherapy patients to help stimulate the production of white blood cells.

Adoptive Cell Transfer

Adoptive cell transfer is the transfer of immune system cells—usually autologous, that is, the patient’s own cells—back into the patient in order to promote immune system function. For instance, this can help combat graft-versus-host disease in bone marrow transplants. The adoptive transfer of tumor-infiltrating lymphocytes has also been used to treat advanced tumors like melanoma and colorectal carcinoma.

Oncolytic Viruses

An oncolytic virus is one that infects and kills cancer cells, which then release new virus particles that move on to destroy more cancer cells. They may also help stimulate immune responses in the
host. Oncolytic viruses as a cancer therapy was conceived of in the early 20th century after observations that some cancer regressions seemed linked to infection by viruses, and attempts to treat cancer through deliberate viral infection began in the middle of the century. Early research focused on poliovirus and other existing viruses in the search for a naturally occurring oncolytic virus, absent the technology to tailor a virus to order. Controlling the infection proved difficult, though at the other end of the spectrum, it was also difficult to prevent the immune system from destroying the virus before it could attack the cancer.

Many of the viruses explored as cancer killers are adenoviruses, a family of nonenveloped viruses originally derived from human adenoids. Adenoviruses are also used as vectors in gene therapy (particularly in treating cystic fibrosis), due to their ability to accommodate large transgenes and affect both replicating and nonreplicating cells.

In the 1990s, clinical trials were conducted using modified herpes simplex viruses to selectively attack cancer cells. Herpes was selected due to its relative harmlessness in the event of infection and the ease with which the virus can be manipulated. Clinical trials on patients with glioblastoma multiforme brain tumors showed no evidence of toxicity or serious side effects and may have assisted in long-term survival. Subsequent trials have targeted melanoma, squamous-cell carcinoma of the head and neck, and other cancers. The first positive phase 3 study for an oncolytic virus in the West ended in 2013, with Amgen's T-VEC (originally developed under the name OncoVEX GM-CSF), a herpes-based virus treatment for advanced melanoma. China had previously approved Shanhai Sunway Biotech's H101, a genetically modified adenovirus targeting head and neck cancer.

**Gene Therapy**

Gene therapy delivers therapeutic DNA to a patient's cells, usually in order to replace a mutated gene with functional DNA. The package with which therapeutic DNA is delivered (usually a virus) is called a vector. Gene therapy has been developed since 1972 and was used first on humans in 1990 in an immunodeficiency treatment. The field saw numerous clinical failures in the 20th century, but the 21st century has seen an upswing in gene therapy successes, and research investments have increased substantially since 2006. One of the dangers of gene therapy is the possibility of inducing a tumor if the therapeutic DNA is mis-integrated in the genome; this has occurred in clinical trials, resulting in several patients developing leukemia, one of whom subsequently died.

Gene therapy remains experimental: Cancer patients who are treated with it are participants in clinical trials for products that eventually may or may not be approved for the market. The only gene therapy treatment approved for the market in either the United States or Europe is Glybera, used in treating lipoprotein lipase deficiency and introduced commercially in 2014. However, it is widely suspected that gene therapy is on the cusp of a commercial breakthrough and that several cancer treatments under development will be available in the coming years—at least to some. Glybera, for instance, costs roughly $1.6 million per patient.

**Trophoblast Glycoprotein**

Trophoblast glycoprotein (TPBG) is not a biological therapy, but its discovery has been important to the development of such therapies. A human protein encoded by a TPBG gene, it is an antigen released by many different carcinomas. It was first discovered in fetal trophoblast and so is sometimes called oncofetal antigen. Its expression by the cancer cells of colorectal, ovarian, and gastric cancers is used as a prognostic measure, and it has been targeted by two different biologic therapies: a monoclonal antibody immunological therapy called mab5T4 (5T4 is another name for TPBG) and the cancer vaccine TroVax.

Bladder Cancer

Cancer of the urinary bladder represents the ninthmost common type of malignancy worldwide. More than 386,000 cases of bladder cancer are diagnosed annually worldwide, and more than 150,000 patients die of the disease each year. The hollow bladder is designed to store urine and has a specialized epithelial lining—transitional cell epithelium or urothelium—that is capable of stretching. Bladder cancers generally arise from alterations in cells within this epithelial layer, although they may also include other rare tumors of nonepithelial origin. It is primarily a cancer of adults, with men being more commonly affected. Prognosis depends on the stage of the tumor, and treatment may involve multimodal therapies including surgery, immunotherapy, chemotherapy, and radiation.

In developed countries, tobacco smoking is considered the most important risk factor for bladder cancer. There is a linear relationship between smoking and risk, and quitting smoking has been shown to reduce this risk. In addition, exposure to aromatic amines (e.g., in occupations that involve dyestuff and rubber manufacturing, leather processing, aluminum smelting, painting, hairdressing, and truck driving), arsenic, and chemotherapeutic agents such as cyclophosphamide have been suggested to increase the risk. Infection with *Schistosoma haematobium*, a bladder fluke commonly found in Africa and the Middle East, has been associated with the development of squamous cell carcinoma, a particularly aggressive type of bladder cancer in that region. Bladder cancer development and progression is also associated with mutations in HRAS, FGFR3, and P53 genes in some cases.

The most common presenting symptom is the presence of blood in the urine, which may be visible to the naked eye or may only be detected by a microscope or specialized dipsticks. Other possible symptoms include pain during urination, frequent urination, or feeling the urge to urinate without being able to do so, although these may not be specific for the presence of cancer. Nevertheless, patients with these complaints need to be evaluated thoroughly to determine the cause of their urinary symptoms. Patients are often initially referred to a urologist to undergo a cystoscopy, a procedure where a flexible tube with a camera is introduced into the bladder through the urethra. More recently, cystoscopy may be also performed under Cysview/Hexvix guidance (blue light cystoscopy), which can reveal lesions that may not be visible with standard white light. Suspicious lesions within the bladder are biopsied and sent for pathologic analysis. Urine cytology may also be used as an adjunct diagnostic test, although it is not very sensitive. Urine-based marker assays have also been used recently for diagnosis and detection of recurrence, including nuclear matrix protein 22 (NMP22) and UroVysion.

Treatment and eventual prognosis of bladder cancer generally is dependent on the stage of the primary tumor, the presence of any metastases to lymph nodes or other organs, and the degree of tumor cell differentiation. Superficial tumors that do not invade the muscle layer of the bladder wall are generally resected transurethrally under cystoscopic view. These tumors have a high tendency to recur following initial resection. Patients with such tumors may therefore also be offered immunotherapy by intravesical delivery of bacillus calmette-guérin (BCG) to prevent tumor recurrence. BCG is a vaccine against tuberculosis that is prepared using attenuated live *Mycobacterium bovis*, a bovine tuberculosis bacillus.

While the exact mechanism by which BCG prevents recurrence is unknown, it is suggested that the presence of bacteria in the bladder triggers a localized immune response that clears residual cancer cells. Intravesical chemotherapy instillations may also be used to treat BCG-refractory disease when cystectomy is not an option. While patients undergoing such bladder-preserving procedures generally retain their voiding function, they need to be monitored closely at regular intervals to determine whether the cancer has recurred or progressed to a higher stage.

Patients whose tumors recur after treatment with BCG and those who present with muscle-invasive disease are generally advised to undergo cystectomy. This is a more radical surgery where the bladder is partially or completely removed, and adjoining lymph nodes may also be dissected. This usually also includes removal of the prostate in males, and ovaries, uterus, and parts of the vagina in females. The urinary stream is diverted into an isolated loop of bowel (called an ileal conduit). In some cases, a substitute bladder (called a neobladder) may be
reconstructed from a segment of intestinal tissue, but this may depend on patient preference, age, renal function, and extent of disease. Micrometastatic disease is a major issue in muscle-invasive cancer, which refers to the possibility of few cancer cells being disseminated to distant organs that can subsequently give rise to metastases. This has implications on long-term survival, and patients with muscle-invasive tumors are often administered neoadjuvant chemotherapy to address this problem. This involves administration of anticancer drugs such as gemcitabine and cisplatin prior to cystectomy to reduce the size of the tumor and kill any potential micrometastatic tumor cells. Following radical cystectomy, and depending on patient performance and tumor stage, adjuvant chemotherapy may also be administered. In this setting, the role of chemotherapeutic drugs is to kill any small foci of tumor cells that may not have been resected at the time of surgery. A combination of radiation and chemotherapy may also be used as an alternative to radical surgery to treat invasive disease. The comparative effectiveness of this form of treatment to radical cystectomy has not yet been fully determined.

Tumor recurrence following radical cystectomy unfortunately heralds a grave prognosis. Most recurrences following cystectomy usually occur within the first two to three years, and if a patient does recur, the survival following recurrence is generally less than two years. However, few patients have a more prolonged survival following recurrence, especially if the tumor recurs in the upper urinary tract or urethra. In such cases, patients may undergo surgical resection of the recurred tumor. Metastatic disease at other organ sites, however, may not be amenable to surgery. Such patients are often administered salvage chemotherapy to limit the disease progression.

Bladder cancer is a major malignancy with debilitating consequences that can impact long-term survival and quality of life. Current treatment options include a gamut of modalities that are dependent of extent of the tumor, patient performance, and patient preference. While early aggressive management is generally successful, the nature of the disease requires lifelong follow-up to monitor for cancer recurrence.

Bladder Cancer, Childhood

The National Cancer Institute lists carcinomas of the urinary bladder as an unusual cancer of childhood, referring to its extreme rarity. Bladder cancers are more common in men than in women and in the age group of 50 to 70 years. In contrast, less than 1 percent of bladder cancers are detected in patients within the first two decades of life. The rarity of this tumor is reflected in the fact that only small series have been described in the literature. In fact, only more than 100 cases of transitional cell carcinoma of the bladder in children have been reported since 1950. In contrast to adults, most bladder carcinomas in children are low grade and superficial and have a good outcome following surgical resection.

The urinary bladder is normally lined by a layer of specialized epithelium called transitional epithelium (or urothelium). This layer is designed to withstand constant stretching when the bladder distends to store urine. Bladder cancer usually originates from this layer and is referred to as transitional cell carcinoma. This also represents the most common type of bladder cancer in childhood. Advanced tumors may infiltrate the underlying muscle layers before involving the entire bladder wall and metastasizing. More aggressive tumors such as squamous cell carcinomas have also been reported to involve the urinary bladder. In this scenario, the overlying
urothelium transforms into an abnormal flat layer of epithelium similar to the skin that is incapable of stretching. This may occur due to genetic alterations or may be seen with chronic infections with bladder flukes (*Schistosoma haematobium*). Bladder cancer in adolescents may also develop as a consequence of alkylating agent chemotherapy given for other childhood tumors or leukemia. The association between the chemotherapeutic agent cyclophosphamide and bladder cancer is the only major established relationship between a specific anticancer drug and a solid tumor. Another rare group of bladder tumors arising from the underlying muscular wall of the organ is called rhabdomyosarcoma. Originating from cells that have primitive features of muscle cells, these generally tend to occur in boys and respond favorably to treatment. It should also be noted here that exposure to secondhand smoke among children increases their risk of acquiring bladder cancer during adulthood by nearly 40 percent.

As in adults, bladder cancer in childhood is relatively more common in males than in females. Children generally present with the painless passing of blood in urine (referred to as hematuria). This may or may not be accompanied by increased frequency of urination and pain during urination. Blood in the urine, however, is not a definitive sign for bladder cancer, and a thorough workup of the patient is essential before a diagnosis is reached. Most bladder tumors in children are generally of low stage and have a low grade of malignancy, with little tendency to recur following surgical resection. A preliminary diagnosis may be made on the basis of examining cells shed in the urine (i.e., cytology) in conjunction with imaging tests such as CT scans, MRI, and ultrasonography.

Urinary cytology alone may not be sufficient to definitively diagnose all cases of childhood bladder cancer as its sensitivity may be limited especially if the tumor is low grade. A diagnosis is usually established based on cystoscopic evaluation wherein the surgeon places a small, hollow viewing tube through the urethra to visualize the bladder. Any abnormal tissue is usually biopsied and sent for pathologic evaluation. Definitive treatment in children is generally surgery, which often involves removal of the tumor tissue by cystoscopy while preserving the healthy part of the bladder. This is generally performed under sedation or anesthesia, and patient recovery after the procedure is generally rapid. Depending on the stage of the tumor, administration of chemotherapy or radiotherapy also may be considered as treatment options. Instillation of bacillus calmette-guérin, a vaccine usually administered to confer immunity against tuberculosis, in the bladder to stimulate the body’s immune response to fight the cancer is also an option for early-stage tumors.

Urachal carcinoma is another rare cancer that sometimes can involve the bladder. This malignancy does not arise from the urothelium but rather from the epithelium in the urachus, which is an embryonic structure located between dome of the bladder and the umbilicus. The most common locations for urachal cancer are the umbilicus and dome of the bladder. While the malignancy commonly presents later in adult life, it is believed to exist for several years without any symptoms. The initial diagnosis can be difficult as there are often no specific symptoms.

As with bladder cancer, the diagnosis of urachal carcinoma generally is confirmed by cystoscopy and endoscopic biopsy. Surgery is the mainstay of treatment for clinically localized disease, and the entire urachal remnant and bladder dome are often resected en bloc. It is unclear whether removal of adjacent lymph nodes, radiation, or conventional chemotherapy is of any benefit to patients with urachal carcinoma. In fact, the cancer does not seem to respond to the usual chemotherapeutics for bladder cancer, but chemotherapy regimens used for bowel cancer may have more success. The overall five-year cancer-specific survival rate is approximately 50 percent. However, the prognosis for patients with metastatic or recurrent disease is poor, with median survivals reported in the range of one to two years.

Bladder tumors in children generally have low malignant potential, and their tendency to relapse after surgical removal is relatively lower than in adults. Nevertheless, patients are monitored closely with regular follow-up visits to detect any early signs of tumor recurrence. During the past three decades, multimodality therapy for childhood bladder cancer has resulted in markedly improved survival. The therapy responsible for this survival, however, can also produce adverse long-term health-related outcomes that manifest months to years after completion of cancer
treatment. These include organ dysfunction and second malignant neoplasms. Physicians and families also need to realize the adverse psychosocial sequelae that may accompany the treatment of children with bladder cancer. Thankfully, however, this yet remains a rare cancer among the pediatric age group.

Bolivia

Bolivia is a large, landlocked country in South America. It is varied in topology with different cultural as well as topographical areas. It is mineral rich, supporting extractive industries. Many workers are miners and are exposed to heavy metals as an occupational hazard. The high altitudes where much of the population lives causes them to be at risk from cosmic radiation and ultraviolet solar rays. The national habit of chewing coca leaves with lime presents a risk of irritation to the mouth, lips, esophagus, and stomach. It is too early to assess these cancer risks as the people suffer from other more immediate problems of poverty, malnutrition, and limited access to doctors and health facilities. In recent decades, the country has made significant progress in development, although it remains one of the poorest countries of Latin America.

A nation’s experience with cancer is directly related to its demographic profile and to the country’s level of social and economic development. A young population will be relatively cancer free, while an aging population will have cancer as one of the most frequent causes of mortality. Bolivia has a young population due to its high fertility rate of about three children per family. Forms of cancer found mainly among the elderly are less frequent in the Bolivian population due, in part, to the low percentage of the population age 65 and above (4.8 percent). In addition, the lack of access to medical facilities, especially in rural areas, may prevent the diagnosis of occult forms of cancer. These characteristics of Bolivian society are shared with many of the world’s countries at lower stages of economic and social development. Historically cancer characterizes Western, industrial countries, often attributed to a rich diet, sedentary life style, and other unhealthy practices. While many social critics focus on these negative sides of modernization, the worldwide rise in cancer is recognized as a product of longer life spans in all countries.

More recently, cancer is seen as a worldwide cause of death and as a rapidly growing threat to less-wealthy countries that are not well prepared for treatment, palliative, and terminal care. According to the World Health Organization (WHO), cancer rates will be rising rapidly among countries least prepared to respond, such as Bolivia. This is a foreseeable health crisis as a third of cancers are preventable and others can be treated successfully if diagnosed early. This health crisis will affect Bolivia greatly as it is at the low end of public health facilities and resources, according to the Pan American Health Organization (PAHO). Bolivia’s demographic profile is of a young population of 10,088,000 with a median age of 24 years. The country is nearly the lowest or is the lowest in many measures of health and development in Latin America. Indicators include limited access to clean water, sanitation, doctors, and hospital beds.

Bolivia is the only country in South America without data on age-standardized mortality rates, although there are some data available on deaths from certain cancers. Based on International Agency for Research on Cancer data, Bolivia stands out as
one of the few Latin American countries in which breast cancer is not the leading cause of cancer deaths among women. Gynecological cancer (cervix uteri, corpus uteri, and ovarian) is the leading cause of cancer among Bolivian women and also is the greatest cause of cancer mortality among all Bolivians, men and women. This is especially tragic as most of these cancers are completely preventable or curable.

Bolivia’s highest cancer mortality is gynecological, and the second is urological (bladder, kidney, prostate, and testis). In third place is stomach cancer. Lung cancer is merely the ninth-most frequent cancer in Bolivia. Facing this projected health crisis, the objective is to provide preventive care and treatment to a population that often finds health care of any kind inaccessible and traditional methods more in accord with their culture and values.

Bolivia has a large indigenous population. The centrality of this previously marginal population has been a recent political phenomenon with the election of the nation’s first indigenous president, Evo Morales. There are three distinctive geographical and cultural regions outside the capital city, La Paz: the High Andean plateau, the region of the valleys, El Chapare, and the tropical Amazonian region. Cultural diversity is reflected in language diversity, with about 45 percent speaking only Spanish and 30 percent bilingual Spanish and an indigenous language. Ecological diversity is represented by traditions of medicinal plants and their use. Ethnographers report more than 2,000 different medicinal plants used by traditional healers. Their main use is for gastrointestinal problems. Despite the rapid spread of hospitals and health posts across the rural areas of Bolivia, their population continues to depend on traditional healers and herbal remedies. WHO cites up to 90 percent of the population of developing countries depending on these traditional sources to meet their health needs. The primary reason for preferences for these traditional methods is the low income of users, inaccessibility of modern facilities, and the perceived effectiveness of traditional healers over hospital doctors.

This developmental and cultural picture complicates the problems of preventive and treatment actions against cancer. The main concern in Bolivia is cervical cancer, which can be prevented through vaccinations, pap tests and human papillomavirus (HPV) tests. The Bolivarian women at risk of cervical cancer is estimated at 3 million. It is unlikely that programs of vaccination will be implemented anytime soon, for economic reasons. This is a major limitation in the developing world generally. It is estimated that most women in these countries do not receive medical services until they have an advanced cervical cancer with is untreatable and leads to an inevitable, tragic death.

However, Bolivian health authorities and doctors are working to control cancer through planning for installation of necessary diagnostic equipment and training of health professionals.

Bonadonna, Gianni

Gianni Bonadonna is a renowned Italian cancer doctor and scientist who has conducted groundbreaking research in the adjuvant treatment of
breast cancer. He also helped lead the battle to convince the surgical establishment of the treatment's efficacy. In addition, Bonadonna pioneered the development of a combination chemotherapy regimen that remains the gold standard for treatment of Hodgkin's disease, a cancer of the lymphatic system.

Born in Milan, Italy, in 1934, Bonadonna received his medical degree from the University of Milano in 1959 and completed his postdoctoral training at the Memorial Sloan Kettering Cancer Center in New York in the early 1960s. He went on to join the Instituto Nazionale des Tumori of Milan and became director of medical oncology in 1976. He was appointed head of the Department of Cancer Medicine in 1991 and served in that position until 1998, before becoming chair of the institute's Committee on Prospective Clinical Trials.

Bonadonna's important contributions to cancer research and treatment began in the early 1970s. Bonadonna and colleagues conducted a landmark clinical trial showing that an adjuvant combination chemotherapy of cyclophosphamide, methotrexate, and fluorouracil (CMF) improved survival in women who had their breast tumors surgically removed. As a result, CMF therapy became the first combination chemotherapeutic regimen for the treatment of breast cancer. Its discovery led to the beginning of a multidisciplinary approach to breast cancer treatment. Eventually, CMF therapy was shown to be not only effective but also to significantly reduce the risk of disease recurrence and death over an extended period of 30 years.

In 1995, Bonadonna and colleagues reported on a 20-year follow-up of an original group of women in his 1970s studies. These women had undergone radical mastectomies and were randomly assigned to groups that received no further treatment with CMF therapy for a 12-month cycle. The results showed that CMF nevertheless continued to provide significant benefits to the patients. In 2005, Bonadonna reported on a 30-year follow-up of these patients to show that the CMF regimen was long lasting in its benefits for patients who had both favorable and unfavorable prognoses.

Bonadonna also discovered a new combination chemotherapy for Hodgkin's disease in the early 1970s. The therapy used a combination of the drugs adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD). A 1974 clinical trial conducted by Bonadonna showed that ABVD was superior to the commonly used mecloretamine, vincristine, procarbazine, prednisone (MOPP) chemotherapy in treating Hodgkin's disease. The results of another trial of ABVD published in 1982 showed that radiation therapy along with ABVD improved long-term outcomes compared to MOPP alone. Overall, ABVD therapy was shown to be easy to administer and had no severe side effects, findings that were confirmed in subsequent trials by other investigators. ABVD remains the most widely used conventional chemotherapy for the Hodgkin's disease, curing more than two-thirds of patients with advanced disease.

Another major contribution to cancer treatment discovered by Bonadonna and colleagues occurred in the late 1980s. Clinical trials conducted by Bonadonna indicated that primary chemotherapy before breast cancer surgery could reduce tumor size. The study also showed that conservative surgery could be an effective alternative to a radical mastectomy (removal of the entire breast as well as underlying chest muscle and lymph nodes of the axilla). Although it took some time to convince the medical community of the research findings, the medical establishment finally accepted that a less-radical surgery could effectively treat some breast cancers while maintaining the patient’s body integrity and self-image.

Bonadonna also founded the Fondazion Michelangelo (Michelangelo Foundation), a nonprofit organization located in Milan, Italy, devoted to advancing cancer research. The origins of the Michelangelo Foundation date back to 1993, when medical oncologists in Italy trained by Bonadonna began contacting him about participating in some of his clinical studies. Bonadonna was initially reluctant to the requests, primarily because he was concerned about a large group's ability to diligently follow research guidelines across groups.

Bonadonna eventually decided that it might be advantageous to get more oncologists collaborating on his clinical research. The cancer researcher reasoned that wider participation would benefit patients, who would no longer have to come to Milan for treatment and participation in clinical trials. Despite his devotion to research, Bonadonna remained dedicated to patients.

Bonadonna eventually invited approximately 15 medical oncologists from northern Italy for a meeting...
Bone Cancer, Osteosarcoma/Malignant Fibrous Histiocytoma

Bone Cancer, Osteosarcoma/Malignant Fibrous Histiocytoma

Osteosarcoma and malignant fibrous histiocytoma of bone (MFH-B) are cancers that affect bone tissue and together are identified with lots of similar and dissimilar characteristics. Throughout history, osteosarcoma and MFH-B have been presented as primary diseases of childhood and adolescence. The prevalence of these diseases in adulthood and old age is usually as a secondary tumor or metastatic disease. The two types of cancers exhibit a variety of similar clinical presentations and need treatment according to the prognostic factors. However, above all, there is a huge impact on social interaction and quality of life of the patient and family. Once these cancers are diagnosed, overall survival (OS) and event-free survival (EFS) of the patient guide further decision making and medical care course.

Definition and Types of Cancer
Osteosarcoma is a malignant tumor of bone tissue in which the neoplastic cells produce osteoid (new bone) and is sometimes accompanied with an excessive proliferation of vessels called telengectasias. The osteosarcoma can be located in

the bone called central (medullary) or toward surface (peripheral). The World Health Organization (WHO) has classified osteosarcoma according to the histological features:

- Central tumors (medullary)
- Conventional central osteosarcoma
- Telangiectatic osteosarcoma
- Small cell osteosarcoma
- Intraosseous well-differentiated (low grade) Osteosarcoma
- Surface (peripheral)
- Parosteal (juxtacortical) well-differentiated (low-grade) osteosarcoma
- Periosteal osteosarcoma
- High-grade surface osteosarcoma

MFH-B (nowadays called undifferentiated pleomorphic sarcoma) is a malignant neoplasm composed of fibroblasts and pleomorphic cells developed on bone with a prominent storiform pattern. The histological characteristics of MFH-B are different than osteosarcoma but have the same clinical staging, and both have similar modes of treatment.

**Epidemiology**

Data from the National Cancer Institute mention an estimate of 4.4 per million new cases of osteosarcoma each year in people age 0 to 24 years. The U.S census bureau estimates that there were 110 million people in this age range in 2010, resulting in an incidence of roughly 450 cases per year in children and young adults younger than 25 years. Osteosarcoma accounts for approximately 5 percent of childhood tumors. In children and adolescents, more than 50 percent of these tumors arise from the long bones around the knee. Osteosarcoma can rarely be observed in soft tissue or visceral organs. MFH-B is relatively a rare tumor, which represents less than 2 percent of all primary malignant bone lesions.

**Etiology**

The main cause of these tumors has not been determined clearly; the origin of osteosarcoma and MFH-B is multifactorial. There are several risk factors involved in pathogenesis, like changes or mutations in our genes. Such genetic mutations in turn act as direct or indirect causes of osteosarcoma and MFH-B. Mutations can be inherited, such as...
mutation that turns off the TP53 tumor suppressor gene or the mutation in retinoblastoma RB1 tumor suppressor gene. Perhaps mutations can be acquired as well, such as radiation therapy in a past form of cancer, random errors that occur when cells reproduce at the time of the teenage growth spurt, or Paget disease of bone that causes rapid bone growth. All of these factors increase the risk of osteosarcoma and MFH-B.

Pathogenesis, Presentation of the Disease and Diagnosis

The clinical course of the disease is highly variable for many types of osteosarcoma and MFH-B, but each one leads to the same result and progression and varies with the time. The diagnosis usually requires a synthesis of clinical, radiologic, and pathologic features. Patients typically present with pain and swelling of the affected area. A plain radiograph reveals a destructive lesion with a moth-eaten appearance, a spiculated periosteal reaction and a cuff of periosteal new bone formation at the margin of the soft tissue mass. A computed tomography (CT) scan of the primary tumor is best for defining bone destruction and the pattern of calcification, whereas magnetic resonance imaging (MRI) is better for defining intramedullary and soft tissue extension. A chest radiograph and CT scan are used to detect lung metastases. A metastases to the bony skeleton should be imaged by a bone scan or by fluorodeoxyglucose positron emission tomography (FDG-PET). Almost all osteosarcomas and MFH-B are hypervascular. Angiography is not helpful for diagnosis, but it is the most sensitive test for assessing the response to preoperative chemotherapy (extent of necrosis). Pathologic diagnosis is established either with a core-needle biopsy or with an open biopsy with an appropriately placed incision that does not compromise future limb-sparing resection. Most osteosarcoma and MFH-B are high grade. The most important prognostic factor for long-term survival is response to chemotherapy.

Management and Treatment

Preoperative chemotherapy followed by limb-sparing surgery (which can be accomplished in more than 80 percent of patients) followed by postoperative chemotherapy is standard management. Current chemotherapy protocols include combinations of high-dose methotrexate, doxorubicin, cyclophosphamide, cisplatin, ifosfamide, etoposide, and carboplatin with leucovorin rescue. Meta-analysis of protocols for the treatment of osteosarcoma concluded that regimens containing three active chemotherapy agents (mainly cisplatin, doxorubicin, and methotrexate) were superior to regimens containing two active agents and, with four agents, were not superior than with three agents. As is known, surgical resection of the primary tumor with adequate margins is an essential strategy for patients with localized osteosarcoma or MFH-B, and more than 80 percent of patients with extremity osteosarcoma or MFH-B can be treated by a limb-sparing procedure and do not require amputation. In such cases, limb-sparing procedures are planned only when preoperative staging indicates that it would be possible to achieve wide surgical margins. Consequently, poor histologic response and close surgical margins have a high rate of local recurrence. After surgery, the reconstruction of the limb can be accomplished with many options including the following:

- Metallic endoprosthesis
- Allograft or allotransplantation
- Vascularized autologous bone graft
- Rotationplasty

There are several factors that involve optimal surgical reconstruction, which include the site and the size of the primary tumor, the ability to preserve the neuromuscular structures of the distal extremity, the age of the patient, and potential for additional growth. Other factors include the needs and desires of the patient and family members. One of the most important components is the delay in resumption of chemotherapy after definitive surgery, which is associated with increased risk of tumor recurrence.

For some patients, amputation is an optimal choice, but in the case of limb salvage, a pathologic fracture at diagnosis has worse outcomes. The local recurrence is considered high risk for death from osteosarcoma or MFH-B. In this case, there are various elements associated with an increased risk of local recurrence, including: nonparticipating patients in a clinical trial, limb-preserving surgery, pelvic primary site of tumor, limb-preserving surgery, soft tissue infiltration beyond the periosteum, poor pathologic response
to initial chemotherapy, failure to complete planned chemotherapy, and performance of the biopsy at an institution different from the institution performing the definitive surgery.

**Prevention and Education**

The risk of many adult cancers could be reduced by making certain lifestyle changes, but at this time, there are no known ways to prevent osteosarcoma or MFH-B. As mentioned before, there are conditions associated with osteosarcoma and MFH-B (Paget disease, radiation exposure, bone infarct, or bone trauma and fibrous dysplasia). The education is given to people to learn the first manifestations at the time of diagnosis in osteosarcoma and MFH-B, symptoms like joint tenderness or inflammation, pain or swelling of a part of an extremity, fractures due to bone weakness, and limited range of motion. Other findings during physical exam may suggest the presence of osteosarcoma or MFH-B and make additional tests to rule out or confirm the presence of disease.

**Bone Marrow Transplants**

Bone marrow transplantation is the common term for the transplantation of hematopoietic stem cells found in bone marrow. The procedure was first established by a Johns Hopkins researcher, George Santos, in 1968, following his development of a chemotherapy cocktail using cyclophosphamide, which targeted cancer cells more specifically than radiation treatment did but had the effect of destroying healthy and necessary bone marrow tissue as well. The transplantation of stem cells from bone marrow into the chemotherapy patient helped undo some of the damage that had been done; Santos based the procedure on work by Georges Mathe, a French oncologist who attempted unsuccessful marrow transplants on Yugoslavian nuclear workers whose marrow had been damaged in a nuclear accident. Most of the standards of bone marrow transplants were subsequently developed at Hopkins.

Bone marrow is a flexible tissue in the interior of bones, comprising about 4 percent of the body weight of the average person. Bone marrow is an important part of both the lymphatic system, producing lymphocytes for the immune system, and of the cardiovascular system, producing red blood cells, platelets, and some white blood cells through hematopoiesis. There are two types of bone marrow: red marrow, medulla ossium rubra, made up mainly of the hematopoietic tissue, and yellow marrow, medulla ossium flava, consisting of stored fat cells. Bone marrow begins as fully red at birth and accumulates yellow marrow over time, being about half and half in most adults. Red marrow is found mainly in flat bones (such as the ribs, cranium, and vertebrae) and the rounded ends of long bones (such as the femur).

Bone marrow also can be divided between the hematopoietic tissue and the stroma, which includes all the marrow tissue not directly involved in hematopoiesis. Stroma includes yellow marrow,
connective tissue, macrophages, adipocytes, osteoblasts, osteoclasts, and endothelial cells. Some of these types of cells indirectly contribute to or enable hematopoiesis; for instance, macrophages deliver the iron that is necessary to produce hemoglobin. Bone marrow stroma also contains mesenchymal stem cells, which are multipotent stem cells capable of differentiating into osteoblasts, chondrocytes, myocytes, adipocytes, and beta-pancreatic islets cells. Though not as differentiable as embryonic stem cells, mesenchymal stem cells have been the subject of much research into the use of stem cells as sources of cures and remedies, particularly in the United States, where until recently, funding for human embryonic stem cell research was strictly constrained. Mesenchymal stem cells also contribute to the progression of cancer, particularly cancers that affect the lymph nodes, blood, or bone marrow, a mechanism that is also the subject of study.

Bone marrow is subject to damage by several different diseases, as well as cancer, and can be damaged by radiation therapy or chemotherapy, accounting for some of the symptoms of radiation poisoning as well as some of the complications and side effects of chemotherapy.

Bone marrow hematopoietic tissue contains hematopoietic stem cells (HSCs), the cells that differentiate into all other blood cells. These stem cells may be harvested, whether for transplant (bone marrow transplants are in fact hematopoietic stem cell transplants [HCST]) or in order to manipulate the stem cells to some other end. For instance, hematopoietic stem cells can be used to treat neurological diseases by inducing them to differentiate into neural cells, and there may be some potential for their use in the treatment of human immunodeficiency virus (HIV). Hematopoietic stem cell harvesting is a minimally invasive procedure performed under general anesthesia and may be either inpatient or outpatient depending on the circumstances.

Such transplants may be either allogenic, meaning that cells are harvested from one person and transplanted to another, or autologous, meaning they are transplanted back into the donor at a later date. HCSTs are used to treat several leukemias (acute myeloid leukemia, chronic myeloid leukemia, and acute lymphoblastic leukemia), especially in cases where the patient would not benefit from chemotherapy as well as Hodgkin’s and non-Hodgkin’s lymphoma, neuroblastoma, Ewing sarcoma, myelodysplastic syndromes, gliomas, thalassemia, aplastic anemia, Fanconi anemia, and immune deficiency syndromes. More than 50,000 transplants are performed each year, mostly in Europe and North America.

Bone marrow is generally extracted from the pelvis, though it can be taken from other bones if there is a need. Another possibility is to administer a drug that releases the donor’s HSCs into the bloodstream. After several days of such medication, the donor HSCs can be extracted through apheresis. The donor’s blood passes through an apparatus that directs it through a centrifuge that separates out the HSCs while returning the remainder to the body. Apheresis kits are single-use in order to prevent the risk of infection from contamination in the centrifuge or tubing. In autologous HSCT, harvested cells are then stored in a freezer until they are needed.

Side effects are minor; other than lingering soreness, most of those from a bone marrow extraction will be due to the anesthesia itself. In the case of apheresis, the process can be mildly uncomfortable, including chills and lightheadedness, and some donors experience flu-like symptoms and difficulty sleeping while taking the medication. Only about 15 percent of donors experience adverse reactions to apheresis. A very small number of donors experience severe reactions to one or more events in the donation process, requiring hospitalization; most commonly, these are cardiovascular-related events, including deep vein thrombosis and myocardial infarction.

Typically, the purpose of autologous HSCT is to safeguard the patient’s health through the preservation of HSCs, while the patient undergoes radiation treatments or high-dose chemotherapy, which in the course of destroying cancer cells, also destroys healthy bone marrow tissue and impairs the patient’s ability to produce new blood cells. The stored HSCs are then transfused back into his bloodstream and, upon being absorbed into the bone marrow, differentiate to form new healthy cells. Autologous HSCT avoids several of the risks of allogeneic HSCT— not just the possibility of rejection (a phenomenon known as graft-versus-host disease [GVHD]) but the risks faced during the immunocompromised period, which in this scheme is considerably shortened. In the treatment
of lymphoma, autologous HSCT has become standard for this reason.

However, the patient’s bone marrow may not always be healthy enough for autologous HSCT to be beneficial. Patients with acute myeloid leukemia, for instance, face an increased likelihood of cancer recurrence when undergoing autologous HSCT, and so allogeneic HSCT is preferred in these and some other cases. Allogeneic HSCT is a similar procedure, but the HSCs are harvested from a second person, a healthy donor. This requires finding a compatible match—close relatives are ideal, but unrelated donors may also have a matching human leukocyte antigen (HLA) type, which is necessary for the body to accept the donated tissue rather than treating it as foreign material. Rejection can be quite serious. In GVHD, rather than the body rejecting the foreign tissue, the white blood cells in the transplanted material attacks the host body’s cells, treating it as an infection. While more common with unrelated donors, there is a chance of this occurring even when the donor is an HLA-identical sibling, due to the presence of minor histocompatibility antigens—genetically different proteins from the donor’s T-cells. Damage is wreaked on organs, including the liver and gastrointestinal tract, the skin, the thymus, and the lungs, as well as on the bone marrow itself. Despite the risk posed by including T-cells in the transplant, they are often deliberately included because they assist in strengthening the immune system and preventing the more familiar host-versus-graft disease. Donor T-cells are especially efficacious in cancer cases, where they help the host system fight against tumor cells. Sometimes called the graft-versus-tumor effect, donor T-cells help to eliminate both tumor cells and, in the case of leukemia, malignant host T-cells. Studies have suggested the effect may be seen in breast cancer cases as well as myeloma, lymphoma, and leukemia cases. The mechanism is not well understood.

Acute GVHD presents in the first 100 days after transplant and is one of the main morbidity and mortality challenges faced by transplant. Common symptoms include rash and gastrointestinal problems, dry or irritated eyes, dark patches of the skin, or jaundice if the T-cells have attacked the liver; women may experience severe vaginal pain and scarring if the donor T-cells attack the mucosa. Chronic GVHD occurs after those first 100 days and can extend its attack to the exocrine glands and connective tissues. In either case, GVHD is usually treated with intravenous or oral steroids and immunosuppressants to reduce the immune response of the donor T-cells; glucocorticoids are commonly prescribed for acute GVHD and corticosteroids for chronic GVHD. Immunosuppressants also may be prescribed for several months after a transplant as a preemptive measure. Most patients enter a state of tolerance within a year after the HSCT.

Bone marrow transplant is one of the few transplantation procedures in which GVHD is more common than the reverse, due to the donor’s T-cells being included in the transplant. Host-versus-graft disease, often simply called transplant rejection or engraftment syndrome, is the more familiar situation of the host’s immune system treating the transplanted tissue as an infection. Recent work on transplant rejection following allogenic HSCT has focused on the possibility of mesenchymal stromal cells as a treatment.

The National Marrow Donor Program (NMPD) was established in Minneapolis in 1986 in order to encourage volunteer hematopoietic cell donation and umbilical cord blood donation for use in transplants. Between 1986 and 2013, more than 55,000 transplants were conducted with the NMPD’s help and that of the Be The Match donor registry, which it operates. NMPD covers the costs of donation (medical, travel and lodging as needed) that are not covered by the patient’s insurance; the donor’s cost is simply the time he or she needs to take off from work to travel and recuperate from the donation procedure. Marrow cells are obtained from the pelvic bones of living adult donors, while umbilical cord blood comes from the umbilical cord of newborn babies after the cord has been clamped and cut (and thus is no longer attached to the baby nor causes it any discomfort). The NMDP is the only federally funded, Congressionally authorized stem cell registry in the United States, but other, smaller donation registries exist throughout the country.

Brain Stem Glioma, Childhood

Within a neuronal network, there exists a symbiosis between neurons and glial cells. Glial cells are classified as supportive cells, providing a structural and dynamic framework within which neurons are able to thrive. Glial cells are ubiquitous within the nervous system and in fact outnumber neurons of an approximate ratio of three to one. These supportive cells modulate synaptic activity and interactions between neurons in various neural structures with an end result to carry out a common function. In the brain stem, for instance, the nodal interactions drive the brain stem network to carry out cardiovascular, respiratory, and proprioceptive control. The brain stem serves as a conduit for many motor and sensory pathways as well as a passage for cranial nerves III through XII. Thus, damage to this crucial structure can result in significant consequences.

Brain stem glioma develops from glial cells of the brain stem. When the cells begin to proliferate and grow uncontrollably, they form a mass (tumor), which leads to symptoms. Tumors are further classified as either benign or malignant. Benign tumors are focal, and although they press on proximal structures, they do not spread. Malignant tumors, however, are invasive and can quickly dissipate to other areas—they are cancerous. Regardless of malignancy, tumors require treatment because they are capable of adversely interfering with function of any tissue they come in contact with. Tumors of brain stem glioma are of two types: diffuse intrinsic pontine glioma (DIPG) or focal/low-grade glioma.

Most brain stem gliomas (approximately 80 percent) occur within the pons region of the brain stem, whereas the remaining occur with the medulla, midbrain, and cervicomedullary junction. Furthermore, most of the brain stem gliomas within the pons are high-grade tumors with the capacity to spread. Brain stem gliomas occurring outside the pons, in contrast, are focal and low-grade tumors. Grading of tumors is based on the World Health Organization (WHO) grading system, which considers cellular irregularity, growth, and vascular involvement.

The frequency of brain stem gliomas is approximately threefold greater in the pediatric population than the adult. Current statistical findings are reporting a frequency of 20 percent for brain stem gliomas within all pediatric brain tumors. This number is greater than what was previously reported in the 1970s and 1980s, seemingly due to improvements in diagnostic techniques rather than a true increase in incidence. No gender or racial preference exists. Population analyses indicate a median age of five to nine years for diagnosis, with symptoms beginning between 2 and 13 years.

As with pediatric brain tumors in general, most cases have no known causes and are considered sporadic. However, there exist possible risk factors for brain stem glioma, which are largely genetic in nature. These include: Li-Fraumeni syndrome, neurofibromatosis type 1, nevoid basal cell carcinoma syndrome, tuberous sclerosis, and Turcot syndrome (associated with colon polyps). Models of genetic susceptibility syndromes (i.e., NF-1 and tuberous sclerosis) are currently studied in research to uncover the involvement of genetic predisposition and signal transduction pathways in the development of brain stem glioma.

Symptoms of childhood brain stem glioma are diverse and largely context dependent. Contextual factors include patient history (age and development), tumor classification, tumor location, and tumor proliferation. Most of the time, cranial
Brain Stem Glioma, Childhood

nerve palsies are the initial symptoms. Usually, cranial nerve VI and VII are involved. Later symptoms can include contralateral hemiplegia and ataxia, dysphagia, and hoarseness. Neck stiffness and discomfort have been reported in a number of cases and even can present with torticollis. Other symptoms include increased intracranial pressure and vomiting, intractable hiccough, facial spasm, personality change, and headache. Eventually, symptoms can become bilateral. On average, there is a six-month duration between symptom onset and diagnosis.

The main diagnostic tools for brain stem glioma are computed tomography (CT) scan and magnetic resonance imaging (MRI) with gadolinium. After a complete physical and neurologic exam, any suspect of brain stem glioma can be assessed preferably with an MRI. In this procedure, gadolinium is injected into a vein and will clearly demarcate cancerous cells. A biopsy is sometimes performed for diagnosis in cases where the MRI scan detects a focal/low-grade brain stem glioma. After the tissue is removed, the pathologists examine for cancerous cells. In these cases, if cancerous cells are found, the mass may be removed during the same surgery.

Standard treatment of brain stem glioma includes: surgery, radiation therapy, chemotherapy, cerebrospinal fluid diversion, and watchful waiting. Surgery, as discussed previously, simply removes the mass. Radiation therapy, considered the treatment of choice, uses radiation to exterminate and control cancerous cells. Radiation is not without consequences, however, and developmental side effects (i.e., growth stunt) from therapy are likely to result. Chemotherapy is under clinical trial for treatment, and because it utilizes drugs to fight cancerous cells, it is seen as a potential replacement for radiation therapy. Cerebrospinal fluid diversion shunts excess cerebrospinal fluid away from the brain to be absorbed by other body areas. Watchful waiting, as suggested, involves close monitoring of the patient and only administering treatment when symptoms begin or change.

Childhood brain stem glioma presents, unfortunately, with the worst prognosis of all childhood tumors. The median survival time ranges from 9 to 12 months. Recent research suggests that certain clinical, CT, and pathological findings are correlated with prognosis. Cranial nerve palsies were found to be correlated with malignant tumors, mitoses in histological findings with poor prognosis, Rosenthal fibers and calcification with better prognosis, and a hypodense tumor on the CT with a poor prognosis. Further experimentation is required to explore these methods as potential treatment predictors.

In conclusion, childhood brain stem glioma is a severe condition that requires urgent and prudent care. Many factors are to be taken into account when deciding treatment options. Much remains to be discovered with regards to the cause and treatment of this condition.

Further Readings
Brain Tumor, Adult

Adult brain tumors involve cancer that grows in the tissues of the brain among people more than 18 years of age. There are approximately 130 different types of brain tumors. Brain tumors usually increase intracranial pressure (pressure in the skull) because of their size and weight. They may therefore cause symptoms such as headaches, vomiting, loss of appetite, seizures, visual changes, gait changes, and changes in cognition, mood, or personality.

Diagnosis of a brain tumor is made by taking a patient history, giving a neurological examination, and typically using magnetic resonance imaging (MRI) and computerized topography (CT) scans. These technologies have complementary roles—CT scans are particularly valuable for identifying bleeding on the brain that is less than one day old, calcification, and skull lesions. On the other hand, MRI is more sensitive for soft-tissue resolution. In some cases, a brain biopsy is necessary.

If the tumors start in the brain, they are called primary brain tumors; if the tumors start somewhere else in the body and spread to the brain, they are called metastatic brain tumors. Metastatic brain tumors are by far the most common—they outnumber primary brain tumors by a ratio of 10 to 1. When metastatic brain tumors occur, approximately 70 percent of cases involve multiple metastases.

Brain tumors account only for approximately 1 percent of all primary malignant cancers. (This statistic does not include benign tumors or those with brain metastasis from primary tumors in another part of the body.) Malignant brain tumors can be fast growing and aggressive, invading the surrounding tissue and spreading throughout the cerebrospinal fluid space surrounding the brain and spinal cord.

Between 20 and 40 percent of all cancer patients develop metastatic brain tumors. The most common primary cancers that metastasize to the brain are lung cancer, breast cancer, unknown primary cancers, melanoma, and colon cancer. Approximately half of all people with lung cancer and one-fifth of people with breast cancer develop metastatic brain tumors.

It is important to recognize, however, that tumors in the brain cannot automatically be assumed to be metastatic, even if a person has a prior history of cancer. They may be new primary tumors, and appropriate treatment may be able to stop their progression.

Few definitive causes of brain tumors have been identified. However, some of the risk factors that have been identified for adult brain tumors include a history of radiation therapy to the brain and certain conditions such as neurofibromatosis, Von Hippel-Lindau syndrome, Li-Fraumeni syndrome, and Turcot syndrome.

The role of mobile phones as a potential cause of brain cancer is highly contested. There is no medical consensus at this stage about the correlation between cell phone use and brain tumors.

Brain tumors constitute between 85 and 90 percent of all primary central nervous system tumors. Sometimes, patients do not experience any symptoms until the tumor has become quite large. At that stage, the tumor may quickly damage a person’s health. In other cases, symptoms develop slowly.
Brain tumors have high morbidity and high mortality rates. However, the precise effects of a particular brain tumor will depend on the size of the tumor, the grade of the tumor cells, the part of the brain in which it is located, and the age of the person at diagnosis. Outcomes are generally better for younger people.

It was estimated 23,380 new cases of brain tumors will be diagnosed in the United States in 2014. Also, approximately 14,320 people in the United States were expected to die from brain tumors in 2014.

Epidemiological studies suggest that the incidence of primary brain tumors is higher in Caucasians than African Americans, and the mortality rate is higher in men than women.

It is best for patients if an interdisciplinary team offers treatment. For brain tumors, such treatment teams usually include a neuro-oncologist, neurosurgeon, oncologist, radiation oncologist, neurologist, and social workers. Patients with brain tumors may report increased quality of life if they receive comfort measures and counseling and if they participate in support groups. If the prognosis is poor, it may be helpful to discuss advance directives, palliative care, hospice, and plans for a living will.

Treatment for adult brain tumors typically involves surgery to remove the tumor completely or, in the case of deep tumor, to remove as much of the tumor as possible while retaining cognitive function. Surgery is particularly important where it is necessary to have a resection of a single brain metastasis, and it is also necessary in the case of large, symptomatic, or life-threatening tumors. After surgery, radiation therapy and chemotherapy are usually used. The use of steroids is also common. If an individual with a brain tumor has been experiencing seizures, treatment also involves the use of anticonvulsants.

Clinical trials are being conducted currently with the use of alternatives to MRI for brain tumors. MRI scans do not show where the nerve pathways are in the brain, so diffusion tensor imaging (DTI) is being tested because it shows the white matter tracts and the nerve pathways. Although medical understanding of the role of molecular-genetic phenomena in the development of brain tumors has increased considerably in recent years, the exact cause of most brain tumors is unknown, and the mortality rate for brain tumors has remained essentially the same for the last 40 years.

Nevertheless, due to advancing scientific knowledge, researchers do have a much better understanding of tumor biology. Treatment guidelines are evolving. New drugs and new combinations of drugs are always being explored in the treatment of brain tumors. Antiangiogenesis drugs, which block the growth of new blood vessels to tumors, have shown some promise. In 2009, the U.S. Food and Drug Administration gave accelerated approval for one of these antiangiogenesis drugs, Bevacizumab, as monotherapy for some patients (those with progressive glioblastoma).

Other clinical trials have helped in the development of adjuvant treatment. Research is also being conducted on the best ways to treat low-grade gliomas so that they do not recur.

Patient advocacy groups are now organizing charity fun runs and walking events to raise funds, improve awareness, and promote the need for a breakthrough in scientific research. These events also give people a chance to meet others who have had similar experiences. Such events and support groups can provide adults with brain tumors a sense of community and also help reduce the sense of isolation that some people experience when dealing with this difficult experience. National groups such as the American Brain Tumor Association provide advocacy as well as support and information for patients, families, and health care providers.

Brain Tumor, Cerebellar Astrocytoma, Childhood

A cerebellar astrocytoma is a form of brain cancer that arises in the cerebellum, the posterior portion of the brain that controls balance, coordination of movements, and motor learning. In particular, an astrocytoma is a type of glioma, a brain tumor arising from cells of the central nervous system (CNS), either astrocytes, oligodendrocytes, or ependymal. Astrocytomas are defined as either low-grade (Grade I or II) or high-grade (Grade III or IV) gliomas based upon histologic review and how closely the cancer cells resemble normal astrocytes. Low-grade cerebellar astrocytomas are the most common form of brain cancer in children over 3 years, accounting for 10 to 20 percent of all childhood brain tumors and generally presenting before age 10. The grade of the tumor determines the prognosis, treatment, and potential for relapse.

Types of Astrocytomas
Astrocytes are the most abundant cells in the brain, acting to perform multiple functions including fluid and ion homeostasis, regulation of blood flow in brain, aid in the growth and repair of neurons, and formation of the blood–brain barrier, among others. When these cells lose the ability to regulate their growth, they become cancerous astrocytomas. In children, approximately 80 percent of all cerebellar astrocytomas are Grade I pilocytic astrocytomas. Pilocytic astrocytomas are slow growing and well demarcated, often forming a cyst, a closed pouch of cells with a clear distinction from other adjacent cells. An important characteristic of Grade I pilocytic astrocytomas is that they do not progress to Grade II gliomas. Additionally, due to the slow growth and predilection for certain environments, metastasis is not common. Pilocytic astrocytomas may also be associated with the genetic disease neurofibromatosis I, but within the cerebellum, most pilocytic astrocytomas are sporadic. It has been found that the majority of sporadic pilocytic astrocytomas arise from a duplication of a portion of a cellular chromosome, 7q34, which forms a genetic rearrangement where the BRAF gene is fused to the KIAA1549 gene within the cancerous cell. The BRAF gene is a proto-oncogene for the B-Raf protein within the RAS/MAPK signaling pathway. This signaling pathway controls the growth and division of cells, cell movement, and self-destruction of compromised cells (apoptosis). Mutation of the BRAF gene activates the genes oncogenic potential, capable of causing the unregulated cell growth known as cancer.

A smaller portion of childhood cerebellar astrocytomas are fibrillary, Grade II diffuse astrocytomas. Compared to pilocytic astrocytomas, Grade II diffuse astrocytomas are six to seven times less common and account only for approximately 20 percent of cerebellar astrocytomas. Most frequently, diffuse astrocytomas are found in the frontal or temporal lobes of the brain but can be found in the cerebellum. Unlike Grade I pilocytic astrocytomas, malignant progression of diffuse astrocytomas to Grade III anaplastic astrocytoma and Grade IV glioblastoma multiforme is possible, although it occurs only in 10 percent of children with this tumor. Grade II diffuse astrocytomas are also slow growing but differ from Grade I tumors by the invasion of the borders spreading into the adjacent brain tissue. Grade II is differentiated from Grade III anaplastic astrocytoma and Grade IV glioblastoma multiforme due to its microscopic histological and radiologic findings.

Symptoms and Diagnosis
Clinically, the symptoms associated with cerebellar astrocytomas are largely associated with their location within the brain. Due to the cerebellum’s role in balance and coordination, the most common symptoms are associated with loss of balance and lack of coordinated movements. Additionally, due to the skull’s requirement of stable pressure, a rise in intracranial pressure due to the tumor’s size or ability to block fluid movement generally causes nausea, headache, and vomiting.

Imaging studies are integral in diagnosing cerebellar astrocytomas and can be useful in determination of grade. Magnetic resonance imaging (MRI) is the primary diagnostic tool in determining disease staging and guiding surgical and treatment strategies. A computed tomography (CT) scan is then often utilized in order to determine whether there is cerebrospinal fluid blockage and further guide treatment strategies. Biopsy is a common procedure used to verify tumor histology in order to grade the tumor and stage the progression of disease.

When inspected through MRI, a pilocytic astrocytoma is defined as a cyst with a contrast-enhancing mural nodule. Microscopically, pilocytic
astrocytomas are identified by the presence of Rosenthal fibers and biphasic tissue structure. In order to differentiate the low-grade gliomas from one another, the Grade II diffuse astrocytomas are seen without well-defined borders and are nonenhancing. Histologically, the tissues appear hypercellular with angulated, irregular cellular nuclei. Grade III and IV high-grade gliomas both show enhancement without well-defined borders, and Grade IV can show necrosis. Histologically, Grade III tumors appear as Grade II tumors with mitoses, or cells with increased numbers of chromosomes. Grade IV tumors appear similar to Grade III tumor tissue, displaying either necrosis or increased blood flow and microvascular proliferation.

**Treatment and Prognosis**

Treatment for all grades of cerebellar astrocytomas includes some combination of surgery, radiation therapy, and chemotherapy. Low-grade cerebellar astrocytomas generally can be resected surgically, and when complete resection is achieved, cure rates are high, reaching 80 to 90 percent. When the location of the tumor makes resection a challenge without serious neurologic danger to the child, chemotherapy is used after incomplete resection. Radiation therapy is withheld in low-grade tumors due to the high cure rate with resection and chemotherapy as well as the severe side effects of long-term cognitive impairment, risk of stroke, and risk of secondary cancer. Treatment for high-grade gliomas generally includes all three of the common treatment modalities—surgery, radiation, and chemotherapy—often along with other emerging therapies or clinical trials. Due to their rapid rate of growth and high likelihood for metastases, the prognosis of high-grade gliomas is not favorable with less than 30 percent five-year survival rates. Certain biological gene markers, including p53 and epidermal growth factor receptor amplification or mutations, can be helpful in predicting clinical outcomes and response to therapy. Due to the invasive high-risk therapy options for these children, those who survive almost all have severe side effects of neurological and neurocognitive defects and susceptibility to stroke and seizure among others.

Brain Tumor, Childhood

Brain Tumor, Cerebral Astrocytoma/Malignant Glioma, Childhood

The normal brain is made up of several cell types: neurons, the main functional cell of the brain, and glia, which play a supportive role to the neurons. Glia are further subdivided into different types, each type with a different function, including oligodendrocytes, which cover the axons of neurons with sheaths of myelin, and astrocytes, which serve many functions including taking up excess neurotransmitters and creating the blood–brain barrier. Gliomas are tumors of the glial cells, particularly astrocytes and oligodendrocytes. About two-thirds of all childhood brain tumors are gliomas.

Gliomas, like other tumors, occur when the mechanisms that keep cell growth in check go awry, resulting in uncontrolled growth and destruction of surrounding normal tissue.

Gliomas occur in the brain, which is particularly problematic because so many essential areas exist in a relatively small and enclosed space. A small amount of abnormal cellular growth can cause significant symptoms depending on the location of that growth in the brain.

Astrocytomas, or tumors presumably derived from astrocytes or their precursors, are the most common type of glioma. There are several types of astrocytomas, including pilocytic astrocytoma, which is generally considered the most benign of this group, fibrillary astrocytoma, anaplastic astrocytoma, and glioblastome multiforme, the most malignant of the gliomas.

As with most other forms of brain tumors, attempts for curative therapy in high-grade gliomas begin with surgical resection. Ideally, the goal of surgery is to achieve a gross-total resection, meaning that the surgeon has removed all visible tumor and, when scans are obtained after the surgery, no apparent tumor remains.

One of the difficulties in achieving a gross total resection is that, particularly for microscopic tumor cells, they are invisible on magnetic resonance imaging (MRI), or the neurosurgeon may extend beyond suspected tumor boundaries. This is because these tumors are infiltrative, meaning they tend to pass in and around normal brain structures. Some tumor cells may have already migrated to the other side of the brain, quite distant from the tumor seen on preoperative scan and at surgery. In certain cases, surgical resection is not feasible, and the surgeon may only obtain a biopsy to confirm the diagnosis.

Following surgery, patients are often treated with radiation therapy to the region of the brain where the tumor was evident on scans and at surgery. Radiation therapy is routinely limited to areas where the tumor was noted prior to surgery.

The role of chemotherapy in the treatment of high-grade gliomas has been somewhat more debated but is often utilized because of the high failure rate of surgery combined with radiation therapy in the treatment of high-grade gliomas. Chemotherapy has been aggressively utilized in very young children in an effort to delay the use of radiation therapy until the children are a little older.

Most patients with high-grade gliomas will eventually have a recurrence of the tumor, usually within three years of the original diagnosis. Disease may recur at the primary tumor site or at the margin of the resection site or radiation bed. They may also occur at other sites in the nervous system.

Further Readings

Brain Tumor, Childhood

Childhood solid neoplasms and cerebral tumors are the most common cause of cancer deaths
among children, and the four most common neoplastic disorders found in children include medulloblastomas, astrocytomas, ependymomas, and gliomas.

Medulloblastomas are highly malignant tumors of the central nervous system (CNS). In 2007, the World Health Organization (WHO) recognized five histological types under the following categories: classic, anaplastic, large cell, desmoplastic and nodular, and medulloblastoma with extensive nodularity. This class of neoplasms represents the most common solid tumor in childhood and is the leading cause of mortality, accounting for nearly 25 to 30 percent of primary CNS tumors in children younger than 18 years of age.

Molecular biology findings point to a group of negatively transformed stem cells capable of regenerating malignant cells and existent among tumor cell populations as the progressive factor. While current treatment options consist of chemotherapy, tumor resection, and radiation, the risks of treatment include severe neurological defects as well as secondary brain tumors.

Further gene profiling has subdivided the group into four categories based on pathways activated; these include the following: Wnt, Shh, Group 3, and Group 4. Moreover, overexpression of OTX2 was determined to be common across most medulloblastomas. These OTX2 mutations are linked with several disabling phenotypes, including those producing ocular and CNS abnormalities such as seizures, short stature, developmental delay, and pituitary hormone deficiency (CPHD).

Several variables are used to determine cancer type and prognosis, including age, completeness of resection, histological subtype, and genetic markers, which now contribute to treatment decisions and prognostication. Patients can be categorized by risk profile to coordinate treatment modalities as well. Across several groups in past years, new approaches to treatment have improved survival rates and reduced mobility significantly. Some of these advances in the treatment of medulloblastomas include restoring normal cerebrospinal fluid (CSF) flow and maximal tumor resection.

Pilocytic astrocytoma (PA) is the most common glial cell tumors arising in children. Sporadic cases have been linked to KIAA1549: BRAF gene rearrangements. Roughly a quarter of pediatric patients develop PA in the context of the neurofibromatosis 1 (NF1) inherited tumor predisposition syndrome. These tumors are disposed to forming in the optic pathway and brain stem. They also arise within the cerebellum, pointing to the involvement of additional inactivation or mutation events involving the NF1 tumor suppressor gene or KIAA1549:BRAF gene product.

Several etiologic theories exist involving the differential risks of preneoplastic neuroglial cell formation in different brain regions under which sporadic PAs form. The most central of these include transformed stem cells populations. These tumors are often seen with GFAP articulation and histological inclusions, including eosinophilic bodies and Rosenthal fibers. Microvascular growth and large amounts of microglia are often features of these cells. Additionally, the mitogen-activated protein kinase pathway, shown to be a hallmark of PAs is often constitutively active and dysregulated. Loss of tumor suppressor neurofibromatosis 1 (NF1) leads to many of these disorders. In individuals with loss of function mutations in NF1, optic and auditory nerves may be at risk.

Pediatric ependymomas arise throughout the craniospinal axis but are found most commonly along the vertebral system. The spine and meninges are deeply affected. Chief histological features include pseudo rosettes and spiral aura of cells around veins. Additionally, large, solid cytoplasmic inclusions and positive stains for GFAP are notable features on immunoassaying. They originate from glial cells, which give rise to ependymal cells during development. These tumors constitute half of all spinal cord gliomas, roughly 10 percent of pediatric intracranial tumors and approximately 15 percent of all cord tumors.

Ependymomas are the third-most common primary brain tumor in children. Intracranial ependymomas commonly arise within the sacrococcygeal region, mediastinum, and ovaries. Intracranial ependymomas are characteristically found in pediatric populations and tend to be rare in adults.

The vast majority of all pediatric ependymomas are intracranial. Supratentorial tumors account for only a third of ependymomas found in this region in pediatric patients. Supratentorial lesions form in the lateral or third ventricles but may also arise within the white matter or rarely in the cortex. Most pediatric spinal cord tumors account for a tenth of all ependymomas.
Pediatric high-grade gliomas (HGGs), which include glioblastoma multiforme, anaplastic astrocytoma, and pontine gliomas, among others, are difficult to treat and are associated with an extremely poor prognosis. Where there are no effective chemotherapeutic treatments for pediatric HGG, new treatment regimens are in active investigation. Differences between adult and pediatric HGG require additional studies in children.

Molecular science has revealed cell markers that are overexpressed in pediatric HGG include PDGFRα and P53. For example, upregulation of EGFR is distinguishable but to a lesser degree than in adult HGG. Unfortunately, key therapeutics including bevacizumab and tipifarnib have been shown to be less active in pediatric patients than that observed in adults. Gefitinib has shown greater effects. After promising phase I findings in children with primary CNS tumors, the integrin inhibitor cilengitide is being investigated in a phase II trial. Studies are underway in pediatric HGG with two EGFR inhibitors: cetuximab and nimotuzumab. Dendritic cell-based vaccinations, boron neutron capture therapy, and telomerase inhibition remain novel therapeutics under investigation.

Further Readings

Brain Tumor, Medulloblastoma, Childhood

Although cancer is rare in children, brain tumors are the most common type of childhood cancer other than leukemia and lymphoma. About one out of five childhood brain tumors are medulloblastomas (MBs). Childhood MB is a disease in which benign (noncancer) or malignant (cancer) cells form in the tissues of the brain, especially in the cerebellum, which is at the lower back of the brain, or posterior fossa and have a tendency to disseminate rapidly throughout the central nervous system (CNS). The cerebellum is the part of the brain that controls movement, balance, and posture.

Epidemiology
MB, as the most common brain tumor of childhood, represents 20 percent of all childhood brain tumors. They are most frequent in children between the ages of 3 and 8 and are slightly more common in boys (62 percent) than girls (38 percent). The disease is more prevalent in younger children than older children. Forty percent of patients are diagnosed before the age of 5, 31 percent are between the ages of 5 and 9, 18.3 percent are between the ages of 10 and 14, and 12.7 percent are between the ages of 15 and 19. The overall incidence rate of MB is approximately 1.5 and 0.62 per million population in the United States. Children (1 to 9 years of age) with MB had an incidence rate of 6.0, compared to 0.6 in adults; and therefore, children are 10 times more likely to be affected by an MB than adults.

Signs and Symptoms
General symptoms are: vomiting (most common) with or without nausea, headaches, clumsiness, difficulty with tasks like handwriting, gradual decline in school performance (impaired attention).

Diagnosis
The following tests and procedures examine the brain and spinal cord to determine if there is childhood MB or to locate exact traces of tumor cells before taking biopsy: computed topography (CT scan), a procedure that makes a series of detailed pictures using X-rays of areas inside the body, which then can be
visualized via a computerized system—a dye may be injected into a vein or swallowed to help the organs or tissues show up more clearly—and magnetic resonance imaging (MRI), a procedure that uses a magnet, radio waves, and a computer to make a series of detailed pictures of areas inside the brain and spinal cord. A substance called gadolinium is injected into the patient through a vein. The gadolinium collects around the cancer cells, so they show up brighter in the picture. The final step for diagnosis of an MB is made by the neurosurgeon taking a biopsy of the tumor. This is taken when the neurosurgeon makes attempts to remove the entire tumor.

Pathophysiology
MB is a cerebellar tumor arising predominantly from the cerebellar vermis. The histogenesis of MB remains controversial. One view suggests that the cell of origin derives from the external granular layer of the cerebellum. This is supported by the finding that the proliferation of precursor neurons in this layer is controlled by sonic hedgehog (SHH), whose receptor PTCH is mutated in a subset of sporadic MBs. Another hypothesis proposes that MBs have more than one cell of origin. This is based on studies showing differential immunoreactivity to a neuronal calcium-binding protein that is not expressed in the external granular layer and to a beta-tubulin isotype, which is expressed in the neuronal cells of the ventricular matrix and external granular layer. Numerous molecular alterations that appear to modulate the biological behavior of MB or its response to therapy have been reported. Recent integrated genomic studies have revealed that MB is composed of four distinct molecular and clinical variants: WNT, SHH, Group 3, and Group 4. Involving of genetic alterations in the pathophysiology of MB is exemplified in a study that suggests that MB expression of neurotrophin (NT3) may modulate the behavior of these tumors by inducing apoptosis, thereby retarding tumor progression and resulting in a more favorable prognosis.

As the tumor grows, obstruction of cerebrospinal fluid (CSF) passage through the fourth ventricle generally occurs, resulting in hydrocephaly. The tumor may spread contiguous to the cerebellar peduncle, or the floor of the fourth ventricle; anteriorly, to the brainstem; inferiorly, to the cervical spine; or superiorly, above the tentorium. It also may spread via the CSF intracranially or to the leptomeninges and spinal cord. Of all the pediatric CNS neoplasms, MB has the greatest propensity for extraneural spread, especially to bone and bone marrow; however, the rate of such events is less than 4 percent. It is currently thought that MB arises from cerebellar stem cells that have been prevented from dividing and differentiating into their normal cell types.

Mortality and Morbidity
Risk group stratification is continuing to evolve but is currently based on three principal features, including age, extent of postoperative residual disease, and the metastasis stage (M stage) derived from the Chang classification staging system. The average-risk disease group is defined as patients older than 3 years who are at stage M0 with less than 1.5 cm² of residual tumor postoperatively. The poor-risk disease group is defined as patients older
than 3 years who are at stage M1 through M4 or with more than 1.5 cm² of residual tumor postoperatively. Infants are defined as patients younger than 3 years. This group has the worst prognosis, regardless of M stage and extent of postoperative residual disease.

**Treatment**

With aggressive surgery, craniospinal radiotherapy, and chemotherapy, more than 50 percent of children with MB can be expected to be free of disease five years later. Using current treatments, 80 to 90 percent of those without disseminated disease can be cured; however, treatment for this disease often results in significant endocrinological and intellectual sequelae. Children greater than 4 years of age who have had a complete tumor resection receive a combination of craniospinal (brain and spine) radiation, followed by a four-month course of intensive chemotherapy. Because of the significant effects of radiotherapy on an infant’s developing brain, children less than 3 years of age receive high-dose chemotherapy immediately following surgery, with the aim to delay or even obliterate the need for radiation treatment.

The progress of using blood stem cell transplants instead of radiotherapy has impacted the overall survival rate of this disease. The overall five-year survival rate is the percentage of people who survive at least five years after the cancer is detected, excluding those who die from other diseases. For children with MB, this depends on several factors, including the risk level for this disease and age at the time of diagnosis. Survival rates for children who had a complete removal of their tumor during initial surgery have risen to 80 percent survival at five years from diagnosis, compared to 50 percent and 60 percent survival rates five years ago. The treatment of infants continues to be difficult (30 percent survival rate). This is because of the delay in the ability to deliver radiation to the entire brain and spine, resulting from the known detrimental effects it has on the developing brain.

**Brain Tumor, Supratentorial Primitive Neuroectodermal, Childhood**

One of the ways in which brain tumors are classified is according to whether they are located in the upper or lower part of the brain. Supratentorial tumors are located in the upper part of the brain, where the cerebrum—the center of thought, emotion, learning, and voluntary movement—is located. A primitive neuroectodermal tumor (PNET) occurs at the neural crest. The neural crest is a migratory cell population at the border of the neural plate, which is formed during neurulation—the folding of tissue that begins the formation of the central nervous system in the developing fetus. While the neural tube forms into the brain, spinal cord, retina, and posterior pituitary, the neural crest becomes ganglia, pigment cells, facial cartilage, the adrenal medulla, and other features. Most of the tissue of a
primitive neuroectodermal tumor comes from the neuroectoderm, the germ cell layer that develops into the nervous system. Primitive neuroectodermal tumors are rare and usually occur in children and young adults. The "primitive" part of the name refers to the fact that the neuroectoderm cells in the tumor have not developed or differentiated like normal neurons. PNETs are divided into two types: peripheral PNETs, which occur on the bone, and central nervous system PNETs, nearly all of which are supratentorial.

Primitive neuroectodermal tumors are part of the Ewing family of tumors (EFTs), all of which develop from the same kind of stem cell. Other EFTs include Ewing tumor of bone, extraosseous Ewing tumors, and Askin tumors (PNETs occurring in the chest wall). As with most childhood brain tumors, the causes of PNET are unknown.

Symptoms of PNET are typical of other brain tumors and include symptoms that may be mistaken for other illnesses—including sleepiness, nausea, vomiting, and headaches—as well as symptoms that are more immediately suggestive, like weakness or change in sensation that is specific to one side of the body, and unexplained weight changes. Changes in personality or behavior may or may not be noticeable depending on the age of the child. Once a tumor is suspected, a computed tomography (CT) scan or magnetic resonance imaging (MRI) is performed to locate it, followed by surgery. During surgery, part of the skull is removed, and a sample of tumor tissue is examined for signs of cancer. If the tumor is cancerous, the surgeon removes it during the same surgical session.

As with other cancers, prognosis is dependent on the size and spread of the tumor and how thorough the surgical removal is. The location and size of the tumor and the age of the child impact treatment options. There is no staging system for PNETs—instead, cases are discussed in terms of poor risk (if the tumor was near the center of the brain, if some of the tumor remains after surgery, if the cancer has spread, or if the child is under 3 years old), which have a high chance of recurrence, or average risk, if the child is over three, nearly all of the tumor was removed, and the tumor has not spread.

Risk groups can be determined through MRIs and chest X-rays as well as a bone scan—during which radioactive material is injected into the patient, which collects in the bones before being scanned—or lumbar puncture, also known as a spinal tap, a painful procedure by which cerebrospinal fluid is extracted from the spinal column.

In addition to surgery, radiation therapy and chemotherapy are used to treat PNETs, as with other brain tumors. Typically, surgery is followed by radiation therapy to the brain and spinal cord, especially if not all of the cancer was removed; radiation helps destroy the remaining cancer cells. However, radiation exposure can have significant effects on the development of the child brain, and so lower-exposure means may be used, or chemotherapy may be used in order to either replace or, commonly, delay radiation therapy. Children under 3 are especially poor candidates for radiation therapy.

The five-year relative survival rate for PNETs is 64 percent for children and 35 percent for adults age 20 to 25. There are only two known survivors over the age of 25. The oldest known PNET patient, 41-year-old Tim Young, underwent surgery for PNET of the spinal cord in 2008; he remains a survivor in 2014.

As with other cancers, there is a chance of PNET recurring. Recurrent childhood supratentorial PNET may come back many years later, and while it usually recurs in the brain or spinal cord, it can occur in other parts of the body instead, such as the lungs or bone tissue.

Brain Tumor, Visual Pathway and Hypothalamic Glioma, Childhood

Anterior visual pathway (optic) gliomas are brain tumors that arise in the structures that convey vision from the eye to the brain. Their origin is not from the nerve cells but from the stellate cells (astrocytes) that are supporting cells in the central nervous system. Optic pathway gliomas account for approximately 5 percent of childhood brain tumors; most patients are diagnosed before age 10. Optic pathway gliomas also can develop in adults, but the natural history is different in those cases, and the outcomes are poorer. This entry focuses on optic glioma in the pediatric population.

Children with optic gliomas typically present with visual impairment, although they can have a number of other problems depending on the tumor location. Symptoms can include abnormal eye movements, eye protrusion, headache, and even endocrine dysfunction. Sometimes the symptoms are not recognized until later in the disease course, especially in younger children because of their limited ability to communicate.

The tumor can be located anywhere along the visual pathway, the route that conveys information from the eye to the brain. From front to back, it includes the optic nerves, the optic chiasm (an X-shaped structure where the optic nerves join inside the skull and where parts of the optic nerves cross), and the optic tracts. The visual information is then transmitted to the posterior portion of the brain (the visual cortex), where higher levels of visual processing begins.

Nearly all childhood optic gliomas are benign and slow growing, and the prognosis for survival is good. The diagnosis usually is made from the appearance of a lesion on brain imaging. The symptoms, management, and prognosis of visual pathway gliomas depend largely on which of the visual pathway structures are involved and to what extent. The main goals in management of all visual pathway gliomas are to retain as much vision for as long as possible and to decrease any other potential complications associated with the disease or its treatment.

If only the optic nerve is involved, then the tumor is known as an optic nerve glioma. About a quarter of visual pathway gliomas are confined wholly to the nerve at the time of diagnosis. Gliomas confined to the optic nerve have fewer complications and higher survival rates than other gliomas of the visual pathway. They result in vision loss in one eye. One significant risk factor for developing an anterior visual pathway glioma is having a diagnosis of neurofibromatosis type 1 (NF1), also known as von Recklinghausen’s disease. This disease is dominantly inherited and is characterized by optic gliomas, nodules on the iris, bone abnormalities, and skin lesions. The cause is a mutation of a gene that encodes a protein known as neurofibromin, which acts in cell signaling. Patients with NF1 account for one in three patients with optic gliomas, and so any patient with a newly diagnosed optic glioma should be evaluated for this disorder. Usually, resection as a treatment choice is considered only for visual pathway gliomas that are confined to the optic nerve because it would be too invasive to try to remove tumors from other areas of the visual pathway, but resection of optic nerve gliomas usually is considered only when an eye no longer has vision and there is severe protrusion of the eye.

The optic chiasm is the next structure back from the optic nerves in the visual pathway. The hypothalamus, which controls metabolism and homeostasis, is located just above the chiasm. Because of their proximity, optic chiasm gliomas can involve the hypothalamus. Hypothalamic involvement can cause developmental delay and hormonal dysfunction, such as early puberty and weight changes.

Some chiasmal tumors also increase intracranial pressure by blocking the normal flow of cerebrospinal fluid, causing nausea, vomiting, lethargy, irritability, and headaches. Sometimes patients with these symptoms undergo shunt procedures to redirect the fluid. Optic chiasm and hypothalamic gliomas have the highest rate of death among the visual pathway gliomas.

Children affected by visual pathway gliomas are seen by a multidisciplinary team of physicians. The treatment options most often elected are chemotherapy and radiation. These treatments can be effective, but their adverse side effects do not warrant their administration unless functionally debilitating symptoms arise. Sometimes visual pathway gliomas spontaneously regress, so there is some controversy about the best way to treat these tumors. Asymptomatic tumors are typically observed with serial eye examinations and imaging studies.

Both chemotherapy and radiotherapy can stabilize or shrink these tumors, but chemotherapy is usually the first-choice treatment for children if observation is not favored. Chemotherapy involves the use of medications that disrupt the tumor cells’ ability to replicate. This can be an effective therapy, but side effects such as nausea, vomiting, and anemia can occur because the drugs do not differentiate between tumor and normal tissue. There are also patients who have tumors that progress or recur despite chemotherapy. Radiation therapy uses high-energy rays to kill and shrink the tumors. Although it is also effective, serious long-term side effects such as cognitive, hormonal, and vascular complications may occur as well as the formation of secondary tumors, especially in patients with NF1. Recent advances in radiation therapy allow for more specific targeting of the treatment to smaller areas, reducing damage to nearby tissues, but given the potential side effects, radiation therapy is often avoided as the initial treatment, especially in younger children. Surgery is also avoided if possible because the visual pathway and other nearby structures can be damaged during resection of the tumor, and resection of gliomas is in any case rarely feasible from a technical point of view.

The management of gliomas of the anterior visual pathway varies depending on the location of the tumor, the age at diagnosis, and the symptoms and is still a work in progress. Further research is underway to find better ways to manage these tumors. Newer technologies and surgical techniques may provide better options for future treatment of this disease.

Brazil

Brazil is the largest country in South America (it occupies about 47 percent of the South American continent). It has approximately 200 million inhabitants, therefore the largest population in the whole continent, encompassing at least five big ethnic groups. Compared to other countries, Brazil has a cancer rate that is lower than Europe, North America, and eastern Asia. The incidence of some cancers in the United States—for example, breast cancer—doubles those in the totality of South America. In the whole continent, there are some transformations, in principle attributable to the transition from a high incidence of infectious diseases to chronic conditions. That situation has resulted in an increase of the incidence of cancer. As a part of Latin America, Brazil reaches the level of epidemics in terms of cancer. Economic inequity, lack of prevention, and lifestyle are actively contributing to the increase of mortality rates.

In Latin America, although the incidence of cancer is lower than in Europe or in North America, the probability of dying of cancer is 60 percent higher than in those continents.
However, chronic diseases such as infections by candida, malaria in some regions like Amazonas, or hepatitis B still have an enormous impact on the population.

**History**
The perception of cancer, as in most countries, underwent a transformation between the 19th and 20th century. At the beginning, it was seen as something exceptional and therefore as a rare social problem. However, once the aging population pushed the incidence of cancer higher, specialized care and philanthropic approaches began to appear.

In the late 1910s, radiotherapy was applied in restricted cases in Brazil—usually limited to skin cancers. In fact, when the National Department of Public Health was created, its main goal was to control cancer, thanks to the connections between dermatology and oncology. Between the 1920s and the 1940s, Brazil made systematic efforts to control cancer in the whole country. In the early 1920s, philanthropic societies provided facilities for patient treatment. On its part, government made investments in order to inform the public and implement prevention programs. Following the examples of Europe and the United States, Brazil implemented in the 1920s the first anticancer policy in the sanitary system. In the decade of the 1930s, the first leagues to fight cancer emerged. Their purpose was to raise funds in order to build centers for diagnosis and treatment. In 1935, during the First Cancer Congress, several experts tried to convince authorities about the need of a generalized system of cancer control. In 1937, the first center of oncology was founded.

All those plans were virtually possible after the creation of the National Department of Public Health, consolidated at the end of the 1940s but was created in the 1920s, when cancer became a priority not only in terms of information to the population but also in a better understanding of cancer as a professional field. Until that moment, the efforts were rather few and not enough to reach the expected goals. However, that priority was relative; most experts were more concerned about infectious diseases with high impacts on the population, like malaria, syphilis, leprosy, or tuberculosis. In fact, many doctors believed that cancer was a transmitted disease, similar to leprosy.

**Brazil in Figures**
In Western countries, and in many developing countries, there are similar scenarios: Most cancers occur among male populations. Besides, in Brazil the highest mortality rates occur among men, especially in the case of lung, prostate, and stomach cancers. But there is a big difference in comparison to Western, developed countries, where cancer used to be the first or second cause of death. In Brazil, it is the third cause, just after vascular diseases and external causes. The highest average incidence was found in the region of Porto Alegre and São Paolo, and it is valid for both males and females.

Contrary to other worldwide trends, the most common malignant tumor in men is nonmelanoma skin cancer, followed by lung, colorectal, and stomach. Among women, skin cancer also is placed at the top of the most common malignant tumors, followed by breast, cervical, and colorectal cancer. Skin cancer (nonmelanoma), although it is the most common cancer, used to be surgically removed with no further consequences for the patient. The high rates of infection by human papillomavirus (HPV) are translated into a high incidence of cervical cancer. From an epidemiological point of view, some programs were implemented in the last years in order to study HPV transmission and to test (effective) vaccines. With regard to breast cancer and in the context of Latin America, Brazil, together with Peru, are countries with worse expectations for those patients due to late diagnoses, when cancers are at advanced stages and the results of the treatments rather poor.

According to the Unity of Prevention and Control of Cancer, from the Brazilian Cancer National Institute, whereas some type of cancers, like prostate, breast, and colorectal, are the consequence of an improvement of socioeconomic level, other malignant tumors—oral, cervical, and penile—are more associated with poverty.

The cancers caused by occupational agents apply to between 2 and 4 percent in the case of Brazil, affecting primarily the lungs, bladder, or skin or even causing leukemias.

In the case of developing countries, like Brazil, around 20 percent of the totality of cancers is attributed to some collateral effects of globalization—sedentary lifestyle, use of alcohol, and inappropriate diet. Despite all of this, it has a low rate compared to developed countries, where the average could be 30 percent.
It is estimated that about 1 million people are under risk of suffering some kind of cancer due to a specific attribute (age, gender, status, etc.) and that 520,000 new cases will be registered annually. In fact, the number of cases annually per 100,000 people is 171.3. The annual number of deaths reached 1,261,100, according to official data from 2013, and it is higher among men than among women.

One of the most important institutions is the José Alencar Gomes da Silva National Cancer Institute (INCA), which provides statistical data as well as general information for the population and specific information for patients. Its fundamental mission is to improve the quality of life of patients, detecting administrative mistakes that could be an obstacle in the process of a patient’s treatment.

The Brazilian Population-Based Cancer Registry (PBCR) was created in 1967 in Recife, followed by the registry of São Paolo two years later. Actually, the Brazilian Cancer Registry is the result of regionalized efforts—it covers a total of 27 states to collect data, to provide indicators, and to publish updated reports. It integrates with other health institutions or programs, like Mortality Information System (SIM), Health Care Management, and NCD Surveillance.

In the last years, some associations to give support to cancer patients have proliferated. The most relevant is the Brazilian Association for Supporting Cancer Patients (ABRAPAC), which gives practical information and advice to cancer patients in order to improve their quality of life not only in terms of treatments but especially in all collateral support (emotional support, how to face hair loss after chemotherapy, etc.). Besides, since 2000, the project Brazilian Association of People Suffering From Cancer (AMUCC) has been in operation, originally created to give support to women affected by breast cancer and later involved in projects related to all cancers and any kind of patient. Its main goal is to ensure the rights of cancer patients.

Finally, the Brazilian Society of Oncology promotes campaigns to fight risk factors of cancer related to lifestyle. They provide information to patients but also resources like specialized publications that can be consulted online.

Breast Cancer

Breast cancer is a major public health problem in the developed world. It is the most common cancer among U.S. women and makes up a significant portion of illness, health care expenses, and loss of life. One in eight women is expected to develop breast cancer in her lifetime. Factors associated with increased breast cancer risk include family history of the disease, higher number of lifetime menstrual periods, and inadequate physical activity; generally, the disease is thought to result from a complex combination of genetic and lifestyle factors. One key to reducing the burden of breast cancer is to detect the disease at its precancerous or early cancerous stages. Tools for early detection include mammography, imaging, and self-examinations.

Studies suggest that breast self-exams lead to increased follow up of noncancerous masses and do not increase breast cancer death rates. The benefits of screening for early detection need to be balanced against the risks of increased anxiety among women whose screening results ultimately may turn out to be negative. Over recent decades, better treatment options for breast cancer have improved the outcomes for patients. The promising outlook for breast cancer is due in part to breast cancer advocacy, which grew immensely at the end of the 20th century. Community involvement has
increased awareness, support, and research funding for this common and deadly disease.

In 2015 in the United States, the American Cancer Society estimates that 231,840 new cases of breast cancer will be diagnosed in women and 2,350 new cases in men. The number of new breast cancer cases increased rapidly throughout the 1980s and since then has risen only slightly. This is likely to be a result of increased screening in the 1980s followed by the use of novel tools for early detection.

Despite increasing numbers of new diagnoses, early detection and improved treatments held the number of deaths attributed to breast cancer among women constant until 1990. Following this time, deaths due to breast cancer decreased substantially. The American Cancer Society reports that, between 1990 and 2003, deaths from all types of cancers in women decreased, and 40 percent of this decline was due to reductions in breast cancer deaths.

In 2015 in the United States, the American Cancer Society estimates that 40,290 women will die of breast cancer, as will 440 men. The disease is currently the second-most common cause of cancer deaths (second to lung cancer), representing an estimated 15 percent of all deaths due to cancer in women. However, among women age 20 to 60, breast cancer is the most common cause of cancer death; African American women are estimated to have the highest rates of breast cancer deaths compared to other women.

Risk Factors
Although we have learned much about a variety of factors that may influence the development of breast cancer, the true cause of breast cancer remains unknown. It is likely that breast cancer results from a combination of genetic and nongenetic factors. Thus, a woman who is at increased risk due to disease in her family may be able to modify this risk with changes in lifestyle factors, such as increasing her frequency of exercise.

Epidemiologic researchers conducting studies of large numbers of women compare characteristics of those who do and who do not develop breast cancer and have found some consistent results. Some risk factors are unfortunately not modifiable. These include being female (women are at much higher risk), being white (African American, Asian, Hispanic, and American Indian women have lower rates), increasing in age (older women are more likely to develop the disease), and having affected relatives (having a mother, sister, or daughter with breast cancer about doubles risk). In addition, starting periods at an early age and entering menopause at a later age increase a woman's risk of breast cancer; this is thought to be due a longer lifetime exposure to estrogens.

Other factors related to the risk of developing breast cancer may be considered modifiable. These include childbearing (women pregnant at an early age and pregnant more than one time are at a lower risk), breast-feeding (women with children who breast-feed seem to be at reduced risk), exercise (physically active women are at lower risk), avoiding alcohol (drinking up to five drinks a day may increase risk), and maintaining lower body weight (children with large weight gain may be at increased risk of later breast cancer and women who are obese after menopause are at increased risk).

There are also more complex, modifiable factors that should be considered in consultation with a physician. Hormone replacement therapy, specifically the use of estrogens combined with progesterone, after menopause has been shown to increase breast cancer risk. A woman’s use of oral contraceptives within the last decade may increase risk as well. There are also medical conditions associated with increased risk including radiation treatment in the chest area, abnormal breast biopsy, and certain formerly used hormonal treatments such as diethylstilbestrol (DES).

A physician should be consulted about the risks and benefits of medical treatments that may lead to modified breast cancer risk later in life.

Less-common factors may also influence a woman’s breast cancer risk. Studies are under way examining specific environmental pollutants that may influence risk at very high doses; however, no results to date are clear-cut. Approximately 7 percent of all breast cancer cases are thought to be due particularly to genetic changes passed down in families. A portion of these truly familial cases are due to changes in the genes, BRCA1 and BRCA2. Changes, or mutations, in these genes lead to an approximate 80 percent chance of developing breast cancer. While the search is under way for similar genes, and for genes conferring more modest increases in risk, it is likely that modifiable factors play a role even among families with these high-risk genes.
Screening and Early Detection

Like other cancers, the burden of breast cancer in terms of medical complications, expense, and most important, death can be reduced if the disease is detected at an early stage, for example, before it has spread to other organs in the body. Early detection of breast cancer can be attained by routine population screening and by easy access to care when any symptoms first develop, assuming symptoms are recognized by the woman experiencing them.

There has been great debate in the recent decade about the utility of monthly breast self-exams. One of the potential harms from breast cancer screening comes from false positive findings leading to unnecessary further testing and anxiety. Several studies, including a large randomized trial in China, suggest that breast self-exams lead to increased follow-up of noncancerous masses and overall do not increase breast cancer death rates.

The traditional approach to breast cancer detection is an annual physical examination by a physician. Many medical organizations, including the American Cancer Society and the American College of Radiology, recommend annual screening mammograms for women starting at age 40. Screening mammograms are X-rays of the breasts (generally two for each breast) done in women with no signs or symptoms of breast cancer in order to find very early stages of breast cancer before they can be found on a clinical exam. It is generally agreed that patients between age 40 and 50 years should be screened every 12 to 24 months. There have been several randomized studies showing the efficacy of annual mammographic screening in reducing breast cancer rates by about 20 to 30 percent in women after age 50. The benefit of an annual screening mammography in women age 40 to 50 or over 70 years is less clear. It is important to note that breast exams performed by clinicians with proper technique can detect up to 5 percent of cancers not picked up by mammograms.

One form of screening mammography uses digital mammograms (as opposed to standard film mammograms) wherein images are captured as in film mammography and then digitally manipulated for clarity. Digital mammography is preferred in women with denser breast tissue; dense breast tissue is seen mainly in women who have not yet entered or are in the midst of menopause. Digital mammography systems are two to four times more expensive than film mammography systems. Some institutions use computer-aided interpretation of mammography, although the benefits of computer interpretations, considering substantial increases in cost, remain to be proven.

Other means of detecting breast cancers are used to complement these methods. Ultrasound of the breast complements a mammogram in evaluating lumps detected by physical examination and can be useful in following up abnormal mammogram findings and is relatively inexpensive. Magnetic resonance imaging (MRI) is a technique that enables the diagnosis of breast cancer that cannot be seen in mammograms in up to 10 to 18 percent of cases. An MRI can be used to identify multiple areas of cancer in the same breast and define the extent of cancer. An MRI of the breasts is increasingly used as a screening procedure especially in high-risk women (such as those with BRCA1 or BRCA2 gene mutations) and in women with dense breast tissue. Because an MRI is expensive, requires injection of dye, has a lower specificity leading to increase rate of follow-up invasive procedures, screening MRI is not advised in average-risk women.
Breast Cancer

Diagnosis and Prognosis

A biopsy of any lump in the breast or a suspicious area on a mammogram is performed using a needle to draw cells from the lump and examine them under a microscope. Cancer diagnosis is then established.

At diagnosis, approximately 60 percent of breast cancers are localized (confined within the breast), 30 percent are regionally spread (e.g., to nearby lymph nodes), and 10 percent have metastasized (e.g., to the liver). African American women tend to be diagnosed at a more advanced stage, consistent with increased rates of breast cancer death in this group and indicative of fast-growing disease. Two types of breast cancer can be diagnosed: Ductal carcinoma in situ (DCIS) is diagnosed if the cancer has not invaded outside the mammary ducts, and invasive cancer is diagnosed when the cancer has spread outside the milk ducts.

When a breast cancer is diagnosed, the staging process begins, involving extensive testing to assess the extent of disease within the body. Medical history, physical examinations, chest X-ray, and blood tests are used as staging tests. If any of these tests are abnormal, then a bone scan (injection of a radionuclide substance intravenously and imaging the whole skeleton), computed tomography (CT) scan or a positron emission tomography (PET) scan are obtained as needed. Some of these tests are very costly and are therefore used only when specially indicated.

Recent data suggest that, on average, 89 percent of women diagnosed with breast cancer survive five years or more. Women diagnosed with Stage I breast cancers (tumors less than 2 centimeters with no lymph node involvement) can have an overall 10-year survival (proportion of patients living 10 years following diagnosis) of up to 95 percent, women diagnosed at Stage II (less than 2 centimeters with or without lymph node involvement) have an average 10-year overall survival of up to 80 percent, and those with Stage III disease (less than 5 centimeters or fixed tumor or several sentinel lymph nodes [SLNs] involved or with inflammatory changes) have 10-year overall survival of up to 50 percent with modern treatments.

Treatment Options

Women with early-stage breast cancer typically undergo surgery. Mastectomy (removal of entire breast) and breast conservation surgery (smaller surgery focused on limited area using a wide local excision or lumpectomy) confer similar prognoses. SLN sampling is routinely done during these surgeries, which involves the removal of the lymph node nearest to the affected area in the breast.

The SLN is examined for the presence of cancer cells, and if the SLN is positive for cancer metastasis, then a full dissection of auxiliary lymph nodes is performed. Tumors that are removed in surgery are tested for estrogen receptor (ER) and progesterone receptor (PR) status, which indicate the presence of these proteins in the nuclei of the cancer cells.

Following surgery, subsequent treatments may include radiation treatment, chemotherapy, or hormonal therapy depending on the size of tumor, lymph node involvement, type of initial surgery, menopausal status, and estrogen and progesterone (ER and PR) status. Patients with breast-conserving surgery undergo postoperative radiation therapy to prevent local recurrence of cancer. Currently, the standard radiation therapy is delivered over a period of approximately five weeks. Finding transportation to and from a radiation facility can be a financial burden for many patients.

Generally, for ER- and PR-positive tumors, hormonal therapy such as tamoxifen or aromatase inhibitors (which block adrenal gland production of estrogen) give maximum benefit in women who have gone through menopause. Even in premenopausal women, the hormonal therapy with removal or suppression of the ovaries may be of benefit. In selected patients with DCIS and ER- and PR-positive tumors, tamoxifen is prescribed for five years to prevent local recurrence and the prevention of a new breast cancer in lieu of or in addition to radiation. These treatments can prolong a patient’s life by anywhere from 20 to 40 percent in Stage II and III patients.

For advanced cancers (large tumors and lymph node-positive tumors), additional chemotherapy is recommended. The cost of chemotherapy further increases because patients need to receive growth factors to boost white blood cell counts or red blood cells to facilitate timely treatment. Recently, herceptin, an antibody to treat certain aggressive breast cancers, has been approved to be used along with chemotherapy. This is an expensive treatment requiring patients to return to the clinic at least every three weeks for a whole year.
The American Cancer Society provides navigators for newly diagnosed patients to help them through the process of treatment and accessing resources. A mentor program links current patients with survivors to provide one-on-one support—for example, accompanying patients to doctors’ visits to help them ask the right questions.

**Issues for Breast Cancer Survivors**

Both hormonal therapy and chemotherapy can cause significant side effects, including hot flashes, severe joint pain, and nerve damage requiring further interventions that can be costly. Patients without insurance may not be able to afford cancer treatments and supportive services.

Lymphedema can occur postoperatively, in which excess fluids build up in certain tissues and organs; lymphedema can adversely affect quality of life and decrease productivity at work. Fortunately, surgical advances removing only selected (rather than all) lymph nodes have reduced the burden of this condition.

The cost of breast cancer to patients and society including genetic testing, screening tests, and treatment of established cancer extends to follow-up testing to detect cancer recurrence. Randomized studies have shown that the majority of breast cancer recurrence is detected by a detailed history and physical exam with annual liver chemicals, mammogram, and chest X-ray monitoring picking up other recurrences. Expensive scans, such as CT, PET, and bone scans, and tumor markers in the blood are not currently recommended when following breast cancer survivors.

For breast cancer that has recurred or spread to other organs, there is no cure. However, these patients can live three or four additional years and be on continuous cancer treatments. Newer drugs such as antibody treatments offer more promise, but costs can be prohibitive, with several thousand dollars per monthly treatment, mostly borne by insurance carriers and Medicare. Many of these patients continue to be productive citizens and view life differently following their diagnoses.

Breast cancer survivors have noncancer issues to deal with as well. Having a mastectomy can be a life-changing event for many patients. Patients may be distraught by the loss of a breast and lose their self-image. Reconstruction of the breast has given hope and solace to women who choose to undergo plastic surgery; insurance companies have recently recognized that this is an important aspect of a breast cancer patient’s recovery and currently cover the costs associated with this operation.

Young women thrown into early menopause by chemotherapy and antiestrogen therapy may suffer from low libido and vaginal dryness, which can interfere with sexual relations and emotional relationships with partners. Belonging to survivor groups has been helpful to many women coping with these issues.

**Advocacy**

Women have proven that they carry a powerful voice. In the last half-century, breast cancer awareness has exploded. The month of October has been designated as Breast Cancer Awareness Month in the United States. Pink ribbons symbolizing breast cancer awareness are worn by patients, relatives, friends, and caregivers to remind people to go in for mammograms and contribute to breast cancer research funds. Major retailers such as Estée-Lauder and the Avon Foundation contribute a portion of their profits to breast cancer research.

Breast cancer survivors have lobbied and obtained reimbursement for breast reconstruction. Survivors attend national research meetings and conferences, and their opinions are heard and incorporated into clinical trials.

The Susan G. Komen Foundation is a successful organization started by the sister of a breast cancer patient. It sponsors annual events throughout the nation to raise hundreds of thousands of dollars to fund major research. Breast cancer advocacy groups such as this and the National Breast Cancer Coalition have paved the way for other cancer groups to be powerful advocates. However, much work remains to prevent and cure breast cancer; ongoing research with community involvement is essential to achieve this goal.

Breast Cancer, Male

Male breast cancer is pathologically similar to female breast cancer but is much less common, while breast cancer is the second-most common cancer faced by women after skin cancer; less than 1 percent of breast cancer cases are male. It is one of the least common cancers among men, with men who live to 95 facing a 1 in 1,000 chance of developing it, compared to the one-in-eight chance of women.

Because breast cancer is overwhelmingly more common in women, most medical knowledge of male breast cancer, including screening and treatment methodologies, is generalized from female breast cancer. Both cancers are functionally the same but behave slightly differently due to the different conditions (hormonal and structural) of male and female bodies.

Risk Factors
Genetic factors are among the possible risk factors for male breast cancer. Like women, men carrying mutations of the BRCA gene—BRCA1 or BRCA2—face an elevated risk of breast cancer, though a man with BRCA mutation still faces a lower risk than a woman without it.

Male breast cancer in the family is itself a risk factor for female breast cancer—a woman whose brother has male breast cancer is 30 percent more likely to develop breast cancer herself than a woman whose sister has breast cancer.

Because most male breast cancer is ER+—meaning the cancer has estrogen receptors—high levels of estrogen, normally found in men only in small amounts, contribute a risk, and so substances that increase estrogen production therefore increase male breast cancer risk. Obesity can lead to elevated estrogen levels, as does cirrhosis of the liver (usually caused by chronic drinking or viral hepatitis) and certain medications for high blood pressure, stomach acid, or prostate cancer. A disproportionate number of men using the baldness treatment finasteride have been diagnosed with breast cancer, but a causal link has not been shown (numerous noncausal correlations could provide an explanation). It is believed that overconsumption of soy proteins increases estrogen levels as well. As with all cancers, there are environmental risk factors, including exposure to radiation or certain carcinogenic chemicals.

The rare hereditary condition known as Klinefelter’s syndrome carries some breast cancer risk. Affecting about one in 1,000 men, Klinefelter’s syndrome is characterized by the presence of an extra female X chromosome (XXY instead of the normal male XY), resulting in larger breasts, higher estrogen levels, smaller testicles, and sparse body hair. Men with Klinefelter’s syndrome have a breast cancer risk that is as much as 50 times that of other men.

Symptoms and Diagnosis
Most male breast cancer is diagnosed after age 60, and it is rarely screened for, except in men facing an elevated risk as a result of genetic factors or previous cancer diagnoses. Genetic factors may be determined by direct relatives having been diagnosed with breast cancer or ovarian cancer (which is linked to breast cancer in some genetic conditions).

Male breast cancer diagnosis usually begins with the discovery of a lump in the breast tissue during self-examination. Discharge from or alterations to the nipple or skin lesions, may less commonly present themselves. After a doctor confirms the presence of the lump, a biopsy is usually performed to determine whether the lump is cancerous; as with women, many lumps are benign.

Male breast cancer can manifest in most of the same types as in women, with ductal carcinoma (cancer of the ducts) similarly being the overwhelmingly most common form. Male breast cancer may also develop as intraductal cancer, Paget’s disease of the nipple, or inflammatory breast cancer, whereas lobular carcinoma in situ has not yet been seen. As in women, male breast cancer spreads through the lymph nodes and
bloodstream, and so it is described with the same staging system.

**Treatment**

Male breast cancer is rare enough that patients may not seek medical attention, assuming other benign causes of whatever symptom they are presenting. However, because the breast is typically much smaller, lumps are more noticeable and easier to find by accident. Cancerous lesions in men tend to be more advanced, because the smaller breast creates less distance for it to travel before reaching skin or muscle tissue, and so about half of male breast cancer patients are stage III or IV.

Treatment usually involves a mastectomy (removal of the breast) or lumpectomy. Though either surgery can leave the chest deformed, fewer pains are typically taken to preserve appearances than have become common in breast surgeries on women. Prophylactic mastectomies—removal of the breasts before any cancer has manifested—is sometimes performed on men with a number of breast cancer patients among their direct relatives.

Chemotherapy and hormone treatment, including tamoxifen for patients whose tumors are ER+, are also used, and radiation therapy often follows surgery in order to eliminate cancer cells that escaped excision. As with any other cancer, chemotherapy has significant side effects, including those caused by the destruction of healthy cells, while hormone therapy typically causes impotence and hot flashes as a result of hormonal imbalances.

**Breast Cancer, Sociocultural Differences and**

In the United States, breast cancer is the most commonly diagnosed type of cancer women face, and it is also one of the most deadly forms of cancer for women. Female breast cancer health care costs are the highest for any single cancer, consuming approximately 13 percent of U.S. total health care expenditures and are expected to increase in subsequent years. Specifically, it is estimated that, in the United States, more than $16 billion is spent yearly on female breast cancer treatment and care costs. One-third of this cost is incurred in the last year of life of a woman with breast cancer.

The importance of breast cancer has been highlighted on the national U.S. health care agenda. The National Cancer Institute (NCI), which is the cancer research and training branch of the National Institutes of Health (NIH), reported funding of breast cancer research in excess of $600 million in fiscal year (FY) 2012. A great deal of this research was spent on clinically related projects examining etiology, diagnosis, and treatment. So while there are great contributions being made to the clinical science of breast cancer, there is still much to be understood about the social aspects of the disease, whose two biggest sociodemographic risk factors are gender (being a woman) and age (getting older). For example, according to NCI, women represent more than 98 percent of the estimated incident (or new) cases in 2014. Additionally, the majority of women diagnosed with breast cancer are 65 or older (more than 40 percent); however, women under the age of 50 represent 25 percent of new cases. In addition to gender and age, other sociodemographic categories are important in terms of breast cancer incidence as well as mortality (death) rates.

**Sociocultural Differences in Breast Cancer**

The sociocultural perspective is a theoretical framework that social scientists use to help explain social phenomena, for example, breast cancer incidence and mortality rates, by describing how an individual or group response to phenomena might be influenced by social and cultural factors, such as race, ethnicity, or nationality. Regarding, racial
or ethnic differences in breast cancer, while whites represent the majority of incident cases, overall mortality rates for minority ethnic women are higher. Specifically, African American women are more likely to be diagnosed at later stages of the disease and subsequently have higher mortality rates than other racial or ethnic groups, regardless of age. While race and ethnicity have not been identified by the scientific community as being causal factors in the risk for breast cancer, mortality rates are considerably higher among minority racial and ethnic groups, which is a continued cause for concern.

According to research in the social sciences, there are a number of reasons for this racial and ethnic disparity in the mortality rate; however, two important contributing factors that social scientists point to are (1) cultural differences in beliefs about breast cancer and (2) cultural bias in health care experience. Both of these issues impact rates of detection and screening for breast cancer as well as adherence to treatment recommendations by health care professionals once diagnosed.

**Cultural Differences in Beliefs About Breast Cancer**

No longer seen as a social stigma to be kept hidden, breast cancer receives a great deal of money in research funding and now has become a popular topic within the discourse related to disease and illness. However, even with all of the new information available to the public and the recent positive attention the disease has garnered, cultural differences in beliefs about the disease and its outcomes persist.

A number of lay misconceptions about the disease have been identified from the perspectives of minority women, which include: breast cancer as contagion (spread through contact with another person), fatalism or unavoidable death (death from the disease is predestined and cannot be changed), breast cancer as a result of direct trauma to the breast (resulting in a lump), and breast cancer as a disease mainly of concern for white women (seeing white women as the face of breast cancer in the media). Moreover, cultural taboos about physical touch (e.g., breast self-exams), reluctance regarding open communication about body parts, and spirituality or religiosity in minority communities have been examined. To some degree, these issues factor into whether or not minority groups seek medical treatment, which subsequently explains the presentation of advanced stage of disease, when eventually diagnosed, and higher mortality rates among minorities.

**Cultural Bias in Health Care Experience**

In general the provider–patient relationship has been explored, with the preponderance of evidence reporting that positive relationships (i.e., trusting, shared communication) between health care providers and patients yield better patient outcomes, such as recurring visits to health care providers and adherence to treatment regimens. Racial (and cultural) bias among health care providers contributes to negative patient outcomes for marginalized groups, such as lower quality of life and higher mortality rates. In fact, based on a recent Institute of Medicine (IOM) report examining racial bias in health care, NIH disseminated a call for research examining racial and ethnic discrimination and its effect on the delivery of health care services. Communications from these sources (IOM and NIH) alert us to the continuing importance of race and culture in the health care experience.

Health care providers are not immune to cultural biases. Stereotyping is a learned behavior and practice within our social world. Some general examples of stereotyping within the field of health care are: racial and ethnic minority groups’ noncompliance with recommended medication and other treatment therapies and nonadherence to diet or exercise regimens. As a result of these cultural biases and stereotypes, minorities often find themselves having poor communication and brief interactions with their providers as well as receiving little information about their diseases or illnesses from their providers. These factors can lead to feelings of distrust and disconnect, which again influence the patients’ decisions to make routine visits to medical professionals and their subsequent health outcomes.

**Conclusion**

As with age and gender, breast cancer is also no respecter of race or ethnicity, which is evidenced by minority groups’ higher mortality rates. Early detection is an important way to increase chances for survival. However, misunderstandings and cultural taboos about breast cancer persist in our society.

Communication and understanding within the provider–patient relationship are key to
Breast Cancer and Pregnancy

Breast cancer that is associated with pregnancy can occur during pregnancy, in the first postpartum year, or during lactation. Breast cancer during pregnancy requires consideration of the health of both the mother and fetus in both diagnosis and management.

Epidemiology

Breast cancer is one of the most common cancers to be diagnosed during pregnancy; however, it is very rare to develop breast cancer during pregnancy. It is estimated to occur in one in 1,000 pregnancies. Breast cancer during pregnancy is becoming more common with more women delaying childbearing. No specific risk factors for breast cancer in pregnancy are known; risk factors are similar to non-pregnant women of similar age. First pregnancy later in life is associated with increased risk of breast cancer during the remainder of a woman's lifetime than pregnancy at an earlier age. First pregnancy is associated with substantial breast cell proliferation. First pregnancy has both a short-term adverse effect on risk and a long-term reduction in subsequent risk accumulation. The longer the interval between menarche and first pregnancy, the greater is a woman's breast cancer risk. Therefore, menarche to first pregnancy represents a window of time when breast tissue is particularly vulnerable to carcinogenic stimuli. Full-term pregnancy induces cellular and molecular changes well documented in animal and human models. Pregnancy induces decreases in the number of hormone-sensitive luminal cells and down regulation of the Wnt signaling pathway in basal stem and progenitor cells, making breast tissue less susceptible to carcinogens. Additionally, first pregnancy induces long-term hormonal changes, including reduced prolactin and estrogen levels and increased levels of sex hormone-binding globulin, which may provide further protection against breast cancer.

Diagnosis

Breast cancer in pregnancy usually presents as a painless lump. Diagnosing breast cancer in pregnancy is challenging and often delayed. During pregnancy, physical changes occur in the breasts...
such as enlargement, fullness, and increased tissue density. These changes make it difficult to detect small lumps or masses in the breasts. Early changes from breast cancer could be mistaken for changes that happen with pregnancy. Therefore, breast cancer in pregnant women is often diagnosed at a more advanced stage than for nonpregnant women. Other causes of a breast mass in pregnant or postpartum women include milk retention cyst, infection, noncancerous growths such as fatty tissue or blood vessels, and less commonly other cancers such as blood cancers.

The initial workup includes imaging studies such as an ultrasound and a mammogram of the breast. Mammograms do have small amounts of radiation exposure that is focused on the breasts. A lead shield is used during mammography to protect the fetus; however, it remains unclear what effect the small dose of radiation may have on the fetus. A magnetic resonance imaging (MRI) of the breast is thought to be safe and does not have any associated radiation; however, there is minimal data to support its efficacy during pregnancy. The contrast material used in MRI crosses the placenta; therefore, the use of contrast material is not recommended during pregnancy. A biopsy of the breast lump or the suspicious area on breast imaging is needed to confirm a diagnosis of cancer.

After diagnosis of breast cancer, further imaging may be required to assess if the cancer has spread to other parts of the body. A chest X-ray with abdominal shielding and a liver ultrasound may be used. If there are signs or symptoms of bone involvement, MRI without contrast can be used for evaluation. Positron emission tomography (PET) scans, computed tomography (CT) scans, and bone scans are often avoided during pregnancy because of radiation exposure.

**Treatment**

Treating breast cancer in pregnant women is complex because it involves treating both the cancer while protecting the fetus from harmful effects of treatment. In the past, there was concern about the hormonal changes of pregnancy and effects on the breast. However, studies have shown that pregnancy termination does not improve patient survival.

Treatment of breast cancer in a pregnant woman depends on the size, the location, the type of cancer, and how far along the patient is in the pregnancy. Treatment involves surgery, radiation therapy, or chemotherapy. Surgery could include either partial removal of breast tissue (breast conservation) or removal of the entire breasts (mastectomy). Surgery could be potentially safe for the fetus in all three trimesters. Certain types of anesthesia such as general anesthesia could have negative effects on the fetus, and this would need to be accounted for in planning the surgery.

The type of surgery performed may depend on ability to treat with postsurgical radiation. Breast-conserving surgeries would require radiation to prevent cancer from coming back. Radiation could have harmful effects on the fetus and is not recommended until after delivery. Radiation can cause miscarriage, birth defects, slow fetal growth, and increased risk of childhood cancer. How far along in the pregnancy a woman is would affect this decision regarding possibility for radiation treatment. A significant delay in starting radiation therapy could cause the radiation to be less effective in preventing the cancer from coming back. A woman diagnosed at the end of her pregnancy could have radiation treatment after delivery without much delay. In contrast, a woman in the earlier stages of her pregnancy would be unable to have radiation treatment without significant delay, and a mastectomy may be required. Lymph nodes also need to be removed from the axilla to check for cancer cells. Treatment must be individualized.

Chemotherapy may be needed either after surgery or by itself (before surgery) for advanced cancers. Decision to administer chemotherapy should follow similar guidelines as that for nonpregnant women. However, fetal age would affect the timing of chemotherapy. Chemotherapy is not recommended in the first trimester of pregnancy because this is the time for fetal organ development. Exposure to chemotherapy in the first trimester is associated with a 10 to 20 percent risk of congenital malformation. This risk declines to less than 2 percent in the second and third trimesters. Studies have shown that certain chemotherapies during the second and third trimesters do not increase risk to fetus. Chemotherapy can lower a woman's blood counts and result in infection or bleeding during delivery. Because of these risks, chemotherapy is not recommended after 35 weeks of pregnancy or within three weeks of delivery. Data on long-term effects of prenatal exposure to chemotherapy is limited.
Standard chemotherapy regimens for breast cancer with fluorouracil, doxorubicin, and cyclophosphamide during the second and third trimesters were not associated with fetal complications. The use of anthracycline chemotherapies such as doxorubicin have not been associated with birth defects. Additional chemotherapy may be offered after delivery.

Hormone therapy is often used in nonpregnant women with tumors that express estrogen or progesterone receptors. Hormonal therapy is not safe for the fetus and is associated with high rates of birth defects. Tamoxifen is the hormonal pill indicated for women before menopause. Tamoxifen is associated with high rates of birth defects and is not used in pregnant women. Aromatase inhibitors are hormonal pills used for postmenopausal women and do not work in women who are premenopausal. Aromatase inhibitors are not effective or safe to use in pregnant women.

Drugs that target HER2 such as trastuzumab (Herceptin) are used for nonpregnant women who have breast cancers that are HER2-positive. HER2 expression is also high in embryonic tissues. Drugs that target HER2 are not recommended during pregnancy due to safety concerns for the fetus.

**Breast-Feeding**

Breast-feeding is not recommended while a woman is receiving chemotherapy, hormones, or targeted drugs because these agents can contaminate the mother's milk. Breast-feeding is possible after treatment is completed but it may be difficult as a result of the surgical and radiation changes. Milk production from the nonaffected breast is not changed by surgery or radiation. If radiation treatment is administered, breast-feeding from the irradiated breast is not recommended because of risk of mastitis.

**Survival**

Pregnancy may cause a delay in diagnosis of breast cancer, resulting in the cancer being found in more advanced stages and thus more difficult to treat. Most studies have found similar outcomes among pregnant and nonpregnant women with similar stages of breast cancer.

**Bristol-Myers Squibb (United States)**

Bristol-Myers Squibb Co. (BMS) is a pharmaceutical company headquartered in the United States in New Jersey. The company conducts drug research and development, licensing, manufacturing, marketing, distribution, and sale of pharmaceuticals as well as other health care products. Its pharmaceutical business segment is the company’s primary source of revenues. The company has developed several cancer drugs, including drugs that show promise in boosting the immune system to fight cancer.
BMS was formed by the combination of the Bristol-Myers Company (Bristol-Myers) and the Squibb Corporation (Squibb). Squibb was founded in 1858 by a U.S. Navy doctor named Edward Robinson Squibb. William McLaren Briston and John Ripley Myers founded the precursor to Bristol Myers in 1887, when they purchased the Clinton Pharmaceutical Company, which was incorporated in 1887. The company was named the Bristol, Myers Company in 1899. In 1989, the two companies merged, creating the world's second-largest pharmaceutical company in the world at the time.

Squibb began to delve into cancer research in 1967 and discovered the drug hydroxyurea to treat leukemia and advanced ovarian cancer. The company was one of the few pharmaceutical firms willing to invest in research into anticancer drugs at the time. Most drug companies wanted to avoid the investment required for research and the risk of not seeing profits from their efforts in the near future. In the 1970s, Bristol-Myers received the rights to market some anticancer drugs developed by other drug companies, academic institutions, and various outside research institutes, including the National Institutes of Health.

In 1973, Bristol-Myers introduced the drug Blenoxane (bleomycin sulfate) as a therapy for squamous cell cancers, head and neck cancers, and non-Hodgkin's lymphomas. The following year, it began marketing Mutamycin (mitomycin) for tumors of the stomach and pancreas and for bone cancer. The company followed up in 1976 with Ceenu (lomustine) for Hodgkin's lymphoma and brain cancer. Then, in 1978, the company introduced the anticancer agents Platinol (cisplatin) and Lysodren (mitotane). In 1983, Bristol-Myers began marketing the drug Vepesid (etoposide) as a treatment. Following the merger of Bristol-Myers and Squibb in 1989, BMS received approval to market Paraplatin (carboplatin) as a therapy for recurrent ovarian cancer.

In the early 1990s, BMS was developing the anticancer drug Taxol (paclitaxel). Made from the bark of pacific yew trees and other similar sources, Taxol would be marketed first to ovarian cancer patients in 1993 following its approval by the U.S. Food and Drug Administration (FDA) in 1992. The approval gave BMS five-year exclusive marketing rights to the drug. Taxol would eventually be used to treat people with head and neck, lung, ovarian, and breast cancers, as well as advanced forms of Kaposi's sarcoma.

At one time, BMS had the only contract allowing a drug company to harvest bark from the endangered trees on United States territory. However, BMS was subsequently accused of overpricing by the U.S. Subcommittee on Regulation, Business Opportunities, and Energy. BMS argued that the price of $6,000 to $8,000 per complete treatment was not excessive. Nevertheless, the company would not supply the data used to set the price. In 1994, BMS researchers discovered a semisynthetic source of paclitaxel that could kill cancer cells with fewer side effects.

In 2002, BMS was accused of maintaining an illegal monopoly on Taxol and faced an antitrust lawsuit. The lawsuit maintained that, if not for the actions of BMS, generic forms of paclitaxel would have been available to more patients much earlier at much less cost. It was also pointed out that paclitaxel was developed by taxpayer money because it was largely developed by the government-funded National Cancer Institute. BMS conducted the late-stage clinical trials. The lawsuit was not the last or only lawsuit BMS faced in regard to Taxol and keeping the price inflated. The company agreed in 2003 to pay $670 million to settle various lawsuits by states, consumers, and competitors. Another lawsuit brought in 2007 led to the company settling for a payout of $125 million.

In 2001, BMS acquired a 19.9 percent stake in ImClone Systems, Inc., a biotechnology company working on a monoclonal-antibody drug to kill cancer cells. BMS went on to help codevelop and market the drug, called Erbitux. Initially, the drug failed to receive approval from the FDA, which finally approved the drug in 2004. ImClone was acquired by Eli Lilly Company, but BMS still co-marketed Erbitux in the United States.

In 2003, BMS acquired the cancer therapeutics company Kosan Biosciences. That same year, the company began a collaboration with Exelixis, a biotechnology company. The two companies would jointly work on developing and marketing a therapy for medullary thyroid cancer and another therapy for advanced solid tumor malignancies. BMS also entered into an agreement with Ono Pharmaceutical Co., Ltd., in 2009, to further BMS's rights to an investigational cancer immunotherapy based on the anti-PD-1 antibody. (PD-1 stands for...
programmed death receptor 1, an immune-cell pathway.) That same year, the company acquired Medarex, which was working on antibody-based treatments for cancer and other diseases.

In 2011, BMS received FDA approval for its anticancer drug called Yervoy to treat melanoma. Yervoy, an anti-PD-1 antibody-based drug, was the first drug shown to significantly extend the lives of patients with melanoma. The drug promotes efforts by the body’s immune system to fight tumors by stopping cancer cells from attaching themselves to PD-1 to escape being destroyed by the immune system. As a result, the immune system has a better chance of fighting and defeating the cancer. The company continued to work on immune-system-boosting drugs that seemed to offer more hope of prolonging life long term for cancer patients.

In 2014, a new drug called Nivolumab, also based on interaction with the PD-1 antibody, was under development by BMS and undergoing clinical trials. The drug has shown promise when used in combination with Yervoy to treat melanoma. However, another trial using the drug combination to treat non–small cell lung cancer showed less promise and also produced more side effects in lung cancer patients. Nevertheless, the ultimate goal in using these drugs is to replace traditional chemotherapy approaches to cancer and potentially establish a long-term cure for various cancers, most notably melanoma, lung cancer, and prostate cancer.

Broad-Spectrum Ultraviolet (UV) Radiation

Ultraviolet (UV) radiation is electromagnetic radiation with a wavelength shorter than visible light and longer than X-rays, with a general range of 10 to 400 nanometers (nm). Because the lens of the human eye blocks light in the 300 to 400 nm range (and the cornea blocks light below 300 nm), UV light is not visible to most humans, with the exception of some young people and people with aphakia (who lack a lens); many birds, insects, and fish can perceive UV light with no difficulty. Both UV and visible light are part of the larger electromagnetic spectrum, the range of all possible frequencies of such radiation; the word ultraviolet refers to UV radiation's position on the spectrum beyond violet, just as infrared comes just before red, on the other side of visible light.

What differentiates ultraviolet light is not simply its invisibility to the naked eye (though in the absence of visible light, it can render some objects visible, as with black lights) but its excitation of molecular and atomic valence electrons, sometimes resulting in the ejection of electrons. This is called the photoelectric effect, which is responsible, for instance, for the dusty atmosphere of the moon (as charged dust levitates off the surface) and is used in night vision devices. UV radiation was discovered in 1801 when physicist Johann Wilhelm Ritter observed that paper soaked in silver chloride darkened when exposed to oxidizing rays (as opposed to the heat rays of the other side of the spectrum, now understood as infrared light). By the end of the century, short-wave UV light was shown to kill off bacteria and thus sterilize an environment—a use to which it is still put—and in 1960, it was shown to have damaging effects on DNA.
World Health Organization has classified ultraviolet light at all wavelengths as a Group 1 carcinogen, and it is responsible for at least 90 percent of all skin cancer cases.

UV can be subdivided into UVA (315–400 nanometer wavelength), UVB (280–315 nm), and UVC (100–280 nm), the last of which is less familiar to the layperson because UVC in sunlight is completely absorbed by the ozone layer and atmosphere and so is not a factor in sunburn or skin cancer risk from sun exposure. It is also useful to distinguish near ultraviolet (NUV, 300–400 nm), which is visible to birds, insects, fish, and some young humans, from middle (200–300 nm), far (122–200 nm), and extreme (10–121 nm).

The UV portion of the spectrum covers radiation with a variety of different effects. For instance, the photoelectric effect is possible only with UV at the shortest range of the spectrum (furthest from visible light), while mid-range UV can break chemical bonds. It is mid-range UV radiation, emitted by both natural light (sunlight) and some artificial lights, that is the most relevant to human health. It is responsible for sunburn, as UV rays disrupt skin cells and can damage DNA through photochemical reactions—resulting in pyrimidine dimers, the primary cause of melanoma skin cancer. Sunburn is often erroneously understood as being caused by the heat of the sun, but actually, it is UV’s chemical-bond-disrupting ability that is more relevant, which is key to realizing that sunburn—and damage leading to skin cancer—can occur on cloudy or cold days as well as the warm, sunny ones that were once celebrated as tanning days.

UV light accounts for about 10 percent of the light emitted by the sun (though the mixture is filtered by the atmosphere and differs at ground level) and is also produced by various artificial lights, including tanning lamps, mercury-vapor lamps (often used as streetlights as well as to illuminate large areas from overhead, such as in factories, parks, or sports stadiums; some retail stores use

Squamous cell carcinoma, which grows faster than basal cell carcinoma and is not as common, is nevertheless on the rise. It occurs most commonly on damaged skin or skin that has been subjected to chronic irritation, usually by ultraviolet (UV) radiation. UV can be subdivided into UVA, UVB, and UVC wavelengths. Melanoma is generally caused indirectly by DNA damage wrought by UVA radiation, while UVB radiation can cause skin cancer and squamous cell cancer. (MorgueFile)
color-corrected mercury-vapor lamps, but otherwise, the light emitted makes Caucasian skin look sickly and so is avoided in sales environments.

At ground level, sunlight is only about 3 percent ultraviolet, 44 percent visible light, and 53 percent infrared. Almost all of the UV light approaching Earth is blocked by the atmosphere; damages to the atmosphere, especially to the ozone layer, threaten to hamper this and significantly increase the amount of UV sunlight Earth life is exposed to, which at a minimum will increase the prevalence of skin cancer and other UV-inflicted DNA damage.

Though the role of the ozone layer in absorbing UV radiation, and the role of anthropogenic causes in depleting the ozone layer is subject to politicized debate, there is no debate about the impact of UV radiation on cancer. UVA and UVB have different carcinogenic effects; melanoma principally is caused indirectly by DNA damage wrought by UVA radiation, while UVB radiation can cause skin cancer and squamous cell cancer. Until recently, the carcinogenicity of UVA radiation was disputed or not well understood. It is now known that UVA's chemical effects on the body can include the generation of hydroxyl and oxygen radicals, which can go on to cause single-strand breaks in DNA and basal cell keratinocytes that lead to basal skin cancer.

UVB, on the other hand, produces pyrimidine dimers by exciting the DNA in skin cells such that aberrant covalent bonds form between pyrimidine bases. The body removes most of these dimers through nucleotide excision repair, but some may escape that process; and of course, the greater an individual's UVB exposure, the more dimers are formed, and the greater the odds that some of them will escape repair. Such dimers cause a mutation in DNA; when DNA is replicated, a CC dimer is read as AA instead, causing the replication mechanism to add a TT pair to the strand, a process called a classical C-T mutation. This is one of the most common ways skin cancer begins.

Because of UVB's effect on skin and resulting pyrimidine dimers, certain individuals with a hereditary condition called xeroderma pigmentosum are disproportionately affected by UV exposure. These individuals have inherited a defect in one of the 30 proteins used in the nucleotide excision repair process, resulting in a greater number of dimers escaping the repair process. Skin cancer is a common side effect.

Skin cancers caused by UV exposure include basal cell cancer, presenting as a pearl-shaped wound in an area of skin exposed to sunlight (often on the face); squamous cell cancer, usually appearing on the face in places with long-term sun exposure and presenting as scaly patches with open wounds, with a high chance of spreading; and melanoma, forming from the pigment-containing melanocyte cells, which looks like a mole in its early stages but can spread to other parts of the body and become fatal. Melanoma is most likely to form on the legs for women and on the back for men.

Less seriously, sunburn is also caused by DNA damage by UVB light, which is why sunburns are often pointed to as a skin cancer risk factor. The pain of a sunburn is thought to be the result of excitation of nerve tissue by overproduction of CXCL5 protein.

UV light's human health impact is not entirely negative. In fact, exposure to UV light is a necessary element of well-being: UVB induces vitamin D production in the skin at rates that make it much more significant to vitamin D availability than diet, promoting immunity and mood and helping to regulate blood pressure, calcium metabolism, insulin secretion, and cell proliferation. The cold-climate phenomenon of seasonal affective disorder, or the winter blues, generally is believed to be the result of insufficient UV exposure and consequent insufficiency of vitamin D: At northern latitudes (or southern ones in the southern hemisphere), there is so little daylight in the winter months and so little incentive to spend time outdoors (especially with exposed skin) that many people simply are unable to produce the amount of vitamin D required for good health. This even may have an impact on the prevalence of winter illnesses due to vitamin D's role in the immune system. UV light therapy also is used for treatment of certain skin conditions like vitiligo, eczema, and psoriasis.

Modern sunscreens are designed to block both UVA and UVB. Despite this, it is not yet clear from the research what protection sunscreen usage offers from melanoma and other skin cancers. Some studies have found melanoma more frequently in sunscreen users than nonusers, but critics of some of these studies have suggested that these comparisons need to take into account relative sun exposure—that is, nonusers may have lower rates simply because they have less sun exposure,
which does not speak to the effect of sunscreen usage among members of groups with heavy exposure (e.g., because of working outdoors). A correlation between sunscreen usage and melanoma would be expected, after all, provided sunscreen offers less-than-perfect protection simply because sunscreen usage correlates with planned UV exposure. More serious are the possibilities than sunscreen ingredients may themselves be carcinogenic—paraaminobenzoic acid (PABA) was banned due to its DNA damage—or cause other health problems. Sunscreen also interferes with vitamin D production.

Tanning beds pose a significant UV exposure risk, producing much more UV light than is found in ground-level sunlight, and regular users of tanning beds are at least 75 percent more likely to develop skin cancer. This is part of the rationale for the 10 percent indoor tanning excise tax included as part of the Affordable Care Act because, as with cigarette smokers, tanning bed users as a group are a greater drain on health care resources.

Bronchial Adenomas/Carcinoids, Childhood

Bronchial adenomas are the most common primary pulmonary malignancy in children and adolescents, appearing mainly in adolescents. Adenomas are tumors, usually benign in adults, of epithelial tissue in the glands or with glandular characteristics. Bronchial adenomas are found in the bronchi—airway passages in the respiratory tract that bring air to the lungs from the trachea (windpipe). There are two main bronchi, left and right, of which the left is smaller around but longer. Each main bronchi divides into secondary bronchi (three in the right and two in the left) to deliver air to the lobes of the lung, and each secondary bronchi divides into tertiary bronchi to deliver air to a bronchopulmonary segment of the lung. These in turn divide into series of bronchioles. The bronchi are critical to the respiratory system and familiar to laypeople through bronchitis, a disease causing inflammation, as well as asthma, which is hyperreactivity of the bronchi. Even benign bronchial adenomas pose health issues and often result in recurring pneumonia in children.

Although benign, adenomas can become malignant adenocarcinomas, a broad class of tumors. When it develops in the distant bronchioles, this adenocarcinoma is called in situ pulmonary adenocarcinoma (AIS), formerly known as brochioloalveolar carcinoma, one of the four types of adenocarcinoma in the lung. A type of non–small cell lung cancer, AIS is a small tumor with an alveolar epithelial appearance and a scaly covering. It grows along preexisting airway structures without invading or destroying the underlying tissue or lymphatics, and so diagnosis is uncertain until after the pathological examination of the tumor during surgery. Prognosis is 100 percent if it can be completely removed in surgery. If the AIS progresses and becomes malignant, recurrence is frequent, as with other non–small cell lung carcinomas. Treatment is usually with a full lobectomy of the lobe containing the tumor.

More than 80 percent of childhood bronchial adenomas develop into carcinoid tumors, tumors that develop from an endobronchial stem cell with neuroendocrine differentiation. They may develop in the submucosal glands or the salivary glands. Usually, the first symptoms are similar to asthma or bronchitis and include coughing, wheezing, recurring pneumonia, and similar respiratory complaints. Lesions are visible to a bronchoscope, and a computed tomography (CT) scan can reveal the degree of obstruction and exact location and size of the tumor. Because even a benign tumor in this area is usually harmful—and
is, in any event, causing bronchial difficulties—a biopsy is not usually performed. The tumor is removed surgically, usually with adjacent lymph nodes removed as well. As with adenocarcinoma, a complete lobectomy is common in order to prevent recurrence.

Bronchial carcinoids can lead to Cushing's syndrome or carcinoid syndrome in less than 10 percent of childhood cases. Cushing's syndrome is caused by excessive cortisol steroids as a result, in this case, of the cancer being close enough to the pituitary gland to cause large amounts of adrenocorticotropic hormone, which in turn causes the adrenal glands to produce excessive cortisol. Cushing's syndrome is characterized by a distinctive “moon face” as the result of rapid weight gain in the trunk and face, as well as excessive sweat, thin skin, and stretch marks from the skin being pulled by the weight gain, insomnia, dry and brittle hair, acne, skin tags, and hypertension. Adolescents may also experience impotence and decreased libido due to hormone imbalance.

Cushing's syndrome can be treated with cortisol inhibitors like ketoconazole, but the symptoms will also fade after surgical removal of the tumor.

Carcinoid syndrome is a series of symptoms that accompany carcinoid tumors about 5 percent of the time. When carcinoid tumors cause the patient to secrete serotonin and kallikrein, the syndrome sets in, characterized especially by flushing of the head, throat, and upper chest, diarrhea that may be intense and debilitating, abdominal cramps, constriction of the bronchioles that can exacerbate respiratory problems caused by the tumor, nausea and vomiting, and in about half of cases, cardiac trouble as a result of serotonin-induced fibrosis of the valvular endocardium.

Diarrhea carries its own complications, including electrolyte imbalances, debilitating headaches, fatigue, and dehydration. As with Cushing's syndrome, the best remedy is the removal of the tumor causing the problem, but if surgery is not available immediately, symptoms may be treated through drugs that reduce serotonin secretion, radionuclide therapy, and antihistamines, as well as antiemetics to control diarrhea and nausea.

In some cases, the symptoms of Cushing's or carcinoid syndrome are the first events that cause the patient's parents to seek medical attention, and so the diagnosis of the bronchial carcinoid may be delayed as these other symptoms act to distract the diagnostician, particularly if the attending pediatrician is not versed in pediatric oncology.

Bulgaria

In July 2014, Bulgaria’s population was estimated at 6,924,716, with a sex ratio of 0.92 male to 1.0 female. The population is experiencing a rate of decrease of 0.83 percent annually (2014 estimate), due in part to migration out of the country (2.89 out-migrants per 1,000 population in 2014). The population in the country was distributed in a
total of 255 cities and 5,047 villages. One-third of the population in the country live in the seven biggest cities, where the total population is more than 100,000 persons.

Health care in Bulgaria is provided by the National Health Insurance Fund, and visitors to the country can use their European Health Insurance Card (EICH) to access health care when needed. Politically, cancer patients often have been overlooked in Bulgaria. The treatment of Bulgarian cancer patients was exclusively an obligation of the government, and Bulgaria is the only European country whose largest hospitals do not always have a foundation associated with them to aid financially in times of illness and hardship, like a cancer diagnosis.

Unlike other European countries, whose health care systems try their best to support people and their relatives through cancer diagnosis and treatment, many diagnosed with cancer in Bulgaria faced a shortage of lifesaving medicines and lack of the support to cope with such an illness. Some accounts even point to prominent government figures stating forcefully that money should not be spent on a disease such as cancer due its high level of mortality. Front-page headlines were made by a former health care commissioner who referred to such patients as doomed. Much has been done to change this outlook in Bulgaria, including a recent patient-centered organization called the Bulgarian Cancer Association.

The Bulgarian National Cancer Registry (BNCR) was established in 1952. Its purpose is collecting, processing, and analyzing data on cancer incidence and death rate in Bulgaria. There exist 13 regional cancer registries, all part of the National Oncological Center Network. Collected data is then sent to the Central National Cancer Registry for analysis. Each year, BNCR publishes its yearbook, Cancer Incidence in Bulgaria, containing the most recent data on cancer incidence, mortality, and prevalence. The registry maintains the national database for cancer patients according to international standards and guidelines for cancer registration. It manages statistical and epidemiological analyses of cancer incidence, including survival rates, mortality, and survival. BNCR has been a member of the European Network of Cancer Registries (ENCR) and of the International Association of Cancer Registries (IACR) since 2000.

The number of cancer patients in Bulgaria increases typically by 2 percent a year, according to statistics released in Bulgaria on February 4, 2010, the World Day Against Cancer, noting that the theme of that year’s Day Against Cancer was that cancer can be prevented no matter what type.

In September 2011, the World Health Organization (WHO) consultants Jill Farrington and Jan Stjernsward traveled to Bulgaria and organized informational meetings in preparation for a workshop entitled Cancer Prevention, Treatment, and Rehabilitation funded by the WHO. The WHO consultants and their Bulgarian counterparts analyzed documents and met with officials on noncommunicable diseases, tobacco use, alcohol consumption, and nutrition. Colleagues from public health institutions were also welcomed to these meetings. The workshop took place in the capital of Bulgaria, Sofia. It was called to order by the Deputy Minister of Health Dr. Kiril Dobrev and the Acting Head of WHO Office in Bulgaria, Dr. Farman Abdulayev. This event gathered oncologists from various hospitals and medical offices in Bulgaria and formed working groups to discuss and develop the relevant documents on the national action plans on prevention, treatment, and rehabilitation of cancer.

In 2012, the Bulgarian Cancer Index indicated that the number of Bulgarian people newly diagnosed with cancer was 32,100, and the risk of getting cancer before age 75 was 23.8 percent. Last, the number of people dying from cancer each year in Bulgaria was 18,100 as of 2012. Risk factors included smoking, lack of exercise, obesity, an unhealthy diet, and excessive exposure to the sun or ultraviolet light.

Specific types of cancer are on the rise in Bulgaria, including breast, cervix, lung, and prostate cancers. According to WHO data recently published, breast cancer deaths in Bulgaria reached 1,428 or 1.67 percent of total deaths. The age-adjusted death rate was 19.55 per 100,000 of population, which ranks Bulgaria 54th in the world for breast cancer, 27th in the world for lung cancer, and 91st in the world for liver cancer.

By the year 2017, it is predicted that incidence rates of all cancers, except stomach cancer (change in risk factors and education contribute to the decline), will increase in Bulgaria. It is further estimated that, in the time frame from 2013 to 2017,
new cases of cancer will be 62 percent higher than from 1998 to 1992 in Bulgaria. Screening programs, educational and awareness programs, and changes in predicative factors will need to be further analyzed, and new programs should be introduced. Changing government and health care structure should also help these numbers change as time goes on.

Burkina Faso is situated in west Africa. It is bordered on the north and east by Mali, east by Niger and Benin, and south by Benin, Togo, and Côte d’Ivoire. It is the 17th-most populous country in Africa and 61st-most globally with a population of more than 13.5 million.

French is the official national language, and there are 67 living indigenous languages spoken by respective ethnic groups in Burkina Faso. The most widely spoken include Bisa, Dagara, Gourmanchema, Jula, Kasem, Lobi, and Moore. Each ethnic group has its own rich traditions of ethnomedicine. For example, a traditional healer who uses medicinal plants for treating cancers and other ailments is called tip-tiim by the Mossi, who speak Moore. Most people in Burkina Faso, particularly those in rural areas, rely on traditional medicine and medicinal plants to treat common diseases.

There are many traditional medicinal preparations used in Burkina Faso. Most of these traditional medicines incorporate use of local plant materials, many of which have shown medicinal properties in laboratory studies. For example, extracts of medicinal plants traditionally used, such as Acacia macrostachya and Lantana ukambensis, demonstrated antiproliferative effects against cancer cells. Research also suggests that use of certain plants may help protect against cancer by reducing oxidative stress and stimulating enzymes and other processes that help the body fight carcinogens. For example, an extract from Nymphaea lotus, locally referred to as beli, demonstrated substantial antioxidant potential.

Medicinal plants are used in Burkina Faso to treat many health problems associated with cancers. For example, the stems and leaves of Cassia nigricans are used to treat uterine tumors; leaves of Ocimum americanum are used to treat stomach tumors; and the stems and leaves of both Lippia chevalieri and Lippia multiflora are used to treat liver pathologies. A root decoction of Hybanthus enneaspermus can be administered for abdominal pain.
There are serious deficiencies of modern pharmaceutical supplies, as opposed to traditional preparations, and in modern medical services for cancer and similar conditions in Burkina Faso. Burkina Faso also has a relative shortage of doctors, with about 920, at a density of 0.58 per 10,000 population. According to the World Health Organization’s (WHO’s) Health System Response and Capacity, as of 2010, there was no general availability of either chemotherapy or radiotherapy in the public health system in Burkina Faso.

Burkina Faso is a signatory to the Single Convention on Narcotic Drugs, Convention on Psychotropic Substances and United Nations (UN) convention against the illicit traffic in narcotic drugs and psychotropic substances; consequently laws exist to control narcotic and psychotropic substances and precursors. Annual consumption of controlled substances is highly regulated to curtail abuse. Accordingly, annual consumption of morphine is 0.00004627 milligrams per capita, fentanyl is 0.00002 milligrams per capita, pethidine is 0.00167 milligrams per capita, and phenobarbital is 60.01271 milligrams per capita. These factors make it very difficult to provide appropriate palliative care for cancers and other conditions.

Due, in part, to the shortage of medical services and supplies, health problems are endemic in Burkina Faso. The 10 leading causes of morbidity, in rank order, are malaria, respiratory diseases, skin diseases, diarrhea, intestinal worm infestation, accidents, pneumonia, eye infections, rheumatism, and urinary tract infections. The average number of cancer cases annually is 103.9 per 100,000 population.

Cancers account for a substantial amount of disability and suffering among those impacted. According to the WHO’s Disease and Injury Country Estimates, the age-standardized disability adjusted life year estimates for 2004, the 10 most prevalent cancers in Burkina Faso were led by liver cancer at 328 per 100,000 population; breast cancer at 248 per 100,000 population; cervical and uterine cancers at 141 per 100,000 population; prostate cancer at 104 per 100,000 population; trachea, bronchial, and lung cancers at 80 per 100,000 population; bladder cancer at 78 per 100,000 population; stomach cancer at 69 per 100,000 population; mouth and oropharynx cancers at 68 per 100,000 population; lymphomas at 62 per 100,000 population; and esophageal cancer at 62 per 100,000 population.

Modern medical supplies and services are generally, if available at all, in short supply in Burkina Faso. Both prescription and over-the-counter products are often unavailable. Consequently, health problems are endemic and limit development. For example, an estimated 300,000 people live with human immunodeficiency virus (HIV) in Burkina Faso, which ranks the country 18th highest in Africa and 25th highest globally. The mortality rate for HIV/acquired immune deficiency syndrome (AIDS) in 2010 was 62 per 100,000 population. Debate continues on the relative risks in Africa for respective cancer types for those infected with HIV. The age-standardized mortality rate for tuberculosis in 2008 was 51 per 100,000 population and for malaria in 2006 was 178 per 100,000 population, while that for cancers in 2009 was 130 per 100,000 population. Nine cancers are among the 50 leading causes of death in Burkina Faso.

Liver cancer is the 17th-leading cause of death; the age-standardized death rate for liver cancer in Burkina Faso is 18.18 per 100,000 population, which ranks it as the 14th-highest country globally for liver cancer deaths. Breast cancer is the 23rd-leading cause of death; the age-standardized death rate for breast cancer in Burkina Faso is 15.48 per 100,000 population, which ranks it as the 107th-highest country for breast cancer deaths. The remaining of these nine cancers and their age-standardized death rates are cervical (12.83), prostate (8.81), stomach (5.06), bladder (3.42), lung (3.20), colon and rectal (3.06), and lymphomas (2.95). Furthermore, according to the WHO’s Global Health Observatory Data Repository, in 2008, the age-standardized estimates of deaths from all cancers was 100 per 100,000 population for males and 101 per 100,000 population for females. As a consequence, life expectancy is only 44.2 years, which ranks Burkina Faso 40th in Africa and 211th globally. There is a clear and urgent need for improved cancer awareness, early detection programs, and health services infrastructure in Burkina Faso.

Burma (Myanmar)

Cancer in Myanmar (formerly Burma) stands among the country’s leading causes of mortality and morbidity. Decades of government neglect of the nation’s health system has served to exacerbate effective cancer controls. Although increasing economic growth and the lifting of economic sanctions have afforded significant opportunities to the health sector, notable challenges remain for the alleviation of noncommunicable diseases (NCDs).

While the majority of the population is composed of ethnic Burmans, 135 distinct ethnic groups are indigenous to the southeast Asian nation of Myanmar. In 1044 C.E., the various ethnicities were unified under a succession of Buddhist dynasties. In 1886, the country was conquered by Britain and subsequently incorporated into British India. After achieving independence in 1948, Myanmar’s government was characterized by a democratic republic until it was overthrown in a 1962 military coup d’état. Following a series of military governments, national elections held in 2010 have marked a transition to civilian, democratic governance.

During British colonial rule, Myanmar doctors were trained in European techniques and health care, and the nation came to be well regarded abroad. Due to cultural factors restricting Myanmar women from engaging in physical contact with males outside their families, nurses were mainly ethnic minorities, with many Myanmar women operating as pediatricians and gynecologists. Under Myanmar’s socialist governments, emphasis was given to achieving national health objectives. However, a lack of application of such principals led to extremely low government health expenditures that both significantly undermined the health care infrastructure and led to lack of available information on the country’s health situation. In recent years, expanding economic growth and the lifting of Western economic sanctions have resulted in significant improvements in health care, though the sector remains highly under-resourced.

As a developing nation with an agricultural-based economy, 75 percent of Myanmar’s 59.13 million citizens reside in rural regions. As a result of improvements in public services and standards of living, there has been a gradual decline in infectious diseases representing a major public health issue, in turn, leading to the increasingly epidemiologic significance of NCDs such as cancer. Cancer in Myanmar has been found to be one of the 10 foremost causes of mortality and morbidity. In 2008, cancer deaths per 100,000 inhabitants were estimated to be 123 among males and 115 among females. Due to an absence of public awareness, coupled with inadequate programs for early detection, the majority of cancer cases are not identified until late stages. This is particularly the case for children with cancer, an estimated 85 to 92 percent of whom are either undiagnosed or not receiving treatment. For the nation’s 18.84 million children (from birth to age 15) and an estimated 1,500 to 2,800 new pediatric cancer cases each year, there are merely two pediatric oncology centers in Myanmar, located at Yangon and Mandalay Children’s Hospitals. Pediatric patients and their families may have to travel for days for treatment.

While there is no pediatric cancer registry in Myanmar, the subnational Yangon Cancer Registry
(YCR) was founded in 1974 in order to determine the pervasiveness of cancer in the nation's capital. Between 1974 and 2001, there were a total of 85,298 registered cancer cases, including 40,486 men and 44,712 women. Morbidity for cancer in Yangon increased from 87 per 100,000 residents in 1981 to 1,172 per 100,000 residents in 1995. From 1974 to 2001, the most common types of cancer within the YCR were digestive tract, respiratory tract, female reproductive organs, breast (female and male), and oral cavity and pharynx. Among women, the leading cancers between 1993 and 2000 were cervix, breast, and lung.

Tobacco use, both by smoking and chewing, remains an important risk factor within attempts at cancer control. A 2001 study reported that 40 percent of Myanmar adults use tobacco. Since 2000, significant developments have occurred in the realm of preventative smoking measures, including the founding of the Myanmar Tobacco Free Initiative Project, the country’s joining of the World Health Organization (WHO) Framework Convention on Tobacco Control and the action of the Control of Smoking and Tobacco Products Consumption Law. Additionally, the government’s launch of the Myanmar Health Vision 2030, representing an ambitious plan to meet current and future health challenges, has focused on a commitment to national health education on the prevention of NCDs diseases such as cancer.

Despite a recent dramatic increase in government health expenditures, the overwhelming majority of health-sector financing comes from the private sector and external assistance. Prior to the lifting of economic sanctions, very few countries provided direct economic support due to restrictions implemented by national governments and the European Union. Rather, developmental health assistance was funneled primarily through international nongovernmental organizations (INGOs), domestic nongovernmental organizations (NGOs), and global partnerships. This has in turn raised notable challenges to the alignment of such assistance with national policies and programs. Currently, funding mechanisms that continue to bypass the government in direct support of INGOs and NGOs remain a threat to the further weakening of an already fragile health infrastructure.

However, national partnerships with United Nations’ (UN’s) organizations play a significant role in health activities. The main contributors in this regard include the WHO, the United Nations Development Program (UNDP), the United Nations Population Fund (UNFPA) and the Food and Agriculture Organization (FAO) of the UN. Furthermore, significant progress in the country’s health development has also emerged from government partnerships with INGOs and NGOs. Myanmar’s Ministry of Health has signed various memorandums of mutual understanding with 10 domestic NGOs and 31 INGOs regarding health development collaboration.

Despite the opportunities afforded by Myanmar’s current political-economic transition, significant challenges remain to cancer control efforts. While Myanmar’s economy is forecasted to grow quickly, increasing global integration inevitably entails NCD risks brought about by Western lifestyle influences, including those pertaining to smoking and obesity. Developmental assistance circumventing government health efforts may also further debilitate a fledgling health sector. Furthermore, reflective of developing nations more broadly, the majority of health costs are currently paid for by patients and their families.

Economic gains have yet to translate among Myanmar’s ordinary population. Associated with Buddhist cultural tradition, it is common practice for patients to provide gifts to their doctors. If economic prosperity is not felt at the level of the population, escalating costs of living could further inhibit people’s willingness to seek medical treatment. Moreover, growing ethnic tensions along the nation’s boarder region threaten to exacerbate the existing divide between access to health care infrastructure between Myanmar’s rural and urban populations. Consequently, without mechanisms to ensure equitability, achievements in Myanmar’s health sector may fail to meet the needs of the most impoverished members of the population while further aggravating existing inequalities.

Burundi

Burundi, officially the Republic of Burundi, is a landlocked country in the African Great Lakes region of southeast Africa. Much of its southwestern border is adjacent to Lake Tanganyika, however. The country is sometimes considered part of central Africa.

Burundi is one of the five poorest countries globally. It has one of the lowest per-capita gross domestic products (GDPs) of any nation in the world. The country has suffered from warfare, poor access to health care, and education and governmental corruption. Burundi is densely populated and experiences substantial emigration. After the president of Burundi was assassinated in 1993, more than 683,000 Burundi residents fled to neighboring countries, towns with poor sanitation, or rural villages with little access to services. According to the Global Hunger Index of 2013, Burundi has an indicator ratio of 38.8, making it the hungriest country in the world.

Health care in Burundi is handled by the World Health Organization (WHO), including the training of sanitarians, public health nurses, and public health services. Burundi students are trained in the Democratic Republic of Congo and in France. The WHO has helped Burundi tackle several campaigns against disease, including malaria, tuberculosis, and smallpox.

Because of its many large-scale problems, Burundi is distinctly lacking in its cancer education, care, and prevention programs. The population of Burundi is about 8.07 million people, with several thousand more men than women. The estimated number of new cancer cases in Burundi for the year 2008 was 5,860, including 2,369 cases in men and 3,491 in women, based on data from Globocan.

The five most common cancers in Burundi are gynecological (corpus uteri, ovary, and cervix uteri), breast, Kaposi’s sarcoma, hematological malignancies (Hodgkin’s lymphoma, multiple myeloma, non-Hodgkin’s lymphoma, and leukemia) and esophagus. If you segment the gynecological cancers, the other most common cancer cases in Burundi are prostate cancer, throat cancer related to smoking, and liver cancer caused by the hepatitis virus. The last two can be prevented mostly by changing one’s lifestyle, and the cervical cancer can be prevented by the human papillomavirus (HPV) vaccine.

Human Papillomavirus and Related Cancers
Burundi has a population of about 2.88 million women age 15 and older who are at risk for developing cervical cancer. Current estimates indicate that about 1,400 women each year in Burundi are diagnosed with the disease, with 1,080 women dying from cervical cancer each year.

Cervical cancer is the most frequently diagnosed cancer among women in Burundi. About 35.8 percent of women in Burundi are estimated to have HPV infections. And 76.5 percent of invasive cervical cancers are caused by HPV types 16 and 18.

Prostate Cancer
In some men, prostate cancer that is not treated can spread (metastasize) and cause death, and there is no real cure for prostate cancer today. Each year, about 150 Burundian men are diagnosed with prostate cancer, and hundreds more may have the disease and never be diagnosed. Every man who lives in Burundi is at risk for prostate cancer, though it occurs most often in men over 50 who are genetically predisposed to the disease. A simple blood test (prostate specific antigen [PSA] test) is the best way to discover an early diagnosis of the disease. Men
should start having prostate cancer screenings in their 40s as those who are diagnosed and treated early in the disease have a much smaller risk of dying from it.

**Lung Cancer**
Lung cancer often can be prevented through a lack of tobacco usage, and preventative campaigns can go a long way in reducing the risk of lung cancer in Burundi. Many Burundians with lung cancer are forced to go outside of the country to receive treatment. Often, this means traveling to India, where treatments are relatively cheap and the doctors are experienced. Of course, many people do not have the means to travel, and they are left in Burundi to suffer without access to the right kinds of medical treatment. Lung cancer is one of the most common killers in the world, and it is imperative that early diagnosis happens to reduce the risk of death for Burundians. Preventative campaigns must be put in place in the future, or Burundi runs the risk of increasing incidences of this disease.

**Challenges to Cancer Care**
Like many African countries, Burundi does not have enough doctors who specialize in cancer care to address the population. Newly diagnosed cancer patients need chemotherapy or radiation therapy, pathology, and surgery. The number of oncologists needed is based on the number of patients needing these services. For developing countries, the International Atomic Energy Agency (IAEA) recommends training radiation and clinical oncologists who can prescribe both chemotherapy and radiation for the major cancers. It is recommended that each city in Burundi have two oncologists on staff, adding up to more than 50 oncologists needed across the country according to WorldCon data. In addition, radiation specialists are also needed throughout the country. Right now, many cancer patients in Burundi must go outside of the country to achieve adequate treatment.

Other concerns surrounding cancer in Burundi include the fact that it is not considered one of the main health threats by the Public Health Ministry. Though the International Cancer Day is held every February 4 (along with a themed workshop in 2014), this is nearly the extent of the government’s involvement. The Burundian Alliance Against Cancer (Alliance Burundaise de Lutte Contre le Cancer), active since June 2008, believes that more should be done.

In Burundi, all many people with cancer can do is take pain medicine and wait for death. The Burundian Alliance has been driving campaigns of sensitization through which it also promotes prevention to address this issue. This is the only way that the alliance can attribute the same level of seriousness to cancer as the government currently does to human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS).

**Conclusion: What Can Be Done**
Several studies have shown that cancer is increasing in developing countries, and holding vaccination campaigns (for HPV) for women in Burundi is one step that the country can take to reduce the risk of cancer for its women. Because there is a lack of oncologists and lack of funds for many patients to be treated in the country, prevention and awareness campaigns are the only currently feasible solutions. Much more has to be done for cancer in Burundi, and February 4 should not be neglected.

Calcium

Calcium is a hard, white mineral. Its molecular weight is 40.08, and its melting point is 842 degrees C. Next to sodium and potassium, calcium is the third-amplest essential mineral in the human body, followed by magnesium.

An adult body contains on average 1.0 to 1.2 kilograms of calcium, 99 percent of which is in the skeleton (bone, teeth, and cartilage). Only 1 percent of body calcium is in the extraskeleton—for example, extracellular fluids (plasma and tissue fluid), cells, membranes, and tight intracellular conjunctions. Plasma calcium is vital for nerve conduction, muscle contraction, cardiac rhythm, and blood coagulation; therefore, its level is strictly controlled. When the plasma calcium levels start to fall, calcium is withdrawn from the skeleton. About 0.8 to 1.2 grams of calcium are absorbed from the gastrointestinal tract each day, while 0.9 gram of calcium is excreted from feces and 0.1 gram from urine. Children can absorb up to 75 percent of ingested calcium, compared with 30 to 40 percent absorption in young adults and 15 percent in adults. Excessive fat, phosphate, phytate in bamboo, and oxalate in spinach reduce calcium absorption from milk and soy.

Parathyroid hormone works with growth hormone to increase the plasma calcium levels. In contrast, thyroid calcitonin and cortisol mobilize calcium and magnesium out of the skeleton. These hormones work on the bone, intestine, and kidney to keep plasma calcium steady.

Calcium Balance and Health

The human body must maintain a proper balance of calcium for optimum health. Hypocalcemia refers to abnormally low levels of calcium, and its signs are osteoporosis, tooth pain or loss, back pain, irritability, magnesium deficiency, menstruation syndrome (painful uterine cramps), nightly leg cramps, and tetany.

Hypercalcemia occurs when there is too much calcium in the body, which can cause arteriosclerosis, blood clots, cardiac conduct abnormal, constipation, polyuria, hypertension, hyperparathyroidism, nausea, and kidney stone formation.

For good bone development, osteoblasts help collagen synthesis and facilitate calcium binding to hydroxyapatite in the bone matrix. Weight-bearing activities stimulate bone formation. Bisphosphine reduces bones breaking down. Other cofactors for bone strength are magnesium, zinc, fluoride, and vitamin C, which is essential for collagen cross-linking. To another end, osteoclasts destruct collagen and dissolve bone mineral. The dynamic balance in the bone is positive in most people before age 30, but thereafter, it starts to be negative. A sedentary lifestyle, acidic foods and beverages, refined grains and sugar, antidepressants, alcohol,
cigarettes, heparin, arthritis, and glucocorticoids weaken bone strength.

Osteoporosis is defined as a reduction of bone density. Radiology shows osteoporosis when bone density declines 30 percent or more. Osteoporosis Type I is a disproportional loss of trabecular bone in postmenopausal woman. Type II occurs in both sexes after age 75. After age 70, hip fractures double every five years and reach 2,750 incidences per 100,000 people per year, compared to 1,300 incidences of vertebral fractures at age 85. The probability of hip fracture in white women age 50 or over is 14 percent compared to 5 percent in white men. Bone density declines after age 65 at a regression slope similar to age-related weight loss. So, keeping muscle helps keep bone mass. After menopause, women have accelerated bone density loss, which is stabilized by age 60. No evidence shows accelerated decline in women age 65 to 74.

**Ideal Daily Calcium**

To attain ideal bone mass in adolescents, the recommended dietary allowance (RDA) extends the total daily allowance of calcium 1,200 milligrams up to age 24. The ideal daily calcium intakes are as follows: age zero to six months: 400 milligrams; age six to 12 months: 600 milligrams; age one to 10 years: 800 milligrams; age 11 to 24 years and pregnant or lactating women: 1,200 milligrams; age 25 years and up: 800 milligrams.

Calcium supplements are used by about 20 percent of Americans to reduce osteoporosis and premenstrual syndrome. Calcium was also used in some colon cancer and depression treatments. Because 87 percent of American adolescent girls lack calcium and many of them have painful menstruation, calcium-rich foods and weight-bearing exercise for 30 minutes a day are most useful at this age. Once cup of low-fat milk or yogurt contains 300 milligrams of calcium, cooked soybeans contain 450 milligrams, and cooked collard greens contain 280 milligrams. Isocaloric substitution of yogurt reduced central adiposity during certain calorie restriction trials. Fortified food means adding 25 to 100 percent of RDA per serving.

Among calcium supplements, CaCO$_3$ contains the highest calcium element (40 percent), followed by CaCl$_2$ (36 percent), calcium citrate (20 percent), calcium lactate (13 percent), and calcium gluconate (8 percent). Ideal CaCO$_3$ supplements should be quickly dissolved in the stomach. A supplement of 400 milligrams of magnesium cooperates with 800 milligrams of calcium (at a ratio of one to two) to optimize neuromuscular function, help bone health, and reduce calcium-related arteriosclerosis, nephrolithiasis, hypertension, and constipation.

**California Blood Bank Society**

The California Blood Bank Society, located in the state of California and abbreviated CBBS, is an organization that develops, educates, and inspires health care professionals in cellular therapy and
transfusion medicine to improve patient outcomes and practices.
To achieve these goals, CBBS holds regional seminars in Northern and Southern California for donor technicians, nurses, donor resource professionals, quality assurance professionals, laboratory technicians, medical technologists, administrators, physicians, and compliance staff. These seminars are held in the first or fourth quarter each year, and they are announced on the official CBBS Web site, which is currently under renovation.

The CBBS also holds its annual meeting, which includes many vendor exhibits and takes place in either Northern or Southern California. This meeting gives attendees the opportunity to network with their peers in a relaxed environment, while also attending quality seminars on a variety of topics related to transfusion medicine.

In addition, the CBBS publishes the CBBS Today journal twice annually. This publication focuses on issues affecting staff working in various areas of blood centers and hospital transfusion services, along with committee activities and the important issues of state emergency planning and safety/compliance. The CBBS employs between 1 and 10 individuals.

Also of mention is the organization's e-network forum, which provides health care professionals working in cellular therapy and transfusion medicine a safe and convenient place to conduct collegial discussions. This forum also acts as an announcement space for relevant meetings, news, and links. The forum began as an e-mail discussion group founded by Dr. Ira Shulman in 1998.

The American Association of Blood Banks
The CBBS is a member of a greater collection of organizations devoted to cellular therapy and transfusion medicine—the American Association of Blood Banks (AABB). The AABB is an international, nonprofit association that represents institutions and individuals involved in cellular therapies and in the field of transfusion medicine.

The AABB's mission is similar to the CBBS' in that it strives to advance the practice and standards of cellular therapies and transfusion medicine to increase patient and donor care and safety. It is committed to improving health by creating and delivering standards, educational programs, and accreditations to further these goals.

The core values of the AABB include integrity, the pursuit of excellence, a focus on the donor and patient, consensus building, innovation, and transparency. The AABB is composed of almost 2,000 institutions and 8,000 individual members, including researchers, scientists, doctors, nurses, health care providers, medical administrators, technologists, and so on. Members are located in more than 80 countries.

History of the AABB
Since 1957, the AABB has been creating standards for transfusion services and blood banks. Beginning in the 1980s and continuing today, standards have been and are being developed for immunohematology reference laboratories, perioperative services, cellular therapies, patient blood management, and relationship testing. The corresponding accreditation programs for these standards strive to improve the safety and qualities of the activities they cover.

The role of the standards and accreditation created and managed by the AABB promote patient quality and safety across various fields. These standards combine internationally accepted quality management system best practices with technical requirements appropriate for each field. These standards then form the basis for the AABB's accreditation program.

Accreditation With the AABB
To become accredited, a facility must meet compliance standards as outlined in the current edition of Standards, as well as the requirements outlined in the AABB's Accreditation Information Manual. The AABB accreditation program is internationally recognized as a symbol of quality.

There are many reasons to become AABB accredited. Facilities that achieve accreditation show the highest level of quality and have systems in place to keep improvements continual. The AABB accreditation program strives to improve the operational systems in place within a facility by improving the safety of testing, collecting, processing, administering, and distributing products.

The AABB accreditation process usually takes about six to nine months, though the total time to
achieve it depends on the state of the facility's preparedness and adherence to quality system requirements. The cost for accreditation depends on several variants, including the activities for which the facility is seeking accreditation and the size or volume of the facility.

Institutions interested in becoming members will be assigned a technical specialist from the accreditation department who will help and guide them throughout the process. This personal assistance will help ensure that all applicants understand what is expected of them at each step along the path to accreditation.

The AABB's accreditation program promotes the highest standard of care for donors, patients, and products in all of the various aspects of cellular therapies, transfusion medicine, relationship testing, and transplantation. The program supports the highest possible standards for clinical application; medical, technical, and administrative performance; and education.

The resulting accreditation program specifically assesses operational areas and quality systems for compliance with recorded standards. The basis for assessment includes compliance with U.S. Code of Federal Regulation, standards, and federal guidance documents. The assessment of operations is independent, and it helps in preparation for other inspections.

The program offers both peer review and educational opportunities. The overall goal of the program is to see that accreditation is recognized at both national and international levels.

Accreditation is granted for a variety of facilities and processes, including storage, testing, administration, collection/procurement, and processing for transfusion medicine activities (e.g., transfusion, donor center, immunohematology reference laboratories, molecular testing laboratories and perioperative); cellular therapy activities (e.g., cord blood, hematopoietic progenitor cell, clinical, and somatic cell); and Specialist in Blood Bank schools and relationship testing activities.

Conclusion

CBBS provides inspiration for medical professionals in the fields of cellular therapy and transfusion medicine to improve the safety and effectiveness of their practices. The CBBS is a member of the AABB—an organization also devoted to cellular therapy and transfusion medicine.

Cambodia

Cambodia remained relatively untouched by the Western world until the French colonization in 1863. Prior to colonization, medical practices were rooted in tradition, including herbal remedies and rituals performed by healers with morals, merits, and power derived from dhamma to care for both acute and chronic conditions. With the onset of French colonization came drastically different ideals of medicine, including the first vaccinations and medical doctors focused on medical care from a Western perspective, that is, acute and chronic care treated with medicines and treatment void of religious and spiritual dimensions. As hospitals and medical care implemented by the French colonizers became more prevalent, tensions between cultures (French and Khmer) kept many Khmer people from taking advantage of the newly introduced health care services provided by the French.

The infrastructure provided for health care services was short-lived due to political instability in the 1960s and 1970s that culminated in the Khmer Rouge victory over the Lol Nol regime, which led to the genocide war from 1975 to 1979 that wiped out
social infrastructures in an effort to create a commun-ist, agriculture-based society. Hospitals, schools, and other social services were destroyed in an effort to take Cambodia back to a state devoid of any colonial influences. Approximately 2 million people were targeted and killed during the genocide, especially well-educated doctors, lawyers, and educators. The aftermath of the genocide left Cambodia in a state of post-conflict turmoil that continued well into the 1990s. Although some hospitals and medical care were available, it was not until the late 1990s that medical care began to create infrastructure capable of providing care for patients. For cancer patients, care has been significantly lacking. It was not until 2010 that oncology became a specialty available to students receiving medical training in Cambodia. With the assistance of international organizations (INGOs) and nongovernmental organizations (NGOs), statistics are becoming more available regarding the prevalence and diagnosis of cancer.

According to the World Health Organization (WHO), with a population of 14,865,000 in 2013, cancer prevalence is approximately 13 percent, the third-most common disease behind communicable, maternal, nutritional conditions (37 percent), and cardiovascular disease (24 percent). The Ministry of Health, with assistance from the WHO and local NGOs, has made access to care for cancer patients a key focus of policy and strategies for increased diagnosis and care are in place. For instance, cancer care and prevention are objectives outlined in the Ministry of Health Strategic Plan 2008 to 2015, indicating the necessity to educate the general population on risk factors contributing to cancer as well as providing access to quality treatment. However, with limited funding (5.6 percent of gross domestic product [GDP]) for health care and statistics, indicating that preventative measures are limited in dissemination, issues such as social habits and socioeconomic issues continue to contribute to the high incidence of certain cancers.

According to Kimman, Norman, Jan, Kingston, and Woodward, the most common cancers for males are lung (29.7 percent), liver (25.8 percent), mouth and oropharynx (16 percent), and stomach (15.3 percent). In contrast, the most common cancers for females are cervical (27.4 percent) and breast (20.7 percent), followed by lung cancer at a much lower rate for females (8 percent) than men.

The stark contrast between the types of cancers between men and women can, in part, be attributed to sociocultural factors regarding proper behaviors for men and women. Cambodia is a male-dominated society in which certain behaviors, including drinking alcohol and smoking, are seen as acceptable for men but generally inappropriate for women. These factors further support the notion that social factors and consumption of alcohol and tobacco are significant contributors to the prevalence of lung, liver, mouth, and stomach cancer in the male population. In the case of women, high rates of human papillomavirus (HPV) and cervical cancer indicate that women, especially those involved in prostitution and drug use, tend to have high rates of the HPV, which contributes to the incidence of cervical cancer among the female population.

Out of a population of almost 15 million people, only 14,000 new cancer patients are being diagnosed each year. This rate mostly likely would be higher if proper diagnostics were made available to the population as a whole and if services were available in rural areas. Only two hospitals currently have public wards specializing in cancer care, the lack of access to local care contributes to the underdiagnosis of cancer. Wealthy Cambodians have the option to travel to regional health care facilities outside of Cambodia, most often Thailand and Vietnam. The access and affordability of health care in neighboring countries is not accessible to most Cambodians, but the proximity of the resources and moderately affordable cost for wealthy Cambodians make traveling for adequate care the best option for those who can afford it.

Late diagnosis also contributes to the high mortality rates of diagnosed people with cancer. More than 70 percent of cancers are diagnosed at Stages 3 and 4. Women with breast cancer, the second-most common form of cancer in women, have been shown to have one of the highest mortality rates. Smaller rates of women have incidences of oral cancers, but this appears to be higher in older women. Contributing to the incidences are the high rates of elderly women chewing betel quid, a compound of tobacco, betel leaves, and slaked lime. The practice of chewing this compound has been shown to increase the incidences of oral cancer.

Alternate forms of medical outreach are currently being implemented to help facilitate access
to care for populations outside urban areas. Telemedicine, the use of e-mail, and other forms of communication are being utilized to communicate with patients in rural areas. Based on preliminary results, use of these forms of communication has been found to reduce the amount of acute care services and increase patients adhering to prescribed care at higher rates. This is especially helpful with cancer treatment, including patient participation in remission follow-ups with medical staff.

While underdiagnosis and issues of care and remission care are significant in Cambodia, efforts are being made to increase the quality of care for cancer patients. As of 2014, the first National Cancer Center has been created in Phnom Penh. Efforts to include the latest technologies available in more-developed economies are paramount to the creation of a facility capable of providing quality care to cancer patients. Eav Sokha, head of oncology at the largest hospital in the capital city of Phnom Penh, Calmette Hospital, is a forerunner in providing adequate care for cancer patients. His insight into the vision of a cancer center has thrust his hospital into the spotlight as the most technologically advanced hospital in the country, with radiography machines, positron emission tomography (PET)–computed tomography (CT) scanners, and a Spectre gamma camera. While these machines are widely available in more-developed economies, the creation of this center is the first of its kind to provide diagnosis and care using these devices.

Although strides are being made to increase the health infrastructure to help diagnosis and treat cancer, Cambodia still has a long way to go in providing adequate care. Through the help of international organizations and NGOs, Cambodia is beginning to establish the necessary facilities and doctors to provide care that should help provide the Cambodian population with the necessary treatments to decrease cancer mortality and increase quality of care.

Cameroon

The central African country of Cameroon is geographically located on the Gulf of Guinea, bordered by Nigeria, Chad, the Central African Republic, the Republic of Congo, Equatorial Guinea, and Gabon. As with many African countries, it has a history of colonization that is still evident in the 21st century. Cameroon was first colonized by the Portuguese in 1520, who established sugar plantations and began the slave trade; they were succeeded by the Dutch in the 1600s, followed by the Germans in 1884, then the British and French in about 1916. Current reports estimate the population of Cameroon at 24 million.

Cameroon has an estimated 250 ethnolinguistic groups and five major cultural groups spread across the region. This ethnic and cultural diversity influences the behavior patterns and perceptions related to seeking treatment for cancer and other diseases. As a result of colonization, the country is underdeveloped, and many of its indigenous citizenry living in rural areas are impoverished and undereducated, which adds to the country’s public health crisis.

Public Health
Cameroon faces the double burden of challenges from communicable diseases such as acquired

See Also: Breast Cancer; Liver Cancer, Adult (Primary); Lung Cancer; Non–Small Cell; Cervical Cancer; Stomach (Gastric) Cancer.
immune deficiency syndrome (AIDS) and human immunodeficiency virus (HIV) infection, malaria, tuberculosis, and noncommunicable diseases such as cancer. Adults and children are plagued by a variety of cancer types that include breast and cervical cancers for women, prostate and liver cancers for men, and Hodgkin’s and Burkitt lymphomas and leukemia in children. This combination of high rates of communicable and noncommunicable diseases in the same population creates an additional burden on already limited human and financial resources to remedy the problem. The high rate of tobacco use is also a major contributor to cancer rates.

Overall cancer is the second-leading cause of death in developing countries. In Cameroon, cancer accounts for 3 percent of all deaths from all ages annually, and the risk for both males and females prior to the age of 75 is 11 percent. Cameroon cancer statistics are generally unavailable at both national and institutional levels as there is no countrywide cancer registry; therefore, the numbers related to incidence rate and mortality are tracked infrequently and considered low.

Cameroon has two major government-run hospitals, Yaoundé General Hospital and Douala General Hospital, both of which have cancer centers with limited resources of equipment, medication, and staff. However, access to quality health services are beyond the reach of some of the primary victims of cancer in Cameroon who are more likely to be poor and have limited access to available health services due to provider location and the high cost of diagnosis and treatment.

National Cancer Control Plan
Cancer is recognized as a public health problem in Cameroon, and as such, Cameroon’s Ministry of Public Health established the National Cancer Control Committee (NCCC) and subsequently its National Cancer Control Plan (NCCP), which was initiated with the help of Dr. Anderson S. Doh, other citizens, and allies concerned with the growing cancer crisis in Cameroon. First published in 2004, this version of the cancer control plan was created with the assistance of the World Health Organization (WHO), American Cancer Society (ACS), International Agency for Research on Cancer (IARC), and the International Atomic Energy Agency (IAEA), among others.

According to NCCC officials, the cost of health services is beyond the means of the average Cameroonian. In addition to financial barriers, the NCCP details the following challenges to the growing cancer burden in Cameroon: cultural beliefs and myths regarding cancer, systemic poverty, and the fact that many cancer patients seek medical assistance only after the disease has reached an advanced stage. Other challenges are related to the role of traditional healers and some health workers treating the disease without proper training and necessary medical resources.

In June of 2013, an assessment of Cameroon’s cancer control measures was completed by the IAEA, which identified areas of continued concern for the NCCP and offered suggestions for improvement.

The Role of Missions and Nonprofit Organizations
Although cancer treatment facilities are few relative to the population, one source of major support in the burgeoning cancer pandemic comes from the Cameroon Baptist Convention Health Board, which provides free health care to rural populations of subsistence farmers and their families. Missionaries and medical professionals run clinics at the following hospitals: Banso Baptist Hospital, Northwest Province; Mbingo Baptist Hospital, Northwest Province; and Mutengene, Southwest province, along with their partners Stellenbosch University, Tygerberg Children’s Hospital, South Africa; and Beryl Thyer Memorial Africa Trust. They assist with cancer diagnosis and treatment along with other public health concerns.

In 2013, the Medical Mission of Hope was organized by two U.S.-based international organizations, the African Women’s Cancer Awareness Association, and the Michael and Mauritia Patcha Foundation and sought to provide professional medical services to those residing in the remote southwest region of Cameroon. A diverse pool of medical and nonmedical professionals from the United States and Cameroon contributed the human resources necessary to screen, diagnose, and treat breast, cervical, and prostate cancers. In addition to providing patient health education and awareness and medical training related to the current trends in cancer screening, diagnosis, treatment, and palliative care were provided to early career nurses, doctors, clinicians, and other allied health professionals.
With the growing number of cancer cases in Cameroon expected to surpass 20,000 per year by 2030, cancer prevention and detection in Cameroon has taken on a multifaceted and multi-institutional design that includes structural policy and fiscal changes, community advocacy, education, and individual behavioral change strategies. Key components to the success of prevention and detection are government subsidies and assistance from national and international philanthropic organizations. It is necessary for a developing country such as Cameroon to combat cancer through educational programs, diagnosis, and treatment.

Canada

Canada is one country geographically belonging to North America; it has a surface of 9,984,670 square kilometers and scarcely 35 million inhabitants, making it the biggest country in the Americas and the one with the lowest population density. Epidemiologically, it shares its registries with those from the United States through the North American Association of Central Cancer Registries, founded in 1987, whose main goal is to provide cancer registration standards in the region in order to obtain reliable and uniform data. Canada follows the general trend in North America in the sense of an increasing trend of prevalence of cancer cases due fundamentally to the combination of an early diagnosis and an improvement in survival.

Canada in Figures
In the last 15 years, the number of people living with cancer continues to rise, and this is especially valid for the leading cancers, like breast, prostate, lung, and colorectal, dominant cancers in Western countries. The differential reality in the case of Canada is that liver cancer incidence has tripled in the Canadian male population and doubled in females in the last 40 years. It is estimated that life expectancy of people suffering from this cancer is not higher than five years. One reason for this is that, when symptoms are detected, liver cancer is already spread to other organs. According to the report “Canadian Cancer Statistics 2013,” the immigration from regions of the world with a high incidence of infections like hepatitis B or C could partially explain the increasing incidence rate of liver cancer. On the other hand, bladder cancer also rose in the last decades, basically affecting Canadians over 70 years old. Smoking and occupational exposure seem to have to do with the increasing number of bladder cancer cases.

About two in five Canadians will suffer from cancer in their lifetimes, and one in four will die because of the disease. Most cancer cases are lung, breast, colorectal, and prostate (52 percent). Lung cancer is, so far, the main cause of cancer death. Canada, as opposed to the rest of Western countries, has a similar rate of lung cancer, which is second in importance, between men and women (13.8 percent for men and 13.3 percent for women).
Cancer affects more men than women, and definitely, the largest group of people diagnosed with cancer is older than 50 (about 88 percent). However, in 2009, cancer was also the main cause of death among children under 15. More than half of all cancer cases (63 percent) go beyond the five-year survival ratio, but it clearly depends on the type of cancer. In 2013, it is estimated that around 96,200 men were diagnosed with cancer and about 91,400 women. The most common cancer in men is prostate (24.5 percent) and breast in women (26.1 percent). Breast cancer notably rose through the 1990s. Although the causes are not totally clear, it is believed that progressive participation in mammography screening and other factors, like early age at menarche, late age at menopause, oral contraceptives, and late age at pregnancy had a direct link with the increase in the incidence.

The incidence of cancer is higher in the western region than in the eastern one. The Atlantic coast and Quebec have the highest incidence in the whole country. Risk factors like smoking and obesity are the main cause.

Cancer Registries
The Canadian Cancer Registry (CCR) is a kind of umbrella institution whose purpose is to collect information from all provincial and territorial Canadian cancer databases. Other organizations, like the Canadian Association of Provincial Cancer Agencies, are tools of control for cancer to make life easier for all citizens and create a network to collaborate with other institutions with similar goals and commitments. Its purpose is to ensure the quality of life of Canadians by reducing the burden of cancer in the country. It has existed since the 1980s, and it was the result of a common effort of diverse provincial, regional agencies that decided to work together. The community-based organization Canadian Cancer Society also has a fundamental mission to improve the quality of life of citizens and users, and it has agencies all over the country in a regional structure.

There are other institutions, such as the Canadian Research Data Center Network (CRDCN), that since 2000 have provided all kind of statistical information, health data among them.

Care and Services
Institutions like the Canadian Cancer Society provide information and guidelines about all the questions and needs affecting any patient of cancer. It highlights four fields of action: prevention, cure (treatment), follow-up or control, and palliative care, basically oriented to diminish the pain and suffering of the terminal patient and to improve his or her comfort. In its information, it also includes how treatments will affect the patient and a complete inventory of the side effects. At the same time, it offers help to families of cancer patients, thanks to the coordination of volunteers and people who have undergone the same experience, among other activities and initiatives.

In general, all the services are good, organized, and properly explained, and they give total priority to patients and their environments. In such a context, the Canadian Partnership Against Cancer has some programs that aim to modify lifestyles to
prevent cancer and other chronic diseases. And, as it was proven that old people were not receiving recommended cancer therapies, like young people were, some policies were launched in order to change this reality.

It is also emphasized that First Nations are an absolute priority in cancer control programs due to the difficulty of reaching remote, isolated, or rural regions.

Other interesting initiatives are related to the possibility of finding a specific trial by type of cancer, location, or even drug, which is a way of connecting citizens to all available and high-quality cancer resources.

**Canadian Association of Medical Oncologists**
The Canadian Association of Medical Oncologists (CAMO) is a national society of the Royal College of Physicians and Surgeons of Canada that contributes to the control of cancer through education, research, and clinical practice in screening, prevention, diagnosis, treatment, palliative and supportive care, and rehabilitation.

The association’s overall goal is to achieve and maintain excellence in scholarly and clinical activity among its members, creating a culture of respect and compassion for human dignity.

Each year, the association holds its annual scientific meeting. The 2015 CAMO annual scientific meeting was April 30, 2015, in Toronto, Ontario. Pricing for the event ranges from free for associate residents and fellows to $250 for individuals.

**Canadian Association of Medical Oncologists Goals**
The goals of CAMO are as follows: Support the continuing education and maintenance of its members’ knowledge base; serve as a national for the discussion of common interest issues for medical oncologists in Canada; provide a national forum at which medical oncology trainees can present their research; advocate for appropriate medical oncology content in the curricula of medical schools and other organizations revolving around health care training; promote postgraduate research and clinical training in the field of medical oncology; advocate on behalf of cancer patients requiring systemic therapy; and advocate with the federal and provincial governments of Canada and other agencies on the need for health human resources to provide systemic therapy services. CAMO strives to reach these goals through its annual scientific meeting and throughout each year.

**Benefits of Membership**
There are many great reasons for organizations and individuals to join the CAMO, including: committee appointment opportunities; CAMO support of regional oncology endeavors; investment in one’s career and support of his or her profession; a network of professional and social contacts in a similar field; a reduced annual meeting registration fee; communication with thousands of medical oncologists through the association’s dedicated Web site; opportunities for research fellowships; continuing professional development through the obtainment of the Royal College Maintenance of Certification program; committee appointments through various subcommittees of the Royal College (allowing
members to be directly involved in setting the conditions of employment and standards of practice at a national level in Canada); the retrieval of the results of ongoing studies of medical oncologists’ physician resource requirements; and maintained support of the Medical Oncology Royal College training program through representation of specialty committees.

**Canadian Association of Medical Oncologists Leadership**

The executive leadership of CAMO has included Dr. Christopher Lee as president, Dr. Hal Hirte as president elect, Dr. Bruce Colwell as secretary treasurer, Dr. Kara Laing (past president), and Alexi Campbell as executive director.

Committees and chairs have included the following: Dr. Michael Vickers, who has been chair of the annual scientific meeting, and Dr. Petr Kavan, who has been co-chair of the annual scientific meeting. Members of this meeting committee have included Dr. Christopher Lee, Dr. Kara Laing, Dr. Bruce Colwell, Dr. Rashida Haq, and Dr. Hal Hirte. The chair of the Continuing Medical Education platform has been Dr. Rashida Haq. The chair of Fellowship has been Dr. Kylea Potvin. The chair of Nominating has been Dr. Renaud Whittom, and members of the same have been Dr. Bill Evans and Dr. Charles Butts. Finally, Dr. Chris Lee has been chair of Human Resources.

**Related Canadian Oncology Societies**

The Canadian Association of Medical Oncologists is only one of several national medical societies across Canada. Other, related organizations include: the Colorectal Cancer Association of Canada (CCAC), the Canadian Cardiovascular Society, the Canadian Anesthesiologists’ Society (formerly the Canadian Anesthetists’ Society), the College of Family Physicians Canada, the Canadian Medical Association, the Libin Cardiovascular Institute of Alberta, and the College of Physicians and Surgeons of Ontario.

**Canadian Association of Medical Oncologists and Quality Improvement**

Presented at the 2014 American Society of Clinical Oncology (ASCO) annual meeting, a study on the role of quality improvement (QI), an essential component of oncology care, was presented via a 13-question online survey to members of the Canadian Association of Medical Oncologists. The study was given due to the fact that few QI studies involving oncology patients are published. The idea was to study the attitudes of Canadian medical oncologists toward QI and to determine causes for the low publication rate of how QI affects patients throughout medical oncology literature.

The 13-question survey given to members of CAMO employed a modified Dillman method and was administered in October 2013. Questions revolved around their attitudes toward QI, barriers to QI involvement and publication, and involvement in QI initiatives (based on criteria from the *Journal of the American Medical Association* in 2000).

The results were as follows: There was a 43 percent response rate (143 out of 332 participants), with 97 percent of oncologists agreeing that QI is an important part of their practice. However, only 49 percent of respondents had participated in QI in the past five years.

There were no significant differences between QI participants when comparing by community versus academic institution type, though administrators were more likely to be involved in QI than researchers or clinicians. The majority of QI participants focus on patient centeredness (67 percent), domains of safety (70 percent), and sufficiency of care (56 percent). Seventy-two percent of participants did not publish their findings due to lack of time. Other pinpointed indicators included uncertainty about how to get involved in QI initiatives, lack of interest, unfamiliarity with QI methodology, and no identifiable journals. QI participants were more likely to be aware of recent practice-changing QI publications than nonparticipants.

**Conclusion**

The Canadian Association of Medical Oncologists plays an important role in oncology in Canada and across the world. The organization continues to grow and expand, and its participation in oncological studies is of the utmost importance.

**See Also:** American Association for Cancer Education; American Cancer Society; American Society of Clinical Oncology; Canada; Canadian Association of Pharmacy
Canadian Association of Pharmacy in Oncology

The Canadian Association of Pharmacy in Oncology (CAPhO) is the national forum for oncology pharmacy practitioners and other health professionals in oncology pharmacy throughout Canada. CAPhO provides a forum for these individuals to meet colleagues, post professional papers, exchange views, discover oncology pharmacy resources, locate contacts in other provinces, complete continuing education courses, and more.

History of the Canadian Association of Pharmacy in Oncology

The first national oncology pharmacy symposium (NOPS) was in 1988, organized by Larry Broadfield and Rosemary Bacovsky, though there was a preceding meeting in 1986, which was organized by Mary and Rosemary Gannon in Toronto, Canada. This meeting has been pinpointed as the first meeting of oncology pharmacists in Canada. Attendees included Linda Chow, Flay Charbonneau, and Carlo DeAngelis, with about 20 attendees in total.

The CAPhO was formed by Larry Broadfield and John McBride, and the first executive committee consisted of Larry Broadfield as president, Jeff Barnett as vice president, and Julie Levesque as secretary and treasurer sometime in 1990 or 1991.

The NOPS meeting was slated to coincide with the National Cancer Institute of Canada (NCIC) clinical trials group (CTG) annual general meeting (AGM), and because of this, it went between Montreal and Toronto each year—getting larger each time. The first major highlight of the event was the hosting of International Society of Oncology Pharmacy Practitioners (ISOPP) III in Toronto in 1993.

At this symposium, a few of the influential members met and decided to form an international society known as ISOPP. John McBride became interested in the NCIC activities, so he discontinued his work with NOPS and created the NCIC Pharmacists’ Network. Larry Broadfield aided him in this task, but he also kept the NOPS meeting on track, with the help of several other members.

Julia Pacchiti was one of these members. She became heavily involved in the NOPS and eventually took over presiding over the meetings. In those years, Larry Broadfield became more involved in ISOPP, setting forth the first legal constitution, helping form the organization, and finally, becoming the third president of ISOPP.

After 25 years, many of the organization’s founders remain committed to its meetings as well as excited about oncology pharmacy. The organization’s members are active NOPS participants, and they continue to produce presentations, publications, and more. New members are always welcome.

CAPhO Advocacy

One of CAPhO’s initiatives is advocating for the field of oncology pharmacy. The organization asserts that “cancer has touched the lives of every Canadian. So has how we treat cancer.” It believes that cancer and cancer treatments must continually be present on the agenda of health care decision makers because oncology pharmacy is of the utmost importance to cancer treatment and oncology technicians and pharmacists are very important members of every cancer-related health care team.

CAPhO advocates for oncology pharmacy in several ways, including: determining target groups for advocacy issues; identifying issues and trends and legislative affairs that impact CAPhO members; being available to CAPhO members and the public who need specific data on oncology pharmacy; and forming, managing, and supporting advocacy initiatives and public relations efforts.
More About CAphO

CAphO is a member of the Canadian Cancer Action Network (CCAN) Associate Membership Program, and the organization works closely with CCAN to support national Canadian efforts to create a strong, sustainable cancer control model for the entire country. CAphO, as a member-directed association, promotes, advances, and supports oncology pharmacy practice.

CAphO has a focus on quality, providing safe and effective oncology pharmacy services to cancer patients throughout Canada. The association prides itself on its accountability and inclusivity to members, including technicians, pharmacy assistants, and pharmacists who are involved in oncology pharmacy services. CAphO is also intent upon engagement and collaboration with patients, health care providers, and organizations, along with professional development for these individuals through education, mentorship, and research.

The executive branch of CAphO is composed of technicians, pharmacists, pharmacy assistants and other health care professionals across Canada. Executive officers of the association include the president, president-elect, immediate past president, and president-elect. These officers are responsible to the executive committee and manage and operate the association. The executive committee is comprised of the chairs of the standing committees of the association, along with the executive officers. Committees are created to recommend policies and programs to the executive officers, and they are ongoing and permanent. Task forces are also formed to deal with specific issues, but they are dissolved once their work is complete. The organization’s bylaws provide a strict framework for the association.

CAphO’s communication is predominately in English, but its Canadian French-speaking members are also catered to through initiatives such as a translatable Web site and bilingual versions of several of its online continuing-education initiatives. CAphO represents the issues and professional interests of oncology pharmacy at a national level.

CAphO encourages new members to join their association as it believes it can efficiently represent the professional interests of those working in pharmacy in oncology. CAphO members in good standing also receive a substantial $150 discount off the registration fee for the association’s annual conference.

Presentations and posters from the annual CAphO Conferences are posted online each year. Members are encouraged to have continual participation in oncology basics, the first release of four oncology practice essentials online education modules, as well as the online education and resources section of its Web site.

CAphO publishes news and updates through its Twitter and Facebook social sites, CAphO Compass blogs through http://www.capho.org/blog and Clinical Pearls for Practice on the CAphO Compass blog. Members are invited to publish on the latter. CAphO also provides travel grants and awards to members as well as tools to promote the association and upcoming conferences.

Canadian Cancer Society

During the Great Depression, the King George V Silver Jubilee Cancer Fund raised $450,000 that in part funded the founding of the Canadian Cancer Society/Société canadienne du cancer (CCS/SCC)
in 1938. The CCS aims to end cancer and enhance survivors’ lives. The CCS has 140,000 volunteers and 1,200 staff under President and CEO Pamela Fralick. The CCS sponsored bone cancer amputee Terry Fox in his 1980 run across Canada to raise money for the CCS. The CCS raises money through its Relays for Life, Daffodil Balls, Days and Months and by selling items like the Thing-a-ma-boob key chains that teach women about breast cancer lump dimensions. The CCS has 11 regional divisions and two national offices (Toronto, Ottawa). The CCS is the largest national charitable funder of cancer research in Canada and its five foci are research, advocacy, prevention, information, and support.

In 1931, the Canadian Medical Association (CMA) recommended forming the CCS. The CCS was formed in 1938, initially funded via the King George V Silver Jubilee Cancer Fund. In 1947, the first CCS office opened in French Canada in Montreal. Also in 1947, the CCS and the Department of National Health and Welfare created the Canadian Cancer Society Research Institute (CCSRI).

The CCS has funded important cancer research. In 1951, Dr. Harold Johns developed Cobalt radiotherapy. In 1961, Drs. Ernest McCulloch and James Till proved that all blood cells come from bone marrow stem cells, allowing for future bone marrow transplants. In the 1970s, Dr. Anthony Miller showed how Pap smear tests reduce cervical cancer deaths in women age 30 to 64. In 1982, Drs. Martin Yaffe and Donald Plewes in Toronto helped develop digital mammography. The CCS has funded 753 peer-reviewed journal articles.

In 1980, the CCS supported Terry Fox’s Marathon of Hope. Fox, who had an amputation above the right knee after bone cancer, left Newfoundland on April 1980 and ran west, aiming to raise $1 million. The CCS set up fund-raising events in the cities and towns that Fox visited. Fox stopped running on September 1, 1980, in Ontario after 3,339 miles (5,373 kilometers) and 143 days when cancer spread to his lungs. A frustrated Fox told the press that the CCS did not organize fund-raisers in the small towns he ran through. However, Fox and his supporters raised more than $24 million by 1981. In 1994, the CCS held the first successful Daffodil Ball in Montreal. The ball is now Canada’s most successful cancer fund-raising gala. In 2000, a daffodil on a blue background became the new CCS logo. The previous CCS logo, two serpents intertwining a sword, is the current American Cancer Society (ACS) logo.

The CCS estimates a 60 percent cancer survival rate, up 35 percent since it began funding research in the 1940s. Cancer is the leading cause of death in Canada, comprising 30 percent of all deaths. About two in five Canadians will develop cancer in their lifetimes and one in four will die of the disease. More than 190,000 new cases of cancer (not including more than 75,000 nonmelanoma skin cancers) and more than 75,000 deaths will occur in Canada in 2014. More than half of all new cases are prostate, breast, lung and colorectal cancers.

In 2002, CCS integrated the 11 regional divisions into one new Web site. The CCS has a Twitter feed that promotes Daffodil Day and Month, Relay for Life, and tobacco and tanning cessation that features cancer survivors and allies as active participants. In 2012, CCS estimated that it doubled its followers on Facebook and Twitter over the previous year. In 2012, more than 5 million visited www.cancer.ca, including people in more than 200 countries. CCS operates online support networks at www.CancerConnection.ca in English and at www.ParlonsCancer.ca in French. CCS mobilized its online followers in 2013 to lobby Canadian Members of Parliament to vote for Motion No. 381 to deem asbestos a dangerous substance.

A toll-free telephone cancer information service was started in 1996 across Canada in both official languages (i.e., English and French). More than 1 million people have used the service since then. In 2002, Quebec started the J’ARRÊTE! (I QUIT!) Smokers’ Helpline. Similarly, Prince Edward Island (PEI), Nova Scotia, New Brunswick, Ontario, Manitoba, Saskatchewan, and Yukon co-fund the Smoker’s Helpline in both English and French with text messaging and interpreter services available in Ontario. In conjunction with these smoking cessation telephone helplines, a Canada-wide online and self-directed smoking cessation programs are available at www.smokershelpline.ca in addition to http://iquitnow.qc.ca (English) and http://jarrete.qc.ca (French). The latter two Web sites are specifically marketed in Quebec but accessible to all online participants. In addition to online communications, the CCS distributed nearly 1.5 million print materials in 2011.

In 2012, CCS spent $45 million on research, $71 million for programs and services for people with
Canadian Red Cross

The Canadian Red Cross/Croix-Rouge Canadienne (CRC) belongs to the International Red Cross and Red Crescent Movement (IRCRCM), an aid organization originating from the Geneva Convention. The CRC was first active during the Northwest Rebellion of 1885. During World War II, the Canadian government gave the CRC control of blood services until 1998, when a tainted blood controversy led to the creation of a new Canadian blood agency. Currently, the CRC offers assistance during natural disasters and conflicts both domestically and internationally, in addition to community health and safety programs.

In 1862, Swiss humanitarian Jean Henry Dunant called for a volunteer society to aid those affected by war after having worked with this population in Northern Italy. In 1863, the Geneva Society for Public Welfare convened a committee that, by 1864, led to 12 nations signing the original Geneva Convention to give aid workers wartime neutrality under the flag of the Red Cross (also called the Geneva Cross). This became the IRCRCM, a movement now operating in 189 countries. Dunant was awarded the first Nobel Peace Prize in 1901.
Canadian Red Cross

sharing it with French economist and arbitrator Frédéric Passy.

Canada first flew the Red Cross flag in 1885, during the Northwest Rebellion at Batoche, Saskatchewan. Dr. George Sterling Ryerson, a wartime surgeon, affixed his hand-sewn flag to his horse-wagon ambulances. The Metropolitan Toronto Reference Library now owns this flag, which is on display in the Canadian Red Cross (CRC) national office in Ottawa. Ryerson founded the Canadian branch of the British Red Cross (BRC) in 1886, the first overseas branch of the BRC. The organization initially provided monetary support during the Spanish–American War in 1898 and material support for the South African War in 1899. The Canadian Red Cross Society Act was passed by Canada's parliament on May 19, 1909, formally establishing the organization.

During World War I, CRC volunteers provided $35 million in relief funds and donations for soldiers and civilians overseas. The CRC funded six European wartime hospitals, recreation huts and ambulance convoys. Starting in the early 1900s until 1984, the CRC operated one-nurse medical outposts in remote northern Ontario. One such nurse, Rene Caisse, gained attention for promoting an herbal remedy named Essiac in 1922 to treat cancer, which she learned from local Aboriginal Canadians. This outpost infrastructure is credited with shaping how medical services in isolated areas would eventually be delivered.

During World War II, 3 million CRC members delivered $80 million of monetary and material relief. Notably, the CRC provided food packages to overseas prisoners of war. At the time, hundreds of aid agencies were competing to control this type of aid, but the CRC is recognized as leading the effort. Starting in 1940 and continuing during World War II, the Canadian federal government gave responsibility for Canada's blood supply to the CRC, a largely volunteer organization, because of its medical experiences and its nationwide network. Canada's health care system was in development at this time. After World War II, the CRC served veterans, orphans, and refugees and administered Canada's blood service. At the height of its program, the CRC accepted blood from more than 1 million volunteer donors each year.

In March of 1983, the Red Cross organization issued advisories urging members of high-risk groups (i.e., those diagnosed with human immunodeficiency virus/acquired immune deficiency syndrome [HIV/AIDS] and men who have sex with men) not to donate blood. By March of 1985, the U.S. Food and Drug Administration (FDA) approved the first commercial HIV blood-testing kits, and by November of 1985, the CRC was using the test. However, from 1980 to 1985, HIV-infected blood was made its way into the CRC-administered blood system along with hepatitis C (HCV)–infected blood collected from 1980 to 1990.

Experts argue that 2,000 individuals were infected with HIV and 30,000 with HCV from CRC-distributed blood and blood products and that 8,000 will eventually die as a result. From 1994 to 1997, a government inquiry into the tainted blood scandal was convened. Chaired by Justice Horace Krever, it was popularly called the Krever Inquiry. One of many recommendations of the Krever Inquiry was that Canada's blood program be managed by an agency separate from the CRC and the Canadian government.

In September 1998, an organization eventually called Canadian Blood Services (CBS) was created to manage Canada's blood and blood products service except in Quebec, where Héma-Québec (HQ) was created. Both CBS and HQ are regulated by Health Canada. Control of the CRC's Unrelated Bone Marrow Donor Registry, established 1989 to treat blood and bone marrow cancers, was similarly given to CBS and HQ.

Currently, the CRC is run by a 15-member board of directors and serves four domestic regions (i.e., Western, Ontario, Québec, and Atlantic) and several other countries, with its 428 branches and a national office in Ottawa. The CRC works with local communities, the Canadian government, and humanitarian organizations. The CRC provides food, shelter, first aid and support in disasters and crises plus programs in communication, first aid, water safety, community health, violence, bullying and abuse prevention, humanitarian law, family restoration and refugee services.

In Canada, the CRC responds to natural and manmade disasters and also offers financial support and transportation assistance to cancer and patients who are seriously ill through its HELP program. Internationally, the CRC collaborates to offer programs for preventing AIDS among intravenous drug users in rural Asia and mother-and-child
health services, including cancer screenings, in South America.

Canadian Society of Surgical Oncology

The Canadian Society of Surgical Oncology (CSSO) has several goals, including: encouraging the creation of surgical oncology training programs in surgical departments in universities across Canada; facilitating communication among oncology surgeons; cooperating with other organizations, including CAGS, the Royal College of Physicians and Surgeons of Canada (RCPSC), and Canadian Oncology Societies (COS) in activities designed to achieve similar objectives; fostering the development of education in cancer for undergraduate, graduate, and continuing medical education; encouraging the development of research in oncologic surgery; and promoting the optimum treating of cancer patients through a multidisciplinary treatment approach. Each year, the society holds its annual scientific meeting. In 2014, the meeting took place in May at the Eaton Chelsea Hotel in Toronto.

Membership in the Canadian Society of Surgical Oncology
Active membership is available for any individual who holds a valid certificate in a surgical specialty or subspecialty, who is a practicing medical practitioner, and who is engaged in the field of cancer or a related field. Senior members include surgeons age 65 or older who have or are currently practicing in the field of surgical oncology or a similar field. Senior members also include members of the CSSO who have retired from active work and wish to continue to participate in the society's activities. Senior members have all of the privileges and rights of the society and are excused from paying any dues.
Honorary members of the CSSO include any individuals who are deemed worthy due to their contributions to the field of oncology or his or her services to the CSSO. Honorary members are proposed by the members of the executive of the society, for memberships may be nominated. If they are then elected by the society's members, they will obtain all of the privileges of the society. They do not need to pay dues, and they may not hold office.
Associate members include scientists, physicians, or other health care workers engaged in the treatment, investigation, or experimental field of surgical oncology, and they are permitted to all of the privileges and offices of the society, except for the positions of president elect and president.

Sampling of Topics Discussed at the 2014 Canadian Society of Surgical Oncology Annual Meeting
Breast Cancer in Manitoba: Do Surgical Oncologists Practice Differently? Under this topic, the application of Canadian guidelines for the management of breast cancer (published in February 1998) were explored, specifically, the statements that breast conservation is the preferred procedure for early-stage breast cancer; the testing of axillary nodes should be standard procedure for invasive breast cancer, though some admissions are allowable; a minimum of 10 nodes should be identified when an axillary node dissection (AND) is done for invasive breast cancer; and axillary surgery should not be completed for ductal carcinoma in situ (DCIS).
The objective of the study was to compare the practices of surgical oncologists to other surgeons in Manitoba with these guidelines in mind. The results for the population-based study showed that breast cancer patients in Manitoba’s surgical care was more consistent with Canadian guidelines when performed by surgical oncologists compared to other surgeons.

Identification of Colorectal Cancer Opinion Leaders for a Knowledge Transfer Program in Ontario. Asserting that accurately staging patients with colorectal cancer (CRC) is imperative because this has a direct effect on diagnosis and treatment, this presentation presented a population-based study in which researchers demonstrated that 73 percent of stage II CRC in Ontario, Canada, are stage based by testing an inadequate amount of lymph nodes. In response to this assertion, researchers devised a multimodal strategy combining continuing education strategies in formal (lectures) and informal (opinion leaders) forums. The study was sent out to 1,243 surgeons and pathologists in Ontario. The study utilized a modified Hiss and Stross OL identification method, and each physician received four formal mailings (containing incentives). Physicians were requested to identify a surgical or pathology OL for CRC and the chosen community leader. The results showed that, although 75 percent of Ontario CRC is done in community hospitals, a disproportionate number of OLs are employed at academic centers.

Rectal Cancer Outcomes Are Affected by Referral Patterns of General Surgeons. This study explored the idea that, in British Columbia, registration of malignant disease in a cancer registry is mandatory, yet despite this fact, referral to a multidisciplinary assessment team is not. Because of this, general surgeons who manage rectal cancer patients have an important role in choosing patients who would benefit from referral to the British Columbia Cancer Agency (BCCA) for multidisciplinary treatment. The study evaluates referral patterns of general surgeons in selecting patients for multiple adjuvant therapies that are based on published guidelines by provincial cancer management. There were 495 patients identified as being treated for rectal cancer, and their referral rates were evaluated. The study shows that surgeons preferentially referred patients to BCCA based on the stage of their cancer. Of 153 Tis or T1 patients, 17 (11 percent) were referred to BCCA, whereas 75 percent (70 out of 93) of patients with T3 lesions were referred. Overall, the results from the survey stated that patients with advanced-stage cancer are more likely to be appropriately referred to multidisciplinary care. These patients have a survival advantage when compared with patients who do not undergo multidisciplinary treatments.

Canadian Urologic Oncology Group

The Canadian Oncology Group (CUOG) is a clinical research investigator network that is owned and operated by its members. The consortium is a national group of leading community- and academic-based urologists, radiation oncologists, and medical oncologists who are committed to furthering urology research, including pharmaceutical trials, throughout Canada.
CUOG is a nonprofit, nonshare corporation that has a cooperative relationship with the Canadian Urology Association (CUA). The corporation partners with the Canadian Urology Research Consortium (CURC) on mutually held oncology studies.

Canadian Urologic Oncology Group Clinical Trials
CUOG pursues clinical trials in tandem with the pharmaceutical industry to discover medicines and cures to undermine urological disorders such as: prostate cancer, renal cancer, bladder cancer, and testicular cancer, among others. CUOG offers enhanced research options, which strive to bring better quality of life to Canadians.

Value of Canadian Urologic Oncology Group
The CUOG creates value by: managing and creating national resources to benefit physicians, the public and pharmaceutical industry; assisting rapid accrual to clinical trials; setting standards for clinical trial performance and research; collectively offering enhanced treatment options; creating awareness campaigns and building continued medical education; incorporating an efficient professional business approach based on credibility, fairness, and transparency; and providing a uro-oncologic focus and specific expertise.

CUOG measures its success on a number of factors, including: giving back knowledge, networking clinical trial performances, managing enhanced clinical trial productivity, publishing research, attracting industry players, being self-sufficient and credible, creating international outreach to the uro-oncology community, and leading urology clinical research to achieve innovation and excellence in clinical care.

Affiliation to the Canadian Urological Association
The CUOG is affiliated with the Canadian Urological Association (CUA), which exists to promote the highest standard of urologic care for Canadians and to advance urology as a science.

The CUA is a Canadian, member-based organization dedicated to enabling urologic oncologists to provide the highest possible standards of care by: fostering excellence in the practice through research, advocacy, support, and practice tools and education; providing continuous professional development for Canadian urologists; providing leadership in public education for urologic conditions; representing the urologic community in Canada in relationships with international and national societies and governments; and leading evidence-based clinical practice.

Recent Studies and Publications by Canadian Urologic Oncology Group
CUOG Randomized Trial of Neoadjuvant Androgen Ablation Before Radical Prostatectomy: 36-Month Post-Treatment PSA Results. This study’s purpose was to test the hypothesis that neoadjuvant androgen ablation prior to radical prostatectomy decreases the likelihood of biochemical progression at 36 months. Two hundred and thirteen patients with localized prostate cancer were chosen at random to a 12-week course of 300 mg of cyproterone acetate daily followed by surgery (CPA, n = 112) or radical prostatectomy alone (Sx, n = 101). Biochemical progression was determined for the entire group and by baseline prostate-specific antigen (PSA), clinical stage, pathologic stage, and Gleason Score.

The results of the study showed that the probability of biochemical progression at 36 months was about the same for both groups. Also, CPA patients with baseline serum PSA between 25 and 50ng/mL had a lower probability of biochemical progression. In terms of Gleason score, no difference was seen in the probability of biochemical progression between groups. The results did show a trend for a higher probability of progression in the neoadjuvant arm in patients with negative and positive surgical margins.

In conclusion, neoadjuvant androgen ablation with CPA reduces the positive margin rate meaningfully but does not result in a difference in biochemical progression at three years. This could be because of insufficient power of the trial to demonstrate a small benefit, a lack of sufficient follow-up, or a true lack of benefit of neoadjuvant androgen ablation prior to radical prostatectomy.

CUA-CUOG Guidelines for the Management of Castration-Resistant Prostate Cancer (CRPC): 2013 Update. Castration-resistant prostate cancer (CRPC) includes a variety of disease types, from patients with metastases and significant debilitation due to cancer symptoms to patients without metastases or systems with rising PSA levels despite androgen deprivation therapy (ADT). This
scholarship studied the management of castration-resistant prostate cancer.

CRPC is defined by disease progression despite ADT and the progression of preexisting disease, and it may exist as either a continuous rise in serum PSA levels, or the presence of new metastases. Advanced prostate cancer has been identified under same names over the years, but it was only recently discovered that extra testicular androgen production plays a significant part in the resistance of prostate cancer cells to surgical or medical castration therapy.

A variety of management techniques were explored for the different varieties of CRPC and patient struggles, including secondary hormonal manipulations with first-generation nonsteroidal antiandrogen and specific medications like docetaxel. The researchers in this study recommend that, based on the results of randomized, controlled trials, men with metastatic CRPC and clinical or biochemical evidence of progression should receive treatment with docetaxel 75 mg/m² IV every three weeks with five milligrams oral prednisone twice daily should to improve disease control, symptom palliation, overall survival and quality of life.

Denosumab and zoledronic acid are also pinpointed as exceptional treatments. In men with CRPC and bone metastases, denosumab (120 mg) or zoledronic acid (four milligrams IV) every four weeks is recommended to prevent disease-related SREs, including pathological fractures, surgery or radiation therapy, or bone or spinal cord compression.

Researchers point out that there were some other positive drug associations for CRPC, but they were not thoroughly explored for this study.

Cancer Association of South Africa

The Cancer Association of South Africa (Cansa) has positioned itself as the leading nonprofit organization dedicated to representing the interests of all South Africans affected by cancer. Cansa was established in September 1931 by 75 delegates representing 24 different organizations and four individuals who gathered at the first National Cancer Conference to share their concerns regarding the increasing rate of cancer in the country. The main topic on the agenda was how to end suffering and gain control of the disease. The outcomes from the conference have developed and evolved over decades and include the establishment of a national cancer registry, special cancer centers and clinics, and educational programs throughout the country.

Located at the southern tip of the African continent South Africa is a large nation with a population close to 52 million people and 11 official languages in 10 provinces. Priding itself on representing all people, each province is represented on Cansa’s board of directors. The entire board consists of a president, vice president, and council of governors, board chairperson, vice chairperson, provincial directors, provincial council, chief executive officer, and executive directors. The provincial directors and council work to develop and implement initiatives tailored to each individual province. Researchers and a Cansa committee are also part of the association leadership. The Cansa workforce consists of 350 staff members and 5,000 volunteers.
With the history of apartheid looming in the nation’s background, CANSA has instituted an extensive code of conduct that explicitly defines its policy of nondiscrimination. A Social and Ethics Committee, a subcommittee of the board of directors, was established in 2010. The role of this committee is to assess and address all ethical risks within CANSA and promote and integrate ethics throughout the association.

CANSA's self-reported purpose is to lead the fight against cancer in South Africa by offering a unique, integrated service to the public that involves holistic cancer care and support to all people. CANSA's mission is to enable research, educate the public, and provide support to all people affected by cancer.

With more than 30 care centers around the country, CANSA utilizes its staff and volunteers to implement various health programs to support cancer patients and their families. In its efforts to support and reach all South Africans, CANSA created a multilingual cancer coping kit, which it distributes free to cancer patients in need. These audio recordings are available in four of the 11 major languages spoken in South Africa: English, Afrikaans, isiZulu, and Sesotho. The coping kits are designed to give a message of hope. Other programs include: cancer screening, cancer treatment, and cancer prevention, 12 CANSA care homes that serve as a home away from home for out-of-town cancer patients, CANSA–TLC lodging for parents and guardians of children undergoing cancer treatment, and individual counseling and support groups.

CANSA is committed to research and in partnership with the Medical Research Council and National Health Laboratory Service through the Cancer Research Initiative in South Africa spends more than an estimated $562,028 (R6 million) annually on various types of cancer research in South Africa. The research findings are used to refine existing programs, develop new ones, create public awareness, and support CANSA’s role as advocates for public health policy in South Africa.

CANSA truly believes that the most effective weapon against cancer is knowledge. In their mission to educate, CANSA works to create public awareness of known cancer-causing agents, which contributes to cancer prevention by not containing known carcinogens.

CANSA's advocacy role includes influencing South African policy makers by lobbying and developing position statements. An example would be CANSA's Position Statement on Patient Rights Including the Rights of Caregivers. The preamble to this statement acknowledges that every inhabitant of South Africa will need to access health care services.

Every single South African citizen in contemporary society has a constitutional right to access health care, and this was not always the case. Historically, for the majority of the South African population, public health services that were offered were often of questionable quality. A person's racial classification had a significant impact on his or her ability to access health care services as well as the quality of health care that was provided. Many people's rights were violated—particularly black South Africans—especially their rights to equality, dignity, and privacy.

The preamble to the position statement goes on to recognize that the end of apartheid did not automatically result in an end to all of these inequalities. Many inequalities still exist and are strongly influenced by service delivery and socioeconomic factors such as class and income. In South Africa, race, class, and income remain closely linked. Since 1994, various laws and policies have been put into place to make sure that the rights of all people who need access to health care services are respected, protected, promoted, and fulfilled. These laws and policies are specifically aimed at improving access and the quality of public health services as well as ensuring that more people are able to access private health care services.

This specific position statement speaks to the commitment CANSA has to all people as stated in its purpose and mission. They are committed to systemic and societal change in cancer care, prevention, research, and education. CANSA offers to all communities, cancer survivors, and those affected by cancer solidarity a message of hope and the opportunity to get involved in the fight against cancer by providing access to information and education.

Cancer Communication

Cancer Communication is the study and application of the use of strategically designed messages delivered through carefully selected media to convey relevant health information to targeted audiences (of health care consumers, cancer survivors, health care providers, researchers, patients, at-risk populations, and others) to educate members of these key audiences about cancer prevention, treatment, and control. Carefully designed cancer communication efforts are used to encourage cancer screening and early detection activities, reduce cancer morbidity and mortality, and enhance the quality of life of those who are confronting cancer. Cancer communication is a relatively young, but an increasingly important and rapidly advancing, area of applied research and intervention.

The powerful influences of communication on cancer prevention, treatment, and control was publicly reinforced in 1999, when the American Society of Clinical Oncology (ASCO), the largest and most prominent professional society for cancer care research and practice, identified communication as a key clinical skill for oncology practice. That same year, 1999, the National Cancer Institute (NCI), the largest and arguably the most influential institute in the U.S. Department of Health and Human Services’ National Institutes of Health, declared cancer communication to be one of the institute’s primary areas of emphasis, an “extraordinary opportunity” for concerted research and outreach activity. NCI’s identification of cancer communications as an area of extraordinary opportunity led to major investments in funding for large-scale cancer communication research initiatives that have advanced the science of cancer communication, encouraged introduction of new cancer communication programs at major medical and research centers, and fostered development and implementation of improved cancer communication policies and practices that influence cancer prevention, detection, diagnosis, treatment, survivorship, and end-of-life care.

Closely related to the NCI’s announcement of the Extraordinary Opportunity in Cancer Communications in 1999, the NCI introduced a new organizational unit that focused on promoting cancer communication research, the Health Communication and Informatics Research Branch (HCIRB). The HCIRB was established as part of the behavioral research program within the NCI’s Division of Cancer Prevention and Population Sciences. It became the focal unit within the NCI for developing and implementing new research programs to fulfill the overarching goal of the extraordinary opportunity in cancer communication to apply new cancer communication programs, policies, and technologies to reduce the national burden of cancer in the United States. The HCIRB staff were charged with developing and conducting major new cancer communication research programs and did this through the introduction of a number of large-scale and innovative intramural and extramural NCI research initiatives.

The cornerstone initiative of the NCI’s extraordinary opportunity in cancer communication and a major source of national data about cancer communication in the United States was the introduction of a repeated measure surveillance research tool, the Health Information National Trends Survey (HINTS) research program. HINTS is a nationally representative, biennially repeated, cross-sectional survey of the American public’s access to and use of relevant health information. It was developed to complement and build upon several other major national federal surveys, including the Behavioral Risk Factor Surveillance Survey (BRFSS), the National Health Interview Survey (NHIS), and the National Health and

See Also: Psychosocial Care/Support; South Africa.

Further Readings
Nutrition Examination Survey (NHANES). HINTS has become an important source of information tracking the state of public knowledge about cancer prevention and control.

Since its first administration in 2003, HINTS has been conducted every two to three years to identify and track how well different segments of the U.S. population were being informed about relevant cancer issues (such as risks and causes of cancers, symptoms and screening methods, and the best forms of cancer treatment). HINTS research identifies which cancer topics are most confusing to different groups of people, where different segments of the population currently get cancer-related health information, and how they would prefer to access relevant health information. In essence, HINTS tracks national cancer communication information access, use, needs, and opportunities.

As the HINTS acronym suggests, this major research initiative provides important insights (hints) about the best ways to meet the American public’s health information needs. HINTS provides researchers, public health promotion professionals, and health policy makers with a continuing source of surveillance data to compare trends in health information usage over time. The survey also provides health communication scientists with periodic opportunities to conduct fundamental research into the basic relationships among cancer-related communication, knowledge, attitudes, and behavior.

In addition to the HINTS research program, the NCI introduced several other important cancer communication research initiatives as part of the Extraordinary Opportunity in Cancer Communications program. Some of the most influential cancer communication initiatives include the Centers of Excellence in Cancer Communication Research, the Digital Divide Pilots, the Health Communication Intervention Research Program, the Multimedia Technology and Health Communication Small Business Innovation Research and Small Business Technology Transfer (STTR) program, and the Cancer Information Service Research Consortium Program.

The Centers of Excellence in Cancer Communication Research (CECCR) initiative provided large-scale funding to establish a cohort of major trans-disciplinary (combining multiple disciplinary research perspectives) research centers to conduct cutting-edge research to rapidly advance cancer communication research and practice. In 2003, the four original CECCR research centers were funded by the NCI for five-year terms. In 2008, the NCI renewed the CECCR grants for the four original research centers for another five-year term and funded a fifth (new) CECCR research center. Each of the CECCR research centers conduct several large, interrelated cancer communication research projects (on issues such as the effective use of online cancer information systems, the influences of news coverage of cancer information on health beliefs and behaviors, communication strategies for reducing cancer health disparities with minority populations, and patient-centered cancer communication) to advance knowledge, research methods, theory, and applications as well as to initiate new novel research projects and train the next generation of cancer communication researchers.

The NCI introduced the Digital Divide Pilot Projects to fund four demonstration research programs to test innovative and culturally sensitive communication strategies for implementing effective online health education programs to promote cancer prevention and control with vulnerable populations (poor, low literacy levels, elderly, immigrant, rural, urban, and minority populations). These demonstration projects illustrated best practices for narrowing the digital divide and helping at-risk groups access and use relevant health information online to promote cancer prevention and control. Similarly, the Health Communication Intervention Research Program funded seven innovative cancer communication intervention research studies to increase understanding about how targeted and tailored communication interventions can be used to promote cancer prevention and control as well as to reduce the burden of cancer, particularly among those disproportionately affected.

The diversity in theoretical approaches and intervention modalities used in these studies contributed broadly to understanding of the role of communication in health promotion and disease prevention. The NCI’s STTR programs fund science-based, theory-driven, user-centered grants and contracts with the goal of translating cancer research across the cancer continuum into programs, interventions, systems, networks, and
products needed by professionals and the public to reduce cancer risk and improve the quality of life of cancer survivors. Still another influential NCI cancer communication initiative was the Cancer Information Service Research Consortium Program, which created an innovative collaboration between the NCI's Cancer Information Service (CIS) health education information dissemination program and NCI’s HCIRB. The NCI funded a large multi-study program project grant (PO1) that engaged both NCI staff and external researchers to conduct applied studies evaluating the effectiveness and impact of the CIS educational and outreach programs; the use of tailored educational materials and interventions for targeted groups of consumers, the use of online information systems and resources; cancer information-seeking patterns; and communication strategies for promoting informed cancer prevention, detection, and treatment decision making.

Through these NCI initiatives and related studies, a large body of cancer communication research has illustrated that strategic communication can raise awareness about cancer risks, prevention strategies, and early detection and give people the information they need to make informed cancer-related decisions. Moreover, effective cancer communication can influence people to engage in recommended health behaviors that can improve their health, such as stopping smoking or undergoing screening for certain types of cancer. Cancer communication research has shown that, while the use of targeted media campaigns can produce behavioral change, the influences on relevant health behaviors are increased when communication efforts are supplemented by other community-based educational efforts. The theoretical basis of this effect is that increased knowledge and understanding alone do not motivate a person to change entrenched health behaviors. Other
factors, such as self-efficacy, skills to implement the change, convenience, and social and cultural mores all influence decisions and the ability to make relevant behavioral changes.

A large body of cancer communication literature demonstrates the powerful influences of communication interventions on a broad range of health behaviors and health outcomes. Research has shown the important influences of intrapersonal, interpersonal, group, organizational, and societal communications on health knowledge, behaviors, and outcomes. Similarly, studies have shown the positive influences of increased patient communicative involvement in treatment on desired health outcomes. Studies illustrate the positive influences of social marketing and diffusion-based strategies in encouraging at-risk populations to adopt important cancer-prevention behaviors.

Cancer is a complex array of different kinds of health challenges, with many different sites, stages, causes, screening strategies, treatment strategies, and responses to treatment. Due to the broad range of different cancer conditions and issues, a great deal of specific information needs to be conveyed to different individuals depending on their unique situations. To add to this complex information environment, active programs of cancer research are generating new information about the biological mechanisms underlying different forms of cancer, new screening and diagnostic techniques, and new forms of treatment and care for different cancers. It is imperative that cancer communication programs provide complete and up-to-date information about the key cancer issues of concern to specific audiences.

Cancer information is often highly emotionally charged due to the serious, often life-threatening, nature of many forms of cancer. Receiving a diagnosis of cancer can be a major shock to most people. It is important that cancer communication programs are strategically designed to address the important psychological and socioemotional issues surrounding different individuals’ experiences with cancer. Care must be taken to coordinate content and relational aspects of communication to inform people about cancer and cancer treatment without confusing or upsetting them.

To further complicate cancer communication programs, we must recognize the complexities of effective communication. Cancer communication messages must be designed and delivered to match the communication skills, needs, and predispositions of specific audiences. To influence entrenched health behaviors, messages need to be relevant and compelling, with health information that provides direction and rationale for making the best health-related decisions and adopting health-preserving behaviors.

Communication is central to providing high-quality cancer care, from primary prevention to survivorship. Interpersonal, group, organizational, and mediated communications are critical parts of cancer prevention, control, and care. The process of communication is central to each of the stages of the continuum of cancer care (prevention, detection, diagnosis, treatment, survivorship, and end-of-life).

Communication is the primary process for promoting cancer prevention. Cancer-prevention efforts typically involve designing and implementing strategic communication campaigns to promote healthy behaviors (such as refraining from smoking or using tobacco products, following a low-fat, high-fiber diet, and engaging in a program of regular exercise). Cancer prevention efforts typically involve the development and distribution of persuasive and informative cancer education programs and materials, as well as the development of behavioral intervention programs, to influence health behaviors that are often entrenched.

Communication is the primary process for informing and motivating people to seek screening for early detection of cancers. Communication is essential for encouraging audiences to engage in early detection and screening behaviors, to promote the development and adoption of screening programs in different health care and organizational settings, and for monitoring cancer trends to determine the best opportunities for screening and cancer detection. Promotion of early cancer detection and screening often involves the use of communication campaigns, educational materials, and behavioral intervention programs.

Communication is the critical process used for gathering and interpreting diagnostic cancer information from patients (often by checking suspicious symptoms, collecting health histories, or examining biological evidence of cancer). Due to the complexity of many cancer diagnoses, interpersonal and group communication are often used
as indispensable social processes for interpreting and clarifying diagnostic information (such as by eliciting second opinions, engaging in multidisciplinary consultations, and conducting tumor boards). Once a diagnosis is reached, human communication is the channel for presenting the diagnosis and plans for treatment to patients. Care must be taken to communicate cancer diagnoses as clearly and as sensitively as possible to help patients overcome the initial shock of receiving a cancer diagnosis, understand the intricacies of the diagnosis, and begin evaluating different plans for treating the condition.

Cancer treatment is an active and, ideally, a collaborative communication process between health care providers and consumers. Providers must explain treatment options and refinements to treatment strategies to their patients to help them make informed decisions about the best available programs of treatment. Once an initial cancer treatment regimen is implemented, the patient’s response to specific treatments must be carefully monitored and evaluated, so the treatments can be refined to produce the best effects and cause the least possible discomfort to the patient. Interpersonal and sometimes group communications are essential processes for seeking information about patients’ responses to treatments and making informed decisions about revised treatment strategies.

There is a growing population of long-term cancer survivors today due to advances in early cancer detection and improved cancer treatments. A recent report in the journal *Cancer Epidemiology, Biomarkers & Prevention* stated that, as of January 2012, there were approximately 13.7 million cancer survivors in the United States, a number that is expected to rise by 31 percent to 18 million by 2022. Cancer survivors have unique communication needs to help them cope with the many uncertainties of living with cancer. For example, cancer survivors typically have to cope with the fear of their cancer recurring. Survivors also need to access social support and relevant information to help them live with side effects of cancer treatments. Peer support from others who have adapted to living with cancer often can help cancer survivors overcome both physical and psychosocial challenges and enable them to readjust to their everyday lives.

Communicating with patients and their loved ones during the end-of-life process is often a very challenging part of cancer care for all involved parties. Death is not easy for most people to communicate about, yet the uncertainties surrounding death demand sensitive and caring communication. The quality of communication at the end of life is critical to providing effective cancer care for patients who are dying. Increasing attention in recent years has been directed toward the role of communication in palliative cancer care, especially at the end of life. The hospice movement also has focused attention on the unique communication needs of cancer patients and their loved ones during the transition to end of life.

There is a great need for cancer communication research to direct cancer prevention and care. For example, in cancer prevention and detection, we need to conduct controlled trials that compare different forms and intensities of communication-based behavior change interventions and examine the use of tailored, interactive, computer-based health communications programs that can contribute to an improved understanding of these new technologies.

Research on consumer–provider communication can help identify strategies for increasing accurate exchange of relevant health information, promote cooperation in the cancer treatment process, and enhance the quality of care for people confronting cancer. Further cancer communication research is needed greatly to fill in knowledge gaps about information needs in cancer prevention and control as well as to capitalize on the unusual opportunity presented by advanced communication technologies to help achieve cancer prevention and detection goals.

A significant increase in the size of the cancer communication research enterprise is needed to develop the next generation of research and interventions. At the same time, the enterprise must be informed by a greater understanding of the mechanisms by which these communications work. New cancer communications research should both increase knowledge and identify practical strategies for enhancing cancer communications and improving prevention and control of cancer. The challenge ahead is to develop cancer communication research programs that can help reduce cancer risk, incidence, morbidity, and mortality.
and promote the highest quality of life for people confronting cancer.

Cancer Council Australia

The Cancer Council Australia (CCA) undertakes a broad range of activities. Cancer councils, in general, are the leading independent funders of cancer research in Australia. In 2014, research grants from these organizations surpassed $65 million. Cancer councils directly funded $42.9 million in research, with an additional $22.2 million contributed by research funding partners. Each year, more than 100,000 Australians contact cancer councils for information and advice.

Cancer councils manage a network of cancer support groups, programs, and services to help improve the quality of life of people living with cancer, cancer patients, and their families and caretakers.

Goals and Values of Cancer Council Australia

The CCA works with the Clinical Guidelines Network (CGN), a countrywide network of health professionals that works to develop guidelines to provide the best evidence-based treatment and care for cancer patients. The CCA also works closely with its clinical partner, the Clinical Oncology Society of Australia, to ensure recommendations on cancer care and to incorporate the advice of experienced cancer specialists across various scientific and medical disciplines.

Cancer Council Australia advises the government on the needs of its stakeholders and establishes an independent voice for improved cancer control policy. The council also publishes the country’s National Cancer Prevention Policy, which advocates for a rigorous and comprehensive national approach to cancer prevention. This policy makes specific recommendations for governments and nongovernment organizations to take national action to create strategies and programs to help reduce the incidence of cancer.
In addition, CCA organizes events, works with its corporate partners to raise money to support cancer control activities, and receives donations and bequests to work with its corporate partners. The CCA has many network affiliations with national and international cancer organizations to help further shared goals.

**History of Cancer Council**

Over its 50-year history, CCA has transformed from a small secretariat to a strong federal body that has become Australia's strongest independent authority on cancer control.

The CCA began in 1961 as the Australian Cancer Society, when the existing six state cancer councils agreed to create a federal body to promote cancer control at the national level. Cancer organizations in the Northern Territory and the Australian Capital Territory (ACT) were then formed and signed on as members of the society. In 1997, the eight jurisdictional members agreed to expand the society, renaming it the Cancer Council Australia and appointing an expert chief executive officer, Professor Alan Coates. In May 2006, Professor Coates retired and was followed by Professor Ian Olver.

**Cancer in Australia**

Each year, about 128,000 new cases of diagnosed cancer in Australia, and those numbers are expected to rise to about 150,000 by the year 2020. One in two Australian men and one in three Australian women will be diagnosed with cancer by the time they turn 85. Cancer is a leading cause of death in Australia. In 2011, more than 43,200 people died from cancer in Australia. Cancer accounts for about three in 10 deaths in Australia. Compared to three decades ago, about 19,000 more people die from cancer each year—predominately due to population growth and aging. However, the death rate has fallen by more than 16 percent.

In terms of survival, 66 percent of Australian people diagnosed with cancer are still alive five years after diagnosis. The survival rate for many common cancers has increased by 30 percent in the past 20 years.

The most common cancers in Australia (not including nonmelanoma skin cancer) are colorectal, prostate, melanoma, breast, and lung cancers. Together, these cancers account for more than 60 percent of cancer cases diagnosed in Australia. More than 434,000 people in Australia are treated for one or more nonmelanoma skin cancers each year, with 543 people dying in 2011.

Cancer costs the direct health system in Australia more than $3.8 billion each year. In 2000 and 2001, 22 percent of all health research funds in Australia ($378 million) were spent on cancer research.

**Skin Cancer in Australia**

The CCA’s early detection and prevention programs aim to aid people to quit smoking, engage in physical activity, protect themselves from the sun, and eat healthier foods to decrease the risk of cancer.

About 95 to 99 percent of skin cancer occurs when skin cells are damaged by overexposure to ultraviolet (UV) radiation from the sun. Each year in Australia, skin cancer accounts for about 80 percent of all newly diagnosed cancers. Each year, general practitioners have more than 1 million patient consultations regarding skin cancer. Australia’s incidence of skin cancer is one of the highest in the world, two to three times the rates in the United States, the UK, and Canada. The main types of skin cancer are: basal cell carcinoma, melanoma (the most dangerous form), and squamous cell carcinoma.

Two in three Australians will be diagnosed with some form of skin cancer by the time they are 70. Over the past several decades, the incidence of skin cancer has risen in Australia. From 1982 to 2010, diagnoses for melanoma increased about 60 percent. Nonmelanoma skin cancer is the most common type of skin cancer, and it is more common in men. Each year, more than 434,000 people are treated for one or more forms of this type of cancer.

Melanoma is the most common cancer in Australians age 15 to 44 and the third-most common cancer in Australian women and men in general. In 2010, 11,405 people in Australia were diagnosed with melanoma, and in 2011, 2,087 people died from skin cancer in Australia. The majority of these deaths were due to melanoma, compared to nonmelanoma skin cancers. The five-year relative survival rate for melanoma is 94 percent for Australian women and 90 percent for Australian men.

The CCA markets a range of high-quality, affordable sun protection products that support the council’s activities, among its other beneficial initiatives.

Cancer Drugs, Costs and Benefits of

The high costs or prices charged for cancer drugs are a major policy concern for physicians whose patients cannot afford to follow therapy and for health insurance or payments plans. This entry summarizes evidence that the prices charged do not correlate with added clinical benefit or with the net research costs to companies.

In 2013, a group of more than 100 oncologists coauthored a remarkable article in *Blood* on the ways in which the very high prices charged by drug companies for patented cancer drugs burdened their patients and became barriers to effective therapy. This is a particularly American story because laws allow and even encourage companies to charge much higher prices that in other affluent countries and because American insurance companies uniquely charge patients a co-payment of about 20 percent of the prices for cancer and other specialty drugs. As cancer drugs, by 2013, were priced at $100,000 or more for a year's supply, even well-insured patients had to pay $20,000 or more from their after-tax household budgets. Patients may have to take one to three anticancer drugs continuously. High prices and co-payments contribute to medical bankruptcy being common in the United States. Outside the United States, the financial burden of high prices for cancer drugs is widely discussed in many other countries that do not have these special features.

Just Price
One moral framework for pricing and social justice invoked by oncologists is *justum pretium*, or just price. This refers to the fair value of a commodity when it affects the lives or health of individuals. Examples include the price of bread during famines, the price of life-saving vaccines, and treatments for chronic medical conditions, such as cardiovascular conditions, hypertension, diabetes, tuberculosis, or multiple sclerosis. This is why medical services are treated as a publicly funded social good in most countries: Prices and costs are dealt with at the systemic level and not as charges to patients, except for some co-payments that usually have low, annual caps. Just prices should reflect some mixture of the benefit of the commodity when critically needed and affordability. The oncologists estimate that effective cancer drugs cost about $400,000 to $800,000 per additional year lived, several times the commonly used worth assigned in several countries because the prices are not just.

Do Prices Reflect High Research Costs?
The two key factors said to affect prices are the costs of research and the added value of new cancer drugs. Pharmaceutical companies commonly explain that they must charge high prices because research involves high risks and costs exceeding $1 billion.

The most widely cited average cost of research and development (R&D) that has a semiofficial status comes from the pharmaceutical industry’s leading policy institute, the Tufts Center for the Study of Drug Development. For more than 30 years, the same team of health economists, led by Joseph DiMasi, has had unique access to R&D costs submitted by companies in confidence to the center. They reported that the average research costs to get a drug to market was $1.3 billion in 2012, including all costs of failures.

An independent analysis of this estimate by Donald Light and Rebecca Warburton found that it was based on several factors or calculations that increased the figures substantially from the initial cost data from the companies. It is difficult to know what these data represent because the sample of companies is small and not disclosed. Those data cannot be verified, and the sample is both small and not random. Neither the names of the drugs nor their classes are disclosed.

Do Prices Reflect High Research Costs?
The two key factors said to affect prices are the costs of research and the added value of new cancer drugs. Pharmaceutical companies commonly explain that they must charge high prices because research involves high risks and costs exceeding $1 billion.

The most widely cited average cost of research and development (R&D) that has a semiofficial status comes from the pharmaceutical industry’s leading policy institute, the Tufts Center for the Study of Drug Development. For more than 30 years, the same team of health economists, led by Joseph DiMasi, has had unique access to R&D costs submitted by companies in confidence to the center. They reported that the average research costs to get a drug to market was $1.3 billion in 2012, including all costs of failures.

An independent analysis of this estimate by Donald Light and Rebecca Warburton found that it was based on several factors or calculations that increased the figures substantially from the initial cost data from the companies. It is difficult to know what these data represent because the sample of companies is small and not disclosed. Those data cannot be verified, and the sample is both small and not random. Neither the names of the drugs nor their classes are disclosed.
If one accepts the data as reported, the independent analysis of the $1.3 billion estimate found three ways in which the estimate was made higher. First, half the estimate is not research costs but rather an estimate of profits that companies would have made if they had not invested their money in research but instead put it in a fund that returned 11 percent compounded per year. There are good reasons for subtracting these profits foregone as not real research costs, which brings the average down from $1.3 billion to approximately $650 million. Second, taxpayers subsidize about half of company R&D through various credits and deductions. This brings the net company costs down to about $325 million. Third, the original authors explained that the R&D costs submitted were based on the most costly fifth of new drugs developed by the companies, but then these estimates were misattributed to all drugs. Correcting for this misattribution brings the average down by about 30 percent to $230 million.

Other factors exaggerate the true net costs of R&D to companies. Because a few costly projects always distort the average cost, one should use the median, which the original article estimates is 26 percent less than the average. This brings the average down to $170 million. Another striking problem is that no accurate estimate of basic research costs to discover new drugs exists because they vary so much, from nearly costless discovery by chance to decades of frustrating efforts costing millions before the correct target and strategy are discovered. For their $1.3 billion estimate, the economists backed in an unverifiable figure for basic research and discovery that made up a third of the total R&D cost estimate. Removing this basic-research inflator brings the net median corporate research costs down to $125 million, plus the highly variable costs of basic research that are paid largely by taxpayers.

Because more than 84 percent of all basic research for discovering new drugs comes from the public and charitable sources, who bear the high risks and failure rates of discovery and early development, net corporate costs for discovery are modest. Companies spend only about 1.3 percent of their total sales revenues on basic research, after deducting taxpayer

By 2013, cancer drugs were priced at $100,000 or more for a year’s supply, and even well-insured patients had to pay $20,000 or more from their after-tax household budgets. High prices and co-payments contribute to medical bankruptcy being common in the United States. The two key factors said to affect prices are the costs of research and the added value of new cancer drugs. (MorgueFile)
subsidies, and the rest goes to developing minor variations or testing. By the time the most promising drug candidates are put into clinical trials, the company risk for a drug success has dropped from one in several hundred to only one in five. The corrected estimate of $125 million in net, corporate development costs, plus discovery, is based on the same R&D figures submitted by self-selected companies that were used to arrive at the $1.3 billion estimate as well as the same failure rates, trial sizes, and trial lengths. The dollars that companies have put into research over the past 15 years have generated six times more in revenue. Andrew Witty, the chief executive of GlaxoSmithKline, stated that the $1 billion cost to develop a drug is “one of the great myths of the industry.”

In the case of cancer drugs, most of the basic research and many clinical trials are paid by the National Cancer Institute and foundations. Further, Salomeh Keyhani found that clinical trials for cancer drugs are smaller and shorter than trials for most other diseases. For these reasons, the net R&D costs to major companies for their own cancer research are unlikely to be higher than for other drugs.

Prices and Clinical Benefits
The group of more than 100 oncologists reported that most of the new cancer drugs provide few or no clinical advantages over existing ones, so the high prices do not reflect added clinical value. Prices charged do not seem related to added clinical value. For example, Gleevec, or imatinib, is widely regarded as the most important pharmaceutical breakthrough for cancer patients in a generation. When imatinib was approved in 2001, its potential benefit in prolonging life was unknown. In his book Magic Cancer Bullet, Daniel Vasella, then chair and chief executive officer of Novartis, explained how the company reluctantly decided to develop imatinib as a goodwill gesture. He discussed the need for healthy profit margins and set the price high at $30,000. Vasella estimated that, with a prevalence of 30,000 patients in the United States, the annual revenue from U.S. sales would be about $900 million, more than enough to recoup the costs of development within two years. After that, the remaining costs of production would be low.

Contrary to most cancer drugs, imatinib transformed the lives of patients with chronic myeloid leukemia (CML) and other cancers. The annual all-cause mortality in CML declined to just 2 percent. If the price reflected added clinical value, Gleevec should have cost several times more than the price of other cancer drugs, or conversely, their prices should be much lower. Instead, Gleevec continued to be priced about the same as much less-effective cancer drugs. Because Novartis earned back its R&D costs by 2005, it has steadily raised the price of imatinib to about $100,000 a year in the United States but not in other affluent countries. Pricing in this case and in general seems to reflect what countries allow. Moreover, the annual increased prevalence of CML (because of the reduction of mortality from 10 to 20 percent down to 2 percent) and additional uses approved by the Food and Drug Administration have greatly expanded the market base beyond 30,000 to about 250,000 patients. Thus, Novartis could make $1 billion a year if the price of imatinib were $4,000. Patients and advocates have made numerous appeals to lower its price.

A different kind of consideration than the low correlation between prices and benefits is the general improvement in five-year survival rates. More effective drug therapy is commonly credited with this overall gain. However, the impressive gains in five-year survival rates for Americans appear due largely to earlier diagnosis so that the five-year count starts earlier. Patients used to have palpable tumors when diagnosed, but more recently, diagnosis is based on microscopic abnormalities. The five-year survival rate is not actually a rate but just the proportion of individuals alive five years after diagnosis, and it has risen as more patients are diagnosed earlier. Even if new screening and treatment strategies were ineffective, the five-year survival rates would increase. Researchers at Dartmouth Medical School and elsewhere have found little relationship between the increases in five-year survival and mortality rates from cancer. The fact that diagnosing and treating cancer is so profitable in the United States provides powerful incentives to promote earlier diagnosis and claim it saves lives.

Factors Affecting U.S. Prices
Some economic experts argue that, in a free market economy, pricing is based on what the market will bear. It is unclear, however, what this metaphor means when sellers have monopoly rights to charge what they like for life-saving drugs. Large data sets from wholesalers like Express Scripts document
that, as in the example of imatinib, sellers keep raising prices on older as well as newer patented cancer drugs, a practice not allowed in most other countries.

A widely believed claim holds that companies must charge Americans more for patented drugs because they cannot recover R&D and other costs at the prices allowed in Europe, Canada, and other affluent countries. These countries are said to be foreign free riders on American patients and payers. An analysis of company and government reports found, however, that companies do recover all costs in other affluent countries. They charge more and make extra profits in the United States because there is no pressure from the buyer side of the market to restrain them, as there is in normal markets.

The foreign free rider argument does not make logical sense either because it assumes the pharmaceutical market is divided off into national cost and revenue silos so that companies can lose in one silo (e.g., Canada) and profit in another (e.g., the United States). But, the pharmaceutical market is international. A cancer drug developed in England at great expense, for example, gets sold throughout the world, so one cannot match up those English costs to English revenues at English prices and claim that the company lost a fortune because the English prices were not high enough. What matters are global sales at a variety of prices, with U.S. prices being two to three times those in other affluent countries.

In the past five years, companies have doubled the prices in the United States for cancer drugs already on the market. This strategy could be called market spiral pricing. Most oncologists say they would prescribe a cheaper drug if there were two or more with similar efficacy and toxicity profiles at different prices, but prices are similar enough through market spiral pricing that there is not enough drug price sensitivity to allow oncologists or patients to select drugs based on costs savings. Market spiral pricing contributes to cancer patients deciding not to begin the treatment recommended or drop it because of costs. Very high prices threaten universal access to critical care for patients facing death.

Three obstacles to affordable prices in the United States for cancer drugs are the lack of cost-effectiveness studies to encourage value-based pricing, pay-for-delay contracts, and clauses preventing Medicare from trying to get the best price within a therapeutic class. A fourth problem stems from creating many small, narrow classes so that many cancer drugs are first in class within them. Cost-effectiveness studies are done much more widely outside the United States than within. As such studies begin at the Patient Centered Outcomes Institute, clauses inserted into federal law impede their results being used in making purchasing decisions.

Pay-for-delay contracts, in which the patent-holding company pays several million dollars a year to a generic company not to put its competing drug on the market, are being allowed despite their antitrust nature, and they contribute to keeping U.S. prices more than twice those allowed by other affluent countries.

The 2003 Medicare Reform Act included clauses added to prohibit Medicare from negotiating drug prices. When the law was implemented, there was a substantial increase in pharmaceutical company profits. Peter Bach is a senior oncologist and leader in drug policy research at the Memorial Sloan Kettering Cancer. In a valuable review, he concluded that rising prices and overall spending for cancer drugs in the United States is due largely to a unique legislative and regulatory framework that shields cancer drugs. For example, to hold costs down, Medicare commonly uses techniques such as coverage limitations for payment, blended-price reimbursement that rewards interchangeable drugs that charge less, and formulary flexibility.

However, special clauses and rulings prohibit Medicare insurance formularies from not including or selecting drugs for cancer and other life-threatening conditions. The buyers’ hands are legally tied. U.S. regulations also prohibit the use of interchangeability by regarding all cancer drugs as unique and sole sourced. Blended-price reimbursement that rewards interchangeable drugs that charge less is blocked. Oncologists and patients concerned about the high prices of cancer drugs in the United States may not appreciate these legal obstacles to having prices reflect added clinical value.

Cancer Therapy Evaluation Program

The Cancer Therapy Evaluation Program (CTEP) was formed by the National Cancer Institute (NCI) within the Division of Cancer Treatment and Diagnosis (DCTD). Its mission is to improve the lives of cancer patients by finding better ways to treat, control, and cure cancer. To this end, CTEP funds a robust national program of cancer research and sponsors clinical trials to investigate new anticancer agents, placing importance on translational research and the practical application of scientific findings.

CTEP uses a scientific process to accomplish its goals. Basic scientific findings are first identified based on scientific criteria and therapeutic needs. New anticancer agents fitting specific criteria are then selected, and clinical trials are developed. Next, the agents are investigated in clinical trials. Finally, promising new cancer treatments are meticulously compared to the most efficacious existing treatments in clinical trials to define the best treatments for specific types of cancer. Importantly, the goal is to find an effective treatment for a disease rather than to find a function for a particular research agent.

CTEP is organized into nine distinct branches and offices, each with its own functions and responsibilities. The Office of the Associate Director (OAD) oversees the other eight branches and CTEP as a whole. Since 2008, Jeffrey Abrams, MD, has served as the associate director. He also currently serves as the NCI’s acting director for clinical research.

Each of the other eight branches has its own branch chief and specific duties and functions.

The Clinical Grants and Contracts Branch’s (CGCB) main function is to oversee translational research grants and cooperative agreements, specifically in the fields of clinical oncology, surgical oncology, and pharmacogenomics, that is, how a person’s genes affect his or her response to drugs.

The Clinical Investigations Branch’s (CIB) function is the scientific oversight, coordination of, and collaboration with all programs, organizations, and forms of research supported by CTEP.

The monitoring and auditing of all clinical trials sponsored by CTEP’s Division of Cancer Treatment, NCI, as well as some cancer prevention trials sponsored by the DCTD, is the responsibility of the Clinical Trials Monitoring Branch (CTMB). In order to ensure that trial data is accurate and in compliance with regulatory guidelines, this branch provides guidance and oversight for the conduct of clinical trials and serves as a liaison with the Food and Drug Administration (FDA), among other regulatory groups.

The Investigational Drug Branch (IDB) manages a cutting-edge research therapeutics program, including phase I, phase II, and phase III trials. The branch is comprised of three sections, each with its own portfolio of research agents under study.

The Pharmaceutical Management Branch (PMB) is responsible for providing pharmaceutical assistance and oversight for CTEP-sponsored trials. Their main functions are providing information related to all aspects of IND (Investigational New Drug) agents, approving the use of IND agents and the subsequent distribution of these agents to participating investigators and institutions, and handling special situations involving the use and supply of CTEP IND agents. In addition, this branch registers all investigators and other staff taking part in CTEP clinical trials and manages these records.
Candlelighters Childhood Cancer Foundation

Candlelighters was officially formed in 1970 by a group of parents of children with cancer. Today, it is named the American Childhood Cancer Organization (ACCO). ACCO is a national organization as well as one of numerous local chapters. For decades Candlelighters and ACCO have served...
as the premiere cancer support groups for families whose children have received a cancer diagnosis. Commonly, a parent member will visit the family of a newly diagnosed child in the hospital during the first admission, bringing educational, emotional, and hospital orientation resources and a parent’s perspective. The support of Candlelighters continues according to each family’s interest. Publications and meetings provide families with information on treatment options, education of the child with cancer, and sibling support. Today, Candlelighters also focuses on strong legislative advocacy for the child with cancer, and although it has changed its name, its central mission has not changed.

Candlelighters and ACCO was started by a group of parents in the Washington, D.C., area in 1968. In that year, Grace Ann and Larry Monaco had an 18-month-old daughter Kathleen who was diagnosed with acute lymphoblastic leukemia. At this time, most children still died rather quickly from cancer, and there were no patient advocates. The Monacos met with other parents of children with cancer being treated at Children’s National Medical Center. Fortunately, it was a powerful group of families that led those first parent meetings, which included scientists, journalists, government workers, and lawyers. There were 25 people in the original group of parents. They built a lobbying campaign for clinical trials and appropriations for childhood cancer research.

By 1970, the original group of parents met regularly at the Rayburn building and invited speakers including the noted pioneer on death and dying Elizabeth Kubler Ross. Meetings were taped, and a newsletter also started in that year. Candlelighters officially formed in 1970 under the name Candlelighters Foundation.

The parent leaders continued to lobby Congress as well as the National Institutes of Health and the National Cancer Institute. Largely because of this lobby, Congress began to allocate money toward childhood cancer research. This parent group also created the Childhood Cancer Ombudsman Program under the Candlelighters name in 1970. By the mid-1970s, Candlelighters had an office in the American Cancer Society. In the early 1980s, Candlelighters separated officially from the American Cancer Society, including their funding. Candlelighters began to build a network among local organizations of parents of children with cancer across the country. A handbook first created by Martha Nathanson in 1986 and updated in 2000 (You Are Not Alone) is still an important resource for families with a child who has cancer.

By the mid-1980s, Candlelighters began to broaden the board of directors to families outside the Washington, D.C., area. The national office expanded and began to develop more educational materials, notably Educating the Child with Cancer. By the 1990s, the work of the group included running the ombudsman program, providing financial advice and medical referrals and searches, and leadership training workshops for parent leaders. Also in this period, the American Cancer Society and Candlelighters ended their financial arrangement, which led to restructuring in Candlelighters. Candlelighters successfully rebuilt its organization. There are approximately 50,000 families in the membership, and advocacy continues to be a large part of the group both locally and nationally. Today, the mission of ACCO is to provide information and support for children and adolescents with cancer and their families, to provide grassroots leadership through advocacy and awareness, and to support research leading to a cure for all children with cancer. Because cancer impacts the entire family, the goal of the ACCO continues to be providing pediatric cancer family support. Their motto is “because kids can’t fight cancer alone!”

Carcinoid Cancer Foundation

The Carcinoid Cancer Foundation was first founded as the Carcinoid Tumor and Serotonin Research Foundation in 1968 after the National Institutes of Health’s (NIH’s) funding for rare cancers ceased. The name change took place in 1995. This organization is a nonprofit charted by the state of New York, and its goal is to encourage and support research and public education about carcinoid and similar neuroendocrine cancers through fund-raisers, educational efforts aimed toward both physicians and patients, helping patients find doctors, and other efforts to improve the care and early discovery of this disease.

A carcinoid is a type of neuroendocrine tumor that grows slowly. They are found most often in the midgut, but metastasis sometimes happens. These tumors also may occur in the lungs and anywhere else in the body but are most often found in the intestines. Since the growth rate is so low in these types of tumors, one could grow for years before any symptoms presented. These tumors usually appear in hormone-producing cells within the small intestine or digestive tract, and they also can appear in the sexual organs and pancreas. The tumor also can create other symptoms such as flushing, diarrhea, and in some cases, heart failure. It is difficult to diagnose at times as the tumors can be too small to identify, and sometimes surgeons make discoveries while in the operating room.

The Carcinoid Cancer Foundation hosts lectures and conferences to gather together physicians and other individuals in order to educate them about these tumors. They also provide resources for the newly diagnosed and individuals who are currently battling this type of cancer. They have events to raise awareness and fund-raisers to assist patients. They connect patients with doctors and provide a lot of helpful information about diagnosis, treatment, nutrition, videos of patient conferences, and other encouraging or helpful resources.

Carcinoid tumors can be difficult to diagnose. If the tumors begin in the gastrointestinal (GI) tract, the substances the tumors produce are released into a blood vessel that carries them to the liver, where enzymes destroy them. Because of this, tumors may not show any symptoms until they have grown much larger or have invaded the liver as well, sometimes destroying it to the point that a liver transplant would be required.

The survival rates for individuals who have been diagnosed with carcinoid tumors depend heavily on what stage and location the tumor is in when it is discovered. A localized tumor means that the tumor has not spread, and the five-year survival rate (chances of the person surviving five or more years) is more than half in all locations. A carcinoid in the rectum, for example, has a 90 percent rate of survival if it is localized when it is found. Regional carcinoma has spread to other areas in the region, whereas distant cells have made it into the lymph nodes or to other distant sites when they are discovered. Distant tumors have the lowest rate of survival.

Tumors in the stomach, duodenum (beginning of the small intestine), appendix, and rectum are much more likely to be discovered before the cancer spreads. Tumors found in other parts of the small intestine and colon usually have grown into nearby tissues or lymph nodes and are already considered distant before they are ever discovered. The symptoms of these tumors can vary from nausea to diarrhea and abdominal pain, which all can be symptoms of more-benign ailments.

Through educational seminars and the collection of information available to carcinoid cancer patients, physicians and patients can be more aware of these medical ailments and know more of what to look for. Because carcinoid tumors are so slow in growing and generally take a long time to spread, nearly half of all of the tumors are found in an early stage before any problems have cropped up. These tumors usually are found accidentally while in treatment for some other problem. They also may be found during surgery on the GI track to alleviate other disease. It is most likely to be found during upper endoscopy or colorectal cancer screenings.

Treatment for carcinoid tumors depend on several factors, such as whether it can be completely
removed by surgery, has moved to other places within the body, has come back from remission, or has not improved with treatment. The Carcinoid Cancer Foundation provides resources to help explain the treatment options in more detail for newly diagnosed patients.

There are several different types of therapy used for treatment: surgery, radiation, chemotherapy, and hormone therapy. Treatments typically require surgery. There is endoscopic resectioning, which is an endoscope with a tool to remove tumor tissue. Local excision is surgery to remove both the tumor and a bit of the tissue around it. In more serious cases, the organ that contains the cancer is totally removed, and a liver transplant may be required.

Treatment for carcinoid syndrome may also be necessary, such as hormone therapy to lessen flushing and diarrhea. Interferon may be used to stimulate the immune system for the same reasons. Medication may be given for diarrhea, skin rashes, and easier breathing and prior to receiving anesthesia for the medical procedure.

With the difficulty present in trying to diagnose and treat this type of tumor, the education offered by the Carcinoid Cancer Foundation is invaluable. This foundation raises money to further research in this field as well as offering resources to connect the newly diagnosed with support groups, doctors, information about diet changes that assist with the treatment, and other information, such as what a patient should do if insurance refuses to pay for the treatment. Carcinoid cancer may currently be one that is difficult to recognize, but thanks to the efforts of individuals working for the Carcinoid Cancer Foundation, research will continue to be done on this matter.

Further Readings

Carcinoid Tumor, Childhood

Difficult to diagnose, carcinoid tumors are slow-growing and rare but can be completely cured if caught early. Most start in the gut (pancreas, rectum, intestines, colon, and stomach). About one-third of the tumors of the small intestine are carcinoid. About one-half of malignant tumors of the small intestine are carcinoid. Carcinoid tumors are also found in the lungs, liver, appendix, ovary, and other areas. These tumors are relatively rare in pediatrics. When they do occur, some of the more aggressive types are associated with increased mortality in this age group.

Generally, less than 1 percent of all cancer cases in the United States involve children. Approximately 10,450 children (under the age of 15) and approximately 5,330 adolescents (age 15 to 19) will be diagnosed with cancer per year. Most will be treated successfully. The number of deaths from pediatric cancer, from the year 1975 to 2010, has decreased by greater than 50 percent. Yet, it is the second-leading cause of death. Approximately 1,350 children (under the age of 15) and 610 (age 15 to 19) will die from cancer per year in the United States.

Carcinoid tumors are the most frequent tumor in the gastrointestinal tract of children and the most frequent primary pulmonary tumor. The appendix is the most common site in the gastrointestinal tract. Carcinoid tumors found in the appendix of pediatric patients are often found during removal of the appendix. Some pediatric patients will present with abdominal pain; however, symptomology is not always present. Carcinoid tumors are more likely to occur in female patients with an incident rate of 2 to 1.5.

Carcinoid tumors are neuroendocrine tumors. They are found in the cells of the nervous and endocrine systems. Because of this, they can secrete excess hormones (e.g., histamine, serotonin)
Carcinoid tumors, childhood

Carcinoid tumor, childhood describes the symptoms associated with carcinoid tumors in the liver. Symptoms can include: redness in the face or neck, warm feeling in the face or neck, fast heartbeat, difficulty breathing, diarrhea, and sudden drop in blood pressure. Carcinoid syndrome is less likely present in pediatric patients as the cancer typically is not present in the liver. However, the larger the tumor, the more likely the liver will be involved.

Carcinoid tumors are diagnosed and staged through a variety of tests that may include: physical exam; physical history; blood chemistry (white blood cell, red blood cell, hemoglobin, and platelet counts); and a 24-hour urine test (urine is collected over a 24-hour period to measure higher- or lower-than-normal substances). The 24-hour urine test is also used when diagnosing carcinoid syndrome.

Treatment for carcinoid tumors typically includes surgical removal and when necessary further interventions. If the tumor occurs in the appendix of children, treatment might include removal of only the appendix, if the tumor is small. When a larger tumor is present, surgery to remove the appendix, lymph nodes, and even part of the large intestine is possible. If the carcinoid tumor has spread, chemotherapy or radiation therapy may also be required. The best chance for a cure is a complete removal of the carcinoid tumor. Approximately 18 percent of pediatric disease will involve a tumor of the appendix.

Carcinoid bronchial tumors in the pediatric population are often treated by resection of the bronchial region. The vast majority will undergo a lobectomy, which is an open surgical procedure. However, some are better treated by other means, and this is due to the specific location of the carcinoid tumor. Recent proposals in treatment of bronchial tumors include sparing as much bronchial tissue as possible utilizing bronchoscopic treatment.

A bronchoscope is a thin, lighted instrument that is inserted through the mouth or nose and is capable of removing small portions of diseased tissue without the need for an open surgical procedure. This method, however, can result in the need for a second resection and may increase the risk for recurrence of the disease. If the disease does recur, a lobectomy may be recommended.

Even though carcinoid tumors can be removed typically with surgery, they must be monitored appropriately. Patients of any age, especially if carcinoid syndrome is associated, are at risk for carcinoid heart disease. Some people develop this disease because carcinoid syndrome can cause a thickening of the heart valves. This makes it difficult for the valves to function. They may leak, as well. Symptoms of this disease can include shortness of breath (especially during physical activity) and fatigue. This disease may lead to heart failure. Surgical repair of the heart valves may be indicated.

It is recommended that parents talk with both the treating physician and primary care physician to develop an ongoing plan for follow-up care. Ongoing computed tomography (CT), magnetic resonance imaging (MRI), observation, screening, and follow-up care are recommended for not less than three months with the treating physician. Treating physicians may also recommend enrollment in clinical trials. Primary care physicians should regularly examine, administer appropriate tests, and monitor recovery for the remainder of childhood. A transition plan into adulthood may include good health guidelines, including not smoking, healthy diet, healthy weight, and regular exercise.

Treatment for cancer is associated with long- and short-term physical side effects; additionally, any cancer treatment in childhood should include a discussion and plan for cognitive and developmental side effects. The follow-up plan should also address quality of life in these areas as well as any emotional concerns. The family should keep an organized and detailed health record with the idea in mind that the child will one day be responsible for his or her own health care. Few children will remember treatment with enough detail to inform physicians in his or her ongoing care. This record can then be given to the child as he or she reaches adulthood. The information will be valuable to any treating physician through adulthood.

Carcinoid Tumor, Gastrointestinal

Carcinoid tumors are best treated when diagnosed early. They are often cured through surgery. Most grow and spread at a slow rate, but because of this, they often do not cause symptoms for multiple years. They start to grow in hormone-producing cells in a variety of organs. However, they are most prevalent in the gastrointestinal tract (i.e., stomach, intestines, appendix, liver, and pancreas).

Thirty-nine percent will occur in the small intestine; 15 percent in the rectum; 7 percent in the appendix; 5 to 7 percent in the colon; 2 to 4 percent in the stomach; 2 to 3 percent in the pancreas; and 1 percent in the liver. Approximately 12,000 persons are diagnosed with a carcinoid tumor in the United States. Of those, about 8,000 occur in the gastrointestinal tract. Approximately 50 percent of all small intestine cancers are carcinoid tumors. However, carcinoid tumors represent only 1 percent of the cancers that occur in the gastrointestinal tract.

Most symptoms of carcinoid tumors are vague and may be similar to symptoms of other conditions. Abdominal pain, bleeding, cramping, bloody stools (typically dark and tarry), or constipation may be present in gastrointestinal carcinoid tumors. Carcinoid tumors may lead to two conditions: carcinoid syndrome and Cushing’s syndrome. Approximately 60 percent of persons with a carcinoid tumor will eventually develop carcinoid syndrome. Heart palpitations, abdominal cramps, shortness of breath, wheezing, flushing of skin, rash, diarrhea, neurosis, and psychosis are all possible symptoms of carcinoid syndrome. When all of these symptoms occur at the same time, it is referred to as a carcinoid crisis. It is a serious complication and can be life-threatening. It can occur suddenly or be brought on by stress, anesthesia, or chemotherapy. Strenuous exercise and alcohol consumption can make these symptoms worse. Cushing’s syndrome may include high blood pressure, high blood sugar, weight gain, muscle weakness, increased facial and body hair, and thinning of the skin.

A high-magnification micrograph of a tumor in the small intestine. About one-third of all the tumors found in the small intestine are carcinoid. (Wikimedia Commons)
There are a number of identified risk factors associated with carcinoid tumors: genetic syndromes (i.e., MEN1 or neurofibromatosis type 1); female gender; African American heritage (gastrointestinal carcinoid tumors); Caucasians (lung carcinoid tumors); stomach conditions that reduce the amount of acid in the stomach; smoking; and age (gastrointestinal carcinoid tumors are most often diagnosed between the ages of 55 and 65). It is important to note that some people with risk factors never develop carcinoid tumors, while others with no risk factors will.

Physicians have a variety of tests to diagnose and stage tumors. Some of these tests also assist in determining the most effective treatments. Most often, a biopsy will be performed to make a definitive diagnosis. Physicians will most often consider: age and medical condition; previous test results; type of tumor suspected; and signs and symptoms.

Blood and urine tests are typically the first step. Physicians use these to look for excess hormones and other substances that carcinoid tumors may produce. Physicians may use X-ray, computed tomography (CT), magnetic resonance imaging (MRI), or a positron emission tomography (PET) scan to visualize suspected tumors. The imaging may include an injection of radioactive material that is attracted to carcinoid tumors. Endoscopy is typically used when gastrointestinal carcinoid tumors are suspected. Endoscopy can visualize nearly the entire digestive tract from the esophagus to the rectum.

When testing is complete and the results are cancerous, physicians will then stage the cancer. Staging describes where the tumor is, where it has spread, and if it is affecting other parts of the body. Knowing the stage helps the physician decide treatment and predict prognosis. There are different stage descriptions for each of the different types of carcinoid tumors. There are three general stages utilized for staging of gastrointestinal carcinoid tumors: localized (the tumor has not spread outside of the affected organ); regional spread (the tumor has spread to adjacent tissues); distant spread (the tumor has spread to tissues or organs not adjacent to the initially affected organ); and recurrent (a tumor that returns after successful treatment).

Treatment for the various stages depends on a number of factors, including possible side effects, patient's preference, and overall health. A localized stomach carcinoid tumor is often removed through the use of an endoscope. Surgery is recommended for both small and large intestine carcinoid tumors. An appendectomy is recommended for carcinoid tumors of the appendix. Carcinoid tumors of the rectum are removed with electro-fulguration (destroys the tumor with an electric current). When regional spread occurs, the primary carcinoid tumor is removed and the tissues and lymph nodes in the immediate area. If distant spread occurs, it is call metastatic cancer. Surgery at this stage typically alleviates symptoms but not necessarily all of the cancer. In this case, chemotherapy, immunotherapy, targeted therapy, or radiation therapy may be recommended. Each of these may also be utilized in conjunction with surgery.

Radiation therapy uses high-energy X-rays to destroy cancer cells. Usually, there are a specific number of treatments over a specific period of time. Radiation therapy can be external or internal. Chemotherapy uses drugs to destroy the cancer cell, usually by destroying the cell's ability to grow. This method also utilizes a specific number of treatments over a specific period of time. Immunotherapy helps the body to boost its natural defenses to fight the tumor. Targeted therapy is meant to target the tumor's specific genes, tissues, or proteins that assist with its growth or division. This treatment limits the damage to surrounding healthy cells.

Remission occurs when the cancer can no longer be detected and there are no longer any symptoms. Remission can be permanent or temporary. If it does return, it is called recurrent cancer. If it does reoccur, it can come back in the same place, nearby, or in another place. These are referred to as a local recurrence, regional recurrence, or distant recurrence, respectively.

Recovery is not always possible. In this case, the disease is called advanced or terminal cancer. Making sure symptoms are as controlled as possible and pain management is in place occurs at this stage. It is at this time that patients and families may discuss final wishes, who will make medical decisions, and what kind of life-saving interventions are desired or prohibited by the patient. If the patient has less than six months to live, hospice may be a good choice. Hospice is designed to increase or maintain quality of life, provide
nursing care and technical assistance, and any special equipment required. Hospice care can be provided in the home or in a facility.

Carcinoma of Unknown Primary

Carcinoma is cancer that develops from epithelial cells, the tissues that line cavities and surfaces in the body, as opposed to sarcomas, which develop from nonhematopoietic mesenchymal cells, and leukemias and lymphomas, which develop from hematopoietic cells. Carcinomas have among the highest mutation frequencies, depending on the type of tissue they develop from and whether, as in the case of lung cancers, that tissue is regularly exposed to DNA-damaging agents like tobacco smoke.

About 4 percent of cancers are cancers of unknown primary origin (CUP), meaning that a metastatic cancer—a cancer that has spread beyond its point of origin—has been discovered, but doctors are unable to determine where it originated. Though CUP properly refers only to those cancers whose origin remains unknown after a thorough and exhaustive investigation—the aforementioned 4 percent—those metastatic cancers that are unknown at first but eventually have their origin located are still important to research and to understanding CUP because they represent the same general phenomenon (cancer metastasizing before symptoms present) and may be caused by the same mechanism.

Most CUP cancers are adenocarcinomas: carcinomas that began in glandular tissue either lining or covering organs in the body. Adenocarcinomas can originate in the breast, lung, pancreas, prostate, stomach, liver, and colon most of the time. Adenocarcinomas, two-thirds of which are well differentiated, account for 90 percent of CUPs, while the remainder are squamous cell carcinomas, undifferentiated malignant neoplasms, neuroendocrine tumors, and mixed tumors.

A number of symptoms may present, including pain that does not go away, a cough or hoarseness that doesn’t go away or worsens, bleeding or discharge, fever, night sweats, loss of appetite or rapid weight loss, constipation, diarrhea, increased urgency in urination, or a lump.

Because CUP is a type of cancer rather than a specific cancer, symptoms can vary considerably, but usually, the cancer is discovered because of a swelling on the body or a mass discovered during medical imaging (either in response to other symptoms or because of some other condition). The defining feature of CUP is that it has spread sufficiently far beyond its origin without causing sufficient symptoms to necessitate a doctor’s visit. Characteristically, tumors in a CUP patient form in unusual areas—this is one reason it is difficult to determine their origin. A full physical examination of the body, including rectal and pelvic exams, and whole-body imaging are necessary to be sure that all tumors are identified. A computed tomography (CT) scan of the chest, abdomen, and pelvis is conducted, which may indicate a helpful pattern of spread. Cancer found in the upper body, for instance, likely originated above the diaphragm such as in the lung, while the pancreas and liver are more likely origins for cancer found in the lower body.

The reason the origin is important is because not all cancers are the same. A tumor in the breast that originated in the lungs is not, ideally, treated the same as a tumor that originated in the breast. Based on their origins, different cancers respond to different treatments. For this reason, immunohistochemical testing can sometimes identify the
cancer's origin by determining the expression of protein markers by the cancer cells and matching that pattern to a known cancer. Even this works only 25 percent of the time.

Treatment and prognosis vary considerably, though the prognosis is generally poor due to the metastasis. The standard modalities—chemotherapy, radiation treatments, surgery, and hormone therapy—are usually employed, often in combination, depending on the location of the tumors.

Research continues to investigate whether there is a common factor or mechanism that could account for the CUP phenomenon, making some cancers more likely than others to spread quickly but asymptptomatically. There are some indications that CUP not only runs in families but is associated with families with a history of lung, kidney, and colorectal cancers.

Careers

The concept of career comes from a person’s work. Work that is specialized through a division of labor is a job. The division of labor creates work that is suited to workers’ abilities, skills, and interests. They can become very good at the work they do through training and experience. A career is more than a job, although it is often confused with a steady job of some kind.

It is the linkage of jobs so that the worker progresses in a planned process of increasing skills and responsibilities. This process takes place within a large organization with many different kinds of work organized in a logical way. As the sociologist Max Weber described it, employees’ jobs are linked in a series of steps. The result is the traditional organizational hierarchy, each step leading to a higher position on the career ladder. The bureaucracy groups jobs and careers into departments and divisions. There is even a department in charge of creating careers. The development of job descriptions, hiring and job placement, and training and career planning is done by human resources.

A worker’s career leads to first-line supervisor, to the manager of such supervisors, and on up the administrative ladder to the president. This is the line. A worker could spend a lifetime moving up step after step. Promotions would take place within the organization rather than bringing someone from outside.

While much that Weber described has been found to fit real organizations, there are problems with his theory. Not all work takes place within this administrative line. A second type of work has been found, carried out by the staff. Staff workers are experts who cannot be trained within the organization due to their highly specialized skills. No one in another job can become a doctor or nurse by receiving training from the office of human resources. Organizational studies have found friction and other problems from an organization
following two contrary operating principles: the specialized authority claims by professional staff and the administrative authority of the bureaucratic line. In a hospital, the question is this: Who runs the organization? Is it the doctors or the hospital administrator?

We see that medical work is organized into professions. When we think of a career in health care, the image of a profession comes to mind. In fact, there are a very large number of specialists doing skilled work, all of which is licensed to do a particular piece of the very broad category of health care. Each type of health care work has laid claim to being a profession. Work only partially recognized is a semi-profession.

The way professions work is very different from the rational bureaucracy. Yet, the professional career also consists of a series of steps. They are a throwback to the medieval guilds of craftspeople and retain many of their ancient features of loyalty to peers, not an employer.

The bureaucratic organization recruits from the general public. The guild gained its recruits from its members’ children. This process emphasized the guild’s unity. The recruit was an apprentice who worked in the home of a craftsperson for seven years. While the apprentice was not paid, he or she received training while living with the craftsperson’s family. This stage is like the college study required by health professions. Then came the stage of the journeyman, eventually becoming established as a craftsperson. The last stage was master craftsman. Each stage required peer acceptance of the candidate, usually by submitting a piece of work that demonstrated the candidate’s skills. These stages live on in the degrees granted by universities and the thesis that demonstrates the graduate’s scholarship.

The difference between the profession and the organizational career lies in the profession’s lack of integration with other work. Each profession operates in isolation. A nurse’s aide does not move up to become a nurse with training and experience. A nurse cannot become an emergency medical technician or become a doctor. A nurse could become a doctor but by starting at square one, getting admitted to medical school. Health care professions have their own stages of acceptance, but once a candidate is accepted into the profession, there is no organized plan to become another kind of professional. In the way organizations operate, these professionals are staff. However, they can move into the positions of the line, as when a nurse becomes the nursing supervisor or a doctor a hospital administrator. Also, there are new skills and specializations that professionals can gain within their professions. A doctor can become a surgeon, and a nurse can become a surgical nurse.

While an organization can hire anyone who is able to do the needed work and can be trained to do it, this does not hold true in hiring professionals. The profession, as did the guild, recruits and trains the professional. Only members can do its work when accepted by their peers and licensed. Professionals decide who to accept as trainees and what standards to require for licensure. Nearly every profession requires a college degree and many more advanced training. While professionals claim that their special knowledge can only be transferred through such education, they also are restricting membership to candidates who have the background that enhances the prestige of the group (profession).

During World War II, the U.S. Army required thousands of health professionals. Among these were pharmacists. As a large organization with power to organize and train its human resources, the army studied the pharmacy occupation logically and found that a good pharmacist could be trained in six weeks. The leaders of the profession loudly complained for their prestige was being undermined. They did admit that the requirement at the time for a college degree to be a pharmacist was not necessary, but it was good for the profession. The problem is that what is good for a profession, in raising the requirements for entry, may be bad for the public, in restricting the number of practitioners, raising the prices that practitioners can charge and holding back the profession from needed change.

This problem has led to a system of health care in the United States that is disorganized and fragmented, with hundreds of different kinds of specialized work being done by professions that do not work together to achieve organizational goals but separately to advance their power and prestige. Each profession works to control its work and who can do it. So, the nursing profession has control over medications. No nurse’s aide can give a pill to a patient, for that is the nurse’s job. Similarly,
Caregivers

Cancer patients often require care from informal caregivers who provide both emotional and instrumental support. Caregivers are often family members who provide, among other responsibilities, assistance with activities of daily life and coordination of medical care. Thus, a caregiver is one who attempts to meet the physiologic and psychosocial needs of the individual. Caregiving comprises an enormous unpaid contribution to health care, and the burden of caregiving brings increased psychological and medical morbidity to the caregiver. Only recently has research begun studying the impact of this distress and exploring interventions that support cancer caregivers to promote better outcomes for families managing a cancer diagnosis.

The Scale and Value of Care Provided

In 2009, roughly 42 million caregivers across all United States patient groups provided an unpaid contribution to health care of $450 billion, a value that approached federal Medicare spending for the same year. This represents an estimated 40,300 million hours of care, most often provided by immediate family members. In the UK, 6 million unpaid caregivers provide a £57 billion ($97 billion) contribution to health care—similar to the annual cost of the entire National Health Service. Collectively,

Further Readings

Caregivers are a fundamental component of cancer treatment—providing approximately 50 percent of the total care needed for patients treated for cancer in developed countries.

Demographics
There were 14.5 million people living with cancer in the United States in early 2014. This number is projected to grow to 19 million by 2024 with similar growth in cancer survivorship expected worldwide. The number of people living with cancer is increasing in part due to earlier detection, improved treatment outcomes, and a resulting shift from the treatment of cancer as an acute illness to its treatment as chronic. As less-intensive treatments have become available and as managed care attempts to reduce health care costs, cancer is increasingly treated in an outpatient setting. As a result, additional involvement from family caregivers is increasingly being required to fill new responsibilities in the health care system.

A spouse or partner of the patient with cancer most often fills the role of caregiver. The second most common caregiving situation for those with cancer is provided by adult children of the patient, with daughters providing the majority of care. Most caregivers are female; however, a rise in prevalence of male caregivers across all types of caregiving has been continuing for many years, with men serving as caregivers for 39 percent of patients in the United States in 2007, reflecting a 25 percent rise in male caregiving since 1987.

The average lost income of caregivers in the United States during the two years after a cancer diagnosis was $47,710, with breast cancer representing the least costly at $38,334 and lung cancer representing the highest caregiving cost of $72,702. The typical caregiver in the United States loses $110 in wages and benefits a day.

Caregiver Burden
Caregiving for a family member with cancer often requires a full-time commitment, with caregivers responsible for monitoring and managing symptoms, tracking and administering medications, conducting basic medical procedures, and providing emotional support. This support is provided despite caregivers having only minimal training. Additionally, care providers often supply transportation for the patient and assist with medical decision making. This care typically occurs in the context of significant role changes at a time when the patient is not able to accomplish activities of daily living. For example, a spousal relationship can transition into providing extensive medical care. The caregiver is frequently required to take on other roles (home finances, cleaning, family transportation, etc.) along with the myriad aforementioned duties of providing care to the patient. These multiple roles and additional workload occur in the context of a grief reaction to the patient’s cancer diagnosis and, in many cases, reduced emotional support from the family member facing cancer. Caregivers are often unprepared for these new roles and increased emotional demands. As such, this confluence of events has been shown to produce a substantial psychological, physical, and financial impact on lay caregivers.

Psychological Impact of Caregiving
Caregivers have been shown to experience significant psychological distress. Indeed, the levels of caregivers’ emotional distress have been shown to be higher than those experienced by the cancer patient. Between 18 and 58 percent of caregivers experience levels of depression that meet diagnostic criteria. Similarly, anxiety is common among cancer caregivers and is observed to reach levels of clinical significance in 20 to 50 percent of family caregivers. Other commonly reported emotions include fear, hopelessness, and loss of control as a result of caregiving.

A number of factors have emerged that predict poorer psychological functioning in caregivers of cancer patients. For example, psychological distress worsens with disease progression, metastatic disease, graver prognosis, increased length of patient illness, and when caring for patients reporting greater distress. Personal caregiving needs, such as helping the patient shower, have been found to increase emotional burden on caregivers than more than nonpersonal needs such as transportation. Family caregivers of advanced cancer patients, those with less than a high school education, and those who experience more disruption of their life experiences are at highest risk for anxiety and depression.

Female caregivers report higher levels of distress, a higher burden due to caregiving, and less self-esteem than male caregivers. It has been theorized...
that this may be due to the influence of gender-role socialization where, in many cultures, women are expected to serve as primary caregivers. Therefore, women may be seen as fulfilling an already expected familial role, whereas men may receive additional positive appraisal from others for filling a gender atypical role. Adult children who are caregiving for a parent have been reported to experience higher levels of distress than spousal caregivers. In addition, caregiving distress has been shown to be higher in younger caregivers.

Studies of patient–caregiver dyads suggest that the quality of communication predicts the amount of emotional distress, depression, hopelessness, and caregiving burden experienced by the dyad. Patient–caregiver dyads that communicate well about their relationship and express authentic concerns about cancer experience lower amounts of emotional distress. Protective buffering is the practice of hiding worries or concerns to protect the other from emotional or physical distress. In caregivers, it often presents as a lack of willingness to bring up fears related to cancer or death and dying as well as not discussing burdensome aspects of caregiving. Protective buffering has been shown to increase distress in partners and lower relationship satisfaction in patients and caregivers undergoing cancer treatment.

Despite the large amount of psychological distress exhibited by caregivers, positive emotional experiences and benefit finding are also reported. For example, a deeper connection to the patient, enhanced experience of meaning in life, and improved self-worth or feelings of increased self-efficacy in the caregiver role are noted. These are often provided as examples of posttraumatic growth or the development of positive psychological change as the result of challenging life experiences.

**Physical Impact of Caregiving**

The physical effects of being a family caregiver for those with any chronic illness have been well documented, affecting sleep, fatigue, cellular immunity, markers of cellular aging, wound healing, cardiovascular disease, hypertension, and mortality.

Sleep disturbance is the most common symptom of distress among the caregivers of early-stage cancer patients. Between 31 and 95 percent of family caregivers of advanced cancer patients report severe sleep problems. Specifically, they report a lack of restful sleep, limited sleep duration, and frequent sleep disruptions due to restlessness of patient bed partners and nighttime caregiving needs. Caregivers also report daytime dysfunction from sleep deprivation. Caregivers may be cautious about taking sleep medications for fear of not being able to address the needs of patients during the night.

Fatigue is a common concern for long-term caregivers. There may be physiologic or psychological etiologies to this fatigue. The demands of multiple roles, emotional distress, anticipatory grief, sleep deprivation, and limited time for rest and recovery all contribute to the development of fatigue. Fatigue is related to caregiver burden, with fatigue increasing along with increasingly demanding caregiver schedules and perceived burden of the caregiving role. In patients with advanced cancer, fatigue has been shown to be interrelated with psychological morbidity, specifically with the level of depression, anxiety, and sleep concerns.

Medical risks conferred to caregivers are caused by increased allostatic load—chronic stress causing wear and tear on the body. Family caregivers experience wide-ranging negative impacts on biomarkers that are established indicators of health. These include reduced cellular immunity, slower wound healing, cytokine dysregulation, autonomic and neuroendocrine disruption, and elevated markers of inflammation and cellular aging.

The well-documented increase in inflammation may be tied to cardiovascular risk. For example, spousal caregivers of cancer patients have an increased risk of coronary heart disease and stroke, which is greater for patients diagnosed with a high-risk cancer, such as lung and pancreatic cancer. Caregiving has also been identified as an independent predictor of hypertension onset, with caregivers being 36 percent more likely to develop hypertension than noncaregivers. Caregiving lasting longer than one year has been associated with a more than doubled risk for hypertension. Elderly spousal caregivers for all types of patients who report strain in their role as a caregiver have a 63 percent increased incidence of mortality when compared to noncaregiver controls. Being a spousal caregiver has been established as an independent risk for mortality.
Support for Caregivers

Lack of resources for basic needs, employment, and finances often represent major sources of concern for caregivers. Families may lose one household income due to cancer, and the other, in full or in part, is lost due to work leave while caregiving. In the United States, the Family and Medical Leave Act (1993) provided one of the first legal protections for caregivers, allowing unpaid medical leave to allow for caregiving provided to a spouse, parent, or child. The Affordable Care Act (2010) granted additional provisions to expand Medicaid benefits for personal attendant care to help provide relief to family caregivers among the lowest income families in the United States. In Europe, caregivers similarly experience many unmet financial needs. Research in Italian and British populations has reported that many families spend a significant portion of their savings in providing care for loved ones at the end of life. Internationally, only 16 countries provide legally mandated paid caregiving with compensation rates ranging from 50 to 100 percent.

Care for the Caregiver: Interventions

Given the psychological morbidity and health consequences of caregiving, caregivers are in the unusual position of being in need of care themselves while providing care at the same time. However, cancer treatment is almost exclusively focused on patients. The focus on patient care can be all encompassing for oncologists, and identification of the unmet needs of the caregiver is often limited. As a result, many caregivers only receive intervention during times of crisis, when their needs are more likely to be outwardly visible to the oncology team and their support system.

Caregivers often value self-reliance and independence and may be reluctant to seek help. Other caregivers are narrowly focused on care for the patient and do not seek supportive services, possibly due to their perception that these services would distract from the care they provide. Indeed, support services that require them to leave the proximity of the patient may be prohibitive. Caregivers also report that they rarely have the time to take care of themselves due to the demands of providing care for their cancer patient.

Research has provided some insight into what interventions are most acceptable and effective at meeting the needs of caregivers. Randomized controlled trials have attempted to isolate intervention components in caregivers of cancer patients. These include, but are not limited to, interventions providing education and training about patient care, including information about the cancer and treatment, those that teach coping, communication and problem-solving skills directed at the caregiver, and those that provide a supportive therapeutic relationship for caregivers.

Interventions that give caregivers information about cancer, what to expect, treatment guidelines for patient care, as well as symptom management have been demonstrated to reduce caregiver distress, increase caregiver confidence and self-efficacy, and improve patient outcomes. It should be noted that many of these components are now considered standard of care. In addition to these targets of caregiver intervention, skill-based training that provides coping skills for managing emotional distress, communication, and problem-solving therapy are effective for many cancer caregivers. These interventions reduce symptoms of anxiety and depression, promote active coping over passive or avoidant coping, and ultimately, reduce caregiver burden.

Interventions providing supportive therapeutic relationships for caregivers are often integrated with other types of interventions. Social support provided by a group setting has been found to help caregivers. Similarly, caregivers with greater perceived social support report an enhanced ability to cope with caregiving as well as less emotional distress, reduced markers of inflammation, and reduced caregiver burden. Home-based caregiver respite services have been demonstrated to reduce the experience of caregiver burden in end-of-life cancer care. However, many caregivers are uncomfortable leaving the patient’s side toward the end of life. Most regrettably, financial support for these interventions is limited.

Conclusion

Caregivers of cancer patients exhibit significant psychological and physical distress, which often go unaddressed. Emerging evidence suggests that informational and skill-based interventions, along with increased psychosocial support, may mitigate the burden of caregiving; however, much of this work is nascent and integrating evidence-based interventions for caregivers into the standard of
Celebrities and Cancer

Celebrities have long held the public's interest, be it with their dating lives, legal troubles, or health and well-being. They can be influential in the public's perception of illness, bringing humanity to a specific disease and raising awareness to new treatments and screening procedures. For the last 50 years, celebrities have been candid about their cancer diagnoses with the public, making it an accessible topic and broadening the larger discussion in society. With this openness, celebrities have worked to create important cancer awareness organizations that reach out to the public.

Important Celebrity Stories

One of the first celebrities to share her story about cancer was Shirley Temple Black, known best as the curly-haired, adorable child star. She came forward in 1972 with her breast cancer diagnosis and resulting mastectomy, something that had never been done before because it was a privately fought disease at the time and rarely spoken about in public. When Temple Black died in 2014, her public declaration, made early in the fight against breast cancer, was one of the most discussed parts of her life even though she had won accolades as an actor and had served as an ambassador for the United States.

Betty Ford became another important early public figure with breast cancer. Her announcement was made even more important because her diagnosis came while she was first lady of the United States in 1974. Then in 2000, Katie Couric, an anchor on the Today Show, underwent an on-air colonoscopy to raise awareness for life-saving cancer screenings. Couric's husband had died in 1998 of colon cancer, and her public action was done to demonstrate to the audience that colonoscopies were not painful procedures but rather simple, necessary screening techniques that could save lives. She created something known as the Couric Effect, whereby gastroenterologists saw an increase in patients having routine colonoscopies after her public appeal. The audience found the demonstration of the procedure compelling and were touched by her story about losing her husband to a form of cancer that is more easily treated if caught early.

Suzanne Somers, known for her role on Three's Company and as the spokesperson for health and fitness products like the Thighmaster, was diagnosed with breast cancer in 2001. She underwent some traditional treatments for her cancer but also chose to publicly discuss her refusal to have chemotherapy and her decision to use alternative medicine and healing practices. The public discussion that ensued from her decision was somewhat critical of Somers's advocacy against traditional medical treatments, which was seen
then discussed on the show that this is the kind of growth that, if left untreated, could turn into colon cancer, and that Oz's diagnosis showed the importance of regular colonoscopies. This kind of early polyp is not uncommonly found, and some in the medical establishment were concerned that Dr. Oz was making this sound like an emergency and could be creating unnecessary panic in audiences. In 2011, Dr. Oz did a follow-up colonoscopy for the television show to underscore the importance of continued contact with your physician and the necessity of following up on these medical crises. Both points of contact with audiences raised awareness for these simple screening procedures that can help detect cancer early in growth, much in the same way that the Couric Effect helped do so 10 years before.

The death of famous celebrities also brings awareness to cancers that have high mortality rates. When Patrick Swayze died in 2009 from pancreatic cancer, followed by Steve Jobs in 2011, people at home saw that having money can buy excellent treatment, but it cannot save you from a cancer that is not as easily detected. In 2013, another public discussion about breast cancer began when Angelina Jolie announced in the New York Times that she had undergone genetic breast cancer screening tests that lead to a double mastectomy. She had two close female family members who had died of breast or ovarian cancer and decided that that warranted some very expensive screening tests. After her announcement, physicians spent the next few days telling the public that most people were not within the parameters to warrant this kind of screening and that they should work with physicians to better understand individual health situations and family histories to know if this would be effective. The major test that Jolie underwent costs close to $3,000 without insurance, and doctors worried that the test might become some sort of status symbol to the public, unnecessarily overused out of panic or status enhancement.

The importance of early detection and treatment and of seeking multiple opinions for a cancer diagnosis were highlighted in the case of actress and producer Rita Wilson, who announced in April 2015 that she had been diagnosed with breast cancer (invasive lobular carcinoma) and had a bilateral mastectomy followed by reconstructive surgery. Wilson, who is married to actor Tom Hanks, issued a press release emphasizing the importance of early detection of cancer and the value of seeking a second medical opinion. In her case, she was aware that she
had lobular carcinoma in situ and had been monitoring the condition through annual mammograms and breast MRIs. However, after a friend suggested she get a second opinion, she was diagnosed with invasive cancer and underwent the mastectomy.

**Celebrity Organizations**

While there are many well-known health-focused organizations that involve celebrities, three in particular were created by celebrities, court major celebrity brand ambassadors, or allow the public to connect with celebrity causes.

In 1982, Nancy Brinker created the Susan G. Komen Foundation after her sister’s death from breast cancer. The Komen foundation is known for its Race for the Cure, held both regionally and nationally, which raises money for breast cancer and has also heavily participated widely in the breast cancer economy, which encourages purchasing products where proceeds go toward the treatment or awareness for breast cancer. Over the years, many celebrities have supported and highlighted the Komen foundation and its events.

The Avon Foundation for Women, created in 1992, supported cancer research funding and later added the Avon Walk for Breast Cancer. The Avon Foundation has given millions of women the opportunity to create community and raise money for cancer treatment. Avon has long courted celebrity ambassadors like Reese Witherspoon and does numerous events across the country every year that encourage women not only to sell their cosmetic products but also to support breast cancer awareness and treatments.

In 1996, Lance Armstrong discovered he had testicular cancer that had spread to several other places within his body. As a famous cyclist who had won the Tour de France multiple times, he was open with the public about his diagnosis. He founded the Livestrong Foundation for cancer research and funding and started a worldwide trend in 2004 by selling yellow plastic wristbands to raise money for his foundation. Many other types of cancer now have wristbands in different colors that serve as fund-raisers for not only large foundations and groups but also for family-run support groups and other disease fund-raisers. Further, the Livestrong Foundation now has a Web site that offers extensive general health information as well as a multitude of information about cancer and medical research.

In May 2008, nine women working in the entertainment industry, including Katie Couric, cofounded the organization Stand Up to Cancer, which funds cancer research differently than most other models: These producers and executives wanted an organization that connected high-profile celebrity personas with cancer fund-raising. Stand Up to Cancer mainly works through celebrity magazine advertisements and television fund-raising specials that include a telethon to raise money for cancer research. Featured celebrities speak about their experiences and their family members’ experiences with cancer, perform for the audience, and answer the phones for callers pledging funds. These funds are then directly given to promising researchers, cutting out the middlemen of traditional funding arms.

Supporting a charity or cause is practically a requirement for the celebrity persona. The Web site Look to the Stars: The World of Celebrity Giving promotes celebrity humanitarian and philanthropic work and allows celebrities to associate their names with specific organizations. The site exists to encourage visitors to support the causes of the celebrities whom they love, respect, and admire through financial contributions, donations of time, or attendance of events, many of which revolve around either types of cancer or rare diseases.

**Conclusion**

Many other celebrities not mentioned specifically here have fought cancer and spoken publicly about their experiences. Michael C. Hall and hockey player Mario Lemieux battled Hodgkin’s lymphoma; actor Robert De Niro and figure skater Scott Hamilton both underwent treatment for prostate cancer; Michael Douglas overcame throat cancer; talk show host and celebrity wife Sharon Osbourne fought colon, breast, and ovarian cancers; and film critic Roger Ebert finally succumbed to thyroid and salivary gland cancer after a very public struggle.

There is a seemingly unending list of celebrities in all avenues of fame that have done their best to shed light on their particular form of cancer, to bring awareness to their fight, to give fans a way to support them, and to raise funds for treatment. Audiences and fans pay attention to these stories, the current status of treatments, and their survival rates. The personal stories of celebrities are a major way that information is communicated about cancer and has proven to have an effect on audiences in participation, fund-raising, and awareness campaigns.

*California State University, Los Angeles*
Celgene (United States)

Celgene is a global biopharmaceutical corporation that focuses on the discovery, development, and marketing of drugs for cancer as well as immune and inflammatory diseases. Founded in 1986 by David Stirling and Sol Barer, Celgene operates worldwide with offices in the United States and Europe. Celgene’s subsidiaries and global partnerships with other pharmaceutical companies, medical institutions, and government agencies across six continents make it one of the largest biopharmaceutical corporations in the world. The company strives to be at the forefront of research and development of new treatments for cancer and inflammatory diseases and to provide all patients in need access to its therapies, regardless of their location or ability to pay for them.

Throughout its 30-year history, Celgene has been known for its pioneering research and development of drugs targeting various cancers. In the 1990s, Celgene began exploring uses for the drug thalidomide, despite its notoriety as the cause of birth defects in thousands of children born in Europe during the 1950s and 1960s. For more than a decade, Celgene developed and tested a derivative of thalidomide known as Revlimid for possible treatment of cancer. Revlimid was first given to human immunodeficiency virus (HIV) patients who had developed a type of cancer known as Kaposi’s sarcoma and subsequently to patients with multiple myeloma. After years of research and clinical trials, Revlimid received Food and Drug Administration (FDA) approval in 2006 as a second-line cancer therapy. Thalomid, another form of thalidomide, was also approved as a first-line therapy for multiple myeloma that same year. Other drugs developed by Celgene have included Focalin XR, used to treat attention deficit hyperactivity disorder (ADHD); Vidaza for acute myeloid leukemia; Abraxane for non–small cell lung cancer; and Otezla, the first oral therapy for active psoriatic arthritis.

In 2003, with its acquisition of Anthrogenesis, Inc., Celgene extended its research and development efforts to encompass stem cell therapy. Celgene Cellular Therapeutics (CCT), a subsidiary of Celgene, was formed to discover and develop new therapeutic uses for stem cells. Celgene’s work in this area has been part of a new field in medical research and treatment—regenerative medicine. Regenerative medicine aims to treat a variety of diseases through the use of stem cells and tissue to repair or replace damaged, defective, or dying cells and tissues in the body. Through the transplantation of stem cells harvested from human placenta, umbilical cords, and amniotic fluid, diseases such as cancer might be defeated at the cellular and molecular levels. Today, CCT is testing various types of stem cell therapies on autoimmune, vascular, and neurodegenerative diseases. To obtain the stem cells and tissue needed for its research, CCT established LifebankUSA, a biobanking business that collects, stores, and disseminates umbilical cord blood and placenta blood and tissue. CCT uses the materials from LifebankUSA in a variety of research projects, from cord blood transplants to treat blood diseases, to organ and tissue regeneration, to wound care products. An example of the last is Biovance, a dehydrated, topically applied wound covering, produced from human amniotic membrane taken from the placenta of a normal, full-term pregnancy. Biovance was created by the Organ and Tissue Therapeutics unit of CCT, which is dedicated to engineering biomaterials that could repair or replace tissue and even organs. Biovance is just one of many products that have the potential to revolutionize patient treatment and medicine itself.

In 2010, Celgene continued its global expansion by establishing the Celgene Institute for Translational...
Research Europe (CITRE) in Seville, Spain. CITRE was Celgene’s first dedicated research and development site outside the United States and was designed to foster collaborative research between Celgene and the European research community. CITRE is incorporated as Celgene Research St. Louis University (SLU) and is a Spanish company financed by private U.S. capital. CITRE’s 25 staff members are scientists drawn from Spain and other European countries, and the institute has formed partnerships with many European cancer research organizations, including university medical schools as well as European government agencies. CITRE also has its own accredited tissue biobank, which houses tissue samples collected from patients who have participated in multicenter Celgene clinical trials held across Europe under the direction of the CITRE Clinical Trials unit.

In addition to its work in developing new therapies for cancer and inflammatory diseases, Celgene also has been active in making a number of its proprietary drugs available to people in impoverished areas of the world who suffer from other deadly diseases such as visceral leishmaniasis (VL), malaria, hemorrhagic fevers, tuberculosis, and HIV. In 2009, Celgene Global Health (CGH) was founded. CGH partners with nongovernment organizations (NGOs), global academic institutions, product development companies, contract research organizations, and other pharmaceutical companies to determine whether their drugs might be effective against the aforementioned diseases. Laboratory facilities are set up, testing and clinical trials are run, and CGH supports the strengthening of health infrastructures in developing countries so that new treatments can be delivered to as many people in need as quickly as possible. One example of a successful collaboration is that between CGH and Advinus Therapeutics Ltd., a pharmaceutical company, to find and disseminate better treatments for those with VL. VL is a parasitic disease that affects 500,000 people annually, and current treatments are difficult to administer, toxic, and costly. Celgene is not only committed to pursuing more effective therapies for cancer in the developed world but also to helping those in the developing world who suffer from lesser-known and often neglected diseases that are just as deadly.

Over the past several decades, the fight against cancer and other diseases has become a global one, and Celgene has been at the forefront of that trend in its search for safer and more effective treatments for cancer as well as its commitment to enabling patients from all over the world and all walks of life obtain access to its therapies. In both developed and developing countries, Celgene has established itself as a pioneer in the discovery and development of new and better therapies for cancer and other deadly diseases.

Cell Phones

Given that cancer is a complex disease, often requiring skillful diagnosis and application of multiple treatment modalities, there are great opportunities for utilizing mobile phones in creative and innovative ways to benefit cancer care. Technological
progress and growing availability and use of cell phones have allowed for extensive and diversified health care applications and opened up new vistas for the use of mobile phones in cancer care. These more-advanced mobile devices are equipped with high-resolution cameras, Internet-based equipment, global positioning devices, and major computing capabilities.

Cancer Prevention and Detection
Consideration of cancer-related use of mobile phones reveals relatively few studies focusing on cancer prevention efforts. Nevertheless, the availability of high-resolution cameras has allowed for encouraging cancer screening applications. Such applications hold particular promise in low-income countries and at remote locations, where traditional screening techniques are not readily implemented. One such example of a successful application of mobile telemedicine has been reported for cervical cancer screening. Physicians and nurse midwives in the United States reported promising results for remote evaluation of cervical cancer among 95 human immunodeficiency virus (HIV)-positive women in the Botswana. Studies also introduced smartphone applications that offer detailed examination of skin cancers or reminders for checking on skin spots for users.

Cancer Treatment and Care, System-Based Prospects
It is well known that the treatment of cancer poses major challenges to care coordination and delivery. In a useful review of the role of information technology in promoting patient-centered cancer care, the authors offer a useful model of patient, provider, and system-relevant applications of information technology in cancer care. They point to the promise of electronic registries, a national cancer database, and electronic health records for actual delivery of cancer care. It is argued that the technology is currently available for integrated uses of Web technology in diagnosis, treatment decisions, and symptom management. Exemplifying the potential value of such systems, they discuss that an optimal information technology-enabled system could help providers and patients in handling side effects of cancer treatment.

A notable project, HealthDesign, specifically targets mobile phone users. Personal health records (PHRs) can collect data about patients’ health behaviors in their daily lives and help to make health care decision. For example, breast cancer patients participating in this project can use their mobile phones as tools for customizing care planning. Accordingly, patients could report symptoms and problems that they experienced by accessing an advanced or smartphone-based symptom reporting system. This system could transfer the data into the patient’s electronic health record, allowing the health care team to offer outreach to the patient by e-mail or telephone. They also advocate the value of computerized decision support at the point of cancer care.

Patient-Focused Prospects
Major uses of patient-focused interventions in cancer care include psychosocial interventions aimed to improve quality of life among cancer patients. This approach is exemplified in a successful intervention with early-stage breast cancer survivors and their partners. The intervention involved telephone health education and interpersonal counseling delivered in eight weekly one-to-one sessions. Patients and their partners used video-phones for communication. Patients who were within one year of cancer diagnosis and who were currently receiving treatment were included in this study. Findings indicated that survivors’ and partners’ psychological well-being improved in the telephone and videophone interpersonal and counseling treatment groups but not in the group receiving health education.

Potential benefits of mobile phones apply throughout the spectrum of cancer survivorship and can be particularly useful in enhancing doctor, patient, and caregiver communication. Success also has been reported in the use of mobile phones to create a more supportive home environment through use of telehealth in palliative cancer care.

General Health-Related Uses of Mobile Phones Applicable to Cancer Patients
As we consider the applicability of mobile phones in cancer care, it is useful to note that some of the relevant applications have not been studied in the specific context of cancer. Nevertheless, there is widely supported utility of mobile phone use in general self-care or management that is relevant to cancer care. General intervention
includes self-management of illness, health-promotion activities such as exercise, and patient empowerment.

The most widely studied mobile phone-based interventions relate to encouragement and monitoring of physical activity. Activity-related interventions involving mobile phones can help clinicians and researchers monitor factors such as walking speed and energy used during exercise. For example, mobile phones can monitor participants’ daily activities and encourage them to increase physical activity. Although interventions have not specifically targeted cancer patients, they offer encouragement to engage in physical activities that can benefit cancer patients. It is notable that the majority of participants in interventions were sedentary or overweight individuals. There was also some focus on specific diagnostic groups such as diabetics or patients with heart disease. However, conditions such as overweight and heart disease may be related to cancer.

Reflecting useful functions of activity monitoring, it has been argued that decline in daily activities after hospitalization could reflect medical complications that need to be attended to in order to avoid rehospitalization. Another salient use of smartphones relates to pain management interventions. Most applications offering pain management are not specifically tailored to cancer patients, even though pain is a frequent symptom experienced by this group. Pain-related applications generally offer information about pain management and in some cases suggest techniques, such as exercise or meditation, to counteract pain.

**Uses of Mobile Phones by Health Care Providers**

Physicians and other health care professionals, such as pharmacists, have even greater access to mobile phones than do patients. A number of studies have focused on utilization of mobile phones in the care provision and professional communication. In a study focusing on the use of smartphone apps by medical providers, the most commonly used apps by physicians included drug guides (79 percent), with a much smaller percentage (18 percent) using medical calculators.

Smartphone applications are also increasingly used by physicians for managing their medical practices. Although some of these applications relate to billing and other office procedures, uses of smartphones extend to transforming doctor–patient relationships. Specific patient-friendly examples include more convenient appointment scheduling and patient access to medical records. These advances would be particularly beneficial to cancer patients who often see multiple specialists. Patients also can benefit from mobile phone applications that assist them in finding appropriate specialists and providing them with global position system information about the proximity of the location of these doctors.

**New Directions**

Many of the promising applications of information technology, and specifically of mobile phone use, have not yet come to fruition. Nevertheless, developments are occurring at a rapid rate. There is likely to be extensive growth built on the modest examples that are currently being implemented in practice. Although we offer optimistic prospects, it is important to note that many of these examples we offered represent funded research projects and interventions and are not yet available on a broad scale to patients receiving cancer care.

A systematic review of smartphone applications for prevention, detection, and management of cancer offers some useful insights about parameters of current use. It is notable that the majority of these applications, 46.8 percent (N = 295), targeted breast cancer with an additional 26.4 percent offering applications relevant to cancer in general. The most frequent applications focused on efforts to raise awareness about cancer and provide educational information about cancer (58.6 percent). There was far more limited attention to early detection (11.5 percent) and disease management (3.7 percent).

Moreover, even as we introduce the topic of mobile phone use for health care applications, it is important to emphasize that the proliferation of this technology has not been accompanied by quality control. There is insufficient data reviewing existing applications by professionals to support use by the patients.

Further, it should be noted that the distributions of smartphone usage and basic cell phone usage are unequal among different income groups. High-income countries have a particularly strong penetration of smartphones, while in lower-income countries, cell phones are utilized mostly as basic text messaging systems. While the majority of the market focused on smartphone applications
for cancer care services, there is limited research on text messaging (SMS), multimedia messaging (MMS), and voice calling based on basic cell phones. Creative applications for basic cell phone users present useful prospects for cancer patients who cannot obtain smartphones.

Central African Republic

Deemed by the United Nations as a failed state in permanent crisis, the Central Africa Republic (CAR) has been described as one of, if not the, grimmest, most dangerous places on Earth. Health and humanitarian experts indicate the level of the health crisis in the CAR is catastrophic.

As one of the most impoverished and perilous places on earth, the former French colony has experienced intense economic, political, and ethno-religious instability, particularly since December 2012, when armed rebel groups advanced on the capital city of Bangui. The protracted crisis and violence in the CAR, which increased in 2013, following the overthrow of President Bozizé, have affected all 4.6 million people living in the nation. The United Nations has indicated risk of genocide is high, and politicized ethno-religious cleansing targeting Muslim and Christian communities is an immense concern. These incidents and concerns, coupled with the violent activities of fighters loyal to Joseph Kony's Lord's Resistance Army, have deeply affected the internal security and health care in the country.

The humanitarian needs have continued to escalate in CAR since December 2012. As reports are changing daily, it is difficult to provide definitive details of the devastation in all areas, including health care. Reports have indicated at least 42 percent of the nation's health facilities have been deeply damaged and 50 percent looted as a result of the crisis, resulting in a shortage of medical staff and about 68 percent shortage of medicines. The World Health Organization (WHO) reported the health care and medical system has completely collapsed. Essential services, including schools and medical facilities, have been abandoned, ransacked, shut down, or completely destroyed in the sectarian violence, leaving no medical help for those who have been subject to the injuries, sexual violence, and torture directly resulting from the violence.

In addition, the ongoing state of emergency, lack of safe drinking water, acute malnutrition, and poor sanitation and hygiene have increased the burden of a range of communicable, waterborne diseases including, but not limited to, cholera, hepatitis A, hepatitis E, shigellosis, diarrheal disease, and typhoid fever vector-borne diseases including, but not limited to, malaria, yellow fever, dengue, Chikungunya; and sexually transmitted infections (STIs) including human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS); and particularly due to population displacement and the overcrowding in resettlement camps, diseases associated with displacement and crowding, including vaccine-preventable disease such as acute respiratory infection, measles, diphtheria, pertussis, meningococcal disease, tuberculosis, and polio.

With the burden on the health system and facilities in the country (only approximately 46 percent of people have access to health services in the CAR), priority is given to provision of primary and secondary health services, improving government infrastructure and capacity, and increasing the capacities of communities to prevent or control
diseases and promote health. Thus, in the short
term, the Health Cluster of the humanitarian com-
community of which the WHO is the leader, is focused
on helping achieve these health priorities, including
improving the management of noncommunicable
diseases such as cancer.

Prior to the protracted crisis, the WHO esti-
mated that 27 percent of all deaths in the CAR were
due to noncommunicable diseases, most notably
cardiovascular diseases, diabetes, chronic respira-
tory disease, and cancer. The nation’s Ministry of
Health had no policy, program, or plan to address
noncommunicable diseases.

The latest estimations prior to the crisis reported
that there were 92.86 per 100,000 cancer cases in
the CAR and an estimated 2,774 cancer cases per
year. Deaths resulting from cancer were estimated
at 74.25 per 100,000 or 2,171 total deaths per year.
The common types of cancer in the CAR are breast
(18.2 percent), cervical (11.2 percent), prostate
(9.7 percent), non-Hodgkin's lymphoma (7.3 percent),
liver (6.4 percent), bowel (4.6 percent), leukemia
(3.4 percent), ovarian (2.8 percent), Kaposi's sarcoma
(2.4 percent), lip (2.3 percent), esophagus (2.2 percent),
and stomach (2.2 percent), among others. Cervical
cancer is the second-most common cancer among
women in the CAR. About 311 diagnoses of cervical
cancer are made each year, resulting in 223 deaths.
The high incidence of cervical cancer in the country
is due to the prevalence of the human papillomavirus
(HPV), which is known to cause the cancer. Cancer
accounts for about 83.1 percent per 100,000 non-
communicable disease deaths in men and about
75.6 percent in women in the CAR, representing a
total of 121 per 100,000 adult deaths per year.

Diabetes, hypertension, obesity, smoking, alco-
hol, and use of solid fuels including coal and char-
ocol are some of the noted risk factors for cancer
mortality and morbidity in Africa generally and the
CAR specifically. The CAR currently has no national,
population-based cancer registry and no integrated
policy or action plan for cancer. Early diagnosis of
cancer is key to treatment and survival. However, in
the CAR due to scarcity of medical equipment and
medical technicians, most cancers are diagnosed
late or underdiagnosed, which inhibits treatments.

Central Nervous System Lymphoma, Primary

Primary central nervous system (CNS) lymphoma
is considered a type of non-Hodgkin's lymphoma.
Non-Hodgkin's is a term that applies to malignant
cancer that affects the lymph nodes. Lymph
nodes, or the lymph system, make up the body's
autoimmune response to infections. White blood cells that are carried in the lymph tissue both help to fight and prevent infections. When lymph tissue is compromised, it becomes difficult for people to fight infections or withstand chemotherapy treatment, which also weakens the immune system.

CNS lymphoma is a rare type of malignant cancer that affects the lymph nodes or lymphatic systems. CNS lymphoma can start in either the brain, spinal cord, meninges, or even the eye. Secondary CNS lymphoma is also rare and refers to cancer of the CNS that has spread from other parts of the body to the brain or the spinal cord.

Diagnosis of CNS lymphoma is particularly difficult as there is no standard method currently in practice. Presurgical diagnosis can be determined through brain scans and imaging software. If the tumors are operable, tissue biopsies are also a viable method of diagnosis. Last, the analysis of cerebrospinal fluid (CSF) can determine whether or not there is a presence of malignant cells. While the causes of this type of cancer is largely unknown, some occurrences have been linked to those who already have compromised immune systems, like those with acquired immune deficiency syndrome (AIDS) or other autoimmune deficiencies or diseases.

Symptoms of CNS lymphoma include fever, headaches, seizure, paralysis, numbness, weight loss, and loss of appetite. Patients may not necessarily experience all of these systems, and they may experience different symptoms as well.

There are various treatments that are available for CNS lymphoma, but treatment options and prognosis generally depend on the stage of the cancer as well as the age and state of health of the person with the disease.

Treatment options include chemotherapy, radiation, steroids, and some clinical trials. The success of these treatment options is different for everyone and is also dependent on age, health, cancer stage, and severity. Surgical removal is also a method of treatment; however, in the majority of cases, the lesions are inoperable due to size and placement.

Aggressive chemotherapy paired with stem-cell transplants has proven to be an effective form of treatment according to recent cancer studies. Patients who respond best to this treatment option typically are not seriously immunocompromised.

Methotrexate (MTX) and cytarabine (AraC) were found to be the most effective chemotherapy treatment options for patients suffering from primary CNS lymphoma. Radiation of the entire brain has also proven to be viable, along with stem-cell transplantation.

These treatment options, however, are the most effective for those patients in the early and less-aggressive stages of CNS lymphoma. The patients who responded best had undergone high doses of either MTX or AraC followed by stem-cell transplantation therapy or radiation treatment followed by high doses of MTX. In general, people who were given radiation or chemotherapy alone did not respond as well as those who received dual treatments. Response to treatment was generally better with the MTX than with the AraC; however, AraC remains a viable treatment option especially if combined with MTX. As with most high-dose chemotherapy treatments, response to treatment is generally better in younger adults with immune systems that are less compromised.

Steroid treatment is also used in conjunction with chemotherapy and other treatments; however, steroid treatment is not a long-term solution, and it is used to shrink tumors and masses in the brain. Steroids can improve neurological functions that may be affected by the stress or pressure caused by the tumor. Steroid treatment can be used during chemotherapy and radiation; however, most oncologists stop the use of steroids in order to gain more accurate diagnosis and to avoid the possibility of weakening the immune system further as steroids can have immunosuppressant effects.

Individuals with acquired immune deficiency syndrome (AIDS) make up a significant percentage of those who develop primary CNS lymphoma. While CNS lymphoma is still a fairly rare disease, reported incidents have increased since the 1980s, with the onset of the AIDS pandemic. The prognosis for patients with AIDS is generally poorer than those who have human immunodeficiency virus (HIV) alone. Studies focusing on the connections between CNS lymphoma and the AIDS virus have been linked to another virus called Epstein-Barr (EBV). EBV is a herpes-like virus that was found in CSF from patients with both AIDS and CNS lymphoma. While it is clear that there is some kind of connection between these viruses, further studies hope to find information that is more concrete.

Overall, patients that respond well to treatment for CNS lymphoma do not experience prolonged
periods of remission, especially if they are already immunocompromised. Doctors struggle to discover new methods of treatment largely because there is trouble crossing the blood–brain barrier. The term blood–brain barrier refers to the layer of blood circulating between the cerebral fluid and the CNS. Research, while progressive, still remains particularly difficult due to the rarity of the disease as well as the inability to conduct a greater scale of clinical trials.

Cervical Cancer

Cervical cancer develops in the cells of the female cervix, the organ connecting the vagina to the lower uterus. Globally, it is the second-most common cancer in women, resulting in more than 500,000 new diagnoses and 270,000 deaths each year. In the United States alone, there are more than 12,000 new cases and 4,000 deaths from cervical cancer annually. Mortality rates are much lower in the United States and other developed countries than in less-developed parts of the world. Much of this disparity results from high rates of routine gynecologic health care in high-income nations that leads to detection and treatment of precancerous lesions and early-stage cervical cancer. Although mortality rates have significantly declined over the past 30 years, major public health organizations, such as the World Health Organization, continue to consider cervical cancer to be a serious health threat to women.

Cervical Cancer and the Human Papillomavirus

The development of cervical cancer and precancerous lesions is almost exclusively linked to the human papillomavirus (HPV) as a predecessor to the disease. The virus infects cells on the outermost layers of the skin and mucous membranes, making the infection easily transmittable through skin-to-skin contact. As a result, the infection is commonly spread through sexual contact. Globally, HPV is the most commonly transmitted sexual infection, with a lifetime risk of infection as high as 75 percent for most individuals. HPV is also the most common sexually transmitted infection in the United States, with more than 14 million new infections among Americans each year. There are more than 120 identified strains of HPV, 13 of which have been conclusively linked to cervical cancer. Of these cancerous strains, two types (strains 16 and 18) are responsible for causing 70 percent of cervical cancers.

Because it is an infection, the body’s immune system responds to the introduction of HPV. Most infections self-resolve within several years of infection. However, infections that persist or recur are more likely to develop into cervical cancer. In females with healthy immune systems, it can take 10 to 20 years for a chronic HPV infection to develop into cervical cancer. In women with compromised immunity, such as human immunodeficiency virus (HIV)-positive individuals, this development may occur in as little as five to 10 years. While cervical cancer is often symptomless in early stages, symptoms of
advanced-stage cancer may include irregular menstruation, weight loss, fatigue, back or pelvic pains, vaginal discharge, or swelling in one leg.

Related Risk Factors
Additional risk factors such as tobacco use, diet, obesity, and genetic predisposition have been identified as possible mediators of cervical cancer. In other words, these factors may increase the risk of cervical cancer for individuals with HPV infections. For example, it is possible that smoking increases risk of cervical cancer by suppressing the immune system, allowing a high-risk HPV infection to persist and advance into cancer.

Screening and Detection
For years, gynecological screening (most often with the Pap test) has served as the primary mechanism through which HPV-associated lesions and other precancerous symptoms are identified and subsequently treated. However, screening for HPV only works to identify the presence of the HPV virus and the development of abnormal cervical cells but cannot determine whether such cells are likely to clear up or persist and develop into cancer. Ultimately, screening can help detect the virus but cannot prevent HPV infections from developing in the first place. A major concern is that, often, HPV infections are symptomless and may not be identified in the absence of routine screening practices. When regular screening is not available, cervical cancer may go undetected for years, until symptoms appear during advanced stages of the disease. Therefore, health advocates are increasingly pushing for a combined approach consisting of prevention, screening, and treatment together in order to combat HPV as an individual and public health issue. In particular, over the past decade, substantial interest in has grown in the use of vaccines as an HPV prevention strategy. Early results suggest that this strategy may prove to be an effective course of action in preventing HPV infection and, subsequently, reducing the incidence of cervical cancer.

Prevention Through Vaccination
Two HPV vaccines are currently available: Cervarix (produced by GlaxoSmithKline) and Gardasil (produced by Merck & Co.). In 2006, the United States Food and Drug Administration (FDA) approved the first HPV vaccine, Gardasil, for females age nine to 26. In 2009, the FDA approved Cervarix for females 10 to 25. Although the two vaccines share many similarities, they have several key distinctions. Cervarix has been approved for use in women starting at age 10 and immunizes patients against HPV types 16 and 18, the two strains most commonly associated with a variety of HPV-related cancers. Gardasil is the more commonly employed of the two vaccines and is currently approved for use starting at age nine. Gardasil is a quadrivalent vaccine as it immunizes against four common HPV types (6, 11, 16, and 18). The vaccine is given in three doses over the course of six months. Overall, HPV vaccination holds the strongest potential to reduce incidence of cervical cancer when administered to girls and young women prior to sexual debut.

In addition to increasing initial vaccination uptake, public health officials are also concerned with how to encourage females to complete the vaccination series once the first shot has been received as individuals often fail to receive subsequent doses.
Given what is currently known about the vaccine, the endorsement the vaccine has received from the medical community and federal health agencies, and the prevalence and severity of HPV-related health outcomes, the HPV vaccine offers an effective first step toward significantly reducing this public health concern. The introduction of the HPV vaccine has been called an important public health achievement. In particular, the vaccination provides the potential for widespread cervical cancer prevention in populations without routine access to female health screening. However, current vaccination rates are far below recommended targets for adolescents and young adults. As a result, public health officials continue to emphasize a comprehensive prevention and detection approach to reduce the impact of cervical cancer.

Further Readings

Chad

The Republic of Chad is a landlocked country in the middle of Central Africa. It is surrounded by Sudan, Libya, Cameroon, Nigeria, Niger, and the Central African Republic. Chad’s climate is composed of desert and savannah regions, and Lake Chad is the country’s largest wetland and the second largest on the continent.

As in the other countries of Africa, the major types of cancer in Chad are related to infectious agents. These include cancers of the urinary bladder, the Kaposi’s sarcoma, the liver, and the cervix. In addition, in 2008, cervical cancer made up 21 percent of the newly diagnosed cancers in African females, while liver cancer was the leading type of cancer for African males, at 11 percent. Though cancers related to dietary patterns, obesity, and tobacco use are most prominent in America, these cancers are becoming more common in developing countries, such as Chad, as well.

In 2012, according to Treat the Pain, more than 4,700 people died of cancer in Chad, with 80 percent of these individuals reporting they were facing moderate to severe pain before they expired.

In comparison, overall in Africa, 715,000 new cancer cases and 542,000 cancer deaths occurred in the year 2008. These numbers are projected to nearly double (1.28 million new cancer cases and 970,000 cancer deaths) by the year 2030 because of the aging population and unhealthy lifestyle factors.

Prostate Cancer

Another large cancer concern in Chad (and across the world) is prostate cancer. According to the GLOBOCAN 2002 database, 416 new cases of prostate cancer will be discovered in Chad each year, with deaths amounting to more than 350 annually. Many more men have prostate cancer and do not know about it. Men are typically diagnosed with prostate cancer between the ages of 50 and 65, and those who have a family member with the disease are at a higher risk.

A regular physical examination and a prostate specific antigen (PSA) blood test are necessary for early diagnosis of prostate cancer. Men should start prostate checkups starting around age 40.

Cervical Cancer

Chad has a population of 3.33 million women age 15 and older. These women are at risk of developing cervical cancer, and current estimates indicate that about 630 women each year are diagnosed with the disease, with about 464 deaths from the same each year.

According to the HPV Center, cervical cancer is the second-most common cancer among women in Chad between women age 15 and 44. Data is not currently available on the human papillomavirus
(HPV) burden in the general population of Chad. However, in Africa in general, about 25 percent of women in the general population are estimated to carry the HPV infection. And 71.3 percent of invasive cervical cancers come from HPV infection types 18 and 16. If prostate cancer is diagnosed and treated early, the mortality risk is small. If prostate cancer is diagnosed late and has spread to other portions of the body, then it is incurable.

**Cancer Care and Prevention**

Across Africa, cancer continues to receive low public health priority despite the fact that it is increasing in prominence across Chad and many other countries. This is predominately due to larger public health issues, such as acquired immune deficiency syndrome (AIDS) and human immunodeficiency virus (HIV) infections, along with tuberculosis and malaria. Other issues may include a lack of awareness of the current and future burden of cancer among the general public, international health agencies and policy makers. Additional effort should be given to raise cancer awareness and promote early detection and prevention in Chad and other African countries.

Most of the cancer incidences in Chad are diagnosed at an advanced stage. In addition to the factors listed, this also may be due to the stigma associated with a cancer diagnosis. Survival after a diagnosis is much lower throughout Africa than it is in the developed world, especially for cancer types that are greatly affected by improved treatment and screening. African patients also have limited access to quality treatment in a timely manner.

As an example, the five-year survival rate for breast cancer is less than 50 percent throughout several African countries, compared to nearly 90 percent in the United States.

Prevention of exposure to cancer-causing agents and risk factors (such as tobacco use, infections, and obesity) is extremely important across Chad and is the most cost-effective solution. Tobacco use, in particular, is extremely preventable. Tobacco-related cancers account for about 6 percent of cancer deaths throughout Africa.

Currently, about 10 percent of African men and 20 percent of African women smoke, which does not initially raise alarm. However, cigarette consumption in Africa is rapidly increasing due to the adoption of new social behaviors and increased marketing from tobacco companies. Smoking among teens is much higher, with smoking prevalence among boys being higher than adults in many African countries.

Obesity awareness is also a top concern. Along with physical inactivity and an unhealthy diet, obesity has been associated with the increased risk of several cancers, including uterine corpus, liver, stomach, colorectal, breast, and kidney cancers. The prevalence of obesity and physical inactivity is increasing in several African countries, especially in urban areas, as a result of increased consumption of calorie-dense food and lower energy expenditures in daily life.

**Conclusion**

There are many risk factors influencing cancer incidences and mortality rates in the Republic of Chad. Unfortunately, because Chad is a developing country, there are limited resources available for those with cancer, and many hospitals are inaccessible to the general population.

Late diagnosis is also an issue, as this often leads to elevated mortality rates. It is extremely important that Chad, along with other African countries, invests in cancer education for its residents. The medical community in Chad must also recognize the fact that cancer is a large health burden for the country; it cannot always be outweighed by communicable diseases such as HIV and AIDS. Prostate cancer and cervical cancer in particular must have educational and preventative programs surrounding them—preferably sponsored by the country’s national health institutions as this is the only way that Chadians will not face an elevated risk of these and other cancers for years to come.

American Cancer Society. “Cancer in Africa.”

ICO Information Centre on HPV and Cancer. “Human Papillomavirus and Related Cancers, Fact Sheet 2013.”
The Chao Family Comprehensive Cancer Center

In the United States, cancer is the second-most common cause of death. In 2014, approximately 1,665,540 new cancer cases are expected to be diagnosed. Of those cases, 585,720 Americans are expected to die, almost 1,600 people per day. In order to fight and understand this disease, the National Cancer Institute (NCI) designates and partners with comprehensive care centers in order to adequately treat and advance the treatment of many different types of cancer. One of these esteemed centers is the Chao Family Comprehensive Cancer Center (CFCCC) at the University of California, Irvine (UCI) which is located in Irvine, California. Here, the CFCCC translates leading-edge scientific findings into clinical cancer treatment and prevention of cancer on all levels.

The Chao Family Comprehensive Cancer Center

The UCI Cancer Center was established in 1989 as a university-based cancer center. In 1994, it was designated for excellence by the NCI. The center achieved comprehensive cancer center status in 1997, making it one of only 41 in the nation. It was later renamed in honor of the Chao family and is now recognized for excellence in cancer treatment, prevention, research, education, and awareness. The CFCCC is affiliated with the UC Irvine Health School of Medicine and the university’s schools of basic sciences.

Located in the UC Irvine Medical Center, the CFCCC integrates research, prevention, and the most advanced diagnostics, treatment, and rehabilitation programs and technologies to provide the best possible care for patients and their families. World-class multidisciplinary teams of UC Irvine Health surgeons, radiation oncologists, medical oncologists, pathologists, nurses, rehabilitation therapists, pharmacists, social workers, and dietitians treat every kind of cancer, including rare and aggressive forms. New patients are offered the best in beginning care, including a comprehensive clinical evaluation with a wide range of diagnostic technologies.

The CFCCC provides the most advanced diagnostic and treatment technologies, including Arc radiotherapy, a groundbreaking method of delivering powerful, targeted radiation faster and more precisely than with conventional radiotherapy. This therapy advances the standard of care with uncompromised treatment in killing or slowing the growth of cancer cells in two minutes or less. Arc plans were found to be equivalent or better at target coverage for all targets and superior in protecting critical structures including the spinal cord, brain stem, eyes, optic nerve and chiasm, parotid glands, and brain.

The center is funded by the NCI, the National Institute of Health, and other public agencies, in addition to a variety of private sources. The CFCCC also offers eight shared resource facilities to help foster innovative educational clinical and epidemiologic research on the causes, treatments, and effects of cancer and allied diseases. These resources include Biobehavioral Shared Resource Facility, Biostatistics Shared Resource, Experimental Tissue Shared Resource Facility, Genomics High-Throughput Facility, In-Vivo Functional Onco-Imaging, Optical Biology Core, Transgenic Mouse Facility, and the collaboration with the Children’s Hospital of Orange County, where an overwhelming amount of children (85 percent) are enrolled in clinical trials at the CFCCC.

Research and Outreach

The CFCCC is at the forefront of research. At any given time, there are approximately 80 to 100 research trials open on the different types of cancer treated at the CFCCC. The purposes of these trials include treatment, prevention, screening, diagnostics, quality of life, and supportive care. Currently, there are 102 open trials with research focusing on cancers such as
as melanoma, liver, colon, pancreatic, prostate, brain and nervous system, and eye and orbit; however, the most predominant type of cancer being researched in the open trials is breast cancer in females.

Though the CFCCC treats all kinds of cancer, the NCI and its designated comprehensive care centers have made translational research a major focus, meaning the transformation of scientific discoveries made in laboratory, clinical, or population-based research into clinical applications that can reduce the cancer burden. At CFCCC, their translational research efforts are focused on four areas of strength: skin, prostate, colon, and women’s cancers. These teams have led to advancements in cancer surveillance, screening and prevention, diagnostics, therapeutics, survivorship and quality of life, and global benchmarks of success.

The CFCCC is also involved in conducting non-traditional research in its effort to find new, effective ways to treat and cure cancer. Notably, the CFCCC’s infusion center has implemented a music therapy program to treat pain, anxiety, and nausea in patients undergoing chemotherapy. The benefits of this program have shown to lessen the proposed treatments, including depression. Funded research is focused on conducting innovative studies such as finding the best time of day to receive radiation treatment to reduce hair loss, stem cell research to advance basic studies to improve cancer, and brain disease treatments. There is also a study measuring kava, a plant grown in the South Pacific, and its ability to cure cancer. The efforts of UC Irvine, CFCCC’s affiliate, have also resulted in advancements in treatments, specifically funding the development and creation of an ovarian cancer app for tablet computers. This advanced approach to treatment will help newly diagnosed ovarian cancer patients learn about and understand the trade-offs among chemotherapy options.

The CFCCC is also involved in national and international outreach that extends to several countries in the Middle East, Russia, Korea, Japan, and China through sponsorship by the NCI. Through the establishment of consortiums, the CFCCC can work to reduce the incidence and impact of cancer through solicitation and support of collaborative research.

The prevention and treatment of cancer heavily overlaps with the need for advancements in research. As the second-leading cause of death, cancer is a disease that requires time and dedication to find a cure. Through the collaboration of the NCI and designated comprehensive cancer centers like the CFCCC, cutting-edge research can help save lives. By focusing on treatment, prevention, research, education, and awareness, the CFCCC and its partners are able to offer the most-advanced diagnostic and treatment technologies and non-traditional, groundbreaking research as possible cures and preventions for all types of cancer.

Chemical Industry

The chemical industry is a key source of toxic exposure to carcinogens for both employees and for people living in nearby neighborhoods. Increasingly, researchers are discovering that the burden of environmental toxin-associated cancers has been greatly underestimated. Due to the
large number of variables and the typically long lag time between exposure and diagnosis, cancer epidemiology is exceedingly difficult. The patient may not show any symptoms of cancer for 20 to 30 years from the time of exposure. Physicians may not know there was an occupational exposure and thus do not make the cause-and-effect connection; the connection goes unreported to cancer epidemiologists. Cancers may be diagnosed years after exposure. Due to a highly mobile population, patients may no longer reside in the area in which they were exposed.

One study found that between 4 and 6 percent of cancer deaths in the United States (about 34,000 people annually) are caused by occupational exposure to carcinogenic compounds. A large proportion of these occupational-related cancers is likely preventable. The rate of workplace-associated cancers has declined, however, with the implementation of greater employee safety controls and governmental regulation of industry practices.

Much of the knowledge about toxic effects levels of industrial compounds comes from research into cancer incidence and prevalence among these populations. Occupational studies are better able to quantify exposures than ambient studies because exposures are often known. Researchers can pinpoint exactly what compounds the worker was exposed to and in what dosage. Chemical exposures in the workplace are typically both prolonged and high dose. They may be either discrete events or long term.

Population-based case-control studies of current and former chemical-manufacturing employees have found increased levels of cancers in these groups. Oftentimes, cancer risks from specific chemicals are identified first among industrial workers. For example, occupational exposure to benzene, a known carcinogen, has been found to put workers at a two- to threefold increase of risk for acute myeloid leukemia and acute nonlymphocytic leukemia relative to the general population. Occupational factors seem to play a significant role in the incidence of bladder cancer, and workers exposed to asbestos are at significant risk of lung cancer. One study found that women employed in the plastics industry were at significant risk for endocrine disruption leading to breast or reproductive cancers. There is strong evidence to support claims that industrial chemicals, for example, inorganic acid mists, benzene, 1,3-butadiene, and formaldehyde, elevate risks for the development of a variety of cancers in exposed populations.

The chemical industry today produces an estimated 70,000 products in nine major areas: petrochemicals; synthetic organic chemicals; inorganic chemicals; resins and synthetic rubber; pesticides, fertilizers, and other agricultural chemicals; pharmaceuticals; paints, coatings, and adhesives; cleaning compounds; and other products, including inks, explosives, and photographic chemicals. Safety data on all of these compounds are not always available or even known. Oftentimes, the science to support safety simply has been done, and as more compounds are developed, the science is unable to keep pace with industry.

Determination of whether or not a particular substance is carcinogenic is time-consuming and often politically contentious. Controversies surrounding some compounds last decades or more without resolve, and the standards of proof have become increasingly difficult to meet. Early toxicological research quantified the levels of toxins at which a person would be expected to die. When animals survived toxicology studies, the compounds were considered safe. If the animals developed cancer, the compound was considered to be carcinogenic. This is no longer the standard for this type of research.

There are increasingly calls for human studies, the rational being that, as humans and animals have differing physiologies, a compound that might be carcinogenic in animals may have no effect on humans or vice versa. A human is not a rat; different compounds have different effects in different species. As it would not be ethical to expose humans to compounds to determine if they are carcinogenic, most human studies involve large-dose exposure accidents of employees in industrial settings. Most compounds known to be carcinogenic were identified in this manner.

Certain occupations in themselves have been identified by the International Agency for Research on Cancer as carcinogenic due to the high incidence of cancers in people employed in these settings. These include employees in aluminum production, auramine manufacturing, coal gasification and indoor coal emissions, coal-tar distillation, coke production, underground hematite mining, iron and steel founding, isopropyl alcohol
manufacturing, magenta manufacturing, painters, and those in the rubber manufacturing industry.

**Determining Levels of Toxicity**

Regulatory agencies, such as the Environmental Protection Agency and state-level environmental agencies in the United States, delimit both short- and long-term health effects for exposure to many different compounds. Short-term limits delineate at what dosage acute, high-dose exposures cause health effects. These are typically averaged over an hour. Long-term limits delineate thresholds at which health effects from low-dose, chronic exposure are expected. These typically are averaged over one year. It should be noted that the specification of the limits are often politically contested and that these levels can vary widely from agency to agency. These levels are informed by research on workplace exposures, occupational health research, and research into industrial accidents, as well as industry data.

Employees experience chronic exposure to known compounds as well as occasional acute events (such as in the case of a spill or leak). This known quantitative aspect allows researchers to more clearly identify cause-and-effect variables along with exposure safety limits relative to research into ambient chemical effects. As with any cancer research, cause and effect can be difficult to determine due to the significant lag between exposure and diagnosis. This lag can impact worker health negatively, delay the recognition of problematic practices, delay the implementation of safety controls, and impede worker compensation. The more prolonged the time effect, the more difficult it is to demonstrate clear cause-and-effect relationships.

Such research has also allowed for intragroup analysis. For instance, many research studies have pointed to excess breast cancers in women employees exposed to chemicals in manufacturing (such as in the plastics industry). There also may be disproportionate exposure among lower-wage workers in more dangerous positions within the factory.

**Employee Safety**

Numerous bio-monitoring studies of employees working in the chemical industry have found elevated chemical burdens and associated health impacts relative to the general population. Contaminants are released during the normal course of production. Workers are exposed to chemical compounds via inhalation of gases, vapors, and dust, as well as through direct physical contact with toxic substances. Exposure is related to the assigned tasks of the worker as well as the levels of safety measures taken by the company. Occupational chemical exposures are more likely to be both higher dose and prolonged than ambient exposures.

Exposed workers can be at much greater risk for cancer than others in the general population. Thus, while the population at large might benefit from the product itself, they do so at the expense of the workers’ health. These types of disproportionate exposures bring up issues of environmental justice and equity.

Workers in the chemical industry are subject to multiple chemical exposures—rarely are they exposed to only one compound at a time, and the synergistic effect of those compounds is typically unknown. They may have an additional burden if they reside in the vicinity of a polluting plant or if they have significant chemical exposures outside of the workplace (including tobacco related). Working conditions of course vary by location and are influenced largely by factors such as the physical layout of the plant, the availability and training in the use of personal protective safety equipment (such as protective clothing, respirators, and other gear), monitoring of employee health, environmental protection controls, ventilation, and regulatory powers.

Research has demonstrated significant reduction in workplace exposures via safety controls and regulatory oversight. Even with safety measures intact, however, breaches in safety protocols, improper use of equipment, and faulty or inadequate equipment can all lead to workplace exposures. In addition, industrial accidents are always possible as well as the possibility of unrecognized hazards in the work environment.

**Regulation**

Researchers have repeatedly demonstrated decreases in risk with improved safety measures, lending credence to regulatory intervention. As regulatory systems vary by jurisdiction, worker safety controls are haphazard, with significant differences in worker protections globally. Some researchers argue that globalization and free-trade
agreements have severely hindered the implementation of worker safety measures and that chemical manufacturing plants are more likely to be physically placed in areas with fewer restrictions as a cost-saving measure for the parent corporation. Industry representatives counter that such protections are both costly and oftentimes overprotective and that some measures are so extreme that their plants would be unable to implement them and be forced to close. Criticisms of industry practice go beyond worker safety to alleged involvement in regulatory lobbying and active suppression of scientific research.

Poor working conditions, lax enforcement of safety measures, and inadequate safety controls all result in an increased toxic burden for both the employees and the residents in surrounding neighborhoods.

**Sacrifice Zones**
Residential areas neighboring polluting industry are often referred to as sacrifice zones. Generally speaking, these neighborhoods are comprised of poor or racial ethnic-minority residents with low levels of social capital. As in the case of employee exposures, questions about environmental justice and equity are raised for residents of sacrifice zones. Researchers have repeatedly demonstrated increased cancer risks for people living in close proximity to chemical plants and other industrial activity. This risk is compounded with the potential for industrial accidents, such as leaks and explosions.

Examples of this type of exposure include pesticide use in heavy agriculture, industrial waste and by-products, air and water pollution from refining and other industrial factories, exposure to particulate matter, along with many others.

**Chemoprevention**

Cancer is a disease in which anomalous cells are created, attack vigorous tissue, and grow overpoweringly. The progression from a normal and healthy cell to a cancerous cell takes numerous years. Cancer may be predisposed by genetic, dietary, and behavioral factors. Cancer chemoprevention is the use of natural, synthetic, or biologic substances to repeal, subjugate, or prevent the expansion of cancer. Synthetic substances are made in a laboratory.
Biologic substances are from a living source. Individuals who have a genetic predisposition risk of acquiring cancer, encompassing those with a previous diagnosis of cancer, an inherited cancer syndrome, or a family history of cancer, typically use chemoprevention. Chemopreventive agents, unaccompanied or combined, can help prevent the development of cancerous cells or delay the development. Chemoprevention is not used to treat existing cancer but may be used in persons whose cancer is in remission in order to decrease the possibility of acquiring new cancers. Chemoprevention is the attempt to prevent cancer from developing by using substances that interfere in the process of carcinogenesis by utilizing natural (biologic) or laboratory-made (synthetic) substances to prevent cancer.

It should be recognized that chemoprevention is a contrast of chemotherapy. Chemoprevention is utilized well in advance of cancer developing to avert cancer or to inhibit precancer in vulnerable individuals, conceivably. In contrast, chemotherapy attempts to execute already infected cancerous cells. As explained, chemoprevention utilizes organic inventions originating from foods or synthetic products created in scientific labs. Due to the long-term usage of chemoprevention, it is imperative for the agents to be nonpoisonous, effectual, administer friendly, and affordable. Subsequently, there are a limited amount of agents recommended for extensive clinical use as lengthy clinical trials lasting up to 15 years are still in progress. Chemoprevention strategies are often based on the results from clinical studies to provoke change and scientific findings. For instance, scientists completed the debut map of the genetic makeup of the human genome in 2002. Because of the human genome map, cancer research has advanced precipitously. Epigenetic events, also known as the modifications in gene expressions absent certain DNA attachment, may perpetuate cancer chemopreventive drug production targeting tumor suppressor genes.

Chemoprevention Drugs
Again, chemoprevention should not be confused with chemotherapy. Chemotherapy's purpose is to defeat cells, especially cancer cells, to prevent cancer progression. Conversely, chemoprevention involves administering innocuous agents to considerably healthy persons who may be highly susceptible to cancer. Chemopreventive agents can act in two ways; they can prevent or stop genetic mutations that lead to cancer, and they can prevent or stop processes that lead to excessive replication of damaged cells. The National Cancer Institute has made chemoprevention research a top priority.

Even though chemoprevention may be a postponement for cancer, it does not protect an individual from being diagnosed with cancer in the future. In this regard, chemoprevention for cancer may be similar to drugs used to prevent heart disease or stroke, such as statins or antihypertensive drugs, which are not 100 percent protective. Chemopreventive drugs include but are not limited to tamoxifen (Nolvadex), an estrogen blocker that reduces the risk of developing breast cancer. Tamoxifen is the first chemoprevention drug to obtain Food and Drug Administration (FDA) approval and is the most recognized chemopreventive drug. Studies have shown that tamoxifen reduces a highly vulnerable woman's chances of developing breast cancer by as much as one-half. Raloxifene (Evista) lowers the risk of acquiring breast cancer in women who have been through menopause. Finasteride (Propecia or Proscar) and similar drugs lower prostate cancer risk by reducing the amount of dihydrotestosterone (a male hormone) produced by the body. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) lower the risk of many types of cancer in people with an average risk of cancer.

Chemoprevention Benefits
Decreasing the risk of cancer is often a benefit of chemoprevention, although undesirable symptoms are a risk. Nutritional factors and lifestyle modifications are significant components in chemoprevention. It is projected that, through dietary improvements, there could be a 50 percent reduction in colon and rectal cancers, a 25 percent reduction in breast cancer, and 15 percent reductions each in prostate, endometrial, and gallbladder cancers. Cancers of the stomach, esophagus, pancreas, ovaries, liver, lung, and bladder also may be influenced by nutritional elements. Nonetheless, these improvements undoubtedly should derive from the diet instead of from dietary supplements. For example, in 2003, the U.S. Preventive Services Task Force disseminated a report that evidence was not conclusive enough to recommend for or against use of vitamin supplements to aid the prevention of cancer. The task force was anti-supplementation.
with beta-carotene because of higher occurrence of lung cancer among those who used certain levels of beta-carotene supplements.

Phytochemicals from food are a source of many chemopreventive agents. Garlic alone contains 30 cancer-preventing compounds including selenium. Broccoli contains indole-3-carbinol as well as phenethylisothiocyanate, a sulfur-containing compound. Soy products contain phytoestrogens such as genistein. Tea, both black and green, contains an abundance of polyphenols such as the catechins that have antioxidant and anticancer activity. Compounds in tea also have antiestrogen activity and can modulate detoxification enzymes. Curcumin from the spice turmeric is gaining attention as a chemopreventive agent. It is both an anti-inflammatory agent and an antioxidant. Laboratory animals have shown curcumin inhibition toward colon, breast, and stomach cancer.

Chemoprevention Risks

Due to the fact that chemopreventive drugs can be administered in high dosages and for extended lengths of time, the risk of side effects is augmented. The Carotene and Retinol Efficacy Trial (CARET) study in the 1980s discovered that beta-carotene actually increased the risk of lung cancer in males who smoked. Continuing use NSAIDs to avert colon cancer can lead to medical consequences such as gastrointestinal issues and liver toxicity. Recent recommendations are to intensify consumption of fruits, vegetables, and fiber in the diet instead of taking supplements.

Some chemopreventive agents can have acute side effects in certain patients, which is a problem when considering long-term management of a drug to vigorous people who may or may not acquire cancer. Because of this, most chemopreventive agents are suggested primarily for people at high risk of developing cancer because they are most likely to benefit from treatment. People who are susceptible to developing cancer consist of those with a family history of cancer. An inherited genetic mutation, such as Familial Adenomatous Polyposis (FAP) and other factors (ethnicity, obesity, smoking, etc.) increase cancer risk. Unfortunately, chemopreventive agents do come with risks and side effects. For instance, tamoxifen has been shown to increase the risk of developing endometrial cancer, cataracts, and blood clots, which is why the drug is considered most beneficial to women under the age of 50. Countless persons ridicule the thought of ingesting a drug for a disease they do not yet have and may never acquire. Moreover, a plethora of doctors either disagree with the published studies regarding chemopreventive drugs or are unaware of the studies’ results.

Chemoprevention Clinical Studies

Altogether, drugs or other substances that have shown evidence of lowering cancer risk are tested in clinical trials. Clinical trials are research studies in people. A chemoprevention study tests a new chemopreventive agent to learn whether it is safe and effective and actually delays or prevents cancer. Often, substances that seem to prevent cancer in the laboratory setting with animals do not prevent cancer when tested in human subjects. In some circumstances, chemoprevention was shown to cause harms, some of which were critical or even life threatening. As mentioned, beta-carotene, a substance found in carrots, squash, and similar vegetables, was thought to help prevent cancer. However, when tested in clinical trials, it raised the risk of lung cancer in participants who smoked. Another clinical trial of selenium and vitamin E for prostate cancer showed that neither selenium nor vitamin E lowered the risk of prostate cancer, and there was even evidence that men who took vitamin E had an increase in prostate cancer.

The National Cancer Institute suggested that approximately 400 compounds are being studied as potential chemopreventive agents, chiefly in laboratory research. More than 40 of these compounds are being studied in clinical trials. Some of these agents are being investigated as single agents; others are being tested in combinations of two drugs. Chemoprevention trials look at possible ways to prevent cancer with interventions that include drugs, vitamins, diet, hormone therapy, or other agents.

Clinical trials often reveal that chemopreventive agents do not work for all patients. This is consistent with other drugs utilized for cancer treatment or for the prevention of other diseases, such as heart malady. When evaluating the results of chemoprevention clinical trials, it is imperative to consider the demographic makeup (family history, environmental and social background, etc.) of the participants. Frequently, people with known, increased risks for cancer, such as those who smoke or have a family
history of cancer, are tested; as such, the results of the study may be atypical and may not be applicable to everyone. For instance, in the tamoxifen clinical trials, the participants were at high risk for acquiring breast cancer.

Clinical trials are currently investigating chemoprevention for people at high risk of certain cancers, for example, to inhibit breast cancer in the second breast of women who has already been treated for breast cancer, for women who have never had breast cancer but are determined to be at elevated risk, or to prevent colon cancer in people with a genetic predisposition for cancer. People not at an exceptionally increased risk can use behavioral and dietary modifications for chemoprevention. Beginning in the 1980s, the National Cancer Institute has acknowledged well over 1,000 natural and synthetic chemicals agents with some degree of cancer preventive element. As of today, more than 400 potential agents are under investigation for their ability to prevent cancer, and at least 40 compounds or combinations are experiencing human clinical trials.

Types of Chemoprevention

Breast Cancer. Antiestrogens can lessen the growth effect estrogen has on several breast cancers. Tamoxifen and raloxifene are two antiestrogens that have been proven in clinical trials to avert breast cancer in women at high risk for the illness. Because of these trials, the FDA has approved tamoxifen as a preventive therapy as well as a treatment cancer. Additional antiestrogens, counting soy isoflavones, are still being investigated. The synthetic retinoid, fenretinide, also exhibits potential in averting breast cancer. Also under investigation is indole-3-carbinol from broccoli.

Colon Cancer. The research of chemopreventive drugs is said to be a shorter process because there are more distinguishable tumor markers recognized for colon cancer. The relapse of cysts rather than the expansion of malignant cancer can be employed as an outcome. Inflammation has been linked to cancer for a lengthy stint, and the anti-inflammatory remedies sulindac and sulindac sulfone in addition to particular cyclooxygenase-2 inhibitors are proving valuable in counteracting colon cancer. Adjoining fruits and vegetables to the pattern of eating correspondingly give the impression from epidemiological studies to have a protective end product on colon cancer.

Prostate Cancer. Both antiandrogens and antiestrogens are important in obstructing prostate cancer. Finasteride is being researched as an antiestrogen to avert prostate cancer in men at risk of this cancer. Finasteride is a prescription drug that can decrease the levels of dihydrotestosterone, which is connected with prostate growth and perhaps cancer. It has been utilized to cure enlarged prostate. Finasteride is currently being explored to avert prostate cancer in men over the age of 55 years. Men at an amplified risk for prostate cancer include those with a history of prostate cancer, those with a high-fat diet, increasing age, and those of African American lineage. Soy products and indole-3-carbinol may also be efficient for this reason. Lycopene, a vitamin A-like compound found in tomatoes and other red fruits and vegetables is associated with a decreased risk of prostate cancer. Selenium and tea are both possible chemopreventive agents that deters prostate cancer.

Skin Cancer. In recent years, the prevalence of skin cancer has noticeably increased, possibly due to the acceptance of sun tanning. Complexes under investigation for the hindrance of skin cancer take into account of compounds from tea, silymarin from milk thistle, vitamin A, and coumarins found in a number of plants.

Natural Chemoprevention

Research indicates cancer is the most dreaded of all diseases. The public instantaneously connects the cancer disease with perishing. Dissimilar from other killer diseases, cancer usually causes a slow death involving pain, suffering, mental anguish, and a feeling of ineptitude. Furthermore, the mental and physical stress it puts on loved ones and caretakers are beyond reckoning. There are 76 trillion cells in the human body that must persistently undergo reproduction if the body is to remain active and operating correctly. Every few days, many of these cells reproduce, while others reproduce after a much longer period. As each old cell reaches the end of its life cycle, it reproduces and is replaced by a fresh, young cell. The natural death of the old cell is called apoptosis. An innate type of gene called the
P53 gene (natural biological clock) controls the rate of death of cells.

It is a known fact that most cancers are initiated by the action of free radicals. Free radicals are unbalanced atoms or molecules with at least one unpaired electron. These unpaired electrons want and need a partner. Subsequently, the unbalanced free radicals, which have the ability to magnetize electrons from other atoms or molecules, go about snatching electrons from stable atoms. This taking of an electron from another atom means that the free radical is now stable and is no longer an unrestricted radical. Nevertheless, the atom or molecule from which the electron was stolen is now injured, and it becomes an unrestricted radical. This sets off a domino-style chain reaction of damage within the body. In their hasty exploration for electrons, free radicals do a lot of structural harm to healthy cells. Aggregate free radical damage initiates the plasma membrane of the cell to collapse and stop functioning. When this happens, transportation of nutrients, oxygen, and water into the cell and removal of waste products and toxins out of the cell become compromised, leaving them at risk. This causes the cell to either die from starvation or die in a sea of accrued toxic waste. Otherwise, if the DNA of the cell is also affected, it can cause the cell to reproduce improperly and, in so doing, causing a cell mutation. The mutated cell is now genetically indecorous and, as such, does not perform as a normal cell. The P53 gene of the cell is affected, and the natural biological clock discontinues, often eliminating apoptosis (natural cell death). Without apoptosis, the mutated cancer cell does not expire. As a way to ensure its growth, a cancer cell steals nutrients from surrounding cells and starts to rapidly replicate in geometric progression (2, 4, 8, 16, etc.). With time, the cancer cell progresses into a cancerous mass or a tumor. Cancerous cells from the mass or tumor can be transferred to other tissues or organs where they entrench and begin to grow and reproduce, also known as metastasizing.

Orthodox approaches treat cancer as a localized disease to be treated in a localized manner by cutting out the tumor, exposing it, or saturating the body with toxic as well as carcinogenic drugs in order to destroy the tumor. Natural healing methods consider cancer to be a systemic disease. Rebuilding the body’s natural immunity is emphasized to strengthen its natural ability to destroy cancer cells. Data on cancer, which has been corroborated by the National Academy of Sciences, the U.S. Department of Health and Human Services, the National Cancer Institute, and the American Cancer Society, discovered that 80 to 90 percent of all cancers are produced because of lifestyle influences that include but are not limited to smoking, alcohol, lack of exercise, exposure to chemicals, environmental factors, and dietary and nutritional practices.

Natural and technologically produced toxins surround everyone. These ecological contagions exist in the air taken in daily, the foods eaten, and the water intake of everyone. In the contemporary, industrial world, humans cannot escape these toxins. Today, people are exposed to more toxins in 15 minutes than their great-grandparents were exposed to during a lifetime. The majority of these toxins are considered cancer-causing carcinogens, and as implausible as it seems, the most toxic atmosphere to which humans are exposed daily is the setting in the personal home. Given that lifestyle, environmental factors, and nutrition are the most common risk factors for developing cancer, it seems logical that many of these cancers can be demolished, substantially decreased, or their growth eradicated by reducing or eliminating the risk causes. Certain risk factors, such as air and water, are difficult to manage. Nonetheless, people have virtually total control over some of the other known risk factors such as smoking, alcohol, intake of chemicals and drugs, and diet and nutrition.

In 60 percent of women’s cancers, diet and nutrition appear to be factors. Dietary and nutritional factors make up about 40 percent of men’s cancers and about 75 percent of cardiovascular diseases. There is some discourse on diet and what foods to consume to decrease potential cancer maturity: a reduction in the intake of fat, red meat, smoked meats, or meats preserved with nitrates and elimination of white sugars from daily food intake as well as white flour products and soft drinks. Ironically, it is not common for doctors to counsel cancer patients or those who are at high risk for cancer about nutrition. Nonetheless, research shows that ingesting the correct foods and supplements may avert cancer and improve the immune system and energy levels in addition to giving the body a real chance to avert cancer or improve itself. In essence, a healthy diet strengthens the immune system, slows tumor growth, protects against further
metastasis, and reduces the side effects of radiation and chemotherapy.

Time after time, research has shown there is a considerable reduction in cancer risk in those who eat the necessary amounts of fruits and vegetables. Only 9 percent of Americans eat the recommended five daily servings. Studies have discovered that the antioxidants in fruits and vegetables bestow additional guards against free radically induced cancer. Low blood levels of antioxidants are connected with an increase in death rates from many types of cancer. One of the most assuring parts in cancer prevention involving nutrition is in the area of chemoprevention. Chemoprevention is the concept that natural substances found in completely fresh foods could provide powerful weapons against cancer and against other chronic diseases too.

Keep in mind that chemoprevention is not to be confused with chemotherapy. In place of toxic poisons, chemoprevention employs nutriceuticals to develop optimal health and to counteract cancer and other chronic and degenerative diseases. Remember, a nutriceutical is a food substance or part of a food that provides medical or health benefits, including the prevention of or treatment of disease. They are naturally occurring compounds found in plants, algae, microbials, and other biological sources that support specific bodily health functions. As mentioned, one of the most powerful nutriceutical chemopreventatives for cancer is an extract from red raspberry seeds called ellagic acid. Ellagic acid contains a naturally occurring phenolic compound that has very strong antioxidant properties. Ellagic acid has the ability to inhibit mutations within a cell’s DNA. It is also known to cause cancer obstruction, which has the ability to develop apoptosis or normal death in various types of cancer cells. Moreover, studies have found that it has antibacterial and antiviral properties. Ellagic acid is a super antioxidant and a potent anticarcinogen that protects the cells against free radical damage.

Chemopreventive agents have been identified that interact with all stages of carcinogenesis: initiation, promotion, and progression. These agents function by deactivating carcinogens, inducing enzymes, or functioning as antioxidants. Carcinogens are cancer-causing agents. As the chemopreventive agents continue to work toward preventing cancer, they may constrain tumor enlargement by acting as stimulating apoptosis or dominators. In essence, chemoprevention is a way to prevent or delay the development of cancer by taking medicines, vitamins, or other agents.

Chemotherapy

Anticancer or antineoplastic chemotherapy generally entails the administration of one or more drugs with the intent to stop further growth of tumor cells (cytostatic) or to kill them altogether (cytotoxic). Chemotherapy is often used with surgery or radiation to treat cancer when the disease has spread, has come back (reurred), or when there is a high probability that it could recur. Chemotherapy may be administered in several forms including by pills, injection, or catheter. Chemotherapeutic drugs enter the bloodstream and travel through the body
Chemotherapy is a treatment that kills mostly cancer cells, but they may also affect some healthy cells in the process. This treatment commonly has adverse side effects that may include a temporary loss of the body’s natural immunity to infections, hair loss (alopecia), digestive disorders, and a general feeling of illness.

Cancer as a Disease of Cells
Cancer is a disease of cells characterized by a shift in control mechanisms that regulate the rate at which cells divide and differentiate. Normal cells undergo a constant life cycle, usually referred to as the cell cycle. This results in cellular growth and reproduction. Cancer cells follow a similar cell cycle, and chemotherapeutic drugs are generally designed to attack specific phases in the cell cycle that cancer cells may be going through. Cells that undergo neoplastic transformation divide rapidly and excessively, forming local tumors that can compress or invade adjacent normal structures. Cytotoxic chemotherapy drugs target rapidly dividing cells. Understanding how these drugs function helps doctors predict which drugs are likely to work well together. Doctors also can effectively plan how often doses of each drug should be given based on the timing of the cell phases. Although chemotherapy drugs attack reproducing cells, they cannot tell the difference between reproducing cells of normal tissues (that are replacing worn-out normal cells) and cancer cells. The damage inflicted on normal cells can result in side effects.

Determinants of Treatment
Chemotherapy is often the first choice for treating many cancers. It differs from surgery or radiation in that it is almost always used as a systemic treatment. This means that the medicine often travels through the entire body rather than being confined to one area or organ. This is important because chemotherapy can reach cancer cells that may have spread to other parts of the body. In some cases, it is the only treatment used in an attempt to cure, control, or palliate cancer. This is termed as adjuvant chemotherapy, which is administered with the intention of preventing the growth of cancer cells remaining in the body after surgery or radiation. Alternatively, it may be used as neoadjuvant therapy, which is used to shrink a large tumor that can be subsequently removed by surgery or can be treated more effectively with radiation.

The first and primary determinant of treatment is the microscopic or histologic diagnosis. Different cancers respond differently to different chemotherapeutics depending upon their location, size, natural history, aggressiveness, and tendency to spread. Thus, the histologic diagnosis, usually made by biopsy or surgical excision of a primary tumor, is a critical first step for treatment planning. Doctors also look for abnormal presentations of common tumors that warrant further investigations and more intense therapy. Treatment in cases lacking a precise histologic diagnosis is usually directed against the most-responsive tumor type within the realm of possible diagnoses. In some cases, tumor subtypes also may be important in deciding treatment options (e.g., as in the case of non-Hodgkin’s lymphoma) as these subtypes have different patterns of clinical response to treatment.

Tumor stage based on the extent of the disease is the deciding next step. This includes an evaluation of whether the tumor is curable by local treatment measures such as surgery or radiation therapy. Doctors also consider whether the cancer has involved lymph nodes and whether those can be removed surgically. Lymph node involvement usually indicates an aggressive tumor, especially if it is involved early in the disease process, necessitating establishment of more aggressive chemotherapy. Spread of the cancer to neighboring or distant organs is termed metastasis and is generally associated with poorer prognosis. In this case, surgeons may consider the possibility of resecting the primary tumor along with the metastasis (especially if they are not too many and are surgically reachable), provided the patient stands to benefit significantly from the extensive surgery. Chemotherapy is almost always recommended in such cases.

The ultimate decision is based on a thorough understanding of the disease process, the clinical pharmacology of the drugs, and the potential benefits and risks of alternative forms of treatment. The oncologist then evaluates all parameters and
decides whether a realistic opportunity for curative treatment exists. A decision to treat with curative intent demands a high degree of adherence to drug dosage and scheduling requirements and an acceptance of treatment-related side effects. When cure is not a realistic expectation, a decision to treat must be based on an expectation for prolonging the patient's life or an improvement in quality of life. When the potential for benefit is low, chemotherapy is usually offered only after frank and thorough discussion of the likely outcome.

**Drug Classes**

Chemotherapeutic drugs are classified based on their action on chemicals or processes within cancer cells and the specific phases of the cell cycle they affect. This knowledge helps oncologists decide which drugs are likely to work well together and, if more than one drug will be used, to plan the exact dosing cycles and intervals for each drug. In fact, using combinations of drugs belonging to different classes are the mainstay of most treatment strategies for advanced cancers. This involves administration of two or more drugs simultaneously or sequentially to obtain maximum response while minimizing the impact of resistance of cancer cells to any individual agent.

Alkylating agents directly damage DNA to prevent the cancer cell from dividing. These agents work in all phases of the cell cycle. Examples of this class include nitrogen mustards (mechlorethamine, chlorambucil, cyclophosphamide, ifosfamide, and melphalan), platinum compounds like cisplatin and carboplatin, triazenes like dacarbazine and temozolomide, and the alkyl sulfonate busulfan. Nitrosoureas like streptozocin and carmustine act in a similar way to alkylating agents. They interfere with enzymes that help copy and repair DNA and are not cell cycle-phase specific. However, unlike many other drugs, these agents can travel from the blood to the brain and are often used to treat brain tumors.

Antimetabolites are a class of drugs that interfere with DNA and RNA growth and damage cells during the S phase of the cell cycle. Examples of antimetabolites include folate analogs like methotrexate and pemetrexed, purine analogs like 6-mercaptopurine, and pyrimidine analogs like 5-fluorouracil, capecitabine, gemcitabine, and cytarabine.

Antacyclines like daunorubicin, doxorubicin, and mitoxantrone are antitumor antibiotics that work in all phases of the cell cycle and interfere with enzymes involved in DNA replication. A major problem is the toxic effects on heart muscle, which may require lifetime dose limitations.

Topoisomerase inhibitors interfere with the topoisomerase enzymes that are crucial for accurate DNA replication. These include topoisomerase I inhibitors like topotecan and irinotecan and topoisomerase II inhibitors like etoposide and teniposide.

Mitotic inhibitors are derived from natural products and include vinca alkaloids like vinblastine, vinorelbine and vincristine, and taxanes like paclitaxel and docetaxel. They can stop mitosis or inhibit enzymes from making proteins needed for cellular reproduction. These work primarily during the M phase of the cell cycle but can cause cellular damage in all phases. Peripheral nerve damage can be a dose-limiting side effect.

Adrenocorticosteroids like prednisone are natural hormones that are useful in treating some cancers and other illnesses. They are often combined with other chemotherapeutics to increase their effectiveness.

Sex hormones, or hormonelike drugs, alter the action or production of female or male sex hormones and are used to slow the growth of breast, prostate, and endometrial (uterine) cancers, which normally grow in response to natural sex hormone levels in the body. These drugs interfere with the normal action of sex hormones required by the cancerous growth or prevent the body from making the hormones. Examples include antiestrogens like tamoxifen and toremifene; aromatase inhibitors like anastrozole, letrozole, and exemestane; progestins like megestrol acetate; antiandrogens like flutamide; and gonadotropin-releasing hormone analogs like leuprolide.

More recently, chemotherapy has diversified to include targeted therapeutics that work primarily on cancer cells but not on normal, healthy cells. These attack cancer cells with mutant versions of certain genes or cells that express too many copies of a particular gene. This results in more specific targeting of cancer cells while reducing the unwanted side effects of conventional chemotherapy by sparing the normal cells. Examples include the protein tyrosine kinase inhibitors imatinib, gefitinib, and erlotinib and the proteasome inhibitor bortezomib.

Immunotherapeutic agents represent yet another recent and atypical group of chemotherapeutic
agents that either stimulate the body’s own immune system to fight the disease or use immune system components like antibodies created outside of the body. A major class of drugs in this field includes monoclonal antibodies, which are artificially made proteins that can target and inactivate specific molecules in cancer cells that are crucial to their development. Some examples of drugs in this class include cetuximab and trastuzumab, which interfere with the conduction of intracellular signals, bevacizumab, which interferes with new blood vessel development that can feed tumor cells, and rituximab, which targets a protein found on the surface of cancer cells in lymphomas.

Side Effects
Chemotherapy administration involves finding a balance between destroying cancer cells in an effort to cure or control the disease while sparing normal cells to limit unwanted side effects. As explained earlier, because cancer cells grow and divide more rapidly than normal cells, many anticancer drugs are designed to kill growing cells. However, certain healthy cells also need to multiply quickly, and chemotherapy can affect these cells too. This damage to normal cells is usually the cause of side effects. The fast-growing, normal cells most likely to be affected include blood cells forming in the bone marrow and cells in the digestive tract (mouth, stomach, intestines, and esophagus), reproductive system (sexual organs), and hair follicles. Some anticancer drugs may also affect cells of vital organs such as the heart, kidney, bladder, lungs, and nervous system. The type and severity of side effects depend on the type and dose of chemotherapy and how the body reacts to the drugs.

Fatigue is the most common symptom reported by cancer patients on chemotherapy. The exact cause is not always known and may be due to the disease, low blood counts, lack of sleep, pain, stress, and poor appetite among others. It usually appears suddenly, and patients feel worn out and drained. It is often not relieved by rest and may last for days, weeks, or months. However, severe fatigue does go away gradually as the tumor responds to treatment. Some people may also experience flulike symptoms for a few hours to a few days after chemotherapy. This may be especially seen in patients receiving chemotherapy in combination with biological therapy.

Nausea and vomiting are also common complaints while receiving chemotherapy. However, this is less common with newer drugs and is less severe when they do occur. In addition to standard chemotherapy, powerful antinausea drugs are often prescribed to most patients. As with fatigue, these side effects are not always predictable and may depend on the type of drug administered and the intrinsic physiology of the patient.

Diarrhea may result when chemotherapeutic drugs affect the rapidly dividing cells lining the intestine. As with nausea and vomiting, medications are available to control this side effect, but persistent diarrhea may warrant administration of intravenous fluids to replace the water and nutrients lost. Often, these fluids are given on an outpatient basis and may not require hospitalization. On the other hand, certain anticancer drugs, pain medicines, and other medications can cause constipation. This may also be the result of decreased activity or if the diet lacks enough fluid or fiber. Laxatives or stool softener are usually prescribed with caution in these cases, especially if the patient’s white blood cell count or platelets are low.

Some anticancer drugs can cause sores in the mouth and throat, a condition called stomatitis or mucositis. Chemotherapy drugs can make these tissues dry and irritated or cause them to bleed. Patients who do not eat well after beginning chemotherapy are more likely to get mouth sores.

Hair loss is another common side effect of chemotherapy, but not all drugs cause hair loss. Because the base of hair follicles has rapidly dividing cells, drugs that kill fast-growing cells often have this accompanying side effect. When hair loss does occur, the hair may become thinner or fall out entirely. It can occur on all parts of the body, including the head, face, arms and legs, underarms, and pubic area. The hair usually grows back after the treatment is over. At times, however, the hair may grow back a different color or texture.

Chemotherapy can cause minor skin problems like redness, rashes, itching, peeling, dryness, acne, and increased sensitivity to sunlight. Certain intravenous anticancer drugs may cause the skin along the vein to darken, especially in people who have dark skin. These areas usually fade a few months after treatment ends. Nails may also become darkened, yellow, brittle, or cracked and may develop vertical lines or bands. A more serious complication
Chemotherapy is called radiation recall. This happens in some patients who receive chemotherapy after radiation and develop red patches on the skin that was exposed to the radiation. The skin over the area may also blister and peel. This reaction may last hours or even days. Treatment is generally topical.

Chemotherapy can reduce the bone marrow’s ability to make red blood cells that carry oxygen to all parts of the body. When there are too few red blood cells, body tissues do not get enough oxygen to do their work, resulting in anemia. Anemia can make the patient feel short of breath, weak, and tired. This can be countered by medicines like erythropoietin, which can boost the growth of red blood cells. Extreme cases may also require blood transfusions. Bone marrow suppression also reduces the white blood cells being made that are in charge of fighting many types of infections. This increases the susceptibility of the patient to contract infections, usually from bacteria normally found on the skin and in the mouth, intestines, and genital tract. Anticancer drugs can also affect the bone marrow’s ability to make platelets, a blood component that helps stop bleeding by making the blood clot. Decreased platelet levels cause patients to bleed or bruise more easily than usual, even without an injury. Reduced white blood cell and platelet levels may be countered by the administration of colony-stimulating factors, drugs that help raise the numbers of these cells.

Chemotherapy drugs can also cause side effects related to the central and peripheral nervous system. Drugs may interfere with certain functions of the brain, causing tiredness, confusion, and depression. These feelings generally go away once the chemotherapy dose is lowered or the course is completed. Peripherally, the drugs can damage nerves, leading to burning, numbness, tingling, or shooting pain, most often in the fingers or toes. This can, however, be relieved by special pain medications.

Chemotherapy may occasionally affect sexual organs (testes in men and vagina and ovaries in women) and functioning. These side effects depend on the drugs used and the person’s age and general health. In males, chemotherapy may reduce sperm count and motility. These changes can result in infertility, which may be temporary or permanent. In females, anticancer drugs can lower the amount of hormones produced by the ovaries, leading to irregular or complete cessation of menstrual periods while on chemotherapy. It may also cause temporary or permanent infertility and premature menopause. Although pregnancy may be possible during chemotherapy, it is not advisable because some anticancer drugs may cause birth defects. Doctors advise female patients of childbearing age to use some method of birth control throughout their treatment.

Normal cells usually recover once chemotherapy is completed, so most side effects gradually go away after treatment ends, and the healthy cells have a chance to grow normally. The time it takes to recover from side effects depends on the overall health of the patient and the type of chemotherapy administered. However, while most people have no serious long-term complications from chemotherapy, some drugs may cause permanent changes or damage to the heart, lungs, nerves, kidneys, and reproductive or other organs. Another major complication with certain types of chemotherapy is the development of secondary malignancies that present many years later. The most frequent secondary malignancy is acute myelogenous leukemia. Certain alkylating agents and ionizing radiation are considered to give rise to this condition. With improvements in the

A patient receives chemotherapy through a port in the chest area. Chemotherapy may be administered in several forms including by pills, injection, or catheter. (National Cancer Institute/Rhoda Baer)
clinical efficacy of various chemotherapeutic drugs resulting in prolonged survival and in some cases cure of cancer, the issue of how secondary cancers may affect long-term survival has assumed greater importance.

**New Classes of Chemotherapeutic Agents**

With increasing knowledge on the molecular biology of cancers, several new classes of chemotherapeutic agents are being synthesized for use in various types of cancers. These agents are being designed to specifically attack cancer cells while leaving the normal cells unharmed. Experimental treatments with the most promising laboratory results are usually moved into clinical trials. During such a trial, more and more information is gained about an experimental chemotherapeutic, and its risks and benefits are evaluated.

Clinical trials are sponsored by a variety of organizations including medical institutions, foundations, voluntary groups, and pharmaceutical companies in addition to federal agencies such as the National Institutes of Health, the Department of Defense, and the Department of Veterans Affairs. All clinical trials have strict guidelines about who can participate and how the study can be conducted. In addition, all trials in the United States are legally required to be monitored by ethics committees and must report their results in accessible forums. A drug that completes a trial successfully is then approved by the Food and Drug Administration for prescription to patients.

Modern research is revealing several new uses of chemotherapy and other agents that hold even more promise for curing or controlling cancer. New drugs, new combinations, and new delivery techniques will improve our ability to cure or control cancer and improve the quality of life for people with cancer. As mentioned previously, targeted therapies are being developed to specifically attack a particular target on cancer cells. These drugs may have fewer side effects than standard chemotherapeutics and may eventually be used along with them. Monoclonal antibodies are being designed to guide chemotherapeutic agents directly to the tumor. Such antibodies (without attached chemotherapy) can also be used as immunotherapy drugs to strengthen the body’s immune response against cancer cells.

Research is also focusing on the targeted delivery of drugs to cancer cells. Liposomal therapy involves using chemotherapeutics that are packaged inside synthetic fat globules called liposomes. These help the drug penetrate cancer cells more selectively and decrease possible side effects. Examples of liposomal medicines already in use are Doxil (the encapsulated form of doxorubicin) and DaunoXome (the encapsulated form of daunorubicin).

Chemoprotective agents also are being developed to protect against specific side effects of certain chemotherapeutics. Agents are being developed that, when given along with chemotherapy, may help overcome drug resistance. Cancer cells often become resistant to chemotherapy by developing the ability to pump the drugs out of the cells. These new agents inactivate the pumps, allowing the chemotherapy to remain in the cancer cells longer, thereby hopefully enhancing their efficacy.

**Personalized Medicine: The New Frontier**

Scientists are now able to sample small amounts of tumor tissues obtained from biopsies to analyze the genetic makeup of individual patients’ cancers. Such information on which specific genes within cancer cells are mutated can be valuable to oncologists who can then assess the relative benefits of chemotherapeutics as their sites and mechanisms of action are known for most of them. This combined approach of assessing the molecular profiles of individual tumors and matching them with the most efficacious drugs is now leading to the personalization of therapeutic regimens. As researchers learn more about the biology of tumors and invent better chemotherapeutics that can specifically target cancers while sparing normal cells, the future is set to witness a radical change in this field wherein more effective chemotherapies with fewer side effects will be combined with or totally replace existing ones, leading to more targeted and rational patient management.

Childcare and Cancer Risk

Parents and caregivers are often concerned about the cancer risk of their children. Helping children to avoid environmental hazards and other risks is, of course, beneficial to reducing children's risks of childhood cancer. Studies have suggested that children enrolled in childcare, such as preschool or day care, have a reduced chance of contacting certain childhood cancers. Children who attend day care, preschool, or play groups have a 30 percent lower risk of developing the most common type of childhood leukemia than those who do not.

Leukemia is the most common cancer found in children in wealthy nations. Leukemia affects approximately one in 2,000 children. Incidence of leukemia has been on the increase for the past several decades. Acute lymphoblastic leukemia accounts for more than 80 percent of all leukemia cases. Most often occurring in children age two to five years, acute lymphoblastic leukemia is often fatal. Acute lymphoblastic leukemia is characterized by the body's overproduction of lymphoblasts, cancerous, immature white blood cells. For patients with acute lymphoblastic leukemia, the bone marrow overproduces lymphoblasts, which continuously multiply, causing damage and death by inhibiting the production of normal cells. For a patient with acute lymphoblastic leukemia, the production of red and white blood cells and platelets is inhibited in the bone marrow and can spread to other organs. Researchers suggest that, for most types of childhood leukemia to develop, a genetic mutation must first take place in the womb. This genetic mutation is then followed by a second trigger during childhood that results in 1 percent of the children with that genetic mutation then developing the disease.

A child suffering an infection, or the timing of that infection, is one of the suspected triggers that might cause one child to develop acute lymphoblastic leukemia. In order to resolve this issue, scientists examined some of the environmental variables that separated those children who developed acute lymphoblastic leukemia and those who did not. Researchers asked parents questions about their child's day care, preschool, and playgroup attendance. The parents were also asked about their child's other forms of social interaction with other children. The various research studies that investigated the effect of social interaction with others on acute lymphoblastic leukemia varied in several ways. The timing, duration, and extent of social contact were investigated and in the age groups and types of leukemia studied. At the end of the process, the researchers in a variety of studies found some indication that social interaction with other children provided a protective effect against contacting acute lymphoblastic leukemia. No study found that children with a greater amount of social contact had an increased risk of being diagnosed with acute lymphoblastic leukemia.

Benefits of Interaction

Children are exposed to a multitude of infections when they have regular interaction with peers in settings such as day care or preschool. As a result, children who attend some sort of childcare are more likely to develop stronger immune systems. This stronger immune system serves to assist the children's immune systems to fight the development of the most common form of childhood cancer, acute lymphoblastic leukemia. This strengthened immune system seems to develop over time. Those children who are new to childcare appear to be the first to contact easily spread illnesses such as those involving the upper respiratory system or viral or gastric diseases. This contrasts with those children who have been in group childcare settings for some time as these children appear better able to manage exposures.

Certain differences appear to exist, however, among children from different racial or ethnic groups. While Caucasian, non-Hispanic children who were enrolled in childcare, day care, or preschool had significantly lower rates of being
diagnosed with acute lymphoblastic leukemia than other Caucasian, non-Hispanic children, this benefit was not enjoyed by children from other ethnic groups. Specifically, Hispanic children who were also enrolled in childcare, day care, or preschool contacted acute lymphoblastic leukemia at the same rate as other Hispanic children who were not enrolled in such services. Further research needs to be conducted to determine how such enrollment affects children from other ethnic groups, such as Asian or African American students.

**Childcare for Siblings of Cancer Patients**

The siblings of children with chronic illnesses such as cancer have been observed as having more adjustment or behavioral problems than do the siblings of healthy children. These adjustment problems are independent of the seriousness of the illness suffered by the sibling. Siblings of children with cancer face major stress themes in their lives, including change, fear of death, and loss. These children also deal with anxiety, social isolation, and fear for their own health. While families of children with cancer obviously place a great emphasis upon the needs of the child facing cancer, the needs of their other children are also significant and must be met. Day care, childcare, and preschool programs can provide excellent options for such families.

The siblings of cancer patients seem most affected by diminished contact with their parents, an understandable condition when considering the increased energy expended on the child facing cancer. This lack of contact may lead to eating and sleeping disorders as the sibling of a cancer patient attempts to find other ways to cope with the loss of his or her parents’ attention. Not surprisingly, this lack of contact most severely affects children who are below school age as they have fewer coping skills and also do not have the support and distraction provided by teachers and peers. When such children are enrolled in a quality childcare program, however, their ability to cope with these problems increases.

The childcare, day care, or preschool in which the sibling of a cancer patient is enrolled should be made aware of the situation facing him or her. Quality programs will help the child to discuss and come to terms with his or her feelings and provide him or her with the support necessary to feel validated and valuable. Merely enrolling in a childcare, day care, or preschool program will provide the siblings of cancer patients with a distraction and a new social set that will assist them in being able to better deal socially with the world around them.

**Support for Families of Cancer Patients**

Families faced with a diagnosis of childhood cancer have a variety of support systems that exist to help them. This support is often necessary for the child diagnosed with cancer, his or her parents, and other children in the family. The American Childhood Cancer Organization (ACCO), for example, provides a variety of services to those families facing childhood cancer, including support for parents and siblings. The ACCO, formerly known as the Candlelighters Childhood Cancer Foundation, was formed in 1970. As it was founded by parents of children with cancer, ACCO is aware of the many needs facing the family after receiving a diagnosis of cancer. ACCO works to advocate for these children’s needs and to support research that increases every child’s chances of survival. It also provides a wealth of materials and resources that can positively affect siblings and parents in such a situation.

The ACCO provides a variety of services intended to assist those children facing cancer and their families. These services include the distribution of books and other materials that provide information regarding the treatment options and late effects of childhood cancer. The organization also maintains a toll-free hotline and Web site where families can connect with volunteers and experts to receive referrals, support, and information regarding childhood cancers. Local affiliates of the ACCO often provide support groups where children facing cancer and their families can meet and discuss their situations with others. These services include peer support groups, in-hospital visits, and assistance programs. Siblings of children with cancer can benefit greatly from such assistance as it can help them better understand what they are feeling and how to best interact with others. Organizations such as the ACCO also advocate with policy makers and Congressional representatives to assure that childhood cancer research is given a high priority when legislative decisions regarding funding are made.

**Childhood Brain Tumor Foundation**

The Childhood Brain Tumor Foundation is one of several foundations that address the needs of children with cancer and their families by providing education and other sources of financial support. The Web site for this foundation is www.childhoodbraintumor.org. The foundation is located in Maryland. The development of this foundation over the past 17 years has added to knowledge through Web-based education and materials and provided research opportunities to improve prognosis for children with pediatric brain tumors.

This organization is a nonprofit whose aims are to improve the quality of life and prognosis for children with pediatric brain tumors and find a cure for the spectrum of medical conditions addressed by the umbrella concept of pediatric brain tumors. Funding for the organization's activities is raised through private donations and community projects (walks to raise money for the organization, galas, etc.). Funding raised by this organization is primarily disbursed through research grants. Additionally, there is an educational section of this Web site that provides critical information about pediatric brain tumors, such as age of onset, prevalence, and medical information.

Another section of the Web page provides the stories of children with brain tumors. These stories and in-memory-of dedications shine a light on the courage that children and their families find to cope with the stress of childhood brain tumors. The stories and memoirs are filled with ideas for hope and fighting for recovery that could both inspire and support parents and children struggling to deal with the devastating impact of brain tumors for children. There also are links to Web sites that provide information about pediatric brain tumors (e.g., neurological information about this disease) and current research centers and initiatives in the field. Those seeking referrals for medical treatment can also find some guidance to treatment centers on the Web site.

Supporting research through grant funding is an important part of the mission of the Childhood Brain Tumor Foundation. Proposals for funding must address the organization’s goals of finding a cure, improving medical outcomes for children with brain tumors, or improving the quality of life for children with brain tumors. Grant proposals are evaluated using a system patterned after the grant review criteria established by the National Institutes of Health, where value also is placed on innovation, scientific merit, and research design of applications for funding. The Web page presents a review of abstracts from a variety of funded projects. The majority of the projects have a medical focus, aimed at understanding biological and genetic underpinnings of brain tumors to spur the field toward cures for these diseases. Some funding is also directed toward improving quality of life as well as assisting children in coping with the late effects related to radiation and other medical treatments for brain tumors.

Childhood Cancers

Childhood cancers refer to those that occur in children, generally defined as taking place in young people from birth to age 14, although the upper age is sometimes used with those as old as 19. The most common childhood cancers are leukemia, brain tumors, and lymphoma, although a variety of other types of cancer can and do afflict children. Tremendous effort and funds have been devoted to finding cures for childhood cancers, and as a result, the survival rates for many of these have risen dramatically over the years. A variety of organizations exist to help children with cancer and their families to obtain treatment, cope with the disease, and to face other issues that may arise.

Globally, more than 175,000 incidents of childhood cancer are diagnosed each year, and nearly 100,000 childhood cancer cases result in death annually. In the United States, only accidents cause more deaths among children than cancer. Each year 16 out of every 100,000 children are diagnosed with some form of cancer, and three out of 100,000 children will die from the disease. This translates into approximately 12,000 new cases of childhood cancer in the United States each year, with approximately 1,300 deaths of those between birth and 14 years of age. In developing nations, the statistics involving childhood cancer are grimmer. In developed nations, childhood cancers have a mortality rate of approximately 20 percent, whereas in developing nations, the mortality rate often ranges from 80 to 90 percent.

Globally, the disparity between childhood cancer mortality rates in developed and undeveloped nations is an issue of concern. When examining the variation in childhood cancer incidence among nations, the greatest difference occurs when high-income countries are compared to low-income ones. Within this difference, however, a variety of factors may cause the disparity between the two groups. The differences in cancer mortality rates between high-income and low-income nations may result from differences in the capacity to diagnose cancer, differences in risks among different racial or ethnic population subgroups, differences in environmental or other risk factors, or a combination thereof. Researchers study these differences in an attempt to provide children living in particular countries the most appropriate treatment possible.

Types of Childhood Cancer

A variety of cancers are found each year in children. Children between the ages of one and four are most frequently diagnosed with childhood cancers, but those between the ages of 10 and 14 are the group most likely to die from cancer. Certain types of cancer are more prevalent in children than others. The most common types of cancer diagnosed in children are leukemia (34 percent of diagnoses), brain tumors (23 percent), and lymphoma (12 percent). Other types of cancer, although less common than leukemia, brain tumors, and lymphoma, are also seen regularly in children. These cancers, and their rates of diagnoses, include neuroblastoma (7 percent), Wilms tumors (5 percent), non-Hodgkin's lymphoma (4 percent), rhabdomyosarcoma (3 percent), retinoblastoma (3 percent), osteosarcoma (3 percent), and Ewing sarcoma (1 percent). Research is ongoing with all of these forms of childhood cancer both so that their causes might be better understood and so that treatment options might be tested and ultimately provided to patients around the globe.

The causes of most cases of childhood cancer are unknown. In between 5 and 15 percent of childhood cancer cases, a variety of familial and genetic factors can be identified as contributing to the disease. When physicians and researchers determine
that genetic factors are at play in a case of childhood cancer, the chance that an interplay between genetic and environmental factors must also be examined. Approximately 10 percent of the occurrences of childhood cancer involve environmental factors, which might include exposure to certain substances, such as medications, tobacco, or other known carcinogens. In the remainder of childhood cancer cases, however, the causes of the cancer are unknown, meaning that for more than 75 percent of these diagnoses, the causes of the cancer are unknown.

Those working with childhood cancer understand that there are significant differences between working with adults facing cancer. First, children have different, and sometimes unique, reactions to exposures to environmental hazards. Unlike adults, children must often rely on others to protect them from toxic environmental agents. Second, children's immature physiological systems often make them unable to clear or metabolize hazardous environmental agents with which they come in contact. As a result, adults must sometimes take additional steps when a child has been exposed to potentially hazardous materials. Third, the growth and development of children occurs in phases known as developmental windows. This can result in certain critical windows of vulnerability, during which a child who is exposed to certain hazardous materials may respond more adversely than a child who is not within that window. Special care must as a result be taken for children at certain ages. Fourth and last, children's longer life expectancies mean that a longer time exists for cancer processes to manifest with long latency periods. This means that children exposed to certain materials have an increased risk of developing some cancer types later in life due to early life events.

Assistance
Children and their families faced with a diagnosis of childhood cancer have a variety of support systems that exist to help them. The American Childhood Cancer Organization (ACCO), for example, provides a variety of services to those facing childhood
cancer and their families. The ACCO, formerly known as the Candlelighters Childhood Cancer Foundation, was formed in 1970 by parents of children with cancer. The ACCO works to advocate for these children's needs and to support research that increases every child's chances of survival.

The ACCO provides a variety of services intended to assist those children facing cancer and their families. These services include the distribution of books and other materials that provide information regarding the treatment options and late effects of childhood cancer. The organization also maintains a toll-free hotline and Web site where families can connect with volunteers and experts to receive referrals, support, and information regarding childhood cancers. Local affiliates of the ACCO often provide support groups where children facing cancer and their families can meet and discuss their situations with others. Organizations such as the ACCO also advocate with policy makers and Congressional representatives to assure that childhood cancer research is given a high priority when legislative decisions regarding funding are made.

**Chile**

The Republic of Chile is a South American country that is located between the Pacific Ocean and the Andes mountains. Chile is considered one of South America's most stable and prosperous nations; however, it still must support the burden of cancerous diseases.

In Chile, cancer is the second cause of death after cardiovascular diseases, making up 20 to 25 percent of deaths annually in the country. In 2008, cancer killed 22,000 people in Chile.

The most common forms of cancer in Chilean men, according to the Chilean Ministry of Health (based on a population of 100,000), are stomach cancer at 26.9 percent, prostate cancer at 20.9 percent, lung cancer at 19.1 percent, colorectal cancer at 6.7 percent, liver cancer at 6.2 percent, and gallbladder cancer at 6.2 percent.

In women, the most common forms of cancer are breast cancer at 16.9 percent, gallbladder cancer at 15.3 percent, stomach cancer at 13.2 percent, lung cancer at 11.2 percent, colorectal cancer at 8.4 percent, and cervical cancer at 7.6 percent.

Cancer incidence is higher among the elderly and middle-aged in Chile, and despite the lack of studies addressing death incidences among different ethnicities, there is evidence of gallbladder cancer being more prevalent in the indigenous population.

**Risk Factors**

Statistical analyses show that risk factors for cancer (gastric, in particular) in the Chilean Provinces include latitude, fertilizer, and rainfall. Results indicate that one major factor influencing stomach cancer mortality rates for Chileans is exposure to sodium nitrate in the form of fertilizer. In terms of gastric cancer, sodium nitrate plays a factor, and studies indicate that the farmers exposed to this compound are experiencing higher death rates.

Male workers in actual contact with the soil, such as farmers (31.2 percent) and miners (18.7 percent), accounted for almost half of all male deaths (837 cases) from stomach cancer in Chile.

Folate depletion is associated with an increased risk of colorectal carcinogenesis. A temporal association between folic acid fortification of enriched cereal grains and an increase in the incidence of colorectal cancer in the United States and Canada has, however, been reported recently.

Studies have shown that colon cancer, may correspond with the beginning of the country's mandatory flour fortification program, which requires 220 micrograms of synthetic folic acid per 100 grams of wheat flour. Studies show an increase
of colon cancer after this program was put in place. Additional Chilean studies indicate that a high risk of bladder cancer is also an issue in the country due to very high levels of arsenic in Chilean drinking water back in the 1950s and 1960s. These findings are not surprising, researchers say, because the cancer would take decades to surface. It is very important that the Chilean health care system promote screening for this type of cancer.

Though the arsenic problem has been under control for more than two decades, people in the region of Antofagasta, in particular, are showing high bladder cancer rates, at 16 cases per 100,000 for men in the region, compared with less than six cases per 100,000 individuals for the other parts of Chile. For women, the bladder cancer rate is 13.5 percent and 2.5 percent, respectively. Finally, studies have shown that there may be a correlation between hypertension and breast cancer in Chilean women. Hypertension is widely spread across Latin America, and reducing this treatable disease may help reduce the risk for breast cancer in the future.

Challenges to Cancer Care
One major challenge for the oncology community in Chile is that many cancer specialists prefer to work for the private health care system in the country due to the fact that it offers higher salaries when compared to the public sector. Many oncologists migrate to the capital city of Santiago to work in these specialized private health care branches. An additional challenge is the lack of specialists in palliative care treatment.

The Chilean public health care system handles 75 percent of the country’s population. The public system has fewer resources than the private system, including less access to targeted therapies and pharmaceutical drugs. Poorer patients often do not have access to the private system, and low-income patients living in distant villages have even fewer opportunities and less access to specialized treatments than low-income patients living in large cities. Chile’s national records indicate there are only 61 registered medical oncologists with specialized degrees and 45 specialists in radiation oncology. The exact number of additional specialists is currently unknown.

Patients who cannot be treated in small cities are sent to the capital, though the country recommends that all large hospitals have their own specialized cancer treatment centers. The National Cancer Institute serves the capital, Santiago, but this location only serves particular areas of the city.

The percentage of cancer-related mortalities is still high despite recent progress on poverty. However, there are bright spots. The National Cancer Institute of Chile was recognized for bringing the survival of patients with cancer to 70 percent over the past five years.

Conclusion
The need for further education and prevention efforts surrounding cancer in Chile is pronounced. Fortunately, there are some efforts currently in place to encourage this education. Beginning in 2006, the Chilean Oncology Foundation has worked with the American Society of Clinical Oncology (ASCO) to present educational courses and symposia in Chile. The organization held its first Multidisciplinary Cancer Management Course (MCMC) in Santiago in 2006. In 2010, it held a second event in conjunction with the Train the Trainer course.

In addition, the Simposio Latinoamericano Gastroenterología Oncológica (SLAGO), or Latin American Gastrointestinal Symposium, was organized as ASCO–SLAGO joint symposiums in 2007, 2009, and 2011. Also in 2011, the first long-term international fellowship (LIFE) was awarded to a Chilean oncologist—Cesar Sanchez, MD—by the ASCO Cancer Foundation. These awards contribute to the development of cancer prevention and treatment in Chile. With positive moves in this direction, the cancer situation in Chile could improve in the near future.

China

With a population of nearly 1.38 billion, China accounts for 19.3 percent of the world population and is the most populous country in the world. Because incidences of cancer often vary between less-developed and developed regions, China faces unique challenges from both domestic and international perspectives. Cancer is the leading cause of death in urban China and the second in rural China (after cerebrovascular disease), accounting for 27.79 percent and 23.62 percent of total deaths, respectively. Compared to other more-developed countries, many of the high-risk factors faced by Chinese people involve lifestyle factors (e.g., smoking). Additionally, the growing industrialization, Westernization of dietary practices, and other unique social determinants (e.g., demographics, ecological, environmental, and cultural variables), and genetic factors have contributed to cancer problems in China. In 2009, the central government announced a ¥850 billion ($128 billion), three-year health care reform plan aiming to provide affordable and universally available health care by 2020. Some of the reforms include plans to expand the medical insurance system, reimbursing essential therapies and upgrading health care facilities in local communities and rural areas.

Common Cancers and Risk Factors

Patterns in cancer incidences can provide insights into the impacts of lifestyle on cancer development. From 1973 through 1975, the top three deadly cancers were stomach, esophageal, and liver cancers. By 1990 to 1992, the top three were stomach, liver, and lung cancers. A comparison of major cancer sites between the China and the United States showed that China has higher cancer incidence rates in four sites amongst males (i.e., nasopharynx, esophagus, stomach, and liver) and six sites among females (i.e., nasopharynx, esophagus, stomach, liver, gallbladder, and cervix uteri). The cancer trends in China indicate that risk factors for cancer such as the deterioration of the environment and Western lifestyles have increased in China since the 1970s, whereas the aging population became a contributing factor as of the 1990s.

Cancer mortality in China has also been increasing rapidly and continuously since the 1970s, with urban China seeing higher rates than rural China. Currently, lung cancer is the leading cause of cancer deaths in urban areas, followed by digestive tract cancers (liver, gastric, esophageal, and colorectal cancer). In contrast, liver cancer is the leading cause in rural areas, followed by lung cancer and other digestive tract cancers.

Lung cancer increased 465 percent between the 1970s and the 2000s. The World Health Organization (WHO) estimated that, by year 2025, more than 1 million Chinese would be diagnosed with lung cancer each year. A major risk factor of lung cancer is smoking. As the largest tobacco producer and consumer in the world, China now has more than 350 million tobacco smokers, among whom are 15 million regular smokers and 40 million casual smokers between 13 and 18 years old. In recent years, although the smoking rate among males (around 60 percent) has decreased, it has increased among female smokers (around 4 percent), with greater increases among young females.

Liver, stomach, and esophageal cancers are the three next deadliest in China in since the 2000s. China accounts for almost 50 percent of the world’s liver cancer cases. Hepatitis B, a causal factor for liver cancer, is highly endemic in China, with a 2006 survey noting an HBsAg carrier rate of 7.18 percent in the overall population (i.e., an estimated 93 million HBV carriers, including 30 million patients with chronic hepatitis B).

Other infectious agents also contribute to high cancer rates in China. For example, *Helicobacter pylori* (H. pylori)—induced gastritis is the single strongest risk factor for stomach cancers. In China,
several reports have shown that *H. pylori* prevalence rates remain around 60 to 70 percent since the 1990s. In contrast, the infection rate is estimated to be around 25 percent in the West due to improved hygiene and widespread antibiotic use. A randomized clinical trial in Shandong, China, found that a short-term treatment with antibiotics to eradicate *H. pylori* was able to reduce gastric cancer incidents by almost 40 percent during a 15-year period.

Nutritional deficiency is believed to play a major role for esophageal cancer development, especially in high-risk areas in China. Other researchers also found that environmental carcinogens (e.g., nitrate nitrogen), dietary practice (e.g., drinking tea at high temperatures), and genetic factors contributed to the high incidence rate of esophageal cancer.

Nasopharyngeal cancer (NPC) is extremely common in southern China, accounting for 18 percent of all cancers in China. It is also known as Cantonese cancer because it occurs in about 25 cases per 100,000 in this region, 25 times higher than the rest of the world. Researchers argued that early childhood exposure to Epstein–Barr virus (EBV) infection and salt-preserved fish in southern China pose significant risk factors. Researchers have also suggested genetic susceptibility and shared environmental risk factors together may also contribute to the high incidence rate in southern China.

**Organizations and Events on Cancer**

Cancer control programs in China focus on prevention, early diagnosis, and treatment. In addition to hospitals that are responsible for general cancer care, nonprofit organizations also play major roles in cancer prevention. The Cancer Foundation of China (CFC) accepts nationwide donations and sponsors public service, education, and cancer research. The Chinese Society of Clinical Oncology (CSCO) focuses on enhancing continuing education in clinical oncology and developing advanced training programs, with targeted services in rural areas.

Similarly, the Chinese Anti-Cancer Association (CACA) is dedicated to the prevention and treatment of cancers by coordinating and supporting professionals across all cancer-related fields. Every two years, CACA hosts the Chinese Conference of Oncology (CCO), China’s most comprehensive and influential conference in oncology. In 1995, CACA designated the week of April 15 to be National Cancer Week. Since then, public events aiming to disseminate cancer-related information and knowledge have been held during this week to raise public awareness and to seek public support. The past annual themes included healthy lifestyles, fighting cancer together, food and cancer, caring cancer patients, early detection and treatment, breast cancer, antismoking, among others.

**Chinese Media Reports on Cancer**

Cancer information is widely broadcasted through mass media in China, with television and newspapers being the most common venues. In urban or suburban areas, the Internet is a common alternative, while in remote areas, radio provides a higher reach. Cancer information presented in mass media includes statistical reports, status reports, cancer trends, the latest cancer treatment and research, and human interest cancer-related stories.

In China, mass media is essential in raising public awareness about health-related issues. For example, cancer village is a social phenomenon first identified through media, resulting in significant shifts in public attitudes and governmental policies. In 2009, *Phoenix Weekly* had the cover story titled “Hundreds of Places in China With High Carcinogenic Risk,” which documented heavily industrialized rural communities that experienced higher cancer rates and cancer-related deaths than the national averages. A so-called China Cancer Village Map was drawn and, together with related stories, spurred great concerns from the government and the public, which in turn promoted more media coverage. After years of research and debates, the Chinese government officially acknowledged the existence of cancer villages in 2013. The public was educated about the issue, and citizen involvement was encouraged. Mass media played a critical role in the process, publicizing these environmental hazards and highlighting China’s struggle to balance public health and economic growth.

In China, entertainment education, providing health-related information through films and television programs, remains a powerful form of health outreach. For example, a highly acclaimed Chinese movie in 2008 named *If You Are the One* followed the story of the main character, who was diagnosed with melanoma. He conducts a living funeral for himself before his death and commits suicide by later jumping into the sea. The movie left a huge impression on many audiences and introduced
melanoma to the public, motivating a large num-
ber of audiences to visit hospitals to have their
moles examined and removed. Media also provided
extensive reports from medical experts, dispelling
common misconceptions.

Media has also played a significant role in cov-
ering Chinese celebrities in the 21st century who
have suffered from cancer. A good example is Luo
Jing (1961–2009), a famous anchor of the national
news program Xinwen Lianbo on CCTV. Luo was
diagnosed with lymphoma in 2008 and died the
following year. Social media is playing an increas-
ingly important role for cancer education as well.
A prominent computer scientist, Li Kaifu, was
diagnosed with lymphoma in 2013. He posted a
Weibo, the Chinese equivalent of Twitter, announc-
ing his fight against cancer. His story was reported
by numerous media outlets and became a popular
topic in the public sphere. Stories of celebrities with
cancer provide rich resources and opportunities for
public awareness and education.

Chlorine

Chlorine (Cl₂) is a nonmetallic chemical element.
It appears as a greenish-yellow gas that is slightly
soluble in water and has a suffocating or choking
odor. Chlorine, in combination with other chemi-
cals, is an ingredient in commonly used household
cleaners and disinfectants and is used to disinfect
water, purify metals, bleach wood pulp, and make
other chemicals. Although chlorine is known to
have health effects such as irritation of the eyes
and lungs, less is known about chlorine and cancer.
Over the past three decades, however, studies have
linked chlorinated water and swimming pools to
increased cancer risk.

Chlorine is found in nature in the form of salt
(sodium chloride) in seawater, and an estimated
10(16) tons of chlorine are present in the world’s
oceans and saltwater seas. Chlorine is also found in
minerals in the Earth’s crust. It was discovered in
1774 by Karl Wilhelm Sheele, an 18th-century Ger-
man-Swiss chemist, via experiments that created a
reaction between hydrochloric acid and manganese
(IV) oxide. Chlorine was first used as a disinfectant
in 1850 when John Snow, who helped pioneer the
field of hygiene, used chlorine to disinfect London’s
water supply during a cholera outbreak when he
tracked down a well in Soho that he identified as
the source of the sickness.

Chlorine’s widespread use as a disinfectant, how-
ever, did not begin until the early 1900s. Eventually,
chlorine was developed to create a new standard
for water purification in the Western world. This
advance, designed to kill harmful microorganisms
in water, was hailed as one of the 20th century’s
major public health achievements. Chlorine is still
the most widely used chemical to disinfect public
drinking water in the United States.

Chlorine has not always been used to benefit
people. It was developed by the Germans as a weapon
and, with the outbreak of World War I, became one
of the first poisonous gases used in warfare. Soldiers
exposed to chlorine gas suffered severe burning of
the lungs and other body tissues.

Despite the beneficial uses of chlorine, various
health concerns about the element, particularly in
water supplies, have been raised. The first concerns
in the scientific community about the relationship
between cancer and chlorine in drinking water
were raised in 1974. Scientists discovered that the
combination of chlorine and organic compounds
could produce dangerous hydrocarbon by-prod-
ucts. Nevertheless, a number of follow-up studies
produced no definitive evidence that chlorination
of water increased cancer risk.

Then, in 1992, chlorinated drinking water was
linked to increases in rectal and bladder cancer
rates by researchers at Harvard University and the Medical College of Wisconsin. The risks were considered small. For example, the findings, published in the American Journal of Public Health, were drawn from the 1970s, when municipal drinking water supplies typically used higher levels of chlorine to treat water. Still, according to the 1992 study, approximately 9 percent of all bladder and 18 percent of all rectal cancer cases were associated with the long-term drinking of hydrocarbon by-products. Overall, this estimation translated into more than 20,000 new cases each year.

Chlorine reacts with other natural compounds in water to form four primary chemical by-products, trihalomethanes, haloacetic acid, bromate, and chlorite. All four are regulated by the Environmental Protection Agency (EPA) in terms of parts per billion allowed in municipal drinking water supplies. The trihalomethanes (THMs) are a group of four chemicals: chloroform, bromodichlorometh, dibromochlorometh, and bromoform. These chemicals are formed when chlorine in water reacts with naturally occurring organic and inorganic matter. THMs produce free radicals in the body that are considered extremely carcinogenic.

According to a report by the U.S. Council of Environmental Quality, people drinking chlorinated water have a 93 percent higher risk of getting cancer than people who drink water without contain chlorine treatment. Furthermore, the Environmental Defense Fund has noted that, despite the low level of THMs in drinking water supplies, scientists are concerned that their presence may increase the risk for many types of the human cancers in the United States. For example, a 2009 study conducted in Hartford, Connecticut, found that female breast cancer patients had significantly higher levels (50 to 60 percent) of organochlorines (chlorination by-products) in their breast tissues when compared to women without breast cancer.

Studies have also shown that there are other areas where even a higher health danger from exposure to chlorinated water may exist. Approximately two-thirds of human exposure to chlorine occurs in the shower, where people inhale steam and water is absorbed into the skin. A 2010 study report also pointed to indoor chlorinated swimming pools as potentially inducing DNA damage that could lead to cancer. In addition to the normal creation of chemical by-products produced by adding chlorine to water, chlorine in swimming pools can also react to various other substances, including urine and cosmetics, often found in public swimming pools.

Research has shown that chlorine can increase the risk of bladder cancer for pool swimmers. The study found that people who were in the water for 40 minutes experienced an increase in risk markers for DNA damage that could have potential carcinogenic effects. According to the researchers, swimming pool water is not worse than tap water in terms of producing potentially harmful by-products. However, swimmers are exposed to a massive dose of these by-products.

As for drinking water, the World Health Organization (WHO) developed guidelines in the later 1990s for the amount of THMs that are acceptable in water supplies. Although some studies show increased levels of some carcinogens in drinking water supplies, many scientists, including those at WHO, warn against the wholesale disuse of chlorinated water. For example, Peru stopped using chlorine in its water supplies. Shortly afterward in 1991, a cholera outbreak led to more than 300,000 Peruvians contracting cholera during the epidemic, which researchers showed was partly due to the water supply.

There has been an ongoing debate about whether or not using chlorine to disinfect water supplies actually increases the risk for some cancers, especially bladder and rectal cancers. Many scientists, including those at the EPA and the WHO, believe health risks due to the concentration of chlorine by-products in the water supply produced by the use of chlorine is minimal compared to numerous risks associated with inadequate disinfection of water supplies. Furthermore, the EPA has not classified chlorine for carcinogenicity. Nevertheless EPA regulations have continued to further limit THMs and other chlorine by-products in drinking water due to chlorination.

Many scientists, including those at the National Cancer Institute (NCI), continue to investigate the issue, and more recent studies have shown associations between long-term exposure to drinking water by-products with increased risk of rectal and bladder cancers. In addition, NCI collaborated with researchers in Spain for the Spanish Bladder Cancer study, which examined exposure via drinking, showering or bathing, and swimming pool use.
The study showed an overall twofold increase of bladder cancer in people who had estimated household levels of THMs above 49 milligrams per liter. Meanwhile, various carbonated and other filters have been devised to reduce the amount of chlorine exposure in home water supplies. However, their effectiveness in removing chlorine THMs remains in question, and some methods are absolutely not effective in reducing the amount of THMs.

In addition to preventing or reducing bacteria and other infectious agents in water supplies, chlorine is also used in some therapies. For example, the drug cisplatin is used to treat testicular, bladder, and ovarian cancers that have spread. Cisplatin contains a platinum atom with two chlorine atoms. Once the drug arrives at the cancer cells, the chlorine atoms separate from the cisplatin molecules and give way to two binding positions that attach to the cancer cells’ DNA, thus helping stop the cancer cell from multiplying and tumors from further developing. Some alternative medicine proponents have also touted the use of chlorine dioxide solutions to help cure cancer. However, the medical establishment has pointed out the dangers of taking such solutions, which are often equivalent to industrial-strength bleach and have the potential to result in respiratory failure.

Chloroform

Chloroform is a trihalomethane, one of four chloromethanes. It is a naturally occurring organic compound with a history of industrial uses, though because of its health effects and contribution to ozone depletion, it is being phased out as a component of refrigerants. Chloroform is naturally produced by both seaweed and fungi. It does not bioaccumulate in marine life, so its production by seaweed does not mean it is found in seafood. It is also produced synthetically. Industrially, chloroform is used mainly to make chlorodifluoromethane, which is used as a propellant and refrigerant, mainly in developing countries that are not signatories to climate change treaties limiting the use of hydrochlorofluorocarbons. The Montreal Protocol, to which the United States is signatory, requires the United States to reduce its consumption of hydrochlorofluorocarbons, and it has been phased out mainly in favor of propane and blended mixtures. The Environmental Protection Agency classifies chloroform as a Group B2 probable human carcinogen.

Trihalomethanes like chloroform are not only environmental pollutants that deplete the ozone layer and pose risks to the water supply, but most of them are known to be carcinogenic. Chloroform is produced through a haloform reaction in swimming pools when the chlorine in the water comes into contact with organic substances—not just urine, but the sweat, hair, and microscopic skin particles that are inevitably washed from swimmers’ bodies.
into the water. Some of the chloroform becomes vaporized in the air and may be inhaled, but most of the absorption is actually through the skin. Studies have found that adolescents who spend a lot of time in public pools—which host a greater number of swimmers than most home pools and thus more haloform reactions generating chloroform—have demonstrably lower testosterone levels.

Chloroform is perhaps most familiar from popular culture, in which a staple of crime fiction since the late 19th century has been the use of a chloroform-soaked rag by a criminal to induce their victim to pass out almost instantaneously (usually with no ill effects upon waking up). This pulp-fiction trope was inspired by the real-life uses of chloroform in turn-of-the-century crimes, both to render victims unconscious in order to rob them and as an instrument of murder. Even today, chloroform is sometimes used by pedophiles to incapacitate their child victims. However, the effect is not as rapid as is depicted in film and television. It takes at least five minutes of inhaling chloroform fumes to pass out, which is unsurprising when one reflects on the fact that even anesthesia in safe doses does not knock the patient out instantly.

The soaked rag trope was also, to be fair, influenced by the 19th-century use of chloroform as an anesthetic, first in Europe, and briefly in the United States, before its health effects were noted. Like other early anesthetics, it was also used as a recreational drug to induce euphoria.

Chloroform is, however, quickly absorbed and metabolized by the body (and eliminated mainly by the lungs). Either inhalation or ingestion causes depression of the central nervous system at high enough doses, followed by coma, respiratory depression, and death by respiratory or cardiac failure. Use as anesthesia was discontinued because some patients experienced nausea, vomiting, or jaundice. In people who have died as a result of chloroform poisoning, liver necrosis is observable in the autopsy.

Chloroform is believed to cause liver and kidney cancer and has been shown to cause tumor formation in rats. Ingesting amounts of chloroform in small doses over a prolonged period of time, because of chloroform in the workplace, in the water supply, or airborne because of evaporation from nearby water sources containing sufficient chloroform, forces the liver and kidneys to gradually take damage as they process too much chloroform, eventually inducing DNA damage during mitosis and the formation of a tumor. Chloroform can be found in drinking water for reasons similar to its presence in swimming pools: The chlorine used to make the water potable interacts with biological materials. This may find its way into food and beverage products that use chlorinated or tap water in their production. People who live near hazardous waste sites, sanitary landfills, swimming pools, or pulp and paper mills may have chloroform in their drinking water from groundwater seepage or may have it in their air.

There is no definite information about the cancer risk of chloroform inhalation. Studies are firmer on the probable association between chlorinated drinking water, which contains chloroform, and cancer of the large intestine, rectum, or bladder, but there are no studies of human consumption in which chloroform is isolated from the other constituents of chlorinated drinking water. Nevertheless the EPA, which is fairly conservative on such matters, considers chloroform carcinogenic in all routes of exposure.

City of Hope

The City of Hope National Medical Center, located in Duarte, California, is a clinical research center, hospital, and graduate medical school. A private not-for-profit organization, the City of Hope was originally founded to treat tuberculosis patients and is well-known for its research prowess, especially with regard to cancer and cancer-related conditions. Founded by Jewish groups, the City of Hope provides nonsectarian services to patients from across the United States. Working with a variety of partner institutions and organizations, the City of Hope is home to the Beckman Research Institute of City of Hope.

Tuberculosis was a major health concern during the latter parts of the 19th and early 20th centuries. As tuberculosis (also known as consumption) is a highly infectious disease that often attacks the lungs, the public desired treatment options for tuberculosis patients, both to provide them with relief and to protect uninfected members of the public. To that end, a variety of treatment centers sprang up in the southwestern United States as a result of the belief that the arid climate there would provide health benefits to those afflicted with tuberculosis. The Jewish Consumptive Relief Association in 1913 raised funds to purchase 10 acres of land in Duarte, California, a rural community located approximately 15 miles northwest of Los Angeles. In 1914, two tents were erected, one for tuberculosis patients and the other for medical providers. This sanatorium, which was immediately successful, soon became known by the nickname City of Hope.

Through the end of World War II, tuberculosis treatment remained the focus of the City of Hope medical providers. Vaccines that inoculated individuals from tuberculosis were introduced at the end of that conflict, at which time the City of Hope’s focus turned to other medical problems. Beginning in 1946, City of Hope Executive Director Samuel Golter began a series of actions intended to transform the institution from a sanatorium into a full-service medical center, supported by a research center and graduate education. The institution’s formal name was changed from Los Angeles Sanatorium at that time, and the research center was founded in 1952, with the graduate school of biological sciences first accepting students in 1953. Golter’s successor, Ben Horowitz, assumed leadership of the City of Hope in 1953 and helped to grow the institution’s cancer research and treatment capacities. With an annual budget of $600,000 when Horowitz assumed control in 1953, the City of Hope’s annual budget had grown to more than $100 million by the time he retired in 1981.

Research

In 1983, the City of Hope received a grant from the Arnold and Mabel Beckman Research Foundation. These monies were used to establish the Beckman Research Institute of City of Hope, which is now the label used for all of the larger institution’s research efforts. Already named a clinical cancer research center by the National Cancer Institute, the Beckman Research Institute permitted the City of Hope to expand its research efforts greatly. The City of Hope has great expertise with specific types of cancer, including that of the brain, breast, gastrointestinal system, gynecologic areas, thorax, and urological systems.

The City of Hope has also conducted extensive work with patients suffering from leukemia and lymphoma. In addition to its cancer research, the City of Hope has also been a leader with regard to studies involving other diseases and medical conditions, including diabetes and human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS).

Researchers at the City of Hope have been responsible for several breakthrough discoveries that have received international attention and that have greatly influenced patient care throughout the world. For example, scientists at the City of Hope were the first to produce synthetic insulin, work that was later licensed to Genentech for development into commercial products including pharmaceuticals. A founding member of the National Comprehensive Cancer Network, the City of Hope works with 20 other U.S.-based cancer treatment centers to develop clinical practice standards for patient oncological treatment. Membership in this network also permits City of Hope researchers the opportunity to cooperate and collaborate with scientists at other member institutions, including St. Jude’s Children’s Research Hospital, Fox Chase Cancer Center, and the University of Texas MD Anderson Cancer Research Center.
Patient Care and Outreach
Despite this growth, the City of Hope has maintained an emphasis upon patient care that is unusual among other research-centered hospitals. The City of Hope views itself as a bench-to-bedside institution. This means that the City of Hope practices what is also sometimes referred to as translational medicine. In these situations, a hospital engages in biomedical and public health research that aims to improve the health of individuals and the community. Unlike institutions that are purely committed to research, however, the City of Hope and like hospitals then translate findings made in their laboratories into diagnostic tools, medicines, procedures, policies, and education that can benefit the patients they serve. The City of Hope’s hospital offers 183 beds to serve prospective patients. Patients who are admitted to the City of Hope are served by more than 675 registered nurses and 30 licensed practical nurses. Annually, the City of Hope also provides more than 145,000 outpatient visits and 3,260 inpatient surgeries. For patients in need of these services, the City of Hope also provides 40 temporary, on-site residential housing units, which provide palliative and hospice services as needed.

The City of Hope maintains several centers and institutes that assist it in its efforts to provide outreach regarding its discoveries. In addition to the Beckman Research Institute, the City of Hope is also the home to the Center for Biomedicine & Genetics and the Irell & Manella Graduate School of Biomedical Sciences. The Center for Biomedicine & Genetics serves as a manufacturing facility for the City of Hope. Specializing in the production of pharmaceutical-grade materials for use in experiments and patient treatment, the Center for Biomedicine & Genetics provides support to clinical researchers with regard to clinical trials and other translational medicine needs. The Irell & Manella Graduate School of Biomedical Sciences provides graduate-level study in cellular, chemical, and molecular biology. Seen as a way to train physicians and others to become research scientists with special expertise, the Irell & Manella Graduate School of Biomedical Sciences has gained a stellar reputation over its existence, and its graduates take positions in higher education, at research hospitals, and in private industry.

Clinical Trials
Cancer clinical trials are trials, or tests, designed to rigorously test the efficacy and safety of a procedure, treatment, screening, or preventive measure designed for a specific type of cancer. Cancer clinical trials are essential to the discovery of new technologies useful for the prevention and treatment of cancer through gene therapy, pharmaceuticals, radiation therapy, and surgical procedures.

The cancer clinical trial is a research study involving individuals as human subjects. In most cases, patients are randomly assigned to either a control (i.e., those receiving traditional cancer care) or an experimental group (i.e., those receiving a new or altered treatment or intervention). Patients participate in cancer clinical trials voluntarily and the results of these trials, or studies, is published in peer-reviewed publications. In this chapter, the key players, types, phases, execution of, and special considerations surrounding cancer clinical trials will be discussed. The cancer clinical trial is a necessity for the continuance of the improvement of cancer control.

Key Players in the Cancer Clinical Trial
Cancer clinical trials function with the assistance and leadership of many parties. To take a cancer clinical trial from start to finish, principal investigators (PIs), coinvestigators (Co-Is), physicians, pharmacists, research nurses, research coordinators, as well as a number of other allied and research professionals must collaborate effectively. Interdisciplinary care is now considered a necessity in the cancer clinical trial.
The patient is the key focus of any cancer clinical trial. Patient participation in a cancer clinical trial is completely voluntary; however, individuals must meet very specific inclusion and exclusion criteria to ensure they are eligible to participate in the study. The location of the patient’s cancer in or on the body, cancer stage, her or his age (pediatric vs. adult), and overall health generally determine study eligibility. Pediatric patients, compared to adult cancer patients, are more likely to participate in a cancer clinical trial. According to the National Cancer Institute (NCI), about 90 percent of pediatric cancer patients under age five and about 60 percent of pediatric patients under age 15 diagnosed with cancer participate in clinical trials. Two percent of cancer patients between 20 and 39 years of age participate in cancer clinical trials. The most cancer treatment success has occurred for pediatric cancer patients, likely because of high participation rates.

PIs and Co-Is are responsible for the design, submission, execution, management, and analysis of the cancer clinical trial. PIs and Co-Is typically possess either or both a PhD or an MD (or equivalent) and have extensive prior research experience. PIs and Co-Is are familiar with the landscape of applying for, managing, and receiving monetary grants to conduct cancer clinical trials. PIs are responsible for working with the institutional review board (IRB), the committee charged with adjudicating the beneficence and fairness associated with a research trial, and must respond to any internal or Food and Drug Administration (FDA) audits. At any point in time, a cancer clinical trial can be audited by an internal (i.e., the IRB) or external agency (e.g., the funding agency, FDA, Cancer Therapy Evaluation Program [CTEP] via the NCI, etc.). PIs are also charged with training and supervising members of their research teams and ensuring patients in their studies are treated with the highest-quality health care.

Pharmacists play vital roles in cancer clinical trials requiring pharmaceutical treatments. Research pharmacists maintain drug and study protocol procedures and store and manage pharmaceuticals. They provide expert advice through the length of the trial. Clinical research coordinators (CRCs) are responsible for organizing the day-to-day operations associated with executing the clinical trial. Some CRCs may be registered nurses (RNs). CRCs recruit patients, gain patient consent, schedule patient visits, collect data, manage data or specimens, and ensure the study is completed according to protocol. Some CRCs assist in developing research trial protocols. The CRC grasps not only the design of the cancer clinical trial but is an expert in carrying out procedural details. CRCs typically work hand in hand with the nurses staffing the research team.

Other research staff will likely be involved in the cancer clinical trial, as well, and often play more behind-the-scenes roles. Other staff aiding in the cancer clinical trial process may include biostatisticians, research specialists, compliance specialists, dieticians, social workers, and grants managers. These allied health science professionals provide additional expertise to the team and may help the team analyze and publish results (e.g., research specialists or associates and biostatisticians) on various types of clinical trials in different phases.

**Types of Cancer Clinical Trials and Trial Phases**

There are five primary types of cancer clinical trials (prevention, treatment, screening, diagnostic, and quality of life or supportive care), each performed for a variety of reasons. Unlike in most cancer clinical trials, prevention trials may include healthy participants in order to test interventions aimed at precluding cancer cell development. Other cancer prevention clinical trials include cancer survivors that participate in interventions aimed at preventing cancer recurrence. In treatment trials, investigators test new procedures, techniques, drugs, or combinations of drugs. The goal of the treatment trial is to discover the treatment’s efficacy. In screening trials, investigators test the safest way to detect cancer, even in early stages. Participants in screening trials may be healthy patients, as well, but generally have a higher-than-average risk of cancer. The goal of the diagnostic trial is to identify, or diagnose, cancer with more precision; therefore participants in diagnostic trials have cancer signs and symptoms. Finally, investigators examine how different types of care can best improve the lives and well-being of cancer patients at various cancer stages in quality-of-life or supportive care cancer clinical trials.

Cancer clinical trial phases are the stages of a cancer clinical trial nested inside a given cancer clinical trial. The NCI describes the four phases (I through IV) of the cancer clinical trial and denotes a pre-phase. The pre-phase occurs prior to the cancer
clinical trial and is also known as a pre-phase I trial, Phase 0, pilot study, or exploratory new investigational drug (IND) study. The purpose of the Phase 0 study is to test an IND on a small number of human participants. Generally, between 10 and 15 patients are provided a drug with a limited dosing duration (often only one course is given), wherein no therapeutic benefit is intended. The goal of Phase 0 is to provide information about how the IND works and increase treatment success rates.

The goal of Phase I of the cancer clinical trial is to determine whether or not the drug is safe and a therapeutic dose of the pharmaceutical being tested. At this stage, investigators seek to examine the side effects of a trial drug. Participation in Phase I trials is limited to a small number of patients (near 20). These patients generally have advanced cancer not responding well to standard treatment (if a treatment does exist).

During Phase II, investigators measure the efficacy of the intervention (generally an anticancer drug) and continue to examine the safety of the intervention. Traditionally, Phase II includes somewhere between 50 and 100 patients, but occasionally, as many as 300 individuals will participate in the trial. Randomization is an important research design feature of Phase II. If a treatment is demonstrated to be ineffective in Phase II, investigators will discontinue the line of research, but if they demonstrate efficacy, a trial moves to Phase III.

The goal of Phase III cancer clinical trials is to examine the efficacy of the new interventional treatment compared to the standard treatment traditionally given for a given cancer type. Clinical trial investigators compare the side effects of the new intervention with those associated with the current treatment standard. Phase III of the cancer clinical trial involves several hundred patient participants—up to several thousands of patients—randomly divided into the control or experimental group. The randomization process, or randomization, ensures patients assigned to each group are essentially equivalent. Finally, in Phase IV, patients undergo cancer treatment approved by the FDA. Phase IV is often referred to the post-marketing surveillance trial and is sponsored by a pharmaceutical company. Hundreds to thousands of patients participate in the fourth phase, and generalizability (i.e., measuring and reporting efficacy of an intervention in the general population) is the goal of Phase IV cancer clinical trials. In some occasions, investigators will examine the efficacy and safety of pharmaceutical treatment for a condition beyond the drug’s intended purpose during Phase IV.

**Designing and Executing the Clinical Trial**

The key players of the cancer clinical trials team must design and execute the cancer clinical trial per strict guidelines and follow the protocol written by the PI and Co-Is. The cancer clinical trial begins with the investigators leading the efforts in writing a study protocol. The study protocol outlines all the steps, from start to finish, that the research team will follow to complete the cancer clinical trial. The protocol includes prior research relating to the cancer study in question; goals to be achieved and methods for achieving those goals; recruitment inclusion and exclusion criteria for participants; plans for treatment and managing adverse events; strategies for data analysis; and ensuring the proper protection of human subjects and human subjects’ personal health information. Protocols will vary slightly depending on the type of cancer and trial phase to be examined or conducted.

Research teams must complete research training and receive IRB approval to begin the study. Patients must be informed of their health information privacy rights (HIPAA), and research team members ensure their information is kept secure. Patients must be recruited to participate in the clinical trial. Recruitment is a difficult process that will last most of the clinical trial. The NCI outlines five steps PIs must enact to recruit patients: (1) determine the number of patients needed to complete the trial, (2) outline strategies the research team will employ to ensure just and safe recruitment, (3) screen potential participants for eligibility, (4) enroll and inform eligible participants, and (5) monitor enrollment procedures and results for quality. Some cancer clinical trials are recruited in an outpatient setting, wherein their provider refers them to the study, and other patients search online or government resources to find and enroll in an applicable trial.

Some physicians are very encouraging of cancer clinical trial participation and make appropriate referrals knowing the trial may help a patient and further scientific advancement. Unfortunately, some providers inadvertently serve as a barrier to
clinical trial participation because they are unaware of existing trials to recommend to patients. Some physicians may be hesitant to recommend clinical trials as they assume participation will lead to an increased administrative burden on their practice, which generally is not the case.

The decision-making process in choosing to enroll in a cancer clinical trial can be quite involved for most patients. Patients should consider (1) how the trial may benefit them (if at all); (2) their goals, values, and preferences surrounding treatment, healing, and mental health; (3) their current health status; (4) their life stage goal; and (5) their family's needs or desires. Socioeconomic status, age, racial or minority status, and comorbidity factors (i.e., other health concerns) predict whether or not an individual will enroll in a cancer clinical trial. Many PIs work especially hard to recruit minorities (e.g., Latinos and African Americans), adolescents, adults over age 65, and individuals of lower socioeconomic status. These groups are underrepresented in cancer clinical trials and often face barriers to entry into the health care system in general.

Once recruited for a clinical trial, participants are assigned to either a control or treatment group and subsequently receive standard cancer treatment or investigational treatments, procedures, screenings, and so on. The types of pharmaceuticals or interventions a patient receives is dependent upon the trial type and phase. Not all cancer clinical trials involve drugs, and some may involve alternative medicine or radiation. Importantly, placebos are rarely used in the cancer clinical trial; ethically, patients assigned to the control group must receive standard treatment as they are not given the experimental drug.

Throughout the length of the study, research coordinators or research nurses do continuous monitoring and care of patients. Health care providers assess the patient’s experience of side effects and record them in health record files. Patients may be asked to follow strict procedures regarding self-care should they participate in a clinical trial wherein periods of a treatment or intervention do not occur in hospital or clinical settings. No matter the trial, the research team must (1) keep participants informed of their health status in general and with regard to treatment or intervention, (2) make themselves available to participants to answer any questions, and (3) join patients in the clinical trial journey. Often, members of the clinical research team will follow up with participants regarding their overall health after the completion of a trial.

During the cancer clinical trial, and especially at the conclusion, the investigative team measures and writes about the results of the trial. These results, in manuscript form, are released, and standards of care are changed for the better. A cancer clinical trial—from start to finish—can last for several years, as bringing a pharmaceutical even to Phase I can take months up to a couple years.

Clinical Trial Sites

Cancer clinical trials are typically conducted at inpatient hospital facilities (e.g., academic hospitals, medical centers, or clinics) depending on the nature of the trial or treatment required. Trials can be conducted at one location (single site) or multiple locations (multicenter trial).

The NCI currently designates 41 cancer clinical trial locations as comprehensive cancer centers (CCCs), and another 27 are NCI-designated cancer centers. CCCs are generally located inside academic medical centers and are given the distinction of CCC due to research and treatment excellence. CCCs provide physicians and researchers with expert training, deliver the superior treatment and care to patients (minus seven centers not providing cancer care), focus on community outreach and education, and house interdisciplinary scholars. CCCs are typically located in areas including special and minority populations. NCI-designated cancer centers are not considered the pinnacle in cancer research but are nevertheless quite prestigious.

The National Health Institute (NIH), via NCI, funds and provides support to the Community Clinical Oncology Program (CCOP) Network. The CCOP Network allows physicians at community hospitals and facilities to participate in cancer clinical trials. Thus, patients do not necessarily have to participate in a cancer clinical trial at a CCC or other large research institution. Rather, patients can enroll in a trial wherein care is provided by a physician at a community hospital using the same treatment or intervention protocol as is used at a CCC. This is especially helpful for patients living in underserved regions, like rural areas.
Funding and Sponsoring the Clinical Trial

While participating in a cancer clinical trial, patients may be responsible to pay for standard or routine cancer treatment and care, including provider visits, laboratory tests, hospital stays, or imaging tests. However, patients are not responsible to pay for investigational treatments, examinations, or procedures not traditionally considered cancer standard of care. In the latter case, PIs use funds from various sources to pay for these treatments and for the personnel required to complete a cancer clinical trial. PIs often apply for and receive grant funds to conduct cancer clinical trials from the NCI, the Department of Veterans Affairs, and the Department of Defense. The federal government appropriates billions of dollars to cancer clinical trial research each year (e.g., $4.8 billion for fiscal year 2013).

Along with receiving funds from government agencies, PIs may conduct cancer clinical trials through monies received from volunteer organizations, foundations (e.g., Damon Runyon Cancer Research Foundation), or biotechnology or pharmaceutical groups (e.g., AstraZeneca or Pfizer). Biotechnology or pharmaceutical groups work with PIs, physicians, and pharmacists to conduct industry-sponsored cancer clinical trials. The biotechnology or pharmaceutical group generally pays for the study drug, manages the testing and handling of biological specimens, offers to cover all or some of IRB processing fees, and reimburses study staff for their time.

Benefits and Drawbacks to Cancer Clinical Trials

A number of benefits and drawbacks to conducting and participating in cancer clinical trials are worth noting. First, experts especially encourage patients to consider the benefits and potential drawbacks associated with cancer clinical trial participation. Patients choosing to participate in any trial phase still will obtain the minimum standard of care per their cancer type. Many patients choose to enroll in a cancer clinical trial after exhausting unsuccessful treatment options. Some find success in the cancer clinical trial treatment, but others do not. No matter the outcome, however, many patients do choose to participate in the trial to advance science and help others. Additionally, cancer clinical trial participation can provide patients with additional health services (e.g., diagnostics, devices, etc.) not generally covered by insurance plans. Those managing the cancer clinical trial must make patients fully aware of any potential known drawbacks to trial participation.

Cancer patients do face risks when enrolling in a clinical trial—the efficacy of a cancer clinical trial treatment or intervention is never guaranteed. Furthermore, at times, the side effects of an experimental treatment could be worse than those of the standard treatment. Some research demonstrates the risk of a treatment not working deters some patients. Negative attitudes toward trials or the medical community, perceived travel time and cost, as well as concerns over health insurance coverage can also discourage trial participation.

Albeit of lesser importance, clinical trial participation also benefits and presents risks to PIs and the research team. Through carrying out the cancer clinical trial, PIs gain even more scientific expertise and can help future or current cancer patients. Similarly, PIs and members of the research team can develop advanced research skills and train others to conduct the next generation of cancer clinical trials. As mentioned, not all trials are successful,
Clothing intersects with cancer in numerous ways. Cancer treatment reduces body movement, so loose-fitting clothing is needed for cancer patients and survivors. Breast cancer survivors benefit from clothing that projects a normal appearance. Chemicals, airborne fibers, and dust created in the manufacture of clothing can be carcinogenic.
and an occupational hazard for clothing workers. For some time, it was thought that men's tight-fitting clothes were a cause of testicular cancer, although there is no current evidence to support this concern. This entry presents the positive side of clothing as a protector of the body against cancer. But to protect, clothing must be comfortable, affordable, and stylish, or it will find resistance in being used. This resistance can be countered with educational campaigns and through supervision at workplaces, schools, and public outdoor venues. Protective clothing in factories and foundries, such as safety helmets, gloves, and boots, is also resisted but becomes habitually used through a combination of safety campaigns and supervision.

The skin is the largest organ of the body and a major site of cancer. In the United States, there are a million cases of skin cancer each year. The world’s highest skin cancer morbidity is reported in Australia, where 400,000 cases are treated annually. The main cause of skin cancer is from exposure to the sun’s ultraviolet rays, which are highly energetic and damage the skin cells’ DNA. Fortunately, skin cancer can be treated, and the patient can fully recover if the cancer is treated early enough. However, cancer prevention rather than treatment is the most recommended approach.

In recent decades, the concern has substantially increased that sun exposure is a major source of skin cancer and a drain on health resources. The main countries experiencing this concern are Australia and the United States. The reduction in the Earth’s atmosphere’s protection against ultraviolet rays was first noticed in Australia, where light-skinned people of European stock were found to be at risk. The ozone hole noticed over Australia was the apparent cause of that increased risk. Atmospheric ozone provides a shield against damaging ultraviolet rays. The loss of ozone removed that protection and led Australia to become the world’s leading advocate for reducing skin cancer through seeking solutions for excessive sun exposure and its carcinogenic effects.

There are four ways to reduce skin cancer from the sun: (1) avoid exposure to the sun by remaining indoors; (2) cover the skin with lotion that blocks the passage of ultraviolet rays; (3) cover the body with protective clothing and the face with a broad-brimmed hat; and (4) restrict sun exposure to hours when the sun is low in the sky and the distance the sunlight must travel through the atmosphere increases its filtering of harmful rays. While sunscreen is more recognized, Australia has led in promoting protective clothing as a method against sun damage.

The advantages of using clothing for skin protection in principle include ease of use, permanence (it doesn’t wash off), and preventing much harmful ultraviolet rays from reaching the skin. Socially, completely covering the body may be seen as an act of modesty. The disadvantages would include limitation of movement, retaining heat on hot days, cost, and social issues of style.

While it would seem clear that covering the skin with cloth would protect against the sun, there are unseen issues with different types of cloth and how they are worn. Light fabrics may not shield the skin in the way anticipated. In studies, one-third of summer fabrics were found to provide an ultraviolet protection factor (UPF) of less than 15. Fabrics with loose weaves can admit the sun. Stretching fabric over the skin can reduce its coverage. Questions about how a fabric responds to perspiration or immersion in water have arisen, with most fabrics losing a majority of their protection when wet. Tight weaves and dark dyes protect more but are uncomfortable in heat. The result has been the development of standardized tests to measure the protective factor of cloth that are the equivalent of the UPF ratings for sun lotion. This has been of particular concern for clothes used for beachwear and outdoor recreation active wear. Parents have been concerned about their children's protection as well. Clothing is now marketed with its protective rating. In addition, chemicals that increase a fabric’s protective strength have been developed and are on the market. They too are rated according to the UPF standard system as well as the number of washing cycles the chemical effects are measured to withstand.

The disadvantages of wearing protective clothing vary with the age of the wearer. Children's skin has been found to be the most vulnerable to sun exposure and resulting skin cancer later in life. So parents have been responsive to public health messages to cover up their children's skin. Schools in Australia have found the parents to be effective advocates for policies to reduce the time at play outdoors, keep the children covered with proper clothes and hats, and provide shade sails.
against playground sun. Children may resist being covered with clothing on hot, summer days and, unless supervised, are likely to remove them. But if parents and teachers are consistent in supervising young children and demanding that they use protective clothing, the habits that they establish will be long lasting. Safety campaigns with protective clothing used in industry have found that consistent supervision will establish those safe habits, along with messages that attempt to change the workers’ orientation to safety. A safety culture will promote the value of preventive actions.

Young adults value their bodies and also resist the use of clothing that cover those parts of themselves they perceive as attractive and want to display. The literature that has appeal to young people is both a reflection of their values and a leader in setting trends and styles. A study of women’s photographs in Australian magazines found that messages contrary to those of public health campaigns were prevalent. The measures of the inherent messages in these photographs included the tanning of the model’s skin, the amount of bodily exposure, whether the model was in the sun or shade, and whether a hat was worn. However, there was no way to discern whether the model had used sunscreen lotion. The messages appeared to be that tanning, bodily exposure, and sunning were socially acceptable and even desirable. Another concern was the finding that the older models were more likely to be shown with less tanning and greater skin covering. So it appeared that the values of young people, who are most vulnerable to skin damage, are the least supportive of prevention. One way that the protection message can communicate with young people substitutes premature skin aging and wrinkles for the risk of skin cancer. By portraying tanning and burning as a precursor to looking old, the risk communicates directly to the target population.

Among the older population, skin damage is likely to be already apparent in skin aging. Covering the skin with clothing is still important for this age, and public health campaigns are needed to directly confront the skin cancer risk these people face from repeated sun exposure. Studies can be done of the effectiveness of public health campaigns to cover up by observing people’s behavior. Australian research work has found some evidence that these campaigns are effective, but after they are over, the public tends to revert to their former behavior. The problem appears to be a disconnect between what people know is good in the long term for cancer prevention and short-term advantages of style and conformity to youthful social values.

There are ways to address this problem. Public health campaigns to cover up can be measured for their effectiveness, and the more-successful messages can be identified and perfected. Locations where attention is needed can be identified for a public health response. Australian studies have found two venues where people are most likely to admit experiencing sunburn, an indicator of excessive exposure. Beaches and sports venues each had a 22 percent admission of sunburn. Prevention messages are needed at both venues and can be targeted to their audiences. With concerted efforts at public health education and supervision where appropriate, the public can learn necessary protective clothing habits.

Coal Industry

Coal is a brownish-black sedimentary rock that is the most abundant fossil fuel on earth. Coal is composed of carbon, oxygen, hydrogen, nitrogen, sulfur, and a mixture of minerals. The carbon
and hydrocarbon content of the coal rock make it combustible and an accessible source of energy. Statistics from the World Coal Association indicate that, globally, coal provides around 30 percent of the world’s primary energy needs and provides approximately 40 percent of the world’s electricity.

Coal is found on every continent, with recoverable reserves that are economically extractable in about 70 countries. The largest coal reserves are found in the United States, Russia, China, India, and Australia. Approximately 25 percent of the world’s coal content can be found in the United States. The majority of coal mined in the eastern United States is located in an area of largely rural and mountainous terrain that extends from southern New York to Mississippi, known as Appalachia. Specifically, eight states are considered the Appalachian coal mining region: Alabama, Kentucky, Maryland, Ohio, Pennsylvania, Tennessee, Virginia, and West Virginia. The majority of coal mined in the western United States is found in the Powder River Basin, which includes the states of Montana and Wyoming. However, several other states have active coal mines that perform underground and surface operations.

Estimates indicate that, at the current rates of production, there is up to 200 years of coal in reserves worldwide. However, with improvements in mining techniques and technology, reserves that are currently inaccessible may be able to be reached and extracted more easily in the future. Due to the abundance of recoverable coal reserves and the longevity of the coal mining industry, it is important to remain cognizant and responsive to the health and environmental impacts of coal mining and what risk-reduction methods can help minimize the occurrence of these associated health consequences. Therefore, after discussing types of coal and coal mining, this entry focuses on environmental and societal concerns of mining coal and control methods in place to alleviate these concerns.

**Types and Uses of Coal**

Coal forms from years of intense physical and chemical pressures that act to transform the Earth's vegetation into peat and eventually coal, a process known as coalification. Coalification is classified by rank, the degree of transformation of the original plant material to carbon. There are four types of coal: lignite, subbituminous, bituminous, and anthracite. These four types of coal vary in rank from lowest percentage of carbon to the highest percentage of carbon, with the lower-rank coal having more hydrogen and oxygen.

Lignite coal is the least mature and softest of the coal types, having been exposed to the extreme temperature and pressure for the shortest amount of time. Lignite coal is more accessible because it is closer to the surface. However, lignite coal also has the highest sulfur content of all the coal ranks. So, when combusted, it results in the release of elevated amounts of pollutants such as sulfur dioxide (SO₂). According to the Lignite Energy Council, about 79 percent of lignite coal is used to generate electricity, 13.5 percent to generate synthetic natural gas, and 7.5 percent to produce fertilizer.

Subbituminous coal, like lignite, is found closer to the surface and thus is cheaper to mine than higher-ranking coal. Similar to lignite, the main use of subbituminous coal is power generation. Both lignite and subbituminous coal are softer coals but subbituminous has been exposed to the extreme conditions for a longer period of time. Subbituminous coal generally has lower sulfur content and, as a result, burns cleaner than lignite. Further transformation, resulting from longer exposure to extreme temperature and pressure causes the lower-ranking coal rock to harden and become darker. As a result, the last two coal ranks are known as the hard coals.

Bituminous coal is the most plentiful type of coal, making up approximately 50 percent of the world’s coal reserves. Bituminous coal consists of two different types: thermal and metallurgical. While thermal coal is used in power generation, metallurgical coal primarily is used in steel and iron production.

Anthracite coal is the hardest, has the highest rank, and contains the highest carbon content of the four coal types. This type of coal is mostly associated with domestic and industrial heating. The World Coal Association indicates that there is less than 1 percent of anthracite reserves in the world.

Although coal is primarily used for power generation, several industries benefit from coal, including alumina refineries, paper manufacturers, and chemical and pharmaceutical industries. For example, coal is necessary to produce cement and steel. In addition, thousands of products have coal or coal by-products included in their component makeups, such as soap, plastic, nylon, aspirin, and dye.
Types of Coal Mining

The coal industry utilizes two methods to mine coal: surface mining and underground mining. Surface mining, also called opencast or open-pit mining, is used when the coal seam is near the surface and the coal can be recovered after the overlying soil and rock, referred to as overburden, is removed. Once the overburden is removed, large pieces of equipment including draglines, power shovels, and excavators are used to retrieve the coal. Large haul trucks and conveyors are then used to transport the coal to where it can be processed or used. Once all of the recoverable coal is removed, the area can be backfilled to promote land reclamation. In surface mining, lignite and subbituminous coal are most often mined.

Underground, or deep mining, is used when the coal is hundreds of feet below the ground. Two methods for underground coal mining include continuous or room and pillar mining and longwall mining. Longwall mining is the most productive underground mining method. In longwall mining, coal mine workers extract coal from a long section of the coal seam using mechanical shearers. Continuous mining machines are also used during development of the longwall sections. Underground mining requires detailed geological exploration and mapping to ensure that the geology is satisfactory to run shafts underground and that the roof can be securely supported to avoid collapsing while the mine is active. Common types of ground and roof support include steel ribs, concrete segments, steel and cable bolts, and wire mesh.

Both surface and underground coal mining result in the production of emissions that can pollute both the air and water. These environmental concerns are discussed next.

Environmental Concerns

Coal mining consists of several phases from mining the coal to processing, storing, and transporting it for eventual use. Throughout these phases, environmental concerns are always present, including harmful emissions into the air and water, potential impacts on global warming, and changes in land surface characteristics.

Air emissions from coal mining mainly consist of fugitive dust, diesel emissions, and methane. Fugitive dust, including coal dust, rock dust, and crystalline silica, is generated during the mining process by breaking the rock and also results from piles of uncovered coal and overburden when wind action suspends the dust into the air. Diesel emissions, including diesel particulate matter and oxides of nitrogen, from the large diesel engines used in mining, are also emitted into the atmosphere. Finally, methane is a greenhouse gas created during the coalification process. The mining of a coal seam with entrapped methane results in methane release. The deeper the coal seam, the greater the methane content of the coal. The World Coal Association estimates that underground coal mining accounts for 90 percent of methane emissions from the coal mining industry. Although the air emissions already discussed are generally associated with occupational exposures, due to the rural and isolated locations of coal mines, once in the air, there is potential for these emissions to reach nearby populated areas, resulting in public exposure to these emissions.

Water emissions from coal mining mainly consist of sediment and acid mine drainage. Sediment can be created during the mining process as water runs through the mine or when rainwater washes over uncovered piles of coal or overburden. Acid mine drainage results from water reacting with minerals released from the rock during the mining process. It is common for water released from mine sites to contain a higher concentration of sulfates, calcium, magnesium, selenium, arsenic, and other metals than their nonaffect counter bodies of water. Additional water contamination occurs as a result of coal washing, a process that applies chemical formulas containing surfactants, flocculants, and other agents to prepare coal for use in combustion. The result of this process is the formation of slurry that is stored in surface ponds that can leach into groundwater or is injected underground into old mining spaces.

In addition to air and water emissions, mining can also change the landscape of mined environments by a mining technique known as mountaintop mining or by land subsidence. Mountaintop mining is a surface mining technique where mountaintops are removed to expose coal. Not only does removing mountaintops change the topographical terrain and destroy forests, but the overburden, once removed, may be placed in valleys or streams, creating additional sediment pollution and further disturbing the natural biodiversity in the environment. Subsidence, although rare, is the readjustment of
the ground surface resulting from the collapse of underground mine workings. Subsidence results in the formation of a sinkhole or trough, which may result in major impacts on surface waterways and structures.

Health and Safety Concerns
In addition to their environmental impacts, emissions resulting from both the mining and the combustion of coal have been linked to adverse health consequences on the human population, including certain types of cancer. Several pollutants released into the environment from coal mining are of particular concern including coal mine dust, crystalline silica, diesel particulate matter, and arsenic.

Arsenic in drinking water can increase risks for lung, bladder, or kidney cancer. Crystalline silica has been associated with increased risks of lung cancer and silicosis, a debilitating respiratory disease. Several U.S. studies conducted by Michael Hendryx and colleagues concluded that living in coal-mining locations, such as the Appalachian region, is an independent risk factor for developing lung cancer and other health-related problems including colon, bladder, leukemia, and kidney cancer. Specifically, studies conducted with adults in two West Virginia communities, one in a mining area and the other in a nonmining area, found significantly higher self-reported cancer rates in the mining area after controlling for age, sex, smoking, occupational history, and family cancer history. Also, in June 2012, diesel particulate matter was classified by the International Agency for Cancer Research as a known human carcinogen.

Coal mine workers are an especially vulnerable population who experience greater risks because they are exposed to occupational pollutants, including respirable coal mine dust, crystalline silica, and diesel emissions, daily and over an extended period of time. Globally, hundreds of thousands of individuals have careers as coal mine workers, indicating a large population being directly and consistently exposed to coal mine-related pollutants. The American Cancer Society noted that occupational exposure to cancer-causing substances, or carcinogens, accounts for about 4 percent of all cancers in the United States. Coal mine workers are thought to be at increased risk for diseases such as heart disease, chronic obstructive pulmonary disease, and lung cancer.

More specifically, Coal Workers’ Pneumoconiosis (CWP), or black lung disease, is the leading cause of death due to occupational illness among underground coal mine workers. Silicosis, resulting from continued exposure to respirable crystalline silica, is more common for those who work on the surface of mine sites, although silica can be inhaled when coal seams are cut as well. With diagnoses of CWP or silicosis also come associated health problems such as lung cancer, autoimmune disorders, pulmonary tuberculosis, and chronic renal disease.

From the early 1980s to 2006, the underground coal mining industry experienced little change in levels of exposure to respirable coal mine dust. However, a chest X-ray surveillance program initiated by the National Institute for Occupational Safety and Health, which conducts preventative and diagnostic screenings of participating coal mine workers, found that, after many years of decline in the incidence of CWP, the prevalence of the disease is on the rise again. For example, between 2000 and 2005, data from the U.S. Department of Health and Human Services (HHS) indicated that CWP contributed to the deaths of close to 3,900 coal mine workers. This recent increase supports the need for additional risk reduction mechanisms to maintain the health of coal mine workers, specifically.

Because of the importance of coal energy to the world economy, it is necessary to continuously evaluate and create methods to help mitigate the exposure of coal miners and the public to hazardous emissions associated with coal mining as well as reducing the impact of coal mining on the environment.

Risk Reduction Efforts for Environmental and Societal Health
The coal industry and pertinent regulatory agencies remain vigilant in researching and adopting methods to help reduce and control respirable dust and pollution levels to help protect the environment and the public. In response, emissions of many of the pollutants that put individual and environmental health at risk are regulated and controlled to some degree.

The Environmental Protection Agency (EPA) proposes and modifies regulations to minimize risks generated from coal power plants and producers. Under the Surface Mining Control and Reclamation Act of 1977, it is required for land impacted by mining
Coal provides around 30 percent of the world’s primary energy needs and provides approximately 40 percent of the world’s electricity. Emissions resulting from both the mining and the combustion of coal have been linked to adverse health consequences on the human population, including certain types of cancer. (MorgueFile)

to be reclaimed for other uses. This act requires that mine companies reclaim land where coal has been extracted already. Closed mines can become housing units, farmlands, forests, or even public parks. For instance, in the European Union, more than half of mining lands are reclaimed as forests or grasslands, whereas in China, a majority of reclaimed mining lands are used for agriculture purposes.

Another environmental regulation is the 1976 Resource Conservation and Recovery Act (RCRA). This regulation indicates that any hazardous waste that results from mining be treated and stored properly and then disposed in a way that protects the environment and surrounding individuals. For example, in 2010, the EPA proposed to regulate coal combustion residuals under the RCRA. Further, in 2012, under the Clean Air Act, the EPA proposed a new source performance standard to limit emissions of carbon dioxide from new, fossil fuel-fired, utility-generating units, which includes coal and natural-gas-fired units. Limiting these emissions is expected to reduce greenhouse gas pollution.

Although regulations require an increase in accurate environmental assessment and rigorous planning, these strategies ensure that mining companies remain in compliance regarding protecting the environment from air, water, and gas pollution, thus providing more protection for individuals who reside in mining areas as well.

Absent of regulations, however, the coal industry makes several efforts to minimize harmful environmental consequences of mining coal. New technology at power plants helps keep air clean during the cleaning and processing of coal. One example of such technology includes an integrated gasification combined cycle (IGCC), which is a coal gasification process that turns coal into a gas before burning it, resulting in cleaner air. In addition, the coal industry has been actively involved in researching methods to extract the methane from coal and preventing its release into the environment. The capture of methane before it is released both reduces emissions of greenhouse gases as well as improves the safety of underground coal mines. Explosions in
underground mines result in loss of lives worldwide, and while any loss of life is too high, the number of explosions has been steadily declining as methane recovery technologies have been improved and deployed on a wider scale.

Due to the nature of their occupation, the environmental-based regulations and research do not fully protect coal mine workers, who are exposed to more respirable dust than the rest of the public. As a result, coal mine workers have a greater risk for various types of cancer and respiratory diseases than the general public. However, there are specific risk reduction efforts that target this at-risk group of individuals.

**Risk Reduction Efforts for Mine Worker Health**

Because the process of mining coal results in the potential for increased occupational exposures to coal dust and other pollutants, risk reduction efforts are needed on regulatory, organizational, and individual levels to best protect coal mine workers. For instance, in the United States, the Mine Safety and Health Administration (MSHA) promulgated regulations that limit the exposure to respirable coal mine dust to an average of 2.0 milligrams of respirable dust per cubic meter of air (mg/m³) over a standard work shift. Mine operators are responsible for regularly collecting respirable dust samples in active, working mines. If the results exceed the allowable average dust level, the mine must take corrective action to reduce the average concentration of respirable dust to below the permissible concentration. In addition, the mine operators must continue sampling until they measure dust concentrations below the allowable limit on five sequential samples.

Internationally, respirable dust regulations vary. In Australia, different mining areas such as New South Wales, Queensland, and Western Australia have separate health and safety regulations. In New South Wales, mine operators at each mine must ensure that no mine worker is exposed to more than 3.0 mg/m³ of respirable dust or 10.0 mg/m³ of inhalable dust over an eight-hour sampling period.

In addition to regulating allowable airborne dust concentrations, new advances in mining technology can help to (1) minimize the creation of dust and (2) allow individuals to more accurately monitor their dust exposure on the job. The National Institute for Occupational Safety and Health (NIOSH) has completed numerous studies to recommend the best methods to control exposure to airborne dust in coal mining. These researchers have found that technology controls, water spray systems, and ventilation systems function as protective devices to help prevent the formation of dust, suppression of dust to prevent it from becoming airborne, and removal or dilution of the dust once it is airborne. For example, water spray systems can help suppress or redirect dust away from mine workers and walkways. In addition, scrubbers can be mounted on existing mining machines to help move air and capture dust while mining coal. Improved ventilation systems can also dilute dust concentrations after becoming airborne.

The control methods already discussed are applied to help reduce the concentrations of airborne dust that reach the inhalable breathing zones of coal mine workers. However, personal protective equipment (PPE), such as an airstream helmet or respirator, can be worn by coal mine workers to reduce the amount of dust actually inhaled. This PPE functions as a barrier between coal mine workers and respirable mine dust. Other equipment can be used to help mine workers monitor their exposure to dust throughout the workday. Specifically, a continuous personal dust monitor (CPDM) is available to the coal mining industry that can provide mine workers with near real-time feedback on their exposure to respirable coal mine dust. If mine workers and mine site safety personnel know how to properly use and communicate about the information provided by CPDMs, they may be able to make adjustments to the workplace and work procedures to try to reduce their exposure to respirable coal mine dust as they complete work tasks.

Even though risk reduction methods are in place, exposure can still occur through breaches in these regulations, accidents, or inability of individuals to recognize and mitigate these hazards in their surrounding environment. Therefore, a final area of prevention includes education that empowers mines and respective mine employees to take action to reduce their exposure to respirable coal mine dust on the job. Educational interventions that seek to motivate and persuade changes in mine workers’ behaviors to lower their exposure to respirable coal mine dust can enhance methods used by mine
workers to reduce personal dust exposure and, consequently, the incidence of CWP. For example, if mine workers are aware of the areas that produce more dust and can stand in different positions, or are trained in the use of technology to reduce the concentrations of dust, they immediately have more control over their dust intake on the job. These changes in work behaviors can ultimately lead to improvements in coal miners’ longevity and quality of life.

Conclusion
This entry discussed the positive uses of coal while acknowledging the negative impact coal mining can have on the environment and individual health. Because of the pros and cons that exist due to coal mining, a systematic approach is needed to address some of the drawbacks, so the nation can continue to benefit from coal and coal by-products. Risk reduction efforts were discussed on a policy, organizational, and individual level that are used to protect the environment, general public, and coal mine workers as much as possible. Specifically, participating in strategic planning before mining, including ways the land can be reclaimed, enforcing health and safety policies, leadership engaging in surveillance of mine worker behaviors, and mine worker education and empowerment are crucial to preventing the onset of cancer and other adverse health effects for individuals who experience consistent exposure to carcinogens emitted from coal.

Cold Spring Harbor Laboratory
Founded in 1890, Cold Spring Harbor Laboratory is a private, not-for-profit research institution that has more than 52 laboratories. Known for its prowess in research related to cancer, genomics, neuroscience, plant genetics, and quantitative biology, Cold Spring Harbor Laboratory also has a strong educational component to its work. The home to many notable researchers, including a group of Nobel Prize winners, the Cold Spring Harbor Laboratory conducts
cancer research that touches upon a variety of cancer genomics, drug resistance, gene regulation, and other topics. Scientists at the Cold Spring Harbor Laboratory collaborate with researchers at a variety of other institutions.

Originally sponsored by the Brooklyn Institute of Arts and Sciences, Cold Spring Harbor Laboratory was initially known as the Biological Laboratory. In its first years, it served as a summer program where college and university students and high school teachers interested in botany, comparative anatomy, nature, and zoology could engage in fieldwork. In 1904, the Carnegie Institution for Science established the Station for Experimental Evolution at Cold Spring Harbor on a parcel adjacent to that of the Biological Laboratory. Through the late 1930s, the laboratory’s major emphasis was eugenics, a now largely discredited field that examined how to improve the human gene pool. During the 1920s, research began on how cancer affected mice, especially their susceptibility to certain types of sarcoma. After Milislav Demerec was named director of the Cold Spring Harbor Laboratory in 1941, however, the institution’s focus shifted to the genetics of the microbe, work which was to prove instrumental in later cancer studies.

Under Demerec’s leadership, the Cold Spring Harbor Laboratory developed what became known as the Phage Course, which played a key role in the development of molecular genetics. Many scientists who took the Phage Course went on to conduct studies that helped determine the physical basis of the gene. In 1953, James Watson first presented his findings on the structure of deoxyribonucleic acid (DNA) at a Cold Spring Harbor Laboratory symposium, a talk that radically changed the future of biological research. In 1968, Watson would return to Cold Spring Harbor Laboratory as its director. Watson changed the laboratory’s focus to concentrate upon the study of cancer. In 1969, Watson succeeded in hiring virologist Joe Sambrook, who began a tumor virus group.

Since this time, the Cold Spring Harbor Laboratory’s cancer studies have thrived, and there has been a large expansion and broadening of its research. The facilities at Cold Spring Harbor Laboratory are world-class and have benefited from expanded educational programs. Since 1998, Cold Spring Harbor Laboratory has been a PhD degree–granting institution, culminating in the founding of the Watson School of Biological Sciences in 1998 and the establishment of the Cancer Genome Research Center two years later.

Cancer Research
Cold Spring Harbor Laboratory has long been on the forefront of cancer research. In 1972, scientists Joseph Sambrook, Phillip Sharp, and William Sugden developed a technique for separating and visualizing DNA fragments that continues to be used throughout the discipline of molecular biology. Nine years later, Michael Wigler discovered the first cancer-causing gene in a human tumor, and in 1988, Edward Harlow and his associates established a functional link between oncogenes and tumor-suppressor genes, the two general classes of cancer-causing genes. In 2004, Scott Lowe and his colleagues established a promising combination therapy for treating many cancers that did not respond to traditional chemotherapy, an approach that has been widely emulated by practitioners worldwide. The same year, Wigler detected a degree of large-scale variation in the copy number of genes in otherwise normal human genomes by using a technique that was initially developed to detect differences between normal cells and cancer cells. In 2005, Gregory Hannon, Scott Lowe, and Scott Powers discovered microRNAs as new targets that helped improve the diagnosis and treatment of a variety of cancers, including lymphoma, colon cancer, and others.

Researcher Chris Vakoc in 2011 began using an unconventional approach to cancer drug discovery. Vakoc’s approach identified new potential treatments for acute myeloid leukemia (AML). AML is an aggressive blood cancer that is incurable in approximately 70 percent of patients. This approach is being developed for therapeutic use for cancer patients by a major pharmaceutical corporation. Working with researchers at five other institutions, Vakoc identified a protein called Brd4 as a novel drug target for AML. Using drugs that impede the activity of Brd4, Vakoc’s team was able to suppress the disease in experimental models. These works are part of Cold Spring Harbor Laboratory’s cancer therapeutics initiative, which seeks to identify new therapeutic targets and then to quickly validate them using mouse models that closely mimic the behavior of specific human cancers. This approach has two advantages. First, it offers insights into
cancers’ molecular mechanisms. Second, this pre-clinical testing approach permits researchers to evaluate a specific cancer’s response to new treatments and to discern information that can adjust and adapt treatment strategies so that the success rates of pharmaceuticals that eventually enter clinical trials are increased.

Through its PhD program, Cold Spring Harbor Laboratory strives to produce researchers who are able to become leading scholars in the fields of cancer research and other disciplines. In addition to its own program, Cold Spring Harbor Laboratory collaborates with the State University of New York at Stony Brook to offer a variety of shared graduate programs. These shared graduate programs include those in genetics, molecular and cellular biology, molecular genetics and microbiology, and neurobiology and behavior.

The Cold Spring Harbor Laboratory annually offers a variety of programs that draw more than 10,000 researchers. In addition, each summer approximately 25 undergraduate students from across the globe come to Cold Spring Harbor Laboratory to participate in a 10-week program that permits them to work with researchers on projects. Summer projects span a variety of disciplines and have included work in cancer biology, neuroscience, plant biology, cellular and molecular biology, genetics, and bioinformatics and genomics. This undergraduate research program has been highly successful as it permits college and university students the opportunity to conduct original research, allows interaction with graduate students and senior researchers, introduces them to the physical and intellectual tools used in biological research, and exposes them to the research process. The program has been widely emulated by other institutions of higher learning and is seen as a key avenue for recruiting future cancer researchers.

Colombia

Colombia, officially known as the Republic of Colombia, is a country situated in the northwestern corner of South America. It is bordered to the south by Ecuador, the northwest by Panama, and the east by Brazil and Venezuela. The country shares maritime limits with Haiti, Costa Rica, Honduras, Nicaragua, Jamaica, and the Dominican Republic. Despite the fact that the republic is comprised of more than 30 percent of the population living under the poverty line (according to the National Administrative Department of Statistics in 2013), it is known as one of Latin America’s main health tourism destinations. This is due to the fact that there are many quality health care professionals, an immense number of architectural and natural sites, and several institutions devoted to health.

The Columbian League Against Cancer
There are many Columbian organizations dedicated to the fight against cancer. One such organization is the Colombian League Against Cancer: a private, nonprofit, nationwide organization that was created in 1960 to take action to promote cancer education, early diagnosis, and prevention-utilizing volunteers.

Over the course of the organization’s life span, more than 30 subleagues and sectional chapters have been created to further its mission to improve the quality of life for cancer patients. The overall organization is committed to quality safe care actions that reduce the risk to the patient, the family, and his or her doctors.

National Cancer Institute
Another cancer-related organization is the National Cancer Institute of Colombia, which is well-known for its resources across the developing world. Some of the best doctors in Colombia work here. The organization has a special partnership (winning
program) with the World Child Cancer organization, which has led to valuable training and mentorship for its doctors.

The institution of the Colombian state works nationally for comprehensive care for cancer patients as well as promotes the training of talented doctors, research for new solutions, and development of public health actions. Some of its guiding principles include commitment, honesty, respect, loyalty, equity, solidarity, quality, comprehensiveness, efficiency, and social participation.

**Types of Cancer**
The leading types of cancer in Colombia are breast cancer (number one for women), stomach cancer (number one for men), lung cancer, prostate cancer, cervical cancer, colorectal cancer, and liver cancer. Many of these cancers have seen a slight decrease over the last decade, due to educational and early prevention efforts.

In terms of prostate cancer, one highlighted diagnosis belongs to none other than Colombia’s president, Juan Manuel Santos, who was diagnosed with the disease around the age of 61. He underwent surgery and was able to recover. Santos is the latest in a long line of Latin American leaders who have been diagnosed with cancer.

**Melanoma (Skin Cancer).** Melanoma is also of large concern to Colombians, as the country sits near the equator. The increased risk of developing skin cancer occurs due to unprotected exposure to harsh sunlight in the first 15 years of life. The disease is cumulative and manifests in adulthood. Colombian state organizations post warnings about the disease and warn citizens to wear long sleeves and dark glasses and use sunscreens. Those who have light skin tones, hair, and eyes are more likely to get skin cancer. Melanoma-based efforts are headed by the Colombian Skin Cancer Foundation.

**Breast Cancer.** Unlike some other cancers in Colombia, breast cancer is on the rise—especially in women. Currently, about 6,000 Colombian women receive a positive diagnosis for the disease each year, and about 2,500 die as a result of it, according to the Colombian League Against Cancer.

According to the World Health Organization (WHO), most of those killed by breast cancer are women from developing countries. This is due to late diagnosis and difficulties in receiving timely and accurate treatment. On a global level, 545,000 women die annually from the disease.

According to the Colombian League Against Cancer, the rate of breast cancer doubled in the country from 2002 to 2007, and the National Institute of Cancerology has pointed out that it may easily become the leading cause of death among Colombian women age 50 to 69 if the current rates of occurrence and mortality do not decrease. Some say the increases are due to chemical used in crops and beauty products, while others blame fast food for the rise. GLOBOCAN, the WHO’s body in charge of health statistics, reports that breast cancer makes up more than 20 percent of all cancers globally.

Unlike cervical cancer, breast cancer in Colombia is highest among wealthy women. Though the cause of this is unknown, risk factors may include late last menstruation, early menstruation, relatives who have suffered breast cancer, obesity, absence of breast-feeding, and frequent alcohol consumption. Women who have had breast cancer are 0.5 to 1 percent more likely to develop breast cancer in their other breast within 10 years of the first diagnosis. Women who are younger than 35 are thought to have a greater risk of a second breast cancer occurrence. Breast cancer is treatable with early detection using mammograms and self-examination to detect lumps that may be cancerous.

**Childhood Cancer.** Each year, more than 29,000 children under 15 are diagnosed with cancer across Latin America. About 9,000 of these children die. In Colombia, specifically, 300 cases develop, and 500 deaths occur, according to the Ten-Year Plan for Cancer Control in Colombia, 2012–2021.

Cancer care for children requires a large effort by families and institutions. Many cancer fatalities in children occur because they drop out of their treatments due to financial issues, treatment inaccessibility, or otherwise. According to the Ministry of Health, children who do not drop out of treatment have a 75 percent survival rate, while those who do drop out of treatment have a survival rate of only 25 percent.

**Conclusion**
Though Colombia is well-known for its resources across Latin America, there are many ways in which it still must strive to become a country that is known
for its dedication to early detection and prevention. New health initiatives and laws across the country should decrease the number of deaths occurring from cancer, though breast cancer, in particular, continues to rise regardless of these efforts.

Colon Cancer

Colon cancer (also known as colorectal cancer when inclusive of rectal cancer) refers to the uncontrolled, unchecked malignant growth that originates in the large intestine, generally as adenocarcinoma. In most occurrences prior to malignancy, an adenomatous polyp forms as the benign neoplastic precursor, of which only a fraction might progress to cancer. Colon cancer may also develop in the setting of inflammatory bowel diseases (ulcerative colitis or Crohn's disease) without an adenomatous polyp precursor. Risk factors include age, family history, race, and also high caloric intake, low-fiber diet, tobacco, alcohol, and low-serum selenium. Low-fat and high-fiber diets, supplementation with calcium or vitamin D, regular usage of nonsteroidal anti-inflammatory drugs, physical activity, and ingestion of fish oils are associated with lower risk. Within the colon, an interaction between colon stem cells and the local environment ultimately triggers genomic instability in a stem cell, which progresses through histological stages from aberrant crypt foci to adenoma to cancer, paralleled with genetic changes that involve the adenomatous polyposis coli (APC), KRAS, and TP53 genes for most sporadic cancers or epigenetic inactivation of the DNA mismatch repair gene hMLH1 to cause microsatellite instability (MSI), a genetic signature observed in 15 percent of sporadic cancers. Patients with adenomas and early colon cancers are generally asymptomatic, and to detect these requires a screening intervention and ultimately colonoscopy to biopsy or remove the lesion if amendable. Patients with advanced cancers may present with iron deficiency anemia, weight loss, stool pattern changes, hematochezia, or abdominal pain.

Hereditary Colon Cancer

A strong family history of colon cancer may indicate a hereditary or familial colon cancer syndrome. Often, cancer presents at young ages in these families and affects more than one generation. There are two groups based on the type of polyps that form: adenomatous and hamartomatous syndromes. Among the adenomatous syndromes, Lynch syndrome is the most common, and families may present with colon cancer, cancers of the female reproductive tract, cancers of the urinary tract, and other gastrointestinal tract cancers. Lynch patients are found with germline mutations in DNA mismatch repair genes, such as hMLH1 or hMSH2, transmitted autosomally. Familial adenomatous polyposis (FAP) families demonstrate multiple to thousands of adenomatous polyps in their colon, with near 100 percent certainty of developing colon cancer without any intervention. FAP families carry a germline mutation in the APC gene that is transmitted in an autosomal dominant fashion. MYH-associated polyposis (MAP) is transmitted in an autosomal recessive pattern through biallelic mutations (one from each parent) of the MYH gene. MAP patients have few to hundreds of polyps in
their colons and present in a similar fashion as FAP patients. The hamartomatous syndromes include juvenile polyposis, Peutz–Jeghers syndrome, and PTEN hamartoma syndrome. These syndromes are rarer than the adenomatous syndromes and require a high index of suspicion for recognition. Most of these syndromes can be determined by genetic testing, with subsequent appropriate surveillance for cancers to reduce morbidity and mortality at young ages.

Screening and Prevention
Because of the asymptomatic nature of precursor adenomatous polyps and early colon cancers, and their curability when found early as compared to symptomatic colon cancer, screening asymptomatic men and women over the age of 50 years for colorectal neoplasia has become the standard and can detect cancers at an earlier stage compared to those not screened, and with some modalities, improve survival. Approved screening tests include fecal occult blood tests or fecal immunohistochemical tests, flexible sigmoidoscopy, colonoscopy, barium enema, computed tomography (CT) colonography, and fecal DNA tests. Each test has differing sensitivity and specificity in detecting cancers or adenomatous polyps, with ultimately colonoscopy being the preferred tool to detect and sample colorectal cancer and remove adenomatous polyps and early cancers. There is variation on sensitivity of detection for right colon cancers versus left colon cancers, and reduction in mortality from colonoscopy is greater for left-sided cancers.

Chemoprevention has not become standard practice except with forms of hereditary colon cancers and in high-risk patients with recurrent polyps or cancer. Epidemiological evidence suggests that nonsteroidal anti-inflammatory agents are beneficial in reducing future risk for colon cancer, but this must be balanced with the risk of side effects of these medications, and usage should be carefully considered in appropriate patients.

Prognosis, Treatment, and Precision Medicine
The prognosis of colorectal cancer is principally based on the stage of the disease at presentation. Staging may be performed using imaging techniques, such as CT or magnetic resonance imaging, or determined at surgery. Rectal cancer is best staged with rectal endoscopic ultrasound. Patients whose tumors demonstrate MSI may have improved survival when compared to patients without MSI tumors.

Therapy for colorectal cancer can be divided into colon and rectal cancer components. The main treatment for colon cancer is surgery. Surgery with wide resection margins is the only therapy needed for stage I and II disease, although some high-risk stage II patients receive chemotherapy. For stage III disease, adjuvant 5-fluorouracil-leukovorin (or FOLFOX: 5-fluorouracil, leukovorin, and oxaliplatin), six months is standard and has been shown to improve survival. For stage IV, surgery may be curative in highly selected patients with resectable bowel disease and resectable isolated hepatic or pulmonary metastases.

Unresectable liver lesions may also be managed locally with transarterial chemoembolization or radio frequency ablation if symptomatic. In many patients with stage IV disease, surgery is often palliative to prevent bowel obstruction. Chemotherapy is offered but may not improve overall survival. Palliative chemotherapy regimens for stage IV colon cancer include 5-fluorouracil-leukovorin, FOLFOX, and FOLFIRI (folic acid, 5-fluorouracil, and irinotecan), and IFL (irinotecan, 5-fluorouracil, leukovorin). Specific growth factor
inhibitors, such as bevacizumab (antibody to vascular endothelial growth factor) and cetuximab (antibody to epidermal growth factor receptor) added to the 5-fluorouracil-based regimens improve tumor shrinkage and add about five months to the survival of stage IV patients.

Rectal cancers are treated surgically by low anterior resection or abdominal perineal resection, often in combination with 5-fluorouracil-based chemoradiation. Stage I disease is approached with wide surgical resection with or without chemoradiation. Stage II and III disease is treated by wide surgical resection in combination with adjuvant or neoadjuvant (with an attempt at anal sphincter preservation) chemoradiation. The approach to stage IV disease is generally palliative with surgical bypass of local bowel obstruction and chemoradiation for local management.

Biologically driven decision making, or precision medicine, is becoming increasingly adopted for optimal care and outcome for colon cancer patients. The assessment of DNA (for direct mutation or epigenetic alterations without a change in sequence), RNA, or protein from normal tissue (blood or buccal swab), feces, or tumor is becoming more commonplace to help screen, diagnose, prognosticate, and perform personalized and precise care and treatment plans for patients at risk or with colorectal cancer.

Molecular screening, and in particular DNA testing, can assess the genetic background of a patient (passed through the germline from either parent) or characterize the genetic makeup of a tumor and, based on knowledge gained from the published human tumor literature for specific DNA changes, inform the physician regarding patient outcome and recurrence as well as inform an optimal approach to surveillance or treatment that will afford the patient the best outcome.

John M. Carethers  
*University of Michigan*

**Further Readings**

Carethers, J. M. “Secondary Prevention of Colorectal Cancer: Is There an Optimal Follow-Up for Patients With Colorectal Cancer?” *Current Colorectal Cancer Reports*, v.6 (2010).

**Colorectal Cancer, Childhood**

Cancers of the large intestines occur rarely in the pediatric patient. Whereas colorectal cancer accounts for one in four cancers diagnosed in the United States, the incidence is one in 1 million under age 20 years. In children, more cancers arise on the right side of the colon compared to adults and are usually associated with a hereditary colorectal cancer syndrome. The finding of one adenomatous polyp in a child should alert the clinician to the possibility of familial adenomatous polyposis (FAP), the most common polyposis syndrome in children. FAP is the result of a mutation in the adenomatous polyposis coli gene (APC) and is characterized by the progressive development of hundreds to thousands of adenomatous polyps in the large intestine, with presentation of adenomatous polyps by the early teen years. The number of polyps increases progressively, and the lifetime risk for colorectal cancer is 100 percent. One large study noted that
FAP patients presented with a colonic adenoma as early as eight months of age with a mean age of presentation of age 13. Polyp burden may also vary within families and are amenable to endoscopic therapy if the burden is limited (less than or equal to 30 polyps). Pediatric patients at risk (by having a family history) should be evaluated with a colonoscopy as early as two years before the youngest, earliest affected member. Plans for colectomy (surgical removal of the large intestine and rectum) should be discussed when the tumor burden becomes great or if high-grade dysplasia, a feature that indicates progression toward cancer, is noted on histopathology. Notable since the widespread practice of early colectomy for FAP are secondary causes of morbidity from FAP, primarily due to duodenal adenocarcinoma, with presentation as early as age 17. As such, new criteria for upper endoscopic surveillance have been recommended to closely follow colonoscopic surveillance.

Colon cancer can also be seen as a primary presentation in children with Lynch syndrome (LS), with presentation as early as nine years of age. LS is caused by a mutation in one of the DNA mismatch repair (MMR) genes. Unlike FAP, patients with LS may only develop one or few adenomatous polyps, thus making early diagnosis more difficult. A thorough family history for cancers involving the large intestines, and the uterus in female family members, is crucial in early detection of the at-risk child. Patients with a positive family history and symptoms should be screened with a colonoscopy (10 years earlier than the earliest index case in the family) and polyps removed as needed. The lifetime risk for colorectal cancer approaches 80 percent in these children, so discussions about timing for colectomy need to be addressed. A newer recognized form of colon cancer known as constitutional MMR deficiency syndrome (CMMR-D) occurs when both alleles of the same MMR gene are mutated. This results in a syndrome that is clinically distinct from LS with features of neurofibromatosis type 1 and a high risk of gastrointestinal cancers along with childhood malignancies to include brain, lymphoma, and leukemia.

Hamartomatous polyposis syndromes comprise a group of rare syndromes with intestinal polyposis along with other extraintestinal manifestations, often with presentation in early childhood. These hamartomatous polyposis syndromes occur at approximately one-tenth the frequency of the adenomatous polyposis syndromes and thus account for less than 1 percent of all colorectal cancers. Thus, the value and the importance of surveillance becomes complex. Recent molecular understanding of germline mutations in genes associated with hamartomatous polyposis syndromes (PTEN, BMPR1A, STK11, ENG) in patients with five or more polyps have helped improve management and surveillance of these patients. Juvenile Polyposis Coli (JPC) is one such syndrome, and patients may have multiple colonic juvenile polyps (greater than 3) that are nondysplastic.

However, JPC patients have a 12-fold increased risk for colorectal cancer and need to be closely monitored with regular colonoscopies. Colectomy is indicated if the tumor burden is great. Peutz–Jeghers Syndrome (PJS) is another hamartomatous polyposis syndrome with associated cancer risk both to the gastrointestinal tracts as well as extraintestinal sites. The relative risk for developing colon cancer in PJS was estimated at 98-fold higher when compared with the general population. Strict surveillance guidelines for PJS have been established for all cancer types in PJS with colonoscopies to commence at age 10. Recently, hamartomatous polyposis syndromes have been linked to various mutations in several different tumor suppressor genes and provide an additional avenue for diagnosis for the clinician through genetic testing.

Pediatric colon cancers usually present with symptoms associated with the site of the tumor. Hematochezia, weight loss, pain, finding of an abdominal mass, and intestinal obstruction can be a common presentation. Treatment involves surgical resection of the tumor and chemotherapy using the drugs 5-fluorouracil and leucovorin along with radiation if the tumor is in the lower pelvis.

Further Readings

Comprehensive Cancer Center of Wake Forest University

The Comprehensive Cancer Center at Wake Forest University is the first hospital focused on cancer in the Winston-Salem area of North Carolina. The center combines the medical curriculum and research parts of the Wake Forest School of Medicine. The center has 148 beds and includes an inpatient oncology intensive care unit (ICU).

As a comprehensive cancer center, this facility is credited as one of the national drivers in the battle against cancer. A comprehensive designation comes from the access patients at this facility have to advanced technology, treatment, and research.

At other medical centers, it may be weeks before a patient sees his or her physician. At the Comprehensive Cancer Center of Wake Forest University, the process has been streamlined so that the diagnosis, treatment, and after care of cancer patients is led by surgical, medical, and radiation oncologists as well as other allied health care personnel.

The center has made achievements since its foundation. It has been awarded full accreditation by the National Accreditation Program for Breast Centers, which is the first such accreditation awarded in the area. In addition to this, the institute is one of only 41 such facilities to be designated by the National Cancer Institute (NCI) as a comprehensive cancer center.

The center has more than 120 clinicians with focuses on every facet of cancer. This allows the institute to offer the best treatment for patients. The institute was also acknowledged as one of the top national leaders in the battle against cancer.

At the center, specialists in medical, radiation, surgical, and other treatments work collaboratively to ensure that patients receive treatments that are optimal for their maladies. Because patients see these experts who are able to cover every area of treatment, the process of investigation is streamlined and care can be given to the individuals more rapidly. In a single day, patients can see a team of professionals who specialize in the types of cancer ailing them.

The center treats many different types of cancer including breast, gastrointestinal, gynecologic, brain tumors, neck and head, oncology and hematology, melanoma, pediatric, orthopedic, prostate, thoracic, sarcoma, and urologic. The treatments offered by the center are multidisciplinary; specialists work in teams to ensure that the best answer for the patient is found as quickly as possible. The treatments available at the center include chemotherapy, radiation, and blood and marrow transplants.

While treatment for cancer is certainly part of treatment, there are other quality-of-life factors for which the center provides support. As cancer is a very stressful diagnosis for both patients and their families, the center offers support services so that patients and their families have experienced counselors to talk to. Counseling support programs offered include cancer patient support programs, psychosocial oncology, survivorship, massage, pastoral, and palliative. Some support programs are run by volunteers. The center accepts donations to help fund these aspects of patient care.

The center helps set up patients with clinical trials, and it has access to more trials than any other facilities in the area. These trials provide innovative treatment options for patients and have tremendous promise for future advances in cancer treatment and survivability. All of the current clinical trials may be viewed on the Wake Forest Baptist Health Web site.

In addition to offering treatment and care services to patients, the center also conducts research into advancing cancer therapies and patient treatments.
This is done by forming teams of professionals across disciplines and departments. Some of the research subjects include the development of pharmaceuticals, cancer imaging, all-natural products, genomics, nanotechnology, tumor microenvironment, survivorship, and disparities.

The center is composed of four different programs that make it easier for experts to interact and collaborate on issues. These programs aim to further acknowledge unity in working toward cancer prevention and cures. The divisions include cell growth and survival, clinical research, cancer prevention and control, and cellular damage and defense. The center also has three centers devoted to research brain, breast, and prostate cancers.

The four divisions of programs have differing goals. The goal of the cell growth and survival program is to explore the biological mechanisms present in proliferative and cell-death signals and to learn how to utilize this understanding to improve therapy and survival rates. Some of the contributions made to the cancer-fighting effort include modulation of cancer using all natural products, the tumor microenvironment, and decisions of cell fate in cancer.

The second division is the cellular damage and defense program. This program, as the name implies, aims to ascertain what role cellular defense and metabolic pathways play in tumor growth and to exploit these roles for therapeutic intervention. Within these research themes are projects with DNA damage, redox signaling, and metabolism on the cellular level.

The third division is the clinical research program. The center provides more clinical trials than every other hospital and medical facility in western North Carolina. There are nearly 250 research studies orchestrated by oncologists from the center or led by other organizations with which the center collaborates.

The final division is the cancer prevention and control program. The aim of this program is to utilize knowledge for the prevention and detection of cancer as well as to improve the quality of living for cancer survivors. The program’s goals are to reduce the occurrence of cancer, slow its progression, lessen morbidity, and increase the chances and rates of survival. The program has four main themes to achieve its objective: studying the effects of natural products, investigating carcinogens and other environmental risks, improving symptom management and survivorship, and elucidating the genetic predisposition to prostate cancer.

In addition to the previously mentioned four program divisions, the center also hosts centers of excellence. The comprehensive cancer center, as the name implies, involves all types of cancer. The centers of excellence have a narrower focus: brain tumors, prostate cancer, and breast cancer.

The Brain Tumor Center of Excellence was founded in 2003 in order to develop a thorough academic program at the center. This center of excellence was born of clinical care and research in patients with tumors as well as growing research interest in the field. The Breast Cancer Center of Excellence has a focus on four specific subjects: biology of carcinogenesis and malignant progression, analysis of data sets to identify predictive markers, survivorship and quality of life support, and novel imaging and therapeutics.

The Prostate Cancer Center of Excellence, founded in January of 1999, facilitates multidisciplinary research related to prostate cancer.

Congo, Democratic Republic of

The central African nation officially termed the Democratic Republic of Congo has had a long
and tumultuous history. In the late 19th century, Belgium made the territory of the Congo into a Belgian colony, and the citizens of the Congo suffered greatly as a result of colonial mistreatment during this time. The Congolese people were granted their independence from colonial rule in 1960, and a series of wars ensued for control of the nation’s governance. Stability still lacks in the Democratic Republic of Congo, as election results as recent as 2011 were lauded as fraudulent.

In the Congo, the lack of access to treatment for cancer patients is an increasingly problematic national dilemma. According to recent studies, it is estimated that less than one out of every two cancer patients in the Congo have access to even the most rudimentary cancer care. Moreover, those who can afford their cancer care are forced to pay fees in excess of $600 every month that care is needed, which is largely unaffordable to the citizens of the Congo; the average monthly wage in the country amounts to just over $150, making it difficult for its citizens to meet even basic health care needs.

Another large problem in the Congo’s fight against cancer is that the country is failing to adequately track information about cancer within the country. As of 2014, the nation has yet to establish a national cancer registry, which would be a vital tool in tracking domestic trends in the disease. Because the Congo has a population of more than 60 million citizens and is quickly growing, it is now more important than ever for the country to begin instituting a nationwide cancer registry in the interest of its cancer patients, physicians, and researchers. Certain groups, like the African Organization for Research and Education on Cancer, are currently lobbying the Congolese government in an attempt to bring cancer registries to the nation.

The Congo is a unique country with a unique cancer situation; there are large obstacles in the way of cancer care in the nation, though with sustained national efforts, these obstacles can be overcome. Diseases like acquired immunodeficiency syndrome, cholera, and malaria are currently huge problems in the Congo, and thus, in light of the nation’s attempt to tackle these other diseases, cancer has not received enough attention over the past few years with regard to research and funding. To compound the problem further, physicians like Judith Nsondé Malanda, who is a cancer specialist at the University Teaching Hospital in the Congo’s capital of Brazzaville, estimate that there might not be even 40 specialists operating within the whole of the African continent, much less the Democratic Republic of Congo. If the Congo is to adequately meet its cancer treatment challenges, the nation will need to bring in more cancer specialists, increase funding and research on the disease, and begin public health campaigns in order raise awareness.

In light of the nation’s lack of a national cancer registry, it is difficult to ascertain with precision the exact nature of cancer incidences in the Congo. However, inferences can be made from the little information that is available on cancer in the country. Presently, it appears that the most prevalent forms of cancer in the Congo are breast, liver, prostate, and uterus cancer. Liver cancer is the most common form of cancer in males in the country, while uterus cancer is the most common incidence of cancer in females here. Data also suggest that certain cancers such as breast and cervical cancer are quickly increasing in prevalence in the nation’s female population, while lung cancer is increasing in prevalence in the male population of the country as a result of increased tobacco consumption.

As mentioned earlier, the Democratic Republic has a serious shortage of cancer specialists, cancer research, and cancer treatment centers. Advocates like Jean-Marie Kasongo Mpolesha of the African Organization for Research and Education on Cancer are currently trying their best to bring nationwide cancer registries to the Congo, and specialists like Judith Nsondé Malanda are providing the full extent of their desperately needed medical expertise in the fight against the disease. In the next several years, cancer researchers hope to see a more centralized and efficient effort in the domestic struggle against cancer.

Cosmetics

According to the definition of cosmetics offered by the American Cancer Society, the majority of women and men in U.S. culture use some kind of personal care product that can be categorized as such. Products may include everything from traditional makeup such as eye shadow, lipstick, and face powder to perfume, cologne, shampoo, and hair colors—even toothpaste and deodorant. Although much current research is not conclusive, significant concerns have been raised that question the presence of possible cancer-causing agents in these products.

To the extent that most Americans use cosmetics on a daily basis that may potentially compromise health, it is important to understand the connections between the use of cosmetics and health concerns. Furthermore, the composition of these products and the regulation of that composition, or lack thereof, have created a number of significant controversies regarding the cosmetics industry.

Cosmetics and Health Risks

The American Cancer Society reports that some cosmetics may result in skin or eye irritation or allergic reactions for some consumers, although these types of problems are usually short term and go away if use of the product is stopped. It is difficult to determine to what extent cosmetic products contain ingredients that may have more serious or long-term consequences, as according to the American Cancer Society, testing has not been adequate to understand effects of many cosmetic brands. The Breast Cancer Fund notes that synthetic chemicals are components in cosmetics and points out that some of these same products are used to clean heavy-duty equipment, implying that health concerns may be an issue for further consideration.

Because the skin is a permeable surface, chemicals are absorbed through the skin, and when products are used regularly and remain on individuals for most of the day or evening, they saturate the body with untested ingredients. Some researchers argue that it is difficult to assess the long-term health effects of saturating the skin with chemicals due to the many variables that affect the speed (or probability) of penetration and absorption. Therefore, the long-term health effects of chemicals in cosmetic products are difficult to assess. The large number of ingredients contained in many cosmetics makes research difficult in understanding the possible impacts of specific ingredients on health. Some ingredients in cosmetic products are hormone disruptors, which can affect how estrogen and other hormones act in the body, by blocking them or mimicking them, which throws off the body’s hormonal balance and may cause hormone-receptor-positive breast cancer to develop and grow. Therefore, it is the recommendation of the Cancer Prevention Coalition to choose cosmetics...
that contain the fewest ingredients to achieve the consumers’ goals. More ingredients in personal care products increase the prospect that a product will cause adverse reactions, including allergy, irritation, and cancer. There are concerns that particular chemicals may lead to an increased risk of cancer in some consumers.

**Commonly Found Chemicals in Cosmetics**

A number of chemicals, commonly found in cosmetics, have been linked to potential health concerns. These chemicals include: phthalates, triclosan, 1, 4-dioxane, parabens, ethylene oxide, 1, 3-butadiene, polycyclic aromatic hydrocarbons (PAHs), placental extract, lead, and aluminum. Chemicals in cosmetic products are linked to a number of health issues that can include early puberty or delayed puberty, hormonal disruption, miscarriage, and fertility problems.

Studies show that, when cosmetics are absorbed through the skin, chemicals are found throughout the body, in, for example, blood and urine samples, and are suspected of interfering with the body’s natural processes. Although, as noted earlier, these connections are very difficult to prove with current scientific methods.

**Links to Breast Cancer**

While a number of common ingredients in cosmetics have been linked to cancer, the greatest number of studies appears to focus on links to breast cancer in particular. For example, some researchers are concerned that underarm cosmetics might be a cause of breast cancer due to the application of deodorants and antiperspirant products directly under or on breast tissues. Researchers argue that the strongest supporting evidence comes from unexplained clinical observations showing a disproportionately high incidence of breast cancer in the upper outer quadrant of the breast, just the local area to which these cosmetics are applied. A biological basis for breast carcinogenesis could result from the ability of the various constituent chemicals to bind to DNA and to promote growth of the damaged cells, describes P. D. Darbre.

Research in this area is especially critical because, if links do exist between chemicals and breast cancer, preventative action might easily be undertaken, though most researchers point out that more research is needed to learn about possible long-term health effects. Parabens are used as preservatives in many products, including a wide range of beauty products and are a group of chemicals that have been widely studied because of their links to breast cancer. Because they have the ability to pass through the skin, they are then able to have an estrogen-like influence on the body’s chemistry. They are found throughout the body due to their expansive presence in products including, but not restricted to, beauty aids. Phthalates, another commonly studied group of chemicals in breast cancer research, are found in nail polish, hair spray, and many other products in which scent is a component of the process. They function as hormone disruptors and disturb the body’s hormones, in particular those that influence estrogen production.

**Controversies**

There are several recent controversies regarding the use of unregulated products containing possible cancer-causing agents in the cosmetics industry. In particular, major companies such as Revlon and Avon have been challenged by consumer groups to reformulate products that contain possible cancer-causing agents. Revlon was alleged to use more than seven controversial chemicals in their products. Avon, Johnson & Johnson, and Procter & Gamble...
all have taken steps to eliminate the use of questionable chemicals in their makeup lines. For example, Avon has agreed ultimately to remove triclosan, a commonly used antibacterial compound, from its product line. Both Johnson & Johnson in 2012 and Procter & Gamble in 2013 have agreed to voluntarily adopt standards that are higher than governmental mandates, eliminating triclosan, parabens, phthalates, preservatives that release formaldehyde, and the phthalate DEP.

Cost of Therapy

Health care costs continue to climb not only in the United States but across the world. As we become more aware of the etiology of disease, complex procedures for more accurate diagnoses, the complexity of treatments, and even the addition of preventative measures have become popular among the masses to maintain overall health. One of the most prominent and rising causes of death in the United States is cancer. Although advances in the oncologic conceptualization and disease have increased over the past years, cancer continues to represent a significant portion of health suffering and substantial financial cost to patients, their families, and their community. The Centers for Disease Control and Prevention reported that cancer was the second-leading cause of death in the United States, regrettably ending more than 500,000 lives in 2011.

In 2014, the American Cancer Society reported that approximately 585,720 residents in the United States alone will likely expire secondary to cancer, representing the second-leading cause of death. Cancer is expected to account for almost one-quarter of all chronic illness-related mortality, and the cost associated with treatment, including end-of-life care, is astronomical.

As the numbers of newly diagnosed cases increases, in the context of more effective but often costly treatments, the number of cancer survivors consequently rises. In 2010, the National Cancer Institute reported more than 13,700,000 cancer survivors living in the United States alone and projected more than 18 million survivors by 2020. On a worldwide spectrum, deaths due to cancer fall only behind cardiovascular and infectious diseases. The cost of cancer prevention and treatment programs continue to rise.

According to National Institutes of Health estimates, $89 billion were spent on cancer care in 2007, with the economic burden totaling
$219.2 billion when including indirect costs associated with lost productivity and death. As the incidence of cancer increases in the aged, and survivors live longer, the cost of care increases. In 2010, the cost of cancer care in the United States grew to $157 billion. The National Cancer Institute noted that the initial cost of cancer therapy increased more than 7 percent from approximately $40,000 dollars to $43,000, while continued care costs increased more than 10 percent, from approximately $46,000 to $52,000. Predictions of cancer therapy costs are astonishing, as the institute assumes that initial and continued care costs in 2020 will rise 19 and 31 percent, respectively. The National Cancer Institute also specified that brain cancer produces the highest cost of care, while melanomas represent the lowest cost of therapy, independent of gender.

Although costs differ on an individual basis, some of the major factors that contribute to costs of cancer therapy include specific cancer treatments, medications, surgeries, lab tests, the number and location of doctor’s appointments, travel, support costs, mental health care, and employment. Therapies can last from a few days to months and, in some cases, into years depending on a variety of factors. Typical cancer therapies include chemotherapy, radiation, and surgery. Oral chemotherapy drugs are expensive, and depending on an individual’s insurance plan, the co-payment may be extremely high, even into the thousands of dollars per treatment. Radiation therapy is usually deployed to arrest the growth of cancer cells. But like surgery, the costs of radiation can vary substantially as a function of individual status, insurance, and provider-related factors. Cancer therapy costs vary widely across modalities of treatment ranging from $1,700 for a single treatment with conventional radiation techniques to more than an average of $16,000 for four treatments using Cyberknife, according to N. Fawcett. Other overt and hidden therapy costs include traveling to appointments, the use of specialized facilities, and even home health assistance. In addition, work productivity can be reduced, employment may be stalled or terminated for the patient or caregiver, and a range of psychological factors and assets may be compromised. This includes the loss of primary and secondary support systems, the cost of depression and anxiety, and a compromised sense of self, explains L. C. Campbell and colleagues. These hidden costs of cancer and cancer therapy are sometimes greater for minority and historically disenfranchised populations.

Costa Rica

Across the world, cancer is the second-leading cause of death and disability. It has moved beyond high-income countries to low-income, developing countries. In developing countries, there is a silence that surrounds the disease that results from
a lack of knowledge and meaningful information on causes and treatment. Many cultures never use the word cancer and rarely discuss the illness. The prevalence of cancer is on the rise in Costa Rica, claiming on average 2,559 deaths among men and 2,035 deaths among women per year. In 2009, there were 7,163 new cases of cancer in Costa Rica, and there is expected growth of 10,627 by 2020. There are many risk factors that contribute to the high rates of cancer. These include tobacco use, fruit and vegetable intake, alcohol consumption, obesity, and low physical activity. However, there are environmental and occupational risk factors that also lead to high incidents of cancer among Costa Ricans. Risk factors include agriculture occupations and the use of pesticides.

There are 14 regions in Costa Rica, and geographically, there are differences in the occurrence of cancer and types of cancers among Costa Ricans. The cancer registry was developed to help keep track of newly diagnosed cancer cases regionally as well as persisting cancer cases. The functioning and quality of the information in these registries is unknown. The cancer registry has catalogued many forms of cancer visible in Costa Ricans. In urban areas of the country, lung, colorectal, breast, uterus, ovary, prostate, testis, kidney, and bladder cancers were more visible. In rural regions, gastric, cervical, penile, and skin cancer were more prevalent. In excessive coffee-growing areas, skin cancer was diagnosed at a higher rate.

The growth of cancer in Costa Rica has been contributed to geographical and environmental differences such as the use of pesticides and occupational exposure to pesticides. Agriculture is the principal economic activity, and it has been this way for decades. In urban areas of Costa Rica, such as the Central Valley, Southern Central Valley, and Northern Central Valley, coffee is the main crop. In these areas, there is a high usage of pesticides, paraquat, lead arsenate, and copper. In rural areas of Costa Rica, noted as the northern mountain chain of Central Valley, Western Central Valley, southern mountain chain of Central Valley, Eastern Central Valley, east mountain chain, mid-north Costa Rica, Northern Central Pacific Region, Southern Central Pacific and South Pacific Region, northwest Costa Rica, mid-south Costa Rica, and east Costa Rica, the main crops are coffee, sugarcane, corn, beans, rice and bananas.

The use of pesticides is high in these areas, with many utilizing more than three or more combinations of pesticides. In these areas, pyrethroids, phenoxyacids, propanil, and fungicides are used, and formaldehyde is frequently used in addition to paraquat, lead arsenate, and copper. In fact, the excessive use of paraquat and lead arsenate in coffee-growing areas has been linked to skin cancer. Lung cancer and female hormone-related cancers have been linked to heavy pesticide use in rural areas among Costa Ricans. Cancer has also been linked to banana plantation workers, where there is use of formaldehyde and fungicides along with the more common pesticides.

High cancer risk has been declared among agricultural workers in Costa Rica. Skin and lip malignancies have been associated with ultraviolet radiation exposure during farming. Leukemia also has been linked to agriculture workers’ exposure to viral zoonosis. Additionally, leukemia in children has been linked to mothers’ occupational exposure to pesticides a year before conception and during the first and second trimesters. It was also found to link with fathers’ exposure to pesticides during the first year of conception and the first trimester. Paraquat, benomyl, and picloram have been noted specifically as pesticides that contribute to childhood leukemia by parental exposure.

Researchers also have found that there were elevated risk estimates among banana plantation workers. Banana production, considered to be labor, and related work has been linked to excessive pesticide use for decades. Researchers have found that, among male banana plantation workers, there was an increase in melanoma and penile cancer. Among female banana plantation workers, there was an increase in cervix cancer and leukemia. Additionally, men’s risk for lung cancer was elevated among those with longer lengths of employment.

Breast cancer has also become an increasing concern among women in Costa Rica. There has been an increase in occurrences between 1995 and 2003 from 32.3 to 40.07 percent per 100,000 women. In 2006, there were 13.14 per 100,000 women breast cancer-related deaths in Costa Rica, the highest occurring in malignant neoplasm. Self-exams and mammography have been the primary intervention focus for decades in Costa Rica, yielding really low coverage. Most are diagnosed at the hospital with
advanced stages of breast cancer. Research has identified a need for early interventions, which includes screening that extends beyond mammography and self-exams to combat diagnosis in advance stages.

The lack of control over work conditions and the lack of attention to environmental emissions from traffic, industry, and agriculture have led to the advancement of cancer regionally in Costa Rica. In fact, attention to the issues recently has become a concern in the country, causing Costa Rica to be behind in addressing these work and environmental issues. Furthermore, this country's developing status and reliability on agriculture to sustain the economy puts the country in a difficult position in addressing the use of pesticides. The new cases of cancer are expected to grow, and researchers offer the country limited alternatives in addressing the issues of cancer while maintaining its position in the agriculture production. Furthermore, there is a need for improvement in early detection of cancers, which include comprehensive advance screenings of breast cancer and cancers prevalent in areas of high pesticide usage as well as a need for cost-effective interventions for all types of cancer.

Côte d’Ivoire

Côte d’Ivoire is situated in West Africa. It is bordered on the north by Mali and Burkina Faso, on the east by Ghana, on the south by the Atlantic Ocean, and on the west by Guinea and Liberia. It is the 15th-most populous country in Africa and 59th in the world, with a population of more than 16.9 million. French is the official national language, and there are 79 living indigenous languages still spoken by respective ethnic groups. The most widely spoken ethnic languages in Côte d’Ivoire include Anyin, Baoule, Dan, Jula, and Senufo. Each ethnic group has its own rich traditions of ethnomedicine. For example, a traditional healer who uses medicinal plants for treating ailments is known as komian in Agni as well as in Baoule and as fil-cha in Jula. Traditional medicine continues to play a very dominant role in health practices for much of the population, particularly those living in rural areas.

There are many traditional medicinal preparations used in Côte d’Ivoire for treating cancers and other associated conditions. Most of these traditional medicines incorporate the use of myriad local plant materials, many of which have shown medicinal properties in laboratory studies. For example, extracts of the inner bark of Kigelia pinnata have demonstrated significant antitumor activities. Research suggests that use of certain plants may actually help protect against cancer by reducing oxidative stress and stimulating enzymes and other processes that help the body to fight against carcinogens. For example, an extract from Bidens pilosa, a plant used by traditional healers, has demonstrated substantial antioxidant potential, as has an extract of Cleome gynandra.

Medicinal plants are used traditionally in Côte d’Ivoire to treat many health problems associated with cancers and associated conditions. For example, the plant juice of Mikania cordata, which the Abe call ndckpacha, the Ebrie call kokotobanji or kuagbo, the Guere call don, and the Shien call bazeru, is drunk traditionally for treating abdominal pain. A stem bark extract of Tetrapleura tetraptera,
which the Agni call *plakasse*, the Ebre call *mberekrechia*, and the Guere call *kussa*, is used traditionally for treating hemorrhoids. A root decoction of *Strophanthus hispidus*, which the Agni call *makwa*, the Baoule call *akueyama*, the Ebre call *salobego*, and the Guere call *bidu* or *zrebudu*, is drunk traditionally for relief of stomach pain. Leaves of *Leptoderris fasciculata* are widely used traditionally in cases of menorrhagia.

There are serious deficiencies of modern pharmaceutical supplies, as opposed to traditional preparations, and in modern medical services for cancer and similar conditions in Côte d’Ivoire. According to the World Health Organization’s (WHO’s) Health System Response and Capacity, as of 2010, there was no general availability of either chemotherapy or radiotherapy in the public health system in Côte d’Ivoire.

Côte d’Ivoire is a signatory to the Single Convention on Narcotic Drugs, Convention on Psychotropic Substances, and UN Convention against the Illicit Traffic in Narcotic Drugs and Psychotropic Substances; consequently, laws exist to control narcotic and psychotropic substances and precursors. The annual consumption of controlled substances is highly regulated to curtail abuse. Accordingly, the annual consumption of morphine in 2010 was 0.00277 milligrams per capita (mg/capita), fentanyl was 0.000365 mg/capita, and phenobarbital was 10.3475 mg/capita. This creates a serious lack of access to basic palliative care for cancer and other conditions.

Cancers account for a substantial amount of disability and suffering among impacted populations. According to the WHO’s Disease and Injury Country Estimates, the age-standardized disability adjusted life-year estimates for 2004, the 10 most prevalent cancers in Côte d’Ivoire were led by liver cancer at 241 per 100,000 population; breast cancer at 208 per 100,000 population; prostate cancer at 206 per 100,000 population; lymphomas at 201 per 100,000 population; cervical and uterine cancers at 177 per 100,000 population; stomach cancer at 99 per 100,000 population; leukemia at 71 per 100,000 population; colon and rectal cancers at 70 per 100,000 population; and bladder cancer at 40 per 100,000 population.

Modern pharmacological supplies, as opposed to traditional preparations, are generally, if available at all, in short supply in Côte d’Ivoire, as are modern medical services. Both prescription and over-the-counter products are often unavailable. Consequently, health problems are endemic and limit development. For example, an estimated 570,000 people live with human immunodeficiency virus (HIV) in Côte d’Ivoire, which ranks the country 12th highest in Africa and 17th-highest in the world. The mortality rate for HIV/acquired immune deficiency syndrome (AIDS) in 2010 was 7,700. Debate continues on the relative risks in Africa for respective cancer types for those infected with HIV. The mortality rate for tuberculosis in 2001 was 75 per 100,000 population and that for malaria was 103 per 100,000 population, while the mortality rate for cancers in 2009 was 170 per 100,000 population.

Nine cancers are among the 50 leading causes of death in Côte d’Ivoire. Prostate cancer is the 22nd-leading cause of death; the age-standardized death rate is 18.65 per 100,000 population, which ranks Côte d’Ivoire as the 12th-highest country in the world for prostate cancer deaths. Breast cancer is the 26th-leading cause of death; the age-standardized death rate is 14.49 per 100,000 population, which ranks 118th globally. The remaining seven cancers that are in the 50 leading causes of death, along with their age-standardized death rates, are cervical (9.53), liver (7.42), lymphomas (5.07), stomach (4.46), lung (3.63), colon and rectal (2.55), and leukemia (2.17). Furthermore, according to the WHO’s Global Health Observatory Data Repository, in 2008, the age-standardized estimates of deaths from all cancers was 80 per 100,000 population for males and 79 per 100,000 population for females. As a consequence, life expectancy is only 48.42 years, which ranks Côte d’Ivoire 28th in Africa, 199th in the world. There is a clear and urgent need for improved cancer awareness, early detection programs, and health services infrastructure in Côte d’Ivoire.

COX-2 Inhibitors

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been a staple of modern medicine ever since the mass production of aspirin began in 1899. Although aspirin and similar early-generation NSAIDs were immensely successful in treating various inflammatory and noninflammatory conditions such as fever, arthritis, and headache, their use was often limited due to adverse effects related to the gastrointestinal (GI) system. Chronic NSAID use is still associated with GI damage that leads to bleeding, ulcers, and perforation. Although most of the therapeutic and adverse effects of NSAIDs were known shortly after the introduction of aspirin to the market, it was not until several decades later that the mechanism of NSAIDs was discovered. NSAIDs inhibit the enzyme cyclooxygenase (COX), which is normally responsible for the synthesis of prostaglandins. Prostaglandins play important roles in both physiologic and pathologic processes including pain, fever, inflammation, cancer, and asthma.

In the early 1990s Needleman, Simmons, and Herschman discovered an inducible isoform of COX, known as COX-2. COX-1 is an isoform that is constitutively expressed in several tissue types, including endothelium, platelets and monocytes, while COX-2 is expressed during inflammation by tissues such as vascular endothelium, macrophages, monocytes, and osteoclasts. COX-2 is also constitutively expressed during reproduction, bone resorption, and renal physiology. COX-1 is constitutively expressed in the GI tract, where it produces prostaglandins that increase mucous release and decrease gastric acid secretion. Thus, the inhibition of COX-1 by traditional NSAIDs such as aspirin contributes to gastric erosion.

The discovery of an isoform that is induced by inflammation made it possible to design drugs that specifically inhibit that isoform without inhibiting the constitutively active COX-1 isoform that protects the gastric mucosa. Therefore, the first COX-2 inhibitors were designed with the intention of sparing users from the GI toxicity of traditional NSAIDs while still treating similar inflammatory conditions. Shortly after their release, the first COX-2 inhibitors (celecoxib and rofecoxib) became blockbuster drugs. However, it was not long before the COX-2 inhibitors were discovered to have their own unique adverse effects. Constitutive COX-2 present in the vascular endothelium is responsible for producing anti-aggregative prostaglandins that counter the pro-aggregative thromboxane A2 produced by COX-1 in platelets. Disinhibiting COX-2 alone disrupts this balance and significantly increases the risk of life-threatening cardiovascular thromboembolic events. It was not long before several COX-2 inhibitors, such as rofecoxib, were withdrawn from the market, and others, such as celecoxib, were marked with black box labels warning about their cardiovascular toxicity.

Although the risk of cardiovascular adverse effects has prevented COX-2 inhibitors from replacing traditional NSAIDs as the standard treatment for most inflammatory conditions, they have novel effects that still make them valuable therapeutic options for some conditions. Along with inflammation, COX-2 has been implicated in carcinogenesis, apoptosis, and angiogenesis, making it a viable target for preventative cancer therapies. COX-2 is overexpressed in most cancers, including colorectal, gastric, lung, breast, ovarian, skin, and esophageal cancer, and COX-2 inhibitors have been proven to significantly reduce the risk of many types
COX-2 and Malignancy
Chronic inflammation has long been considered a leading cause in the development of cancer, and recent evidence suggests that COX-2 may directly link chronic inflammation to cancer. COX-2 expression is directly induced by inflammation, and the overexpression of COX-2 alone is capable of stimulating all of the processes that eventually lead to carcinogenesis. These processes include mutagenesis, apoptosis inhibition, angiogenesis, metastasis, and immune system evasion. COX-2 can be found in all tissues involved in the progression of carcinogenesis, including premalignant lesions, carcinoma in situ, invasive cancer, and metastases. Furthermore, various molecular studies have identified COX-2 overexpression in all types of cancer. Overexpression of COX-2 contributes to the development of malignancy in many ways. COX-2 increases the production of reactive oxygen species that contribute to mutagenesis, increases the production of prostaglandins that promote cell proliferation, stimulates vascular endothelial growth factor (VEGF) release to promote angiogenesis, and increases matrix metalloproteinase production, which augments metastasis. It also leads to up regulation of the BAX gene (anti-apoptotic) and down regulation of the Bcl-2 gene (pro-apoptotic). New evidence continues to arise that suggests that the overexpression of COX-2 directly contributes to the cellular and molecular changes that precede and prolong malignancy. Therefore, there is interest in research studying the use of COX-2 inhibitors as effective agents of chemoprevention.

There is also evidence that there are COX-independent mechanisms by which traditional NSAIDs and COX-2 inhibitors prevent the progression of malignancy. Even in in vivo models with significantly decreased expression of COX-2, celecoxib still inhibited the development and progression of several cancer cell lines. Celecoxib has also been shown to be more efficacious in preventing certain cancers than rofecoxib, a much more potent COX-2 inhibitor. Studies show that COX-2 inhibitors have COX-independent pro-apoptotic properties by inhibiting NF-kB at the level of nuclear translocation, increasing p53 activity and inducing NSAID-activated gene-1 (NAG-1) activity. By another mechanism, β-Catenin, a protein that is appreciably elevated in both familial adenomatous polyposis (FAP) and most colorectal carcinoma tissue, was extensively degraded only two hours after celecoxib treatment was administered to human colon carcinoma cells. The existence of COX-2-independent mechanisms in celecoxib has incited interest in the development of a celecoxib analog that retains its antitumorigenic properties without inhibiting COX-2. Such a drug would be void of many of the adverse cardiovascular effects that currently limit the use of celecoxib in many potential patients.

As research continues to implicate COX-2 in contributing directly to carcinogenesis, there is an increasing interest in research studying the use of COX-2 inhibitors as effective agents of chemoprevention and adjuncts to standard chemotherapy. The next several sections review the usefulness of COX-2 inhibitors as chemopreventative agents in a variety of different cancers. Most of this focuses specifically on celecoxib as both valdecoxib and rofecoxib were removed from the market.

Colorectal Cancer
Human colorectal cancer is an ideal model for the study of carcinogenesis for a variety of reasons. For example, it develops in a step-wise fashion from premalignant lesions to malignancy over a long period of time (10 or more years from premalignant polyp to invasive cancer). This provides researchers with a long period of time to observe and intervene at various stages in carcinogenesis and a wide window to provide chemopreventative therapy. There are also conditions, such as FAP, in which an inherent mutation of a gene involved in carcinogenesis leads to a significantly increased number of precancerous polyps that overexpress COX-2. The step-wise development of CRC in people with and without FAP essentially remains the same, except that one of the steps is skipped in FAP. This shortens the time required for carcinogenesis and increases the number of precancerous polyps that arise. The similarity in the development of malignancy in FAP and spontaneous CRC makes FAP an ideal model for studying the carcinogenesis of CRC in normal subjects, albeit with a much higher incidence of cancerous and precancerous lesions in FAP. COX-2 plays an important role in initiating...
and maintaining the step-wise process that leads to the development of both CRC and the vast number of precancerous and cancerous lesions in patients with FAP. A major discussion point concerning the effect of COX-2 inhibition on the development of polyps in FAP is that it translates into similar results regarding the development of uncomplicated CRC.

A 2000 study by Steinbach's group was one of the earliest studies to investigate the effect of celecoxib in patients with FAP. Patients were given either celecoxib, 100 milligrams (mg), celecoxib 400 mg, or a placebo twice a day for six months and underwent an endoscopy before and after the trial. Changes in the size and number of polyps in the test subjects during the six-month period were then analyzed. Subjects receiving the high dose of celecoxib had a 28.0 percent reduction in the number of polyps and a 30.7 percent reduction in the total sum of polyp diameter, while those receiving placebo had 4.5 and 4.9 percent reductions in size and diameter, respectively. Subjects receiving the lower 100 mg dose twice a day had an 11.9 percent reduction in polyp size and 14.6 percent reduction in total polyp diameter, which was not statistically significant. A separate study confirmed these results with similar findings, and as a result, the Food and Drug Administration approved celecoxib as an oral adjunct to the standard care (endoscopic surveillance and surgery) of FAP.

There also have been studies to evaluate the potential use of celecoxib to prevent recurrent adenomatous polyps in subjects with recently removed adenomatous polyps. The Adenoma Prevention with Celecoxib trial studied more than 2,000 patients with high risk of adenoma recurrence. Patients were given a placebo—200 mg twice a day or 400 mg twice a day—for an average span of 33 months. Follow-up at that time revealed a significant reduction in polyp recurrence, particularly in the recurrence of more high-risk polyps. Thus, the patients taking celecoxib who did have recurrences presented with polyps that were far less likely to develop into adenocarcinoma.

Although the benefits of COX-2 inhibitors in the chemoprevention of patients with baseline risk for CRC are questionable due to the risk of cardiovascular events, the benefits of therapy far outweigh potential adverse effects in patients already at an elevated risk for developing CRC. Future therapies will focus on retaining the benefits of COX-2 inhibitors in the prevention of CRC while reducing the potential for catastrophic cardiovascular events. Nonetheless, COX-2 inhibitors, particularly celecoxib, are important agents in the chemoprevention of high-risk polyps and CRC.

More recent studies have examined the role of celecoxib as an adjunct to traditional chemotherapy, hoping to augment the effects of the chemotherapy on cancer cells without increasing toxicity. The combination of celecoxib with a regimen of folinic acid, fluorouracil, and oxaliplatin improved the quality of life and three-year survival rate in patients with advanced colorectal cancer. Celecoxib has also been established to decrease the risk of hand-foot syndrome, a common side effect in patients undergoing capecitabine treatment (an oral prodrug to fluorouracil).

Gastric Cancer
Although there is less existing literature regarding the use of COX-2 inhibitors to prevent gastric carcinoma than colorectal carcinoma, there is still a widely recognized progression in the carcinogenesis of gastric cancer that provides a foundation for the study of chemoprevention. A recent study revealed that two years of celecoxib treatment resulted in a significant regression of high-grade gastric lesions that was comparable to Helicobacter pylori (H. pylori) eradication, but there was no combined benefit of H. pylori eradication and celecoxib treatment. However, there have been recent studies that link celecoxib treatment in adjunct with traditional chemotherapy to decreased levels of VEGF, an indicator of tumor angiogenesis and progression.

Esophageal Cancer
Similar to gastric and colon carcinoma, both types of esophageal carcinoma have recognizable progressions from benign to malignant lesions. Esophageal squamous cell carcinoma is preceded by squamous dysplasia just as esophageal adenocarcinoma is preceded by Barrett’s esophagus (intestinal metaplasia in the esophagus). Both precursor lesions provide a basis for the study of COX-2 inhibitors in the chemoprevention of esophageal cancer. There is not a large body of evidence to support or negate the effectiveness of COX-2 inhibitors in the prevention of esophageal squamous cell carcinoma, but a phase IIb multicenter randomized placebo-controlled trial of celecoxib for patients with Barrett’s esophagus did
not significantly prevent progression of Barrett’s esophagus to esophageal adenocarcinoma. However, studies of celecoxib as a chemopreventative agent in both Barrett’s esophagus and squamous dysplasia warrant further consideration.

Breast Cancer
Breast cancer is the most common cause of cancer in women and the second-leading cause of cancer death in women. There is continuous intensive effort by the research community to novel therapies for the detection, prevention, and treatment of breast cancer. Among these novel therapies is the use of celecoxib as both a chemopreventative agent and adjunct in chemotherapy. Studies have shown that there is a significant risk reduction in the incidence of breast cancer in high-risk patients who have taken celecoxib for two or more years. There are also more recent studies that support celecoxib therapy in adjunct with cyclophosphamide for patients suffering from high-grade breast carcinoma. Dual therapy of celecoxib with aromatase inhibitors has also shown promise in high-grade cancer.

Lung Cancer
Lung cancer is the most common cause of cancer death in men and women, on average causing more deaths a year than breast, prostate, and colon cancer combined. Studies have estimated that COX-2 activity is increased in 70 to 90 percent of lung cancers. Lung carcinogenesis also has been associated with the alterations of the arachidonic acid cascade, which is inactivated by NSAIDs and COX-2 inhibitors. A key reason for the lethality of lung cancer is that there is no effective, noninvasive method of detecting precancerous and early malignant lesions. Therefore, lung cancer is often not diagnosed until it has progressed to late-stage disease. This also makes it difficult to develop a model with an appropriate end point to test the chemopreventative efficacy of various therapies, such as COX-2 inhibitors. Before the true potential of celecoxib in the chemoprevention of lung cancer can be exploited, an effective method of early detection must be developed. There has been at least one case-control study that has observed a significant risk reduction in high-risk patients (several pack a year history of smoking) taking NSAIDS and celecoxib, but two phase III trials regarding the effect of celecoxib on overall survival in non–small cell lung cancer showed no significant improvement. These results, however, do not negate the potential use of celecoxib in treating certain subpopulations. A recent study found an inverse relationship between the plasma level of VEGF and the impact of celecoxib (compared to placebo) on survival. Low plasma levels of VEGF were present in patients with cancer more likely to respond to celecoxib and improve survival. One possible explanation for this is that VEGF directly blocks the antitumor effects of celecoxib.

Non-Melanoma Skin Cancer
The use of celecoxib in the prevention of nonmelanoma skin cancers (NMSCs) has been studied in a limited context. NMSCs have an increased risk of developing in easily identifiable precancerous lesions, such as actinic keratosis, making patients with actinic keratosis (AK) viable candidates for preventative celecoxib treatment. One double-blinded, placebo-controlled, randomized, multicenter trial revealed that, although celecoxib did not reduce the risk of developing actinic keratosis, it did reduce the incidence of new NMSCs in patients with AK. However, due to the good prognosis of NMSCs and the possible risk of thrombotic cardiovascular events while on celecoxib, the study was stopped prematurely. Although the mortality from NMSCs is low, there are certain conditions where the mortality from NMSCs is significant enough to warrant further consideration of celecoxib chemoprevention. Patients with basal cell nevus syndrome (BCNS) often develop hundreds to thousands of basal cell carcinomas that may lead to significant functional disability and aesthetic disfigurement at an early age. A study of 60 patients with BCNS showed a promising but nonsignificant decrease in the tumor burden of patients taking celecoxib. A similar condition in which patients may benefit from celecoxib therapy is Xeroderma Pigmentosum (XP). In XP, patients have nearly 10,000 times the risk of developing NMSCs compared to the general population. No known trials have been performed involving XP patients and celecoxib, but they are a population of interest.

Bladder Cancer
Bladder cancer is the most common malignancy of the genitourinary tract, with more than 60,000 new cases and almost 13,000 deaths suffered annually.
The majority of these new cases (less than 80 percent) are transitional cell carcinomas that do not invade the bladder muscle. Nonmuscle invasive bladder cancer (NMIBC) is generally treated with surgical resection and postoperative Bacillus Calmette–Guérin (BCG) therapy to prevent recurrence. Nonetheless, recurrence is estimated to occur in anywhere from 30 to 80 percent of treated patients. The implication of COX-2 in the carcinogenesis of NMIBC and the efficacy of COX-2 inhibitors in the chemoprevention of various malignancies have garnered interest for celecoxib therapy to prevent NMIBC recurrence. Although a clinical trial revealed no significant prolongation of the time to recurrence (TTR) in patients with resected NMIBC receiving celecoxib, there was still a trend toward an increase TTR compared with placebo. BOXIT (Bladder COX-2 Inhibition Trial), an ongoing phase III trial that will report the recurrence of NMIBC over three years, will provide physicians with further insight regarding the potential of celecoxib in NMIBC chemoprevention.

Ovarian Cancer
Although most ovarian cancer is initially treatable with platinum-based combination therapy, most patient experience disease recurrence within two years of treatment. Overexpression of COX-2 plays a large role in the carcinogenesis of ovarian cancer and is directly related to poor prognosis. A recent trial found that the addition of celecoxib to first-line treatment plus docetaxel did not significantly improve progression-free survival or overall survival. Platinum-based treatment, generally used as first-line treatment, is often repeated in recurrent ovarian cancer that has already received first-line treatment and additional nonplatinum-based chemotherapy. The response rates for platinum-based retreatment are low, ranging from 6 to 23 percent. COX-2, which plays a role in platinum resistance in ovarian cancer, is suspected as a viable target to improve retreatment response. A separate phase 2 trial evaluated the effect of combined celecoxib and cisplatin treatment on heavily treated recurrent ovarian cancer. Patients receiving the combination therapy experienced an overall response rate of 28.9 percent with a median progression-free survival of five months. This compared favorably to response rates to platinum-based treatment alone and are particularly promising because many of the patients in the study had already demonstrated primary or secondary resistance to platinum-based treatment. Furthermore, the response rates showed no relation to the degree of prior platinum resistance, suggesting that celecoxib disrupts platinum resistance. Future treatments with adjunct celecoxib may be tailored to individual patients based on their cancer’s expression of COX-2 and related markers.

Conclusion
COX-2 overexpression is widely accepted as pathologic in all types of cancer and plays a significant role in both the carcinogenesis and malignancy of cancer. The potential of celecoxib and related COX-2 inhibitors as cancer therapies is based generally on two uses: as a chemopreventative agent or as an adjunct to traditional chemotherapy. Numerous studies reveal that celecoxib is effective at reducing the risk of various types of cancers, particularly if an identifiable precancerous state exists for that cancer. Celecoxib has also proven effective as an adjunct to chemotherapy by increasing tumor response to treatment and decreasing tumor recurrence rate. Future utilization of the drug will be dependent on controlling adverse effects and developing a further understanding of the COX-2-independent mechanisms of action of celecoxib.

Croatia

Croatia, officially known as the Republic of Croatia, is a unitary democratic parliamentary republic known for its large tourism market and is situated at the crossroads of central and southeastern Europe and the Mediterranean. The population of Croatia is more than 4 million people across 20 countries, with most of these inhabitants being Croats (who have their own Croatian language).

Like the rest of the world, Croatian citizens are affected by all of the various forms of cancer, though lung cancer is a particularly large threat in this country.

Lung Cancer

Lung cancer has been a threat to many Croatians over the last several years due to the popularity of cigarette smoking. According to the Croatian Medical Journal, lung cancer incidence and mortality rates in Croatian men under 70 saw a sharp decline between 1998 and 2008; however, the same is not true of Croatian women. According to the journal, lung cancer prevalence and mortality rates in women increased significantly in all age groups older than 40 years and decreased in women between 30 and 39 years old.

Though lung cancer is decreasing overall in Croatia, the republic is still among the highest in number of deaths and incidences for men across European countries. And, though women's rates may be increasing for the younger population, the female age-standardized incidence rates are still fivefold lower than in men. The trends can be explained by the fact that more older women are taking up smoking in Croatia, while men are slowly beginning to quit. This denotes the need for additional cessation and prevention policies across the republic.

Today, lung cancer is the most common cancer in Croatian men and the fifth-most common cancer in Croatian women, and more than one-fourth of all Croatian adults smoke every day. Unfortunately, there are many barriers to creating smoking prevention programs, including limited resources, the social acceptability of smoking, and the transnational tobacco industry’s interest in the republic.

Prostate Cancer

Incidences in prostate cancer are rapidly increasing for Croatian men. Mortalities from this cancer are also on the rise, contrary to trends in countries with higher incomes. To improve this situation, prostate cancer units and different treatment methods should be established across the republic. Increases are likely due to an aging population. In addition to age, risk factors for prostate cancer include ethnic origin and heredity. Other possible factors include exposure to UV radiation, alcohol consumption, sexual behavior patterns, and nutrition.

Leukemia

Leukemia trends in Croatia have stayed relatively the same over the past decade or so, though mortality rates are significantly more unfavorable in Croatia when compared to other countries in western Europe. The lack of improvement in these numbers stems from a late introduction of optimal therapies, though health insurance companies are beginning to cover these needs more efficiently throughout the republic. There are several different forms of leukemia, and it is difficult to determine what may cause the disease, but some breakthroughs have been made over the past several years to address it. We expect that this, combined with greater insurance coverage, will cause mortality rates in Croatia to decline in regard to this disease.

Melanoma

Melanoma occurrences are on a shocking rise in Croatia, with similar trends to countries with intermediate and lower incidence. According to the Croatian Medical Journal, over the span of
20 years, from 1988 to 2008, the overall melanoma incidence increase between the first and the last five-year period was 149 percent for men and 130 percent for women. With numbers this shocking, there is a desperate need for targeted public policies to curb these issues. Sun exposure is a major risk factor for melanoma, and the Croatian coast and islands have more than 2,600 hours of sunshine every year.

Breast Cancer
According to the Canadian Medical Journal, breast cancer rates for women of all ages are increasing in Croatia, though mortality rates remained stable from 1998 to 2008. This increase could be due to lifestyle factors such as alcohol consumption and the use of hormonal replacement therapies and oral contraceptives. According to GLOBOCAN estimates, in 2008, Croatia is among the European countries with an intermediate breast cancer frequency. In 2006, Croatia introduced its national breast cancer screening program, called Mamma, which urges women age 50 to 69 to obtain regular mammograms.

Organizations and Famous Faces
There are a number of cancer-related organizations across Croatia. One such organization is the Croatian League Against Cancer, which was founded in the capital of Zagreb in 1966. The organization specifically focuses on breast and cervical cancer treatment and prevention, and it hosts several symposiums annually to discuss these topics. The Croatian League Against Cancer has been an associate member of the International Union Against Cancer (UICC) since 1967.

Famous Croatians who have been afflicted with various forms of cancer include Vanja Drac (lung cancer), a theater and film actor; Emil Glad, a film actor; Vida Jerman (lung cancer), a film, theater, and television actress; Josip Kuže (leukemia), a football coach and player; Tomislav Ladan, an essayist, critic, and novelist; Antun Gustav Matoš (throat cancer), a poet, short story writer, journalist, travelogue writer, and essayist; Krsto Papić, a Croatian screenwriter and film director; Mate Parlov (lung cancer), a Croatian boxer and Olympic gold medalist; Vjekoslav Šutej (leukemia), a prominent Croatian orchestral conductor; and Franjo Tuđman, the country’s first president.

Conclusion
Despite the fact that new and comprehensive data about cancer incidences and mortality rates in Croatia is now available, more educational investment is needed to ensure early detection and prevention. In terms of lung cancer, more education is needed about the hazards of smoking tobacco, especially among young women. Men should be educated about the dangers of prostate cancer, which is widely spread across the country. Finally, all Croatians should be alerted to the dangers of melanoma resulting from sun exposure.

Cuba
Cuba is the largest island in the Caribbean Sea, the Pearl of the Caribbean. Its rich soil has been the basis
of its economy since the Spanish conquest, leading to the production for export of sugar and tobacco and the import of African slaves for this labor-intensive work. The Spanish colony established there was supplanted by the United States in the Spanish–American War of 1898, with Cuba under North American influence for the next half century. Another abrupt change came when a physician, Dr. Fidel Castro, led a revolutionary movement to oust the ruling dictator and turn the country toward a socialistic state, with the support of the Soviet Union. Since that time (1959), the country’s situation has been dominated by an embargo imposed by the United States and the eventual fall of the Soviet Union in 1989. These events have pressured Cubans to become independent, improvise from their limited resources, and adopt prevention and innovate new treatments as their way to address public health.

In recent decades, Cuba has achieved the same life expectancy (79 years) for its citizens as has the United States, with a far less costly health system. Thus, the Cuban experience is a natural experiment in how different health systems work. The importance for cancer lies in the study of preventive actions, compared with a costly treatment approach. Cuba does not have the resources to provide advanced cancer treatment to many of its citizens, but it does provide them access to medical doctors.

Medical education in Cuba has been successful enough to produce a surplus of tens of thousands of doctors and dentists. These professionals have provided a national outreach for Cuban influence. Acting as volunteers or part of economic exchange outside the economic embargo of the United States, medical professionals have spread the Cuban medical approach. In Venezuela, a major petroleum producer, there are 31,000 Cuban doctors and dentists serving the people of Venezuela, and in exchange, the Venezuelan government has provided Cuba with an estimated 100,000 barrels of oil a day. Other arrangements for Cuban medical professionals have been made in 80 countries. It is fair to say that this outreach has created the basis for an evaluation of many preventive and treatment outcomes, but this potential has hardly been realized. Due to the political conflict that has characterized Cuban—United States relations over the decades, Cuban successes are ignored on one side, while their limitations are buried in politicized claims of success on the other. This is troublesome, for the experience with diverse cancer prevention studied on a large scale would be a great advance due to the foreseeable demographic changes that the world’s developing nations will experience. Cancer has not been a major health problem in countries with relatively low life expectancy. But the World Health Organization forecasts that cancer will become a leading cause of mortality as these developing countries experience modernization and its accompanying demographic changes. We see these changes in Cuba today.

According to the Pan American Health Organization (PAHO), Cuba’s demographic profile is an aging population of 11,253,700 with a median age of 39.5 years. The country is facing a growing number of cancer cases along with pressure to add treatment and palliative care to its emphasis on preventive health strategies.

As the population of Cuba ages, it joins industrialized countries with their increasing concerns about cancer diagnosis and treatment. Currently, Cuba has 12 percent of its population at 65 years of age and above, while half of its cases of malignant cancer appear in this older population. The rate of cancer increases markedly with advancing age. Thanks to a national cancer registry, created in 1964 and fully operating since 1986, the details of mortality from every type of cancer in Cuba are known. The result is that, since 2012, cancer has become recognized as the primary cause of mortality.

The national health services have responded to increased cancer mortality, for a third of cancers are preventable and others can be treated successfully if diagnosed early. The limits of the Cuban health system and its preventive medicine are apparent in the problem of lung cancer. This is the leading cause of cancer mortality in Cuba. However, due to the historic place of tobacco in Cuban society, efforts to reduce tobacco use in Cuba have been resisted. The nation lacks a ban on tobacco advertising, while bans on smoking in public places are widely ignored. Nonetheless, there has been a two-thirds reduction in tobacco use over 20 years. The number of people admitting smoking also has declined, from 53 to 36 percent. Adolescent use of tobacco has declined among males but not among females.

Prostate cancer is the second-leading cause of cancer mortality in Cuba. Among women, breast cancer is the greatest cause of mortality, from a Westernized life style of few children and greater levels of education and income (about half the
Czech Republic

The central European nation officially termed the Czech Republic is a relatively new country on the world stage, having been formed in 1993 out of the peaceful dissolution of the state of Czechoslovakia. In recent years, the economy of the Czech Republic has been excelling, and the nation is regarded internationally as having one of the most effective and reliable democratic governments in the world. The Czech Republic is presently home to nearly 11 million citizens, one-tenth of which live in the nation's capital, Prague.

The national cancer registry of the Czech Republic was first established in 1977. In recent years, it is regarded internationally as one of the most robust and effective cancer registry systems in place in the entire world. All of the nation's hospitals and universities are mandated to report every domestic cancer incidence that is observed, so the coverage of the registry is comprehensive. Researchers who utilize the database have access to well-kept domestic records that have proven invaluable in the country's fight against cancer as the records accurately indicate mortality, diagnosis, and treatment rates with the nation.

Data from the cancer registries of the Czech Republic suggest that mortalities from cancer are decreasing in the nation at one of the most distinctive rates of all central Europe. Generally, cancer incidences are down in both the male and female populations of the country, but there is much still to be done. The Czech Republic's elderly population has some of the highest rates of cancer incidence in all of Europe, so more effective preventative measures and screening methods will need to be utilized in the country. Also, the government of the Czech Republic will need to better campaign against certain cancer risk behaviors such as the above-average usage of alcohol in the country. The population of the Czech Republic has been shown statistically to have some of the heaviest drinkers in all of Europe, and researchers believe that such behavior is most likely the cause of the nation's high rates of stomach cancer. To reign in stomach cancer incidences in the country, the government will need to take a more active role in making the Czech public aware of the risk factors of certain behaviors.

As of late, the most prevalent forms of cancer in the Czech Republic are breast, bowel, lung, prostate, and stomach cancer. Lung, bowel, and stomach cancers are the most dominant forms of cancer incidences in males in the nation, while breast, bowel, and stomach cancers are the most common

See Also: Bolivia; Developing Countries; Venezuela.

Further Readings
incidences of cancer in females there. Nationwide, incidences of bowel, breast, prostate, and stomach cancers have been consistently increasing over the past two decades, while occurrences of cervical, liver, and gastric cancers have been steadily decreasing.

Unfortunately, many citizens of the Czech Republic have experienced cancer throughout the nation’s history. The popular Czech politician and social advocate Pavel Dostal died in 2005 as a result of struggling with pancreatic cancer for over a year. Arnost Lustig, the critically acclaimed Czech fiction writer and Holocaust survivor, passed away in 2010 after suffering from non-Hodgkin’s lymphoma for several years. Furthermore, the beloved Czech hockey player Miroslav Dvořák died in 2008 at the age of 56 as a result of his bout with throat cancer.

Presently, the Czech Republic is well prepared to deal with the nation’s domestic cancer incidences, and the situation is improving every year. There are currently 19 regional cancer centers, one national cancer institute, two pediatric cancer facilities, six hemato-oncological centers as well as numerous outpatient care locations. Moreover, the National Cancer Control Program of the Czech Republic is currently hard at work educating all age groups of the Czech population regarding cancer prevention behaviors. The institute is also set to begin initiating a new system of audits within the hospitals of the country in order to better screen for domestic cancer incidences. Nationwide, new hospices, palliative treatment facilities, and outpatient care centers are being constructed every month in a sustained effort by the Czech government to effectively combat the disease. International researchers are optimistic that the Czech Republic is taking all the proper steps it needs to meet the domestic challenges of cancer in the decades to come.

Daiichi Sankyo (Japan)

Daiichi Sankyo is a corporation created from the merger between Sankyo Company, Limited and Daiichi Pharmaceutical Company, Limited in 2005. As of early 2014, the corporation has 17,256 employees worldwide, including subsidiaries, but excluding the 15,535 employees within the Indian Ranbaxy group from which Daiichi Sankyo disinvested its majority share in April 2014. Daiichi Sankyo ended up as number four in Japan and as number 20 on a global basis in the Medical Care & the Pharmaceutical Industry 2013 overview of 2011 pharmaceutical corporations’ sales.

Overall turnover for fiscal year (FY) April 2013 to March 2014 was approximately 87 percent domestic pharmaceuticals, 4.5 percent pharmaceutical sales abroad, and 8.5 percent health care products. There is as of 2014 a distinct domination of drugs related to remedying high blood pressure and antihypertension. The most-selling pharmaceutical products in FY 2013 to 2014 were the antihypertensive agent olmertasan and related products marketed as Olmetec and as Rezaltas in Japan; as Benicar, Benicar HCT, Azor, or Tribenzor in the United States; and as Olmetec, Olmetec Plus, Sevikar, or Sevikar HCT in Europe. In FY 2013 to 2014 the products Benicar, Azor, and Tribenzor held the number one ($857 million), number three ($174 million), and number five ($90 million) positions of the corporation’s U.S. turnover.

Sankyo was first founded as Sankyo Shoten in 1899. It was established by three businessmen as a joint investment, with the main product takadiastase, which was a digestive enzyme discovered by the chemist Jokichi Takamine (1854–1922) in 1894. The company subsequently launched the adrenal cortex hormone agent adrenalin in 1902. In 1913, the corporation changed its name from Sankyo Shoten to Sankyo Co., Ltd. As for internationalization, subsidiaries were established in 1985 in the United States and Germany. Daiichi was established in 1915 as Arsemin Shokai, based on the launch of the antisyphilitic agent arsemin. It attained the name Daiichi Pharmaceutical Co., Ltd. in 1918.

After having established a joint holding company in 2005, the new fully merged corporation began operations on April 1, 2007. Apart from the main Daiichi Sankyo, there is a group of subsidiaries including Daiichi Sankyo Healthcare Co., Ltd. (est. 2006), generic products specialist Daiichi Sankyo Espha Co., Ltd. (est. 2010), and Kitasato Daiichi Sankyo Vaccine Co., Ltd. (est. 2011). Moreover, Japan Vaccine Co., Ltd. is a joint venture with GlaxoSmithKline K. K. (est. 2012). Asubio Pharma Co., Ltd. was originally Suntory Institute for Biomedical Research, founded in 1979 and reorganized as a fully owned subsidiary in 2010 focusing on pharmaceutical research and development (R&D). Internationally, Daiichi Sankyo acquired during 2008 through 2011 a number of companies including U3 Pharma GmbH of Germany, based mainly
on antibody drugs (2008); Ranbaxy Laboratories Ltd. of India (2008, but disinvested in large parts in 2014); and oncology-focused Plexxikon Inc. based in Berkeley, California (2011). Zepharma, which had been an Astellas Pharma over-the-counter drugs subsidiary, was acquired in 2006 and later integrated within Daiichi Sankyo Healthcare.

Corporate Philosophy and Recent Strategy
The corporation’s global slogan is Passion for Innovation, Compassion for Patients, and was implemented in 2012 along with its cornerstone business management plan for fiscal years 2013 to 2017, focusing on becoming a global pharma innovator. The first business plan (2007–2009) after the merger had been focused on maximizing synergies from integration and accelerating global expansion, whereas the second plan (2010–2012) was focused on the development of a hybrid business model, which meant being present within both prescription and generic drugs.

The R&D expenditures are relatively high; 18.3 percent in relation to sales as of FY 2011 to 2012. Daiichi Sankyo maintains what they call an R&D culture, including a willingness to change working and behavioral patterns. The corporation states as key words for such a culture taking challenges in a respectful way, empowerment of employees, proactive engagement of stakeholders, and taking calculated risks. Daiichi Sankyo focuses on cardiovascular metabolics when it comes to R&D, as evidenced by its current high-selling products but also on oncology together with subsidiaries Plexxikon (United States) and U3 Pharma (Germany). Plexxikon uses a special scaffold-like screening library trademarked as Scaffold-Based Drug Discovery Platform early in the drug lead-generation process together with compound and target structural data in order to attempt the design of new drug candidates. One inherent aim is to leverage target-specific chemistry investments for multiple targets within a given family. Plexxikon had already before the acquisition by Daiichi Sankyo discovered and subsequently developed in conjunction with Roche the mutation-specific medicine Zelboraf (vemurafenib), its first oncology drug to have reached the market. Plexxikon has, as of mid-2014, a number of compounds in clinical trial processes, including for melanoma, pancreatic cancer, colorectal cancer, and hairy cell leukemia. U3 Pharma has several projects, including two that concern interfering or inhibiting tumor growth.

A new biologics oversight function was established in 2013 and integrates the previously dispersed biopharmaceutical function. Biologics Pharmacology Research Laboratories was created within this function. In addition Venture Science Laboratories, which is comprised of a small number of scientists challenging new approaches, was established in April 2013. Daiichi Sankyo started a collaborative drug discovery project called TaNeDS (Take a New challenge for Drug diScovery) in 2011, consisting of receiving funding applications from Japanese universities and public research centers. The program was expanded to Germany, Austria, and Switzerland in 2013. In April 2014, Astellas Pharma and Daiichi Sankyo announced that they planned to form a joint compound library sharing partnership for approximately 400,000 selected compounds to enable them to promote their R&D efforts.

Further Readings
Several aspects of daily life can contribute to the cause or prevention of cancer. However, once diagnosed with the disease, life often changes drastically in many aspects, and patients and caregivers need to be educated on how to deal with them. Equally important is to counsel cancer survivors when they are ready to return to their daily lives after finishing treatment. Even after diagnosis, lifestyle changes improve outcomes; for example, smoking cessation prolongs life among survivors.

**Causes of Cancer Encountered in Daily Life**

The evolution of cancer is considered to be a multistep process where external insults to underlying defects in the body keep accumulating until cells start behaving and growing abnormally, leading to tumor formation. Such insults are generally in the form of carcinogens—substances that are implicated as causative agents of cancer. We encounter many such carcinogens in our everyday lives. These may be a part of our habits, diet, work, or environment.

The most important carcinogen identified thus far is tobacco. The carcinogenic effects of tobacco have been associated with cancers of the lung, stomach, liver, pancreas, cervix, bladder and kidney, and (in combination with alcohol) the larynx, mouth, pharynx (except nasopharynx), and esophagus. Although tar levels in cigarettes are steadily decreasing, smoking-related cancers are still on the rise globally. Certain dietary habits also contribute toward cancer causation, and risk in old age may depend as much on diet in early life as on current habits. Heavy alcohol intake, consumption of foods contaminated with aflatoxin, and a few local customs (such as feeding Chinese-style salted fish to infants, which causes nasopharyngeal cancer) have been consistently associated with increased risk of cancer. Obesity, a major problem in developed countries, has also been linked to postmenopausal breast cancer and tumors of the endometrium, gall bladder, and kidney.

Reproductive and hormonal factors also contribute to carcinogenesis. Changes in hormonal levels due to endogenous dysregulations or exogenous hormone administration can lead to breast and ovarian cancers. Breast cancer incidence is increased transiently by pregnancy and estrogen administration as oral contraceptives or hormone therapy (HT) and is lowered by late menarche, early menopause, early first childbirth, and a high number of pregnancies. Western diet is associated with earlier age at menarche and postmenopausal obesity, which increase endogenous estrogen production and hence breast cancer risk. Endometrial cancer incidence is also increased by HT. Ovarian cancer incidence declines with increasing number of pregnancies, and endometrial and ovarian cancers are less common among oral contraceptive users.

Daily exposure to carcinogens at the workplace has been an important cause of many cancers. Exposure to the combustion products of coal can increase the risk of lung cancer. Uncontrolled asbestos use in the construction industry was common from the 1940s to the 1970s, which can result in development of mesothelioma among workers exposed to it at that time. Individuals exposed to certain aromatic amines in the dye industry have an increased risk of developing cancer of the urinary bladder, especially if they harbor genetic traits that cause them to eliminate the compounds slowly.

Chronic infections with certain pathogens can also have carcinogenic effects. These include human papillomaviruses causing cervical cancer, hepatitis B and C viruses causing liver cancer, and *Helicobacter pylori* causing stomach cancer. Other pathogens that contribute to substantial cancer risk in certain populations include Epstein–Barr virus (associated with various B-cell malignancies and nasopharyngeal cancer), human T-cell lymphotropic virus type 1 (some T-cell leukemias and lymphomas), human herpesvirus 8 (Kaposi’s sarcoma with human immunodeficiency virus [HIV]), schistosomiasis (bladder and colon cancer), and liver flukes (cholangiosarcoma).

Apart from skin cancers due to exposure to ultraviolet rays from sunlight, the only substantial and widespread cancer risk known to be caused by an avoidable environmental factor in developed countries is the higher risk of lung cancer among smokers caused by indoor radon escaping from the ground or building materials, although both indoor and outdoor air pollution from fossil fuels may also contribute to the risk.

**Everyday Measures to Prevent Cancer**

Cancer prevention aims to reduce mortality by lowering the incidence of the disease. This can be
accomplished by avoiding a carcinogen or altering its metabolism, pursuing lifestyle or dietary practices that modify cancer-causing factors or genetic predispositions, and medical intervention (chemoprevention) to successfully reverse preneoplastic changes.

Much of the promise for cancer prevention comes from studies that show associations between modifiable lifestyle or environmental factors and specific cancers. Examples of modifiable risk factors include tobacco and alcohol consumption, physical inactivity, and obesity. Studies have shown decreased incidence of cancers associated with smoking and alcohol when the respective habits were ceased. Dietary modifications, intake of a balanced diet, exercise, and dietary supplements and micronutrients can also modify cancer risk. Aspirin and folate supplements can potentially reduce colorectal cancer incidence in the long term. Risk of various cancers is also likely reduced by intake of foods containing carotenoids, vitamins C and E, and selenium.

HT and other hormonal therapies are usually administered after considering all possible benefits and side effects to decrease the risk of hormone-associated cancers. Screening for precancerous lesions and immunizations against and treatment of infections that can cause cancer may be important in preventing neoplastic growths.

Use of sunscreens and other agents that protect against the harmful effects of ultraviolet radiation can help prevent development of skin cancers. Several countries now have regulatory bodies that monitor carcinogen levels in the workplace. Rules generally require workers to use protective equipment and work in shifts and necessitate industrial processes to meet standards that limit exposure. Stringent measures and legislations are required to limit or ban the use of proven or suspected carcinogens in industry, provide adequate health benefits and examinations to workers exposed to such hazards, and compensate those affected.

Living With Cancer

Facing each day after a diagnosis of cancer can be stressful for many patients. A multitude of challenges including treatment side effects, reduced income, inability to perform routine tasks, and psychosocial effects can impact daily tasks.

Patients need to cope with changes in appearance including hair loss and weight loss. Chemotherapy tends to drain the body of energy, leaving patients feeling relatively weak to perform even everyday chores. For some, in-home care is unavoidable, and access to social services in such cases becomes essential. In-home hospice services may also be needed for those in the final stages of their disease, especially when family members are unable to shoulder the burden.

Dealing with the financial implications of treating cancer can also be a serious concern, especially if the patient is a major earning member for the home. Many patients are able to sustain a regular schedule, but others will need to stop working or take some time off. Here, a dialogue with the employer on health benefits, sick pay, leave of absence, or disability is essential. Involvement of a financial or investment planner and a lawyer may also be required. Social workers and organizations may be able to assist in cases where debts need to be repaid and income is low or absent due to disease. Depending on a patient’s age and insurance coverage, treatment for cancer and other related costs
can be expensive. Additionally, knowledge of what the insurance policies cover and what, if any, out-of-pocket expenses are involved, is important. Financial counseling or social work intervention may be necessary and should be discussed with the health care provider. Local service organizations may have grants available to cover some costs of transportation or treatment.

Most cancer survivors look forward to resuming normal life after treatment, but for many, the experience does not end with their last oncology visit. Survivors often deal with psychosocial issues that affect their work performance, finances, sexual health, and self-identity. The range and severity of these issues can vary based on the type of cancer, disease management, patient age, and personality traits.

Returning to work represents a return to the routine that survivors were used to before they had cancer. Survivors should be educated to pace themselves when returning to work and that they may require a workplace accommodation to manage long-term effects. Suffering emotional fallout from their disease is a common problem among survivors. This may include worrying about recurrence or new cancers, thereby leading to depression. Positive attitude and self-identification can help them cope with these aftereffects. Sexual problems may include loss of desire for sex, impaired fertility, erectile dysfunction in men, and painful intercourse in women. Interventions including cryopreservation of sperm, eggs, and embryos; conservative surgical and hormone treatments may also help in these cases.

After being diagnosed with cancer, patients may face different challenges related to physical health, support systems, financial status, and access to health care that may influence their daily lives in many ways. While government and health care services need to address those issues thoroughly, they also need to promote public awareness of the different causes of cancer and educate everyone on steps that can be taken each day to minimize risks of acquiring the disease.

Dana-Farber Cancer Institute

Dana-Farber Cancer Institute (DFCI) was formed in 1947 by Sidney Farber, M.D., as the Children’s Cancer Research Foundation. Farber’s goal was to provide a facility that would not only advance the development of childhood cancer treatments but also provide a place for young cancer patients to receive cutting-edge care. In 1969, the foundation expanded its reach to welcome patients of any age.

In 1974, the organization’s name was changed to the Sidney Farber Cancer Center as a tribute to its founding father. The name was modified to its present incarnation in 1983 to recognize the enduring support of the Charles A. Dana Foundation, a private philanthropic organization that supports brain research through funding and educational programs. DFCI also is supported by the National Cancer Institute, the National Institute of Allergy and Infectious Diseases, numerous foundations, and individuals who contribute to specific clinical or research programs or to DFCI’s charity, the Jimmy Fund.

As of 2014, DFCI was supporting more than 300,000 patient visits annually and actively participating in approximately 700 clinical trials. It is a principal teaching affiliate of Harvard Medical School, a federally designated center for acquired immune deficiency syndrome (AIDS) research, and a founding member of the Dana-Farber/Harvard Cancer Center. DFCI also conducts community-based programs in cancer prevention, detection,
and control throughout New England and maintains joint programs with other leading health care institutions in Boston, including Boston Children's Hospital, Brigham and Women's Hospital, and Massachusetts General Hospital.

Dr. Sidney Farber

Sidney Farber, M.D., was a pathologist at Boston Children's Hospital when World War II ended. At that time, a boom in medical research was helping to revolutionize treatments for a number of diseases. Leukemia, however, was not one of them. The deadly disease, which originates in the bone marrow and affects white blood cells, was aggressive and painful. Farber wanted to find a way to treat it.

He reviewed studies made during the war that had shown how some types of anemia, which are also caused by immature cells in the bone marrow, could be cured with vitamin B12 and folic acid. Farber felt that he could achieve similar results with leukemia using the same idea. Folic acid was known to stimulate the growth and maturation of bone marrow, so Farber felt that, if a drug could be created that chemically blocks folic acid, it would shut down the production of abnormal marrow associated with leukemia. A U.S. pharmaceutical manufacturer called Lederle was actually testing a folic acid inhibitor at about the same time. In November of 1947, Farber was ready to try the drug Aminopterin on a group of 16 children who were suffering from acute lymphocytic leukemia. Ten of the recipients achieved temporary remission of the cancer, marking the first clinical remission ever reported using chemotherapy for childhood leukemia.

Shortly after, Dr. Farber and his colleagues at what is now DFCI also achieved the first remissions in a common form of childhood kidney cancer known as Wilms's tumor. The application of research that moves scientific knowledge from the laboratory floor to the hospital bed became the model for DFCI's approach to cancer treatment.

The Jimmy Fund

The Variety Club of New England, a charitable organization made up of members from the entertainment community, organized a national radio broadcast in May 1948 from the bedside of a young leukemia patient who was being treated by Dr. Farber as part of his work with the Children's Cancer Research Foundation. During the broadcast, the boy—who Farber insisted be called Jimmy rather than by his real name as a way to protect the child's privacy—was visited by members of his beloved Boston Braves baseball team.

After the airing, contributions flooded in from all over to help buy Jimmy a television set so that he could watch the Braves play their games from his hospital bed. The financial gifts resulting from the broadcast totaled approximately $250,000, with the funds going to support Dr. Farber's groundbreaking work in the fight against childhood cancer. The donations became the starting point for the Jimmy Fund, which has raised millions of dollars for DFCI throughout the years and helped support cancer advances that have become the standard of cancer care and research across the globe.

One of the first substantial uses of Jimmy Fund donations was the construction in 1952 of a dedicated Jimmy Fund Building, which would later become the Sidney Farber Cancer Institute, to house state-of-the-art laboratories, business offices, and a patient care clinic.

Research Philosophy

Dr. Farber envisioned a facility where scientists in upper-floor laboratories would make discoveries that could be applied in the treatment of cancer patients in ground-floor clinic rooms. He wanted there to be a close proximity between research and patient care, not only in terms of philosophical approach but also in respect to physical distance. In particular, he wanted scientists to routinely encounter the beneficiaries of their efforts—patients and their families—as a way to inspire scientific creativity and human compassion. DFCI has continued to follow the same agenda since its founding, dividing its facilities, funding, and focus just about equally between research endeavors and provision of patient care.

Research at DFCI always has been based on the principle that scientific and clinical investigations are complementary activities that strengthen each other. The insights from research inform and invigorate patient care and vice versa, according to the institute's underlying belief and modus operandi. From the start, DFCI has followed an organizational framework that promotes inquiry, free-flowing information exchange, and unbridled collaboration among professionals from all disciplines. The unfettered environment has helped
DFCI create one of the largest cancer clinical trials programs in the United States, which has fostered a significant number of advances in the understanding of cellular and systemic processes in the battle against cancer.

A distinguishing factor of DFCI is the quality and extent of the organization’s scientific collaborations, which include nationally recognized leaders from nearly all fields of cancer research, affiliations with Harvard Medical School and other leading teaching and health care institutions, and significant grant awards from the National Cancer Institute and National Institutes of Health programs, among others.

Danish Cancer Society  
A cancer society’s work involves all matters of cancer prevention, education, and support to cancer patients or interested parties and cancer research. The Danish Cancer Society (DCS) remains in line with other cancer society’s roles and responsibilities.

The beginning of the DCS can be traced back to 1904, when leading Danish physicians came together to fight against cancer. The discovery of radium to treat cancer motivated the Danish physicians to combine their efforts in the fight against cancer.

Denmark ranks the DCS as the largest cancer-fighting organization in their country; it is located in Copenhagen. Their membership comprises 455,000 members. The goals of the DCS consist of (1) prevention of cancer, (2) support of cancer patients and significant others, and (3) cancer research.

The DCS aspires to the goals of preventing the development of cancer, to enhance patients’ abilities to recover effectively, and to reduce the physical, emotional, and social adverse effects of cancer. The DCS uses multiple ways to accomplish these goals. The DCS belongs to the Union for International Cancer Control (UICC). The UICC, established in 1933 and based in Geneva, Switzerland, involves more than 800 organizations covering 155 countries. Membership in UICC consists of leading cancer societies, ministries of health, research facilities, and patient groups. A convergence of the members, major partners, the World Health Organization, and World Economic Forum take on the challenge of the growing cancer crisis on a worldwide degree. The UICC brings together the cancer community to decrease the worldwide cancer burden, to encourage profound justice, and to assimilate cancer control into the global health and advancement strategy.

The DCS supports two research institutes: the Institute of Cancer Biology and the Institute of Cancer Epidemiology. In 2008, the members of the two research institutes put out more than 200 articles in prominent scientific journals. The majority of funds raised by the DCS function to support the research activities of the two institutes.

The Institute of Cancer Biology aims to produce research to expand the understanding of the molecular mechanisms causing cancer and to link the chasm between basic and clinical research for progress in the care of cancer patients. This institute contains six divisions composed of (1) cell cycle and cancer, (2) proteomics in cancer, (3) molecular cancer biology, (4) apoptosis, (5) breast cancer, and (6) laboratory of cancer genomics. Two other research centers are associated with this institute, the Danish Centre for Translational Breast Cancer Research and the Centre for Genotoxic Stress Research.

The Institute of Cancer Epidemiology aspires to achieve two primary goals. The first goal aims to determine yet unidentified causes of cancer in the environment and in our genes. This goal helps
health care practitioners more efficiently preclude the existence of new cases of cancer in the Danish population. The second goal intends to examine and explain critical adverse consequences of therapy for cancer among cancer survivors. This goal assists physicians to alter and individualize the treatment for cancer and improve the quality of life of the cancer patients.

The Institute of Cancer Epidemiology contains seven research sections: (1) genetics, (2) diet and lifestyle, (3) psychosocial cancer research, (4) virus and hormones, (5) occupational cancer, (6) environmental exposures, and (7) statistics. This institute works to achieve the publication of new and original research findings into peer-reviewed international journals of high distinction. The researchers in this institute published 151 articles in 2009.

The research institutes contribute to the advancement of scientific knowledge by publishing innumerable articles every year. S. O. Dalton, T. M. Laursen, L. Ross, P. B. Mortensen, and C. Johansen published a stellar article on depression and cancer in 2009; likewise, L. Groth-Pedersen and colleagues put in print their article on novel research on lysosomal activity and targets for drug therapy in cancer. These types of articles provide impetus for further research to benefit people with cancer.

In keeping with the vision of life without cancer, the society plays host to international symposiums to present the latest study results in all lines of research on cancer from molecular to epidemiological. The Cancer Society Symposium on the Immunotherapy of Cancer—Present Status and Future Promise represents an example of a state-of-art meeting sponsored by DCS. This symposium, held in September 2013, concentrated on subject matters about adoptive cell therapy, therapeutic vaccination, cellular regulators in the tumor microenvironment, and immune-regulatory pathways to attack cancer cells. These subjects embody the latest lines of immunotherapy research on cancer. Other symposiums cover the multiple lines of research under study at the DCS, like epidemiological, other molecular subjects, and breast cancer research, to name a few.

The DCS carries out an annual nationwide campaign to assemble capital to support their mission. The organization collects money from lotteries, membership fees, and donations. Another 5 percent comes from the public system. The DCS’s income rose to 87.6 million euros in 2009. The society distributes costs of 37.5 million euros for research, 16.6 million euros for patient support, 11.3 million euros for prevention and information, and 4.2 million euros for administrative cost to manage the business of DCS.

In summary, the description of the DCS indicates a prominent, national organization based in Copenhagen, Denmark, with the mission of conquering the scourge of cancer. As evidenced by the publications and symposiums, the society truly supports its mission.

DDT

Dichlorodiphenyltrichloroethane (DDT) is a pesticide once widely used to control insects in agriculture and insects that carry diseases such as malaria. It is a white, crystalline solid with no odor or taste. DDT was used with great success in World War II to control malaria and typhus among civilians and troops. After the war, it was made available for use as an agricultural insecticide. American biologist Rachel Carson published the book *Silent Spring* in
In 1962, which explained the environmental impacts of indiscriminate DDT spraying in the United States. After publication of this book and public outcry, its use in the United States was banned in 1972 because of damage to wildlife and concern over carcinogenicity, bioaccumulation, and health effects on wildlife. However, it is still used in some countries to control mosquitoes that carry and spread malaria. Also, it has been used as an insecticide for crops because DDT is effective and relatively inexpensive to manufacture.

DDT is a persistent organic pollutant that is readily adsorbed by soils and sediments. It entered the air, water, and soil during its production and use as an insecticide before its ban in the United States in 1972. DDT is present at many waste sites, and releases from these sites still continue to contaminate the environment. Large amounts of DDT were released into the air, soil, and water when it was used on crops as an insecticide and to control malaria. It also evaporates from the contaminated water and soil, and while in the air, it may get deposited on land or surface water. This cycle of evaporation and deposition may be repeated many times. For example, atmospheric deposition continues as a current source of DDT contamination in the Great Lakes. Some soil particles with attached DDT, DDE (dichlorodiphenyldichloroethylene), and DDD (dichlorodiphenyldichloroethane) may get into rivers and lakes in runoff. It accumulates to high levels in fish and marine mammals in their adipose tissue.

These chemicals can be carried long distances and have been found in bogs, snow, and animals in the Arctic regions. DDT enters the environment by improper use and disposal, soil and sediment runoff, and atmospheric deposition. It can be absorbed by some growing plants from soil and by animals. DDT remains in the environment for long periods of time and degrades into DDE, with further degradation into DDD. DDT and its degraded byproducts DDE and DDD are persistent and toxic. These pesticides strongly adhere to soil and generally remain on the surface of soil for long periods of time.

People are exposed to DDT via consumption of contaminated fish, shellfish, and food and via breastfeeding to infants. Fish consumption advisories are in effect for DDT in many waterways, including the Great Lakes ecosystem. The amount of DDT might have decreased since its ban, but the largest fraction of DDT in a person’s diet comes from meat, poultry, dairy products, and fish, including the consumption of leafy vegetables. Today, in the United States, DDT, DDE or DDD enters the body mainly when a person eats contaminated food. The actual amounts of this pesticide absorbed from food intake depend on both the concentration in the food and the amount eaten. DDT metabolites leave the body mostly in urine but may also leave by breast milk and pass directly to nursing infants. DDT from the mother can enter her unborn baby through the placenta. DDT has been found in amniotic fluid, human placentas, and umbilical cord blood.

Research has shown that DDT and its metabolites have harmful effects on humans. Eating food containing a large amount of DDT over a short period of time would most likely affect the nervous system. People excessively exposed to DDT, while working with the chemical or through accidental exposure, report a prickling sensation of the mouth, nausea, dizziness, confusion, headache, lethargy, incoordination, vomiting, fatigue, tremors in extremities, anorexia, anemia, muscular weakness, hyperexcitability, anxiety, and nervous tension. Many studies have found that DDT can induce adverse effects on the liver, nervous system, and reproductive system.

DDT is a probable human carcinogen. The Department of Health and Human Services has determined that DDT is reasonably anticipated to be a human carcinogen. Similarly, the International Agency for Research on Cancer (IARC) has determined that DDT is probably carcinogenic to humans. The Environmental Protection Agency (EPA) has determined that DDT, DDE, and DDD are probable human carcinogens. Theoretically, DDT could contribute to breast cancer either by being a complete carcinogen, an initiator, or a promoter. However, evidence from epidemiological studies have not been consistent and may support the hypothesis that exposure to DDT or DDE increases the risk of cancer in humans. Previous studies of DDT and breast cancer assessed exposure later in life when the breast may not have been vulnerable, after most DDT had been eliminated and after DDT had been banned. B. Cohn and colleagues investigated whether DDT exposure in young women during the period of peak DDT use predicts breast cancer. They conducted a prospective, nested, case-control study with a median time to diagnosis of 17 years using samples obtained.
from young women during 1959 to 1967, which was the peak time of DDT pollution and exposure. After the research, they proposed that exposure to DDT early in life may increase breast cancer risk. Many U.S. women heavily exposed to DDT in childhood have not reached 50 years of age. The public health significance of DDT exposure in early life may be large. Research studies have proposed that women with the highest exposure to the pesticide DDT had four times the breast cancer risk of women with the least exposure. Some scientists reported in the April 29 issue of the *Journal of the National Cancer Institute* that men with the highest blood levels of DDE were 1.7 times more likely to develop testicular germ cell tumors than those who had the lowest levels. Studies suggest that genetic differences in metabolism may interact with body burden to predict breast cancer risk. Direct toxicity of DDT and induction of enzymes that produce other genotoxic intermediates and DNA adducts are possible mechanisms in causing cancer.

Limited studies have examined the association between exposure to DDT and increased risk of liver cancer, lymphoma, endometrial cancer, and prostate and testicular cancer. However, outcomes have been inconclusive or do not support an association. Recently, risk of both seminomatous and nonseminomatous testicular germ cell tumors (TGCTs) has been reported to be associated with increased exposure to \( p,p' \)-DDE.

At this time, most people are exposed to DDT and its metabolites products as a result of eating foods or drinking liquids that may be contaminated with small amounts of DDT. The Food and Drug Administration (FDA) analyzes a wide variety of imported food items as well as domestic products to ensure that pesticides residues are below FDA guidelines. Adults and children might get exposed to this harmful pesticide by eating certain types of fish or wildlife caught from certain locations. Many states have fish advisories to warn people about DDT contamination and to educate the public about bodies of water that have restrictions. In 1972, the EPA issued a cancellation order for DDT based on adverse environmental effects of its use, such as those to wildlife and potential human health risks. Since 1996, the EPA has been participating in international negotiations to control the use of DDT around the world. In September 2006, the World Health Organization (WHO) declared its support for the indoor use of DDT in African countries where malaria remains a major health problem, citing benefits of the pesticide, which outweigh the health and environmental risks. This is consistent with the Stockholm Convention on persistent organic pollutants, which bans DDT for uses except for malaria control.

DDT can remain in the environment for persistently long periods of time and can still be found in air, water, and on land, even in places where it has been banned. People are exposed to DDT when they eat food grown in soil contaminated with DDT or they eat fish from water polluted with DDT. Many studies have supported the fact that DDT is harmful to humans, wildlife, and the environment. The EPA banned DDT in 1972 in the United States due its harmful effects and probable risk of causing different types of cancers, such as liver and breast. DDT still is used in many countries for agriculture, although that goes against the Stockholm Convention. The WHO only supports
limited indoor use of DDT in the countries where malaria poses a great risk for human populations. Many studies have supported banning its use in agriculture all over the world because spraying DDT on plants exposes the land, air, and water to dangerous contamination. People may put themselves at great risk in consuming DDT exposed fish, wildlife and plant products, depending on the warnings and advisories issued for specific lakes, ponds, and other places.

Denmark

The northern European nation officially termed the Kingdom of Denmark is one of the oldest states in all of Europe, and the royal lineage of its current ruler, Queen Margrethe II, can be traced back all the way to the 10th century C.E. The nation of Denmark has a long history of being a dominant player on the world stage, acting as a European superpower between the 13th and 17th centuries. After a series of lost conflicts in the 19th century, Denmark lost much of its territory, though its economy blossomed during this period. The modern political rendition of Denmark was instituted in 1918, when constitutional and governmental reorganizations were achieved.

Denmark instituted one of the earliest national cancer registries in all of Europe when it created the Danish Cancer Registry in early 1942. Now, every single individual case of cancer within the Kingdom of Denmark is accounted for by the registry. The Danish Cancer Society, the Danish Medical Association, and the National Board of Health all work closely together to maintain and analyze the registry archives. Such efficiently maintained data has allowed the relevant domestic and international specialists the ability to closely track mortality statistics and incidence trends in the nation. Unfortunately, the detailed information provided by the Danish Cancer Registry has led to the revelation that Denmark has the highest rate of cancer incidences in the entire world.

To further compound the fact that the Danes experience the highest levels of cancer in the entire world, contemporary data suggests that the average Danish citizen who suffers from cancer is diagnosed with the disease when the cancer is at a much more advanced stage than his or her European peers. Cancer incidences in Denmark are believed to be as high as they are because a large proportion of the Danish population is smokers and consumers of alcohol, though proactive diagnosing practices used in the country also contribute to the higher levels of incidences. Currently, an average of 321 out of every 100,000 Danish citizens will be diagnosed with some type of cancer in their lifetime.

Presently, the most prevalent forms of cancer in Denmark are bowel, breast, lung, prostate, and uterus cancer. Prostate, bowel, and lung cancers are the most dominant forms of cancer incidences in males in Denmark, while breast, bowel, and uterus cancers make up the most common forms of cancer incidences in females there. In fact, Denmark has the highest incidences of lung and uterus cancers in all of northern Europe. Also, as tanning beds have become
Deodorizers

Deodorizers include various substances and products to mask, absorb, or neutralize odor for both consumer and industrial use. This includes substances added to virtually all bar and liquid soaps, including shampoos and conditioners, as well as deodorants, laundry products, dishwashing and household cleaning products, baby wipes, some toilet paper and tissues, body sprays, air fresheners, mothballs, pet odor removers, and so on. Most of them include a number of ingredients that are bad for human health. A National Resources Defense Council study found that most of the household air fresheners they studied (drawn from the most popular brands) included dangerous chemicals that included carcinogenic phthalates, toxins that could aggravate asthma, and various compounds that impact reproductive development. Many hormone-disrupting chemicals are especially dangerous to young children and babies. In the case of plug-in air fresheners, this is especially concerning of Population Based Cancer Registry Data.” London School of Hygiene and Tropical Medicine (November 2010).

Storm, H. H. “Appendix 3 (a) The Danish Cancer Registry, a Self-Reporting National Cancer Registration System With Elements of Active Date Collection.” Danish Cancer Society (February 1991).

Further Readings

given the 24-hour release of these chemicals, if the product is used as directed. It is also important to note that many of these chemicals were found even in products labeled organic or green, or promoting their usage of essential oils. (In many such cases, the essential oils do provide the fragrance itself, but more dangerous chemicals are used as dispersants to make the air freshener easier to spray or to affect the thickness or viscosity of the liquid or gel. Thus, while the essential oils are being used instead of synthetic fragrance chemicals, the chemicals they replace are a small part of the larger picture.) One plug-in air freshener included in the study contained more than 20 different volatile organic compounds, eight of which were classified by federal law as toxic or hazardous.

Deodorizing products have become almost ubiquitous since the mid-20th century. In 2007, the market for air fresheners alone was $1.72 billion, and a *Time* article found that plug-in, spray, liquid, and gel air fresheners were used in 75 percent of American households.

Many deodorizing products contain significant amounts of phthalates, a group of chemicals used in plastics, which pose a number of health concerns, including carcinogenicity. A Centers for Disease Control (CDC) study in the Fourth National Report on Human Exposure to Environmental Chemicals, conducted 2003 and 2004, found that phthalate exposure is widespread in the American population and that adult women have significantly higher levels of exposure than men because of greater use of phthalate-containing products like soaps, body washes, shampoos, cosmetics, and personal care items. Banned from use in personal-care and beauty products in many countries, they are much less regulated in the United States.

Phthalates are esters of phthalic acid (produced by oxidizing napthalene). In addition to being used in plastics like polyvinyl chlorides (PVCs), in which form they may be found in the containers of many beauty products, they are used as gelling agents, stabilizers, dispersants, suspending agents, and emulsifying agents and so are found in the majority of beauty products that come in the form of any kind of liquid, spray, or certain nonpowder solids (like soaps, lipsticks, and underarm deodorant blocks). Their ill effects result both from direct contact and from the release of phthalates into the environment, though, in the latter case plastics, PVC, linoleum, and various coatings are the larger culprits. The major concern with phthalates is not single incidences of exposure but the cumulative effects of exposure. Phthalates are suspected to be endocrine disruptors, for instance, which can lead to birth defects, changes in hormone levels, and cancers, especially breast cancer in women, and there are multiple studies finding correlations between phthalate exposure and female breast cancer. Phthalates may also be implicated in the obesity epidemic, especially in men, and in the increase in type 2 diabetes. Phthalates also have been shown to cause damage to the liver and testes.

One suspected reason for phthalates’ correlation with male obesity is because phthalates are xenoestrogens—chemical compounds that imitate estrogen. Xenoestrogens pose a significant human health risk in the environment and have been tied with increases in precocious puberty (and consequently early menarche, a breast cancer risk factor). Studies have confirmed a positive correlation between early thelarche (breast development in girls) and phthalate exposure, with phthalates’ functionality as xenoestrogen presumed as the responsible mechanism. In men, xenoestrogens can result in elevated estrogen levels, causing weight gain and breast development and decreasing testosterone and libido.

There are different mechanisms by which deodorizers work, depending on the purpose for which they are meant. Mothballs, for instance, which both repel clothes moths and prevent the stale smell associated with long-term storage of clothing, accomplish both with para-dichlorobenzene, replacing the older use of naphthalene, which has been discontinued largely because of its flammability. Both substances sublimate (evaporate directly from a solid to a gas without passing through a liquid phase first) at room temperature and do so slowly, thus gradually producing a gas.

That gas is toxic enough to moths to repel them and kills off moth larvae that may already be present. It also produces a sweet odor that displaces the aforementioned stale smell. Para-dichlorobenzene is a likely carcinogen, as listed by the National Toxicology Program, the International Agency for Research on Cancer, and the state standards of California; research on humans have not been conducted at full scale, and this classification is based on animal studies.
Similar chemicals are found in urinal cakes, the solid sublimating blocks used to reduce the smell of urine in public urinals. Like mothballs, such cakes or pucks were originally made with naphthalene; though flammability is not really a concern in this application, para-dichlorobenzene nevertheless phased naphthalene out, though in some jurisdictions, usage of para-dichlorobenzene for this purpose has been banned. Newer formulations use water-soluble surfactants that keep the interior of the urinal reasonably clean so that deodorizing is less necessary. Still newer, greener formulations use blocks of bacteria selected for their ability to neutralize key components of the urine that passes through them, which can be used in waterless, no-flush urinals.

Para-dichlorobenzene is used in many air fresheners, including unscented or fresh-air air fresheners for a simple reason: When dispersed in the air, it coats the nostrils in a film that deadens the sense of smell, not freshening the air but rather impairing your ability to smell it. This also helps cloak the chemical smell of some of the additives.

Benzene, an organic chemical compound, is found in many detergents as well as being used in rubbers, explosives, pesticides, and as a gasoline additive. It is widely known to contribute significantly to acute leukemia, bone marrow abnormalities, acute myeloid leukemia, aplastic anemia, myelodysplastic syndrome, chronic myeloid leukemia, and acute lymphoblastic leukemia and is a Group 1 carcinogen. Benzene exposure also can result in birth defects, male infertility, chromosomal problems leading to birth defects regardless of which parent is exposed, and damage to the liver, kidney, lungs, heart, and brain.

Acetaldehyde, an organic compound that occurs naturally, is also included in many beauty and deodorizing products. An irritant in large concentrations, it is also a toxin and carcinogen. Large concentrations in the air result in irritation to the respiratory tract, throat, eyes, mucous membranes, and sometimes the skin within a few minutes. In some workplaces where acetaldehyde concentrations are over the safe threshold but not dense enough to cause immediate obvious health problems, workers may notice respiratory troubles, dry or irritated eyes, or irritated skin, similar to allergy attacks or the effects of dry winter air and plausibly mistaken for same. This can happen as the result of heavy use of acetaldehyde-containing cleaning agents, especially with poor ventilation. Acetaldehyde also builds up in indoor spaces for reasons that are not entirely understood, possibly as a result of off-gassing from flooring, laminate, linoleum, and building materials, so the use of deodorizers can be just enough to push the concentration over the limit. Acetaldehyde is also one of the carcinogens in cigarette smoke and linked to lung, liver, and gastrointestinal cancers.

Dioxane is found in shampoos, deodorants, toothpastes, mouthwashes, and cosmetics and, in a 2008 study, was found to be present in almost half of the organic personal-care products surveyed. It is classified as a Group 2B carcinogen, known to be carcinogenic in other mammals and suspected to be carcinogenic to humans but not yet proven to be one by epidemiological studies.

Underarm deodorant usually contains aluminum chlorohydrate if it is also an antiperspirant. However, while a small amount of aluminum is absorbed into the skin, aluminum chlorohydrate is not the same as the neurotoxin aluminum chloride. It is a common urban legend that underarm deodorant is a cause of breast cancer, but there is no apparent link, at least not through aluminum; though it is theoretically possible that underarm antiperspirant use could lead to dangerously high levels of absorbed aluminum, this would require numerous applications of antiperspirant every day, for many days.

Air fresheners and other deodorizers also contain terpenes, chemicals derived from citrus oils. On their own they pose no health risk. In the air, they react with ozone and form formaldehyde, which is highly toxic and classified as a known human carcinogen with specific links to nasal sinus cancer and nasopharyngeal cancer and has suggested links with leukemia.

A number of harmful substances that may not be carcinogenic also are found in deodorizing products. Chloromethane, for instance, is a common ingredient. Though it is not believed to be carcinogenic, chronic exposure is linked to birth defects, and short-term exposure can result in seizures or central nervous system depression.

Detergents

Detergents, whether in liquid, cake, or powder form, are perceived as being largely safe household products. Scientific research, however, has shown that many common detergents contain substances that can adversely affect human health. These include several cancer-causing substances.

Detergents are substances that help remove dirt, both in the home and in industry. Around the middle of the 19th century, the first experimental synthetic detergents were produced. These experimental detergents were developed further in Germany during World War I. Advances in various chemical processes in the 1930s finally made it feasible to produce synthetic detergents in large quantities, leading to the first commercial use of such detergents in the 1950s. Detergents are found in many products, including dry-cleaning solutions, toothpastes, mouthwashes, antiseptics, laundry soap, dishwashing soap, and antiseptics.

Over the years, most complaints about detergents were associated with polluting the environment because many of the chemicals they contain were not easily biodegradable. In terms of human health, skin and eye irritations were the most common problems associated with detergent use. Some research has also determined a link between detergents and the risk of allergies, asthma, and various other health dangers.

Most of the research focusing on links between detergents and some forms of cancer is in the preliminary stages. Nevertheless, ongoing research of detergents has revealed that some of the ingredients used or produced as by-products of the production process are associated with increased risk of various toxicological problems. For example, liquid detergents emit benzene vapors.

Benzene

Benzene is a colorless, flammable liquid that evaporates almost immediately when exposed to the air. Both animal and human studies have shown that benzene can cause cancer. Most of the research has focused on leukemia and other blood-cell cancers, such as multiple myeloma and non-Hodgkin’s lymphoma. In addition, animal studies have shown that benzene can cause chromosome changes in bone marrow cells.

Agencies that have evaluated the cancer-causing risks associated with benzene include the International Agency for Research on Cancer (part of the World Health Organization), the National Toxicology Program, and the U.S. Environmental Protection Agency (EPA). All have classified benzene as a known carcinogen for humans. Linear alkyl benzene sulfonates (LASs) are typically listed as anionic surfactants on detergent labels and are often major cleaning agents in granular, tablet, and powdered detergents.

Although no definitive link has been established between cancer in humans and benzene in laundry and dishwashing detergent, it is known that the benzene in LAS gets into clothes. As a result, benzene can then be absorbed by the wearer via the skin when a person sweats and via the underarms into the lymphatic glands. Benzene exposure can also occur in some workplaces, including the manufacturing facilities for detergents.

1,4 Dioxane and Acetalehyde

Classified as an ether, 1,4 dioxane is an organic compound and colorless liquid. According to the EPA, dioxane is a probable human carcinogen. Studies have revealed increased incidence of cancer in animal studies. However, no relationship has been definitively observed between dioxane and workers who use the compound or at concentrations found in products such as detergents. According to the EPA, animal studies have found that the greatest risk is likely to be due to dioxane vapors that are inhaled.

Further Readings

Detergents

Dioxane is found in numerous laundry detergents. Dioxane is not an additive to cleaning products but rather is a contaminant left behind by the use of ethoxylated ingredients found in many cleaning products. A 2011 study conducted by the nonprofit Women’s Voices for the Earth (WVE) found that Tide Free & Gentle laundry detergent and the company's regularly formulated detergent both contained dioxanes at levels of 89 parts per million (ppm) and 63 ppm, respectively. Some animal studies have estimated that daily exposure at levels above 50 ppm for two years can cause liver damage. Other laundry detergents were also found to contain the substance, but Tide had the highest levels.

In 2013, Procter & Gamble, the company that manufactures Tide, announced that it was reducing the amount of the chemical in its Free & Gentle and regular detergents. This announcement came after the company ignored initial calls from WVE and then faced a lawsuit brought by a group called As You Sow, which claimed the company was unnecessarily exposing customers to high levels of 1,4 dioxane without notifying them via the products' labels. Although this lack of notification did not violate any federal law, it did violate California's Proposition 65 labeling law concerning toxic chemicals. After losing the suit, Procter & Gamble stated it would reduce levels of the chemical in these products nationwide to below 25 ppm.

Acetaldehyde is another compound found in some detergents. Although it occurs naturally in the environment and also during normal metabolism in the body, extensive exposure can cause acetaldehyde to become a neurotoxin leading to depression, headaches, irritability, lethargy, and poor memory. Animal research has shown that acetaldehyde can increase the risk for nasal and throat cancer. However, data gathered from humans on its carcinogenic effects are inadequate. The EPA has classified acetaldehyde as a probable human carcinogen.

Scented Detergents
Manufacturers do not have to disclose all the ingredients in laundry products, including substances used to scent the product. In 2011, a study noted a potential health risk due to scented detergents and dryer sheets. In a small study in the August 2011 issue of *Air Quality, Atmosphere and Health*, research looked at the effluent from dryer vents in two households. Comparing scented laundry cycles with unscented laundry cycles, researchers found that scented cycles contained 25 volatile air pollutants, including the carcinogens benzene and acetaldehyde.

The researchers estimated that, in the Seattle, Washington, area, where they conducted the study, acetaldehyde emissions from scented detergents would be approximately 3 percent to all acetaldehyde emissions from cars. They also noted that they determined that emissions from the top five brands of laundry detergents would be equal to about 6 percent of acetaldehyde emissions from cars. Other research has indicated that possibly one-third of all scented detergents have at least one chemical ingredient that the EPA considers carcinogenic.

In another study conducted in Seattle, researchers examined what chemicals classified as being
hazardous to human health were in scented detergents and other fragrance products. The study, however, did not examine any links between exposures to these chemicals and health problems. Nevertheless, researchers examined the air in an isolated space for volatile organic compounds (VOCs), which are small molecules released into the air from the surface of the products. The study found almost 100 VOCs at levels in the air considered to have potential health concerns due to exposure to them. Three of them were classified as hazardous air pollutants, including acetaldehyde and 1,4 dioxane.

The study pointed out that none of the product labels listed these substances on the ingredients label. For example, in the case of 1,4-dioxane, the carcinogen is created when detergents are processed using ethoxylation. Because 1,4-dioxange is a by-product of ethylene oxide reacting with other substances, it is considered a contaminate and not required to be listed on the label. Industry spokespeople noted that the amount of potentially carcinogenic ingredients in the various products have not been shown to be hazardous to human health. They also point out that people sensitive to fragrances can simply avoid using them.

**Cancer Patients and Detergents**

Because of the many substances used to manufacture most popular laundry detergents, cancer patients undergoing chemotherapy are warned to avoid detergent residue on their clothes and other articles in the house, such as bedsheets. According to the National Cancer Institute (NCI), pruritus, or dry skin and itching, often occurs in cancer patients, and one of the causes could be detergents. NCI notes that traces of laundry detergents and fabric softeners can help make pruritus worse in cancer patients.

NCI recommends using one teaspoon of vinegar per quart of water in the laundry rinse cycle to help prevent trace residues. NCI also suggests using milder detergents, such as detergents specifically made to wash baby clothes. In addition, mild bath soaps have less detergent in them to irritate the skin.

**Drinking Water**

A 2010 study published in *Environmental Science & Technology* implicated detergents, along with shampoos and fabric softeners, as potential precursors to the formation of carcinogenic contaminants in treated wastewater. The contaminants are nitrosamines, which are found in numerous products, including detergents. Treating wastewater with chlorine or ozone does not reduce the formation or nitrosamines, resulting in their presence in drinking water and recreational water.

The primary concern is over a nitrosamine called N-nitrosodimethamphetamine (NDMA), which is a toxic organic chemical and has undergone studies indicating it may be a human carcinogen. Researchers stress that the study results are preliminary. Furthermore, it is unlikely that any one compound or product, such as a detergent, would cause most of the NDMA formation. Detergents also varied widely in their formation of nitrosamines.

Consumer advocates have noted that people may want to consider going with “green cleaners” that, as far as it is known, do not contain or produce potential carcinogens. In addition, they recommend carefully reading detergent labels. For example, signs that the detergent may contain dioxane, which is not listed, include ingredients such as polyethylene, polyethylene glycol, PEG, polyoxymethylene, and words containing “oxynol” or “eth.”

Developing Countries

The prevention, detection, treatment, and palliation of cancer can be an economically daunting task for the poorer nations of the world. Combined with an increasing prevalence of cancers, many of which have an infectious etiology, lack of economic stability, a burgeoning population, the acquired immune deficiency syndrome (AIDS) pandemic, and inadequate health care services, these countries are on the verge of a crisis. However, the shift in paradigm from cancer treatment to prevention and early detection may possibly avert a major catastrophe.

Cancer in Developing Countries

Estimates of global cancer incidence and progression indicate that there will be approximately 17 million cases detected by 2020 and 27 million by 2050. Approximately two-thirds of cancer cases by 2050 will occur in the developing countries of the world. Compounded with problems of increasing population and life expectancy, greater influence of Western lifestyles, and lower cure rates, a higher incidence of cancer in the future will translate into increased mortality rates due to the disease in this part of the world.

The typical epidemiology of cancer in developing countries differs from that of the developed world in certain major aspects. Developed countries have higher rates of lung, breast, colorectal, prostate, and bladder cancer, possibly due to the earlier onset of the tobacco epidemic, exposure to occupational carcinogens, influence of the Western diet, and a relatively sedentary lifestyle. In contrast, developing countries have higher rates of stomach, cervical, and liver cancers due to the prevalence of infections that are strongly implicated as causative agents in these types of tumors. Incidences of lung and breast cancer, however, are comparable between developed and developing nations.

The causes of cancer vary worldwide. In developed nations, tobacco is a major causative agent, causing a third of all cancer deaths. It has been calculated that a quarter of all tumors are smoking related. Tobacco consumption is becoming a growing cause of concern in developing countries as well. Smoking has been primarily implicated for the high incidence of lung cancer, which in turn currently accounts for the highest numbers of new cancer cases and cancer-associated deaths among males in developing countries. Oral tobacco consumption is also an important carcinogen for oropharyngeal and laryngeal carcinomas.

Nearly one in four cancer deaths in developing countries are associated with chronic infections. These particularly include the human papillomavirus (HPV) that is associated with cervical cancer, Helicobacter pylori that causes stomach cancer, and hepatitis B and C viruses (HBV and HCV) that are major causes of liver cancer. Together, these agents account for more than 90 percent of cancers due to an infectious agent. Dietary ingestion of substances produced by the mold Aspergillus flavus, specifically aflatoxin B1, is associated with development of liver cancer. Improper storage of grains and similar foods after harvesting, especially in humid, developing countries, is a major cause of contamination of this mold. Superimposed exposure to aflatoxins in a person infected with HBV increases his or her chances of developing liver cancer.

Kaposi’s sarcoma, a formerly rare and indolent cancer, has emerged as a new cancer problem in sub-Saharan Africa. For many years, Kaposi’s sarcoma was the most common cancer observed in AIDS patients, and indeed this, in part, initially defined the AIDS epidemic. However, this is no longer the case since the advent of highly active antiretroviral therapies for human immunodeficiency virus (HIV) in the 1990s. Where these therapies are available to those infected with HIV, Kaposi’s sarcoma has again become a rare diagnosis. However, due to the limited availability of antiretroviral therapies in sub-Saharan Africa, Kaposi’s sarcoma is now one of the most common cancers and can also affect young children.

Health services in developing countries are currently struggling with a growing population, lack of funds, wars, natural disasters, cultural biases, and the HIV pandemic. However, in the midst of evaluating the logistical and natural differences between
the developed and developing world, the disparities in experiences of patients diagnosed with life-limiting illnesses are generally ignored. Studies have shown that, while cancer patients from developed countries describe unmet psychosocial needs, the problem among patients from developing nations is more acute where physical needs are often unmet. Unaffordable and inaccessible health care services mean that not all cancer patients can obtain treatment or painkillers. The main issue in these cases, therefore, is the physical suffering associated with cancer. This is notably absent in developed countries where patients have direct and affordable access to health care. A diagnosis of terminal cancer in developing countries is often met with acceptance and a long wait for death that can be especially discomfiting in the absence of adequate medical support.

**Interventions for Cancer Control**

When developing national strategies to control cancer, the World Health Organization recommends that countries follow four broad approaches: primary prevention, early detection and secondary prevention, diagnosis and treatment, and palliative care. In addition, health care providers in developing countries also examine the cost-benefit ratios of such interventions before their mass implementation.

The goal of primary prevention is to minimize or eliminate exposure to cancer-causing agents, including environmental carcinogens and lifestyle factors related to nutrition and physical activity. With infectious agents being a major and preventable cause of cancer deaths in the developing world, primary prevention of cancer in these countries needs to focus on immunization and treatment of infectious, cancer-causing agents. The HBV vaccine was designed to prevent liver cancer and is now widely used in several developing countries. Efforts are also underway to develop vaccines to prevent *H. pylori* infection. Cervical cancers are strongly associated with HPV. Use of barrier contraception can protect against this infection, but many developing countries do not have health and family planning programs in place to impart education regarding use of such contraceptives. An HPV vaccine is now available that protects against two viral subtypes that are responsible for approximately 75 percent of all cervical cancer cases.

Tobacco consumption is the most important cause of lung and esophageal cancers. Effective national tobacco control programs need to encompass health promotion, education, and health service interventions with tobacco control policies, including regulation of tobacco advertising, increased taxation, and smoking bans in public places. This also can reduce secondhand smoking, which is a major factor for development of many cancers and other diseases of the respiratory tract. Excessive alcohol use also can be a major contributor for liver and esophageal cancers, and control of alcohol consumption can tackle this problem too. Prevention of food-grain contamination along with dietary supplementation of food rich in chlorophylls can reduce the carcinogenic potential of aflatoxins. For those infected with *H. pylori*, reduced consumption of salted, pickled, and smoked food that is otherwise typical of cuisines in some developing countries can avoid the formation of gastritis and ulcers, which are common precursors to stomach cancer.

Screening for cancers, especially among susceptible population subgroups or geographic locations, remains the mainstay of early detection and effective intervention in developing countries. Screening for liver cancers includes ultrasound examination and blood tests to detect specific proteins that can be elevated in cancer. Screening for colorectal and stomach cancers includes fecal examination, routine radiology including contrast studies, and endoscopic examinations. Urea breath test is a specific screening test to detect presence of *H. pylori* infection and is gaining popularity in mass screening programs. Methods of early detection of breast cancer include screening by mammography, clinical breast examination, and breast self-examination.

Cytology-based examination using the Papanicolaou (Pap) smear has been the main screening method for secondary prevention of cervical cancer worldwide. However, this is often difficult to sustain in developing countries due to lack of expertise and infrastructure. An effective alternative approach is by visual inspection of cervix after application of acetic acid, which can be performed by trained health workers. Studies have shown that this may be as effective as a Pap smear and is being increasingly employed by developing countries with a see-and-treat approach. This involves detection of suspicious cervical lesions followed by immediate
Diesel Exhaust treatment using electrosurgical excision or cryo-therapy as an outpatient procedure so that patients are not lost to follow-up.

Developing countries often face a multitude of problems with respect to diagnosis and treatment of cancer due to poor infrastructure and laboratory support, lack of adequate hospitals and clinics, low physician-to-patient ratios, absence of insurance and social security policies, lack of government funding, superimposed political crises, and social misconceptions. In addition to the traditional therapeutic interventions for cancer therapy, developing nations need to focus on the treatment and eradication of infections that are major causes of cancer. Important examples include treatment of *H. pylori* infection using various antibiotic regimens, use of sterile needles (to avoid HBV infection), and safe blood for transfusions (to avoid HCV infection) to prevent liver cancer. In addition, the high morbidity and mortality rates of cancer in the developing world imply a greater need for access to palliative drugs and painkillers that can help relieve the pain associated with cancer therapy and the natural course of the disease.

**Diesel Exhaust**

Diesel exhaust is the product of combusted diesel fuel used to power many larger vehicles and machinery. The first diesel engines emitted high amounts of soot, or diesel particulate matter, which has now been shown to be a cause of lung cancer. Although technologies have decreased the amount of particulate matter released by these diesel engines, there is still a measurable link between its inhalation and increased risk of cancer. Exposures still occur today on a wide scale in occupational and public settings from diesel industries from mining and professional driving to residential metropolitan areas.

Exposure to diesel exhaust is a known occupational hazard to truckers, railroad workers, and miners using diesel-powered equipment in underground mines. Adverse health effects have also been observed in the general population at ambient atmospheric particle concentrations well below the concentrations in occupational settings. The first diesel engines started to be used more frequently in the early 20th century; the engine was patented by the German scientist, Rudolph Diesel. Not until the mid to late 20th century did the diesel engine really become commonplace. These trucks, cars, and machines emitted large amounts of particulate matter and other gaseous products from the combustion of diesel fuel, which at the time was not known to be hazardous. In the 1960s through the late 1980s and even today, government regulation on diesel exhaust standards has dramatically reduced the amount of particulate matter and other components released; however, there is still reason to be concerned about this carcinogen.

**Constituents of Diesel Fuel and Exposure**

Diesel fuel is burned to extract the energy it withholds to power an engine. The exhaust released by this process is a source of atmospheric soot, fine particles, and gaseous chemicals with unique characteristics. Diesel engine exhaust depends on many factors including size, temperature, lubrications, and fuel composition ratios. These factors may affect the composition of the exhaust, although significant particulate matter is associated with all diesel engines. Diesel engines produce 50 to 200 times more particulate matter than catalyst-gasoline engines. The rough surfaces of these fine particles make it easy for them to bind with other toxins in the ambient air, thus increasing the health hazards of particle inhalation.

Fine particles from diesel exhaust are a group of air pollution hazards linked to cancer and heart and lung damage. Fine particles less than 2.5 microns in
size can penetrate deep into the lung issues, where gas transfer occurs between red blood cells, lodging themselves in the tissues permanently. Because these particles cannot be removed, they often cause irreversible damage. This particulate matter is one of the most-recognized harmful components of diesel exhaust and may account for many of the lung-related illnesses associated with diesel exhaust.

Accompanied by soot, there are other harmful chemical compounds. Some of these components include acrolein, benzene, carbon dioxide, carbon monoxide, formaldehyde, nitrogen dioxide, and sulfur dioxide. Nitrogen dioxide is used as a marker for traffic-related pollution such as in a city and can be a good tool in measuring the public’s estimated exposure. Exposure to trace amounts of nitrogen dioxide is almost constant due to the combustion of fuel in all populated places. Most of the components of diesel exhaust are either irritants, asphyxiants, or suspected or confirmed carcinogens. Some of the components are released in such small quantities, however, that they are not above allowable occupational exposure levels.

Types of Exposures
Occupational exposures can happen to a wide variety of workers in many different diesel-related industries. Public exposure can occur indirectly from occupational sources or simply living near high-volume traffic. Industries that see high exposures to diesel exhaust, in particular diesel exhaust particulate matter, include professional driving (e.g., trucks and buses), railroads, construction, agriculture, and maritime fields as well as specific jobs, such as: traffic police, garage mechanics, taxi drivers, tunnel workers, and gas station attendants. Because the public is usually woven into all of these jobs, it is not uncommon for the general public to receive small exposures also. The extent to which these small exposures affect the general public are still unclear, although there are clearer trends between occupationally exposed individuals and health effects.

Mining is one of the most commonly studied diesel exhaust exposure industries. Vehicles are used in underground mines to assist tunneling and removal of debris. These vehicles are powered by diesel fuel and release diesel exhaust into underground mines that may not be well ventilated. Studies have shown a relationship between underground miners and increased risk of lung and esophageal cancer as well as pneumoconiosis. The evidence, however, may be complicated by the synergistic effects of other hazards associated with mining, including coal dust, silica particulate matter, and smoking. Professional driving, or operation of large diesel vehicles, is another industry that may pose a measurable, elevated risk of cancer due to the close proximity of the worker to exhaust release.

Public exposures can occur from daily life, travel, as well as nondiesel related occupations (i.e., office adjacent to a busy highway); however, exposures are usually much less than that of an individual working near or with diesel machines (i.e., miners and professional drivers). Workers exposed to diesel exhaust on the job also commute and spend free time where significantly smaller, but prevalent, exposures can occur. The adding relationship that some exposure reports are urging is that normal exposures to nitrogen dioxide (a traffic exhaust marker) are added upon when working in a diesel industry. These researchers are basically urging that the exposure never stops; it merely decreases. This relationship may be a concerning factor in certain metropolitan situations where traffic exhaust pollution and diesel industry are large issues.

Carcinogenicity and Health
Short-term or acute exposures to diesel exhaust have been linked with symptoms such as headache, dizziness, nausea, coughing, and irritation of the eyes, nose, and throat. Research has shown an inflammatory response in respiratory epithelial cells that line the airways, causing some of these acute exposure signs and symptoms. Acute exposures usually cause no further long-term damage to the body, although continued exposure has this potential.

Long-term exposures can lead to chronic, more-serious health problems such as cardiovascular disease and respiratory cancers. The reason diesel exhaust is thought to be a carcinogen is that it is made from many components that are proven carcinogens. These components, combined together, may result in an increased negative health effect or synergistic effect. Chemical components of diesel exhaust have the ability to enter directly into the bloodstream due to the systemic nature of inhalation. Similar to how oxygen is transferred from the alveoli chambers of the lungs to the red blood cells in the bloodstream, inhaled chemicals can diffuse into the bloodstream in the same manner.
Additionally, each constituent of diesel exhaust has separate carcinogenic effects, and not all fuels are the same. For example, benzene, a chemical component of diesel exhaust, is thought to cause leukemia, and carbon monoxide is an asphyxiant. There are some fuels richer in certain components, making them possibly more or less hazardous than others. Chronic exposure can lead to an increased risk of developing cancer due to repeated exposure contact with possible carcinogens and human cells (i.e., lung tissue cells). The exhaust’s fine particles can come in contact with lung tissue and cause cells to mutate. Diesel exhaust particulate matter has been shown to be a mutagen in the way it can affect human DNA, causing usually long-term health problems and possibly death. There is clear evidence of this mutation in occupational exposure studies, many of which lead to lung-related cancers and illnesses.

Studies have shown associations between diesel exhaust exposure and increased incidence of lung cancer, even in nonsmokers. While smoking increases the risk of cancer by itself, smoking while exposed to other carcinogens, like diesel exhaust, can create a multiplying or synergistic effect, dramatically increasing the risk of developing cancer. As both of these exposures are respiratory, the lungs are usually a target site for cancer when exposed to both.

The means associated with development of cancer concerning diesel exhaust are source, exposure, and the mutation site, creating a potential for cancer. First, there must be a source of diesel exhaust, usually motor vehicles or machines that use diesel fuel. The exhaust these machines create is released into the surrounding air and, depending on weather conditions and wind, may be quickly dispersed or linger around the machine or inside of a vehicle’s cab in varying concentrations. Once the source is established, the exposure occurs through an individual’s respiration. As the exhaust enters the lungs, the particulate matter sticks to the moist tissues in the respiratory system, some of which make it into the smallest segments of the lungs. The chemicals in the exhaust may be exhaled or enter into the bloodstream to be removed and excreted or deposited in an organ or tissue within the body. The particulate matter still in the lung tissues has the potential to mutate the cells that it comes in contact with, possibly resulting in a tumor or scarring of tissues. Mutation occurs when the particulate matter changes the DNA of the targeted cell in the lung.

That cell can become a cancer cell, able to replicate and reproduce more cancer cells, which leads to a tumor and lung cancer.

**Conclusion**

Diesel exhaust is a conglomerate of many carcinogens and hazardous substances that pose a threat to both occupational and public settings. There is considerable evidence that diesel exhaust exposure, especially chronic exposure, increases the risk of lung cancer and possibly a host of other health problems. Exposure can occur in both occupational and public settings and wherever diesel-powered machines are used. Diesel exhaust is thought to be a carcinogen due to its components, including diesel exhaust particulate matter as well as many chemical compounds. Synergistic effects of diesel exhaust and other carcinogenic inhalation hazards may create compounding factors that have the potential to increase cancer rates among many occupationally exposed workers. It is hard to measure the public’s exposure and cancer response to diesel exhaust due to its nature of components and other confounding factors that affect each individual’s susceptibility.
Diet and Nutrition

The importance of diet in maintaining health and preventing disease, including cancers of many anatomic sites, has been recognized for millennia. Despite contradictory results from prospective cohort studies, most but by no means all of the tens of thousands of scientific papers on the subject support the role of diet and nutrition in causing cancer or affecting survival. After tobacco use, diet and diet-related factors (such as body weight) appear to be the most important determinants of cancer risk.

More than 30 years ago, Drs. Richard Doll and Richard Peto estimated that 35 percent of all human cancers are caused by diet. Despite the large degree of uncertainty around this estimate, it still is considered widely to be a reasonable, well-informed guess. The uncertainty accompanying any global estimate of the effect of diet and nutrition on cancer results from: the complexity of dietary exposures; the wide variety of the kinds of evidence that exist; methodological difficulties involved in conducting studies that assess diet and cancer risk in humans; reductionist approaches that, in their attempts to simplify research questions, are at high risk of providing erroneous inferences about human cancers; the desire for researchers and the public to sensationalize results from individual studies; and the fact that cancer represents a wide variety of diseases that vary in terms of anatomic site, histology, molecular biology, morphology, and a variety of other characteristics.

**Total Caloric Intake**

Some of the earliest studies linking diet and cancer were laboratory experiments showing that animals on calorie-restricted diets were less likely to get cancer than animals that ate freely. Those animals that did get cancer on such calorie-restricted diets (e.g., ones that were given a known carcinogen or cancer-causing agent) were often found to have fewer or less-aggressive tumors. Corroborative evidence comes from international comparisons showing that countries with high rates of estimated energy consumption and in which individuals tend to be sedentary have very high rates of certain cancers such as breast, prostate, and colon. Findings from a number of “natural experiments” in which humans who were deprived of sufficient food for short periods of time—the World War II–induced Dutch Famine of the winter of 1944 and 1945 have yielded conflicting results, indicating the complexity of diet–cancer relationships in terms of timing, recall bias, and mechanisms of carcinogenesis. Recent work showing that caloric excess can be pro-inflammatory, which in turn may increase cancer risk, underlines the importance of regulating total intake. As with work conducted in the 1970s on cardiovascular disease, it appears that increasing physical activity with a concomitant need for additional energy appears to reduce cancer risk.

**Specific Nutrients and Other Dietary Constituents**

Early on in the scientific study of diet and cancer, it was shown that dietary fat increases risk in certain animal models of cancer. Subsequent work in humans, especially focusing on breast cancer, has led to equivocal results. Population-level comparison studies (usually comparing countries with very different cancer death rates) have supported the
laboratory animal trials. Studies that are thought to be methodologically stronger, that is, cohort or prospective studies of free-living humans, tend not to support the fat–cancer hypothesis. There are a variety of methodological issues that may explain these discrepancies, including the limited range of exposures within specific populations in comparison to both the cross-national comparisons and many of the laboratory animal experiments. As for total caloric intake, most categories of fatty acids are pro-inflammatory.

The study of other macronutrients (nutrients that contribute calories to the diet, i.e., protein, carbohydrate, and alcohol in addition to fat), facing similar methodological barriers and challenges, have come to similar conclusions. One striking exception is alcohol: In the presence of tobacco, it is a strong cocarcinogen for most of the sites of the upper aerodigestive tract, including the oral cavity, larynx, and esophagus. In addition, there is evidence that alcohol increases breast cancer risk.

Over the past several decades, there has been greatly increased focus on specific micronutrients (nutrients such as minerals and vitamins that do not contribute calories to the diet) and other constituents of the diet, including compounds in spices and categories of fiber (e.g., some nondigestible components). On balance, patterns of nutrient consumption associated with vegetarian diets and certain traditional foodways (e.g., East Asian, South Asian, and Mediterranean cuisines) are associated with lower overall cancer rates. In the past several years, intensive research has shown that most of these micronutrients and other constituents such as flavonoids are anti-inflammatory. There is a complementary body of evidence showing that meat (especially processed and red meat) intake is both pro-inflammatory and is associated with increased cancer risk.

Whole Diets: Special Populations
Despite heavy use of dietary supplements among a small minority of individuals, the vast majority of nutrients are consumed as part of individuals’ diets. Nutrients and other components of diet are therefore rarely eaten as separate components. They occur together within foods and usually are eaten as part of complex sets of rules and social behaviors. There is therefore an organic connection between individual dietary components, both in terms of how people relate socially and psychologically around food and how individual food constituents interact with one another in the body.

For example, membership in a group can reinforce a pattern of food intake that is high in dietary fiber and will include many antioxidant vitamins (e.g., of which beta-carotene is but one of many hundreds of carotenoids). The diet will be generally low in fat and very rich in many other micronutrients besides the carotenoids. It also will tend to be anti-inflammatory and antioxidant, factors that are known to be associated with lower risk of many cancers. Based on encouraging evidence from epidemiologic studies, intervention trials that have given research subjects high doses of specific micronutrients have generally met with failure. Notable examples include two large randomized trials begun in the late 1980s in which beta-carotene was associated with increased risk of lung cancer. The International Agency for Research in Cancer (IARC) concludes that greater consumption of vegetables and fruits is associated with decreased risk of lung, esophageal, stomach, and colorectal cancer. The connections with other cancers are considered probable. In contrast to studies that have attempted to reduce the dietary prescription to a few nutrients, there is a substantial body of evidence showing that special groups within high-risk populations and members of cultures eating whole food, predominantly vegetarian or near-vegetarian diets, have low rates of cancer and other chronic diseases. These include vegetarian Seventh-Day Adventists in the United States and certain major population groups in east and south Asia. Some of these groups, in particular Indians, eat relatively large quantities of spices and natural flavorings that have been found to be protective against cancers in laboratory animal experiments. Some of these, including garlic, ginger, cumin, and onion, are common to many cuisines.

Studying Diet and Cancer
In general, the strongest evidence for diet and cancer comes from free-living populations that choose to eat diets that diverge from the Western norm. Cross-cultural studies designed to measure and test the effect of diets of individuals who differ from one another to as great a degree as countries represented in cross-national comparisons have not been undertaken.
Besides the complex mix of nutrients, individuals adhering to vegetable-based, whole-food diets may avoid exposures known to increase cancer risk such as tobacco and alcohol. They also usually engage in a range of other healthy behaviors related to stress and physical activity. Often, these other behaviors and the social support they entail reinforce the commitment to healthy eating. It is widely known that individuals’ attempts at dietary change almost always fail. The kind of randomized clinical trials the biomedical community considers definitive require removing the specific dietary component from the larger dietary regimen in which it can react with many other components of diet. Additionally, such studies rarely provide the durable social support structures that make it possible for individuals to maintain a long-term commitment to consume such whole-food diets (and the many nutrients they contain).

One notable exception to the natural tendency of people to avoid making dramatic dietary changes is cancer patients who may be highly motivated by having had a life-threatening illness diagnosed. There are some small studies that have shown that vegetable-based, whole-food diets may decrease the recurrence of breast and prostate cancer and colon polyps.

Clearly, any study of cancer in humans will have to face the complexity of diet, including food preferences, preparation techniques (e.g., charring of food is related to cancer), serving size estimation, consumption of foods outside of meals and away from home, natural and intentional food contaminants and additives, and a host of problems with recall. Any attempt to simplify the study system will need to account for eliminating the other aspects of diet and lifestyle that appear to interact to reduce risk.

Conclusion
Whole food, vegetarian, or near-vegetarian diets are associated with lower rates of cancer. Supportive findings derive mainly from studies outside the nutritional mainstream in countries such as the United States. Many of the components of these diets appear to be protective. Attempts to study specific dietary components, especially in humans, generally have not met with much success.

Disability

People with cancer can have a complex relationship with the word disability. Some see it as a very negative word, focusing on what they cannot do, and they do not want to see themselves that way. On the other hand, when people have severe symptoms, they may need to get some welfare assistance, such as Social Security Disability Assistance.

People with cancer also may experience health-related prejudice and discrimination. In such circumstances, they are protected by the Americans With Disabilities Act (ADA). This act has recently been broadened to include a much wider range of people and conditions than originally thought.
Attitudes Toward Disability
Disability is traditionally considered a very negative category—where people are seen as the tragic victims of various health-related conditions. Additionally, people tend to focus on the negative things about someone identified as disabled as opposed to what they can do. For this reason, many people with cancer are reluctant to identify as disabled. However, others feel that they have no option: Their health has deteriorated to the point where they are unable to work, or they need employment or income assistance. In such circumstances, they often rethink their attitudes toward people with disabilities and disability in general.

Protections Under Legislation
On January 1, 2009, the Americans With Disabilities Act Amendments Act came into effect. This act was follow-up legislation to the original 1990 ADA and aimed to restore its original intent of providing a broad-scale means to reduce discrimination. The ADA and this subsequent piece of legislation aim to make it unlawful to discriminate against a person because of his or her disability status. This new disability definition includes people with cancer.

In the 2008 act, Congress clarified the definition of “disability” by identifying a number of major life activities that may be affected by a person with a disability. The act specified activities such as caring for oneself and performing motor tasks, including walking, standing, lifting, speaking, breathing, hearing, and eating as well as cognitive tasks, including learning, reading, concentrating, and thinking. The phrase major life activities was also expanded to include routine operation of major bodily functions, such as normal cell growth; immune system activity; digestion; bowel activity; bladder operation; neurological activity; and respiratory, circulatory, endocrine, and reproductive functioning. All of these major life activities can be affected by various forms of cancer.

The ADA and the subsequent Amendment Act also demand that employers provide reasonable accommodations to people with disabilities, which includes things such as making existing facilities accessible to individuals with disabilities, changing employment to duties, and providing equipment, devices, or interpreters to afford a person with a disability the opportunity to perform his or her occupational role. The act stipulated that employers must provide these accommodations unless providing them would impose extreme hardship on the employer, which was determined on account of the size of the firm and the nature and cost of the accommodation.

Disabling Barriers
While many services afforded to individuals with disabilities are helpful and make a difference in disabled persons’ lives, there remain a number of barriers disabled persons continue to face. Major disabling barriers experienced by people with cancer include barriers in employment, transport, the built environment, insurance, and vocational and educational areas. People with cancer can also experience stigma. People with disabilities have civil rights protections that recognize they are entitled to engage in regular activities, and employers, educational institutions, and businesses need to make their services accessible.

Stigma is a major issue for people with disabilities, including those with cancer. Unfortunately, in everyday interactions, some people are misinformed and prejudicial toward those with cancer. This leads many people with disabilities to be sad or angry about being misunderstood and mistreated. There are many ways of dealing with such prejudice, from ignoring it to challenging it by being assertive. Responding to such problematic behavior is always an individual decision, and it is important to try not to become depressed because depression can have secondary health effects for those with cancer.

Employment barriers, including prejudicial attitudes and failure to provide reasonable accommodations are sometimes reported by people with cancer. An example of a reasonable accommodation for someone with cancer might include needing a different type of chair in an office, needing regular breaks during the day, or needing to switch some duties with another employee. If an employer refuses to provide such reasonable accommodations, individuals may be entitled to take legal action.

Transportation barriers are another common experience for people with disabilities, including people with cancer. For instance, some people will develop mobility problems as a result of cancer. They may not be able to drive or move freely and may use wheelchairs. Accessible transport
therefore becomes a major priority. While some people are able to afford to purchase or rent accessible vehicles, many more become reliant on public transportation. The supply of accessible transportation varies from city to city. In some places, there are a lot of buses, taxis, and trains that are accessible, whereas in other locations (particularly small towns and rural locations), getting around is much harder for those with mobility impairments.

Problems With the Health System and Insurance
A number of financial resources are available to people with cancer. Individuals may be afforded access to government-funded insurance plans, private health plans, health insurance risk pools, and other options. Some government-funded options include Medicare, Medicaid, state-sponsored plans, as well as veteran and military benefits. Private options include both individual and group plans as well as access through government-maintained marketplace plans such as those available through the Affordable Care Act. For those individuals who are uninsured, insurance help may be found at some hospitals.

Nonetheless, a number of people with cancer face obstacles finding, receiving, and enjoying the benefits of health insurance. As a result of their health problem experiences, people with cancer may find themselves needing to access disability assistance programs. They are usually entitled to such programs and to the legal protections offered to people with disabilities under relevant legislation because of their health problems. However, like many people with disabilities, they may face many gaps and barriers in service provision and problems with the affordability of necessary procedures.

Disinfectants and Antiseptics

Antiseptics and disinfectants are commonly used in hospitals and other health care settings as the primary method to control infection and prevent nosocomial infection. Antiseptics are biocides that destroy or inhibit growth of microorganisms in or on living tissue. Disinfectants are similar but are used on inanimate objects or surfaces. Biocides have been used for hundreds of years for antisepsis, disinfection, and preservation, displaying wide activity that inactivates various microorganisms. To communicate the wide variety of action carried out by biocides, suffixes are attached including “–static,” referring to agents that inhibit growth (e.g., bacteriostatic, fungistatic, and sporistatic), and “–cidal,” referring to agents that kill the target organism (e.g., sporicidal, virucidal, and bactericidal). Antiseptic and disinfectant activity on microorganisms can be influenced by the presence of an organic load, synergy, temperature, dilution, and test method.

Types of Antiseptics and Disinfectants
Acetic acid (vinegar 8 percent) has shown substantial activity against two gram-negative bacilli, P. aeruginosa and S. choleraesuis. Acids deactivate many microorganisms, but because concentrated solutions can be casuistic, cause chemical burns, and are toxic at high levels in the air, they have been limited as disinfectants. Acidic-electrolyzed water is made from the electrolysis of ordinary water and measured amounts of salt such as sodium chloride (table salt). When combined with chlorine, the water solution possesses bactericidal activity against mycobacteria and spores of Bacillus subtilis.

Alcohols produce rapid, broad-spectrum antimicrobial activity against vegetative bacteria (including mycobacteria), viruses, and fungi, with an optimal level in the 60 to 90 percent range. It is fast acting with most bacteria killed within five minutes of exposure. Alcohols are used for
Disinfectants and Antiseptics

Surface disinfection, topical antiseptic, and in hand-sanitizing lotions. They are highly flammable, can cause damage to rubber and plastic, and can be very irritating to injured skin. Ethyl alcohol (ethanol and alcohol), isopropyl alcohol (isopropanol and propan-2-ol) and n-propanol are widely used for both hard-surface disinfection and skin antiseptics. Generally, isopropyl alcohol is considered slightly more efficacious against bacteria, and ethyl alcohol is more potent against viruses. They are not considered sporicidal and are not recommended for sterilization.

Alkalis, such as sodium hydroxide (lye, caustic soda, and soda ash), are highly caustic and are used to disinfect buildings. Protective clothing should be worn when mixing and applying the chemical. Water should not be poured directly into lye as violent reactions will occur and produce high heat that can melt plastic containers. Sodium hydroxide is corrosive for metals. It is considered an effective foot-and-mouth disease (FMD) disinfectant.

Aldehydes are effective against bacteria, fungi, viruses, mycobacteria, and spores. They are non-corrosive to metals, rubber, plastic, and cement. Glutaraldehyde is a dialdehyde used primarily in low-temperature disinfection, in sterilization of endoscopes and surgical equipment, and as a fixative in electron microscopy. It has broad-spectrum activity against bacteria as well as spores, fungi, and viruses. However, it is caustic, producing mucous membrane-irritating effects, bronchial asthma, and contact dermatitis. O-Phthalaldehyde (OPA) has been suggested as a replacement for glutaraldehyde in endoscope disinfection as it is less volatile and irritating while maintaining potent bactericidal and sporicidal activity. Formaldehyde is bactericidal, sporicidal, and virucidal, generally used as a disinfectant and sterilant in liquid or in combination with low-temperature steam. When formaldehyde is used as a fumigant, it is done in an air-tight building, which must remain closed for at least 24 hours after treatment. The carcinogenicity of formaldehyde in rats and mice after long-term inhalation exposure has led to reduced use.

Anilides are antiseptics commonly found in cosmetic soaps and deodorants and rarely used in clinics. Triclocarban is active against gram-positive bacteria and does not stay on skin well.

Chlorhexidine is a biguanide with broad activity substantively for the skin, with low irritation, making it one of the most widely used biocides in antiseptic products. It is found in hand-washing and oral products and also used as a disinfectant. Mycobacteria are generally highly resistant to chlorhexidine; it is not sporicidal, and the antiviral activity of chlorhexidine is variable.

The bis-phenols are hydroxy-halogenated derivatives. They exhibit broad-spectrum efficacy but have little activity against \( P. \) aeruginosa and molds and are sporostatic toward bacterial spores. Triclosan and hexachlorophene are the most widely used biocides in this group, especially in antiseptic soaps and hand rinses, and have persistent effects on the skin. Concern over the toxicity of hexachlorophene has limited its use as an antiseptic.

Halogen-releasing agents and halogen compounds are popular as they are considered to have low toxicity and low cost and are easy to use. They lose potency over time in the presence of organic debris, sunlight, and some metals. To be effective, they must be applied to thoroughly cleaned surfaces. Chlorine- and iodine-based mixes are the most prevalent microbicidal halogens used in clinics and have both antiseptic and disinfectant applications. Chlorine-releasing agents (CRAs) are typically used as hard-surface disinfectants. Sodium hypochlorite solutions (household bleach) can be used for disinfecting spillages of blood containing human immunodeficiency virus or hepatitis B virus (HBV). CRAs at higher concentrations are sporicidal; CRAs also possess virucidal activity. Iodine is rapidly bactericidal, fungicidal, tuberculocidal, virucidal, and sporicidal, though less so than chlorine. Aqueous or alcoholic (tincture) solutions of iodine have been used for 150 years as antiseptics; however, they are associated with irritation and excessive staining.

Hydrogen peroxide \( (H_2O_2) \) is a widely used biocide for disinfection, sterilization, and antisepsis with broad-spectrum efficacy against viruses, bacteria, yeasts, and bacterial spores. At higher concentrations and longer contact, hydrogen peroxide has sporicidal activity. Hydrogen peroxide is available in a variety of concentrations, from 3 to 90 percent in many stores, and is considered environmentally friendly because it degrades into oxygen and water. Peracetic acid is more potent than hydrogen peroxide, being sporicidal, bactericidal, virucidal, and fungicidal at low concentrations. It remains active in the presence of organic loads and
is also environmentally friendly, breaking up into acetic acid and oxygen. Peracetic acid has applications as a low-temperature liquid sterilant for medical devices and as an environmental surface sterilant.

Physical disinfection, such as the use of heat, is one of the oldest methods to control against microorganisms and somewhat reliable for sterilization. Heat can inactivate microorganisms in moist form (autoclave and steam) and dry (flame and baking), but moist heat is more effective and requires less time. Sunlight and ultraviolet (UV) radiation inactivate viruses, mycoplasma, bacteria, and fungi. Light may be also be particularly useful against airborne microorganisms. UV light sterilizing is limited on surfaces because it cannot readily penetrate obstructions. Gamma radiation and microwaves are also used.

Polymeric biguanides including Vantocil are active against gram-positive and gram-negative bacteria and not sporicidal. Polymeric biguanides are used as disinfecting agents in the food industry and for disinfecting swimming pools.

Phenolic-type antimicrobial agents are antibacterial, antifungal, and antiviral and traditionally have been used for their antiseptic and disinfectant properties. They can be found in mouthwashes, disinfectant soaps, hand washes, and other forms of household disinfectants.

Silver compounds have a long history of antimicrobial applications and have been used to prevent infection of burns and some eye infections and to destroy warts. The most relevant silver compound used is silver sulfadiazine (AgSD). Silver metal, silver acetate, silver nitrate, and silver protein, all of which have antimicrobial properties, have also been used.

Vapor-phase sterilants, including ethylene oxide, are broad-spectrum alkylating agents. They are used to sterilize heat-sensitive medical devices and surgical supplies. Their main advantages over other vapor-phase systems include low toxicity, rapid action, and activity at lower temperature; the disadvantages include limited penetrability and applications. In 1994, ethylene oxide (ETO) was upgraded in the overall evaluation from being probably carcinogenic to humans to be a human carcinogen.

Disinfection by-products (DBPs) are formed when disinfectants (chlorine, ozone, chlorine dioxide, or chloramines) react with organic matter, anthropogenic contaminants, bromide, and iodide in water. Trihalomethanes (THMs) and haloacetic acids (HAAs) are the most common DBPs formed in chlorinated drinking water, of which the THM chloroform has been linked to cancer in laboratory animals. Many DBPs are bioaccumulative and stored in body tissues. A person can receive exposure to THMs through showering, bathing, or swimming in addition to drinking water. Chloroform and bromodichloromethane have been classified by International Agency for Research on Cancer (IARC) as 2B, possibly carcinogenic to humans. The U.S. Environmental Protection Agency (EPA) Integrated Risk Information System (IRIS) describes bromodichloromethane as B2, probable human carcinogen. The EPA concludes that, as long as exposure to chloroform remains under a given threshold, the risk for cancer is very low and that standards set for chloroform in drinking water are far below these values. The health effects of THMs in humans remain controversial in the scientific community.

Disparities Within Nations (Elimination of Cancer)

Disparities are defined as the dissimilarities or inequalities between groups. Disparities may exist in the distribution of known cancer-related risk factors or simply may be evident in cancer rates. The distinction between establishing cause and that to which cause cannot be attributed is extraordinarily important. Epidemiologic studies have long focused on disentangling the underlying intrinsic factors that determine cancer from those that are within individuals' control to modify or remediate. Understanding what individuals can do to reduce risk is absolutely essential to making progress in moving toward eliminating disparities.

 Observable differences in cancer rates between groups may arise because of inequities that concern the nature of underlying factors that affect health and the quality of accessible health care. Underlying factors may vary according to place, time, and a wide variety of socioeconomic factors ranging from access to financial and educational resources to racism. These factors condition virtually everything to which individuals are exposed in the environment—from industrial contaminants that may have leaked into the water supply or ambient air to access to educational resources, food, and recreational facilities.

 Health equity refers to the absence of disparities in factors known to be the causes of cancers or that determine their clinical course. Inequities can be traced to some kind of economic, social, environmental, or health care-related injustice. It is conceivable that these underlying factors could be eliminated and that there still may be differences in cancer rates between populations because of some intrinsic (e.g., genetic) factors. However, it is generally assumed that the vast majority of factors that condition the probability of having a cancer diagnosis and the outcomes associated with that diagnosis are determined by factors within our power to change—individually or in the aggregate via public policy.

Data Requirements: How We Know What We Know

Understanding disparities requires access to high-quality data. Population-based cancer registries collect data from entities (often hospitals, but also including pathology laboratories) within defined geographical areas in order to produce statistics on cancer incidence and the severity of the disease (e.g., grade and stage) that are expressed as rates per unit population per year (usually newly incident cases per 100,000 persons per year). These registries
collect additional data on sociodemographic factors, including race, sex, age, place of residence, and ethnicity. Usually, they also include additional data on characteristics of specific cancers (e.g., anatomic subsite and morphologic characteristics) and treatments provided. Without access to this kind of information, it can be only conjecture as to whether or not a disparity, or inequity, exists.

The presence, and even quality, of cancer registries is associated with an array of socioeconomic factors that condition the probability of ever getting diagnosed with a cancer. A very enlightening example is provided by comparing two common cancers, breast and prostate, in India versus the United States. While India has a number of hospital-based cancer registries, less than 10 percent of the country has coverage by population-based cancer registries. By contrast, virtually the entire United States is covered by high-quality cancer registries that are based within the states, regions, and territories. Overall incidence rates of breast and prostate cancer are much higher in the United States than they are in India; by factors of about four and 10, respectively. By contrast to the situation in India, where mortality per unit incidence is much higher, both prostate and breast cancer are relatively indolent diseases in the United States; only 17 and 19 percent of individuals, respectively, diagnosed with these diseases actually die of them. Also, while prostate cancer incidence is much lower than breast cancer in India, the rates are roughly equal in the United States, with slightly higher rates of prostate cancer, which spiked with the advent of prostate specific antigen-screening in the early 1990s and then leveled off.

Analysis of population-based registry data from the United States and India showed very clearly that stage of disease (which is an indicator of the size of the primary tumor and its spread to other organ sites) was inversely associated with incidence. These analyses revealed other, very interesting, differences. For example, while the stage distributions of breast and prostate cancer are very similar within the United States—that is, about 85 percent of both are diagnosed at local, early stages—in India, early-stage diagnosis accounts for about 40 percent of all breast cancers but only 12 percent of all prostate cancers. This is clearly observed in the aggregate data reported by all registries within the United States but appears to be more much more extreme in areas such as the Deep South, where there are large numbers of African Americans. For example, mortality-to-incidence ratios are much higher for virtually all cancers among African Americans in South Carolina and Georgia in comparison to their European American counterparts. These contrasts provide very interesting insights into the geographic distribution of cancer. For example, the distribution of mortality-to-incidence ratios in South Carolina, which is primarily a rural state, look very similar to those in Georgia, after excluding the metropolitan Atlanta area. Indeed, ecological-level data analyses in Georgia indicate that some of the differences may be related to disparities or inequities in

**Existing Disparities**

Underserved and racial and ethnic minority subgroups within populations often have unusually high cancer rates. While incidence often is higher than the observed population-average rates, mortality rates and factors related to survival and quality of life are typically much worse. This is clearly observed in the aggregate data reported by all registries within the United States but appears to be more much more extreme in areas such as the Deep South, where there are large numbers of African Americans. For example, mortality-to-incidence ratios are much higher for virtually all cancers among African Americans in South Carolina and Georgia in comparison to their European American counterparts. These contrasts provide very interesting insights into the geographic distribution of cancer. For example, the distribution of mortality-to-incidence ratios in South Carolina, which is primarily a rural state, look very similar to those in Georgia, after excluding the metropolitan Atlanta area. Indeed, ecological-level data analyses in Georgia indicate that some of the differences may be related to disparities or inequities in
the availability of health care facilities and related access. In South Carolina, analyses of environmental data indicate that differences may be related to varying concentrations of minerals (e.g., zinc, selenium, and uranium) in soils and groundwater supplies. Some of these exposures may, in turn, be related to historical factors associated with agricultural practices that were prevalent in these regions. Unlike the rest of the United States, there is very high African American representation in rural areas in the South. This calls into question historical factors related to slavery, which was an important part of the economy of the South through the Civil War. Vestiges of these social injustices continued in the form of Jim Crow laws through much of the 20th century, and some still exist in more subtle forms today.

Data on African American cancer rates make for the most stable and compelling contrasts due to the fact that African Americans traditionally have been the largest well-defined population subgroup represented in the registry data. However, there is emerging interest in looking at rates among Hispanic subgroups as they are currently growing at the highest rate within the United States. Although the data are not as robust, other groups that appear to have disparate cancer rates include Asian Americans, Hawaiians and Pacific Islanders, Alaskan Natives and American Indians, and underserved populations such as those located within Appalachia. All of these populations share common features including economic and social stress. Disproportionately, they reside in rural and impoverished urban communities that are unsafe, offer limited access to healthy foods, and provide little opportunity for physical activity. They tend to have low rates of education and health literacy and occupy insecure service-sector jobs that typically entail little physical activity and frequently require working odd and long hours. Given that it is estimated that diet, physical activity, tobacco use, and appropriate screening account for 90 percent of all cancer incidence and mortality, it is easy to see how factors related to socioeconomic stress could explain a large portion of the disparities within populations.

Although cancer rates have gone down in the United States and other developed countries, relative disparities have often gotten worse. For example, within the United States, incidence and mortality rates of breast cancer have fallen in nearly every group over the past 40 years. However, the relative difference between blacks and whites has grown over this period. Incidence, as mentioned previously, is at least partly an artifact of screening. However, overall screening rates in places where high-risk subgroups reside (e.g., in South Carolina) do not differ much by race. Mortality differences also may be ascribed to intrinsic, genetic differences. While the effect of highly penetrant genes do not account for much of the overall cancer burden, genetic factors appear to be particularly important in highly virulent cancers that present at younger ages (often well below standard age cut points for general population screening). This is certainly true for hormone-sensitive cancers such as breast and prostate, for which incidence at very young ages is much more common in blacks than whites.

Owing to its large size, diverse population, and availability of excellent cancer registry data, the United States presents the best examples of cancer disparities within a particular nation. However, there are many instances of documented disparities in other populations, most notably those considering stage at diagnosis. The United Kingdom provides an interesting case study in that it also documents clear disparities by race or ethnicity as well as excellent information on social class. As in the United States, it appears that a sizable portion of racial and ethnic disparities can be attributed to social justice issues related to socioeconomic status.

Future Directions
The debate that has raged about the relative contributions of social, environmental, and biological factors as determinants of cancer is crucially important to understanding how we can prevent the disease and ameliorate its effects. In order to understand how to intervene effectively in order to reduce disparities, it will be important to link registry-derived information to data on other factors, including those associated with residence and place of work. With the advent of statistical methods associated with geographical information systems, it will become much more feasible to relate putative risk factors that are distributed in space in order to disentangle modifiable risk factors (i.e., those related to socioeconomic conditions) from intrinsic factors that are not within the control of individuals to modify. While the problem of
population heterogeneity in relation to data quality has been pretty well solved within the United States and other developed countries, it will be important to maintain vigilance in terms of data quality and to extend knowledge and techniques to other populations where it is very likely that the same factors that underlie differences in cancer rates also affect data quality.

Addressing cancer-related health disparities in effective and comprehensive ways will require confronting the nexus between social justice and health outcomes. For example, there is a well-established literature on environmental justice that links exposure to known or suspected carcinogens to a variety of socioeconomic factors, including racism. There are vested interests that would prefer that these issues not be addressed. However, the evidence over the last many decades indicates that simply ignoring them is associated with increased relative disparities.

Further Readings

Dominican Republic

The Dominican Republic is a developing country that makes up the Greater Antilles Islands located in the Caribbean Sea. This nation occupies the eastern end of the Hispaniola Island. The island was a Spanish Colony until it gained its independence in 1844 and was officially named Dominican Republic.

In December of 1492, Christopher Columbus disembarked on the Samaná peninsula at the north coast. At that time, the island was inhabited by the Taino people and called Quisqueya. One of the earliest measures Spain undertook was building hospitals. The first known European settlement in the New World, reports say that, in January 1494, at Hispaniola was where Columbus constructed a building to keep supplies and ammunition for the soldiers, a church, and a hospital. Afterward, the capital of Hispaniola was founded during August of 1496 on the eastern bank of the mouth of the Ozama River. The location for the capital was chosen because it was believed that the winds that came to the island from the north produced diseases. The capital was originally called Villa Nueva Isabela. This name in turn was later changed to Santo Domingo de Guzman.

In 1503, Nicolás de Ovando, governor of Hispaniola, built what would be considered a hospital and
named it Hospital San Nicolás de Bari. The hospital was a hut situated in the same place as the Chapel of Our Lady of the High Grace. It is believed that, originally, it belonged to a pious black woman who gathered all the poor people she could and treated them according to her skill.

De Ovando followed the instructions received from King Ferdinand and Queen Isabella to build hospitals in towns where he saw greater need and where the Christian poor and the Indians could receive care. In 1590, brothers and officials of the Brotherhood of the Conception laid the first stone of what was at that time known as the old hospital. The aim of the hospital was to treat the poor and care for no more than six patients at a time. Although historical primary sources of evidence cannot be identified, it is proper to infer that the established medical model at Hospital San Nicolás de Bari, such as in Spain and its colonial possessions during the XVI century, was guided by the Hippocratic and Galenian humoral theory. The four humors were considered to be the basic units and fundamental building blocks of all nature. Good health was believed to be the result of the harmonious balance of those four humors throughout the body. Illness was thought to be the manifestation of the disturbance of that balance. As such, a malignant tumor treated from this medical perspective was the direct result of the aforementioned imbalance.

In Spain, as in many western European countries, experimental medicine models started to develop at the beginning of the 17th century. Cancer began to be understood as a local or regional disease, related to the tumor nodes. Medical doctors advocated for breast cancer surgery, which included the removal of the tumor, nodes, and pectoralis major. During the 19th century, pathology and cancer surgery advanced. During the 18th century, the Hospital San Nicolás de Bari adopted the experimental medical model and mainly cared for ill soldiers. As result, its name was changed to Hospital Militar.

Contemporary Context

Presently, the country is politically and administratively organized into 31 provinces and a national district, with a total of 117 municipalities and 56 municipal districts. From 1994 to 2000, the country occupied the top places in leadership in economic growth in Latin America and the Caribbean. As of 2012, Dominican Republic has an estimated total population of 10,135,105. Its residents can expect an average of 12.3 years of schooling, and a gross national income per capita of $5,762. The estimated life expectancy at birth in 2012 was 72.04.

The age-standardized adult mortality rate by cancer at ages 30 to 70 per 100,000 population in 2008 was 270. In 2010, there were 8,433 estimated cancer-reported deaths. Despite Dominican Republic’s sustained economic growth, public health research shows that it has not corresponded with a sustainable human and social scale strengthening. That is, the rise in the production of wealth has not been met by a similar rise in the promotion of an environment that provides viability for the exercise of full human capabilities. In 2012, the density of physicians per 10,000 population was 8.1. Based on official estimated data, as of 2012, the five most common cancers in Dominican Republic are (1) urological (bladder, kidney, prostate, and testis), (2) gynecological (cervix uteri, corpus uteri, and ovary), (3) breast, (4) lung, and (5) head and neck (lip and oral cavity, nasopharynx, other pharynx larynx, and thyroid). The number of oncologists needed for the 2010 population estimated, and based on 2008 research data on new cancer cases at Dominican Republic’s two most populous cities (Santo Domingo: 3,389 cases and Santiago: 723) are Santo Domingo—at least two hematologist oncologists, four surgical oncologists, 17 radiation or clinical oncologists, two urologic oncologists, and seven pathologists and in Santiago—at least two hematologist oncologists, two surgical oncologists, four radiation or clinical oncologists, two urologic oncologists, and two pathologists.

Dominican Republic approved an extensive health financial reform in 2001, which began full implementation at the end of 2007. Prior to the reform, cancer lacked financial protection. Most specialized services were provided by two nonprofit oncological hospitals as well as private facilities primarily serving high-income groups. The public hospitals offered only basic services to low-income patients in the early stages of their disease. Most insurance plans provided limited coverage for cancer; further, only minor support and subsidized care were available from civil society organizations and not-for-profit hospitals, respectively. Thus, patients were forced to finance treatments out of pocket.

The Liga Dominicana contra el Cancer Inc. (Dominican League Against Cancer Inc. [DLAC]) is a pioneer in the management of cancer in the
Dominican Republic. It was founded on September 13, 1942, and incorporated in 1947, by decree No. 4134 of the Executive. At its inception, the institution was called Cuerpo de Voluntarias del Instituto de Oncología Milagro de la Caridad (Miracle of Charity Voluntary Institute of Oncology). The institution was later named after Dr. Heriberto Pieter, a Dominican hospital benefactor. One of this nonprofit private institution’s main objectives was to engage in social and health issues such as education, detection, prevention, treatment, and cure of cancer. The institution also provides assistance to low-income patients who need medical services such as hospitalization, chemotherapy, radiation therapy, and diagnostic studies, among others. DLAC has 70 years of work in the prevention, detection, and treatment of cancer attending daily an estimated 1,200 to 1,600 patients, which represents around 327,000 a year.

Founded in 1982, the Dominican Society of Hematology and Oncology (DSHO) is a group of Dominican medical doctors specialized in diverse branches of oncology. Originally, DSHO was organized under the name of the Dominican Society of Hematology and Oncology, attached to the Dominican Association Medical College. It is also a private nonprofit organization that aims to promote the development of oncology in the Dominican Republic through communication and integration of all its stakeholders whose objective is also to improve the life quality of cancer patients.

Other establishments in the private, nonprofit sector offering treatment are: the General Maternal and Child Hospital—Plaza de la Salud, the Nordestano Cancer Center, the Marcelino Vélez Santana Hospital, and the Oncology Institute of Cibao. Also, the Ministry of Health provides partial services (diagnosis and surgical treatment) in 16 of its hospitals; these services also are offered in four centers in the Armed Forces and National Police Institute and, for teachers of the public segment, the SEMMA Medical Center. Most recently, the government created the National Cancer Institute Rosa Emilia Tavares, which will run a hospital with 120 beds and new medical technology, with large capital spending in infrastructure and equipment. Partial services (diagnosis, chemotherapy, and surgical treatment) are offered in about 87 private, for-profit health institutions.

Drugs

Human life has been tremendously improved through the significant benefits of drugs and modern medicines. This entry examines drugs and their implications for cancer in society. A drug is any substance (solid, liquid, or gas) that changes the functions or structures of the body in some way. This excludes food and water, which are required to maintain normal body functioning. The drugs of most concern are those that affect an individual's central nervous system. These are the psychoactive drugs. They act on the brain and can change the way a person thinks, feels, or behaves. Drugs have achieved some of the millennium development goals in terms of longevity, life span, and decreases in morbidity and mortality. Drugs play major roles in cancer control and management. In other words, drugs have significant influence in preserving, protecting, maintaining, and restoring the health of individual members of society. Broadly, a drug is a medicine or other chemical substance that has a physiological effect when injected or otherwise introduced into an individual's body.

In pharmacology, a drug is a chemical substance used in the treatment, cure, prevention, or diagnosis of disease or used to otherwise enhance physical or mental well-being. Drugs may be used for a limited duration or on a regular basis for chronic disorders. Furthermore, the World Health Organization (WHO) defines drugs to be any substance or product that is used or intended to be used to modify or explore physiological systems or pathological systems for the benefit of the recipient.

In terms of sources, drugs come from three natural channels. The first is naturally from plants. They are used to prepare herbal medicines, and some have been produced into tablets and capsules. Second is through animals, such as honey from bees, oils of certain fish, and others. The third source is from microorganisms. For example, penicillins are drugs from fungi. Synthetically, there are various chemical reactions that can be carried out in the laboratory to obtain potent or active drugs. The drugs from synthetic sources are usually larger in quantity than those from natural sources. Put differently, drugs come from a range of sources. Many are found in plants, for example, nicotine in tobacco, caffeine in coffee beans, and cocaine from the coca plant. Morphine and codeine are derived from the opium poppy, while heroin is produced by the chemical modification of morphine. Marijuana is the leaf, buds, and seed heads of the cannabis plant, while hashish and hash oil are the plant's resin. Alcohol is produced by the natural process of fermentation that happens when fruit, grain, or vegetables decompose. Certain fungi, such as mushrooms and cactus plants, are considered drugs in Nigeria because of their hallucinogenic properties. Medicines can be manufactured from both natural and artificial chemicals.

Names, Uses, and Sources of Drugs

Most drugs have at least three names: (1) full chemical names usually too long and complicated to use regularly, for instance, para-amino acetamido phenol (paracetamol) or acetyl salicylic acid (aspirin); (2) generic or nonproprietary names, that is, accepted internationally as common names that are shorter and easy to pronounce or say, for example, chloroquine or paracetamol (more acceptable for prescriptions); (3) brand or trade or proprietary names given by pharmaceutical manufacturers or companies for their own particular brands, for instance, Seprin and Maloxine.

There are three major uses of drugs. One is to cure diseases, and another is to control or eliminate symptoms and, last, to prevent diseases. In all, drugs exist for the purpose of legally prohibiting certain substances (natural or synthetic) that affect the body's functioning or structure and are used in the diagnosis, mitigation, treatment, or prevention of a disease or relief of discomfort. They are also called legal drugs or medicine. A legal or medicinal drug, however, can be harmful and addictive if misused.

In terms of sources, drugs come from three natural channels. The first is naturally from plants. They are used to prepare herbal medicines, and some have been produced into tablets and capsules. Second is through animals, such as honey from bees, oils of certain fish, and others. The third source is from microorganisms. For example, penicillins are drugs from fungi. Synthetically, there are various chemical reactions that can be carried out in the laboratory to obtain potent or active drugs. The drugs from synthetic sources are usually larger in quantity than those from natural sources. Put differently, drugs come from a range of sources. Many are found in plants, for example, nicotine in tobacco, caffeine in coffee beans, and cocaine from the coca plant. Morphine and codeine are derived from the opium poppy, while heroin is produced by the chemical modification of morphine. Marijuana is the leaf, buds, and seed heads of the cannabis plant, while hashish and hash oil are the plant's resin. Alcohol is produced by the natural process of fermentation that happens when fruit, grain, or vegetables decompose. Certain fungi, such as mushrooms and cactus plants, are considered drugs in Nigeria because of their hallucinogenic properties. Medicines can be manufactured from both natural and artificial chemicals.

Cancer-Related Drugs

There are some cancer-related drugs such as Alimta (pemetrexed disodium), Avastin (bevacizumab), Erbitux (cetuximab), Gleevec (imatinib mesylate), Herceptin (trastuzumab), Nexavar (sorafenib tosylate), Revlimid (lenalidomide), Sprycel (dasatinib), Sutent (sunitinib malate), Tarceva (erlotinib) and Xeloda (capecitabine). These cancer drugs such as chemotherapy, hormone therapy, and other biological or genetic treatments, are used to destroy cancer cells. Most times, the goal of cancer drugs is to cure. When cure is not possible, cancer drugs can often prolong life or improve quality of life. Many
Drugs Can Work in a Number of Ways to Kill Cancer Cells

Chemotherapy drugs can slow down cancer cells from growing or multiplying. They can also encourage these cells to die naturally (apoptosis). In general, chemotherapy drugs can harm some of the healthy cells in the same way, causing side effects. Hormone drugs usually stop the body’s hormones from helping some cancers to continue to grow. Biological therapy involves drugs that help the immune system in the body to fight against cancer. Targeted drug therapy includes drugs that are designed to attack only certain areas found mainly in cancer cells. These drugs tend to cause less harm to healthy cells, which means fewer side effects.

Chemotherapy uses drugs to treat cancers of the blood and bone marrow as well as for cancers of the lymphatic system (lymphomas). Chemotherapy is also used to treat cancer when it has spread, when it has come back, or when there is a strong chance it could come back (recur). Hormone therapy uses drugs to interfere with hormone production or hormone action to kill cancer cells or slow their growth. Surgery is also used to remove hormone-producing glands to slow or kill cancer cells.

Chemotherapy is recommended to patients as an option based on the following:

1. Does the specific cancer react to chemotherapy? Only certain types of cancers (the ones with large proportions of dividing cells) are responsive to drugs. These are usually small tumors (either because they are detected early or because most of the tumor has been removed by...
surgery or radiation) or are systemic cancers like leukemias and lymphomas (systemic means they are everywhere in the body).

2. Even if the tumor can respond to cancer drugs, its actual location will affect the choice of treatment. In some cases, tumor location will make cancer drugs, perhaps combined with radiation therapy, the only treatment option. For example, certain brain tumors cannot be removed surgically, so cancer drugs or radiation therapy are the only choices.

3. The body has to be otherwise healthy in order to tolerate some chemotherapy drugs. Cancer patients are often shocked when they hear medical personnel refer to them as healthy. How can someone with cancer be healthy? When doctors term a cancer patient healthy, they are referring to how well the body is functioning, except for the site of the cancer. When they speak about a cancer patient being sick, they are talking about a serious breakdown in the functioning of vital organs and systems.

Pain Control

Pain control is a significant issue in cancer care, particularly in end of life care. The World Health Organization (WHO) has developed a three-step “ladder” to help guide the provision of relief from cancer pain. The general principle is that pain should be treated promptly, with drugs provided until the patient is free of pain. Drugs should be administered in three steps, with the second and third steps used only if necessary to provide pain relief: first non-opioids such as aspirin, then mild opioids such as codeine, then strong opioids such as morphine. In addition, adjuvant drugs should be provided as necessary to deal with related issues such as fear and anxiety. Drugs should be provided on schedule (e.g., every 3–6 hours) rather than on demand. According to the WHO, following this laddered approach provides effective pain relief in 80 to 90 percent of cases.

The WHO Essential Medicines list has included palliative care medicines since 2013, but sufficient pain relief is often not provided to patients, particularly in low- and middle-income countries. An estimated 80 percent of cancer patients suffer moderate or severe pain at the end of their lives. One reason for the lack of adequate pain control for many patients is that few countries have integrated palliative care with their medical system. A second is that opioid drugs, which can provide relief from severe pain, are subject to additional scrutiny in most countries due to their high potential for diversion and abuse.

Types of Drugs

The three main types of drugs, classified by their effects on the central nervous system, are namely depressants, stimulants, and hallucinogens.

Depressant drugs slow down, or depress, the functions of the central nervous system (however, they do not necessarily make a patient feel depressed). Depressant drugs include: alcohol; opiates and opioids, including heroin (also known as H, hammer, smack, and gear), morphine, codeine, methadone, and buprenorphine; and cannabis (also known as green, smoke, weed, pot, dope, cone, and mull), including marijuana, hashish, and hash oil. In stronger concentrations, such as in hashish and resin, cannabis can also act as an hallucinogen in addition to being a central nervous system depressant as can minor tranquillizers and benzodiazepines (benzos), including diazepam (Valium), oxazepam (Serepax), nitrazepam (Mogadon), temazepam (Normison and Euhypnos), and some solvents and inhalants, including vapors from petrol, glue, chrome paint, and lighter fluid. In moderate doses, depressants can make people feel relaxed. Some depressants cause euphoria and a sense of calm and well-being. They may be used to wind down or to reduce anxiety, stress, or inhibition. Because they slow a person down, depressants affect coordination, concentration, and judgment. This makes driving and operating machinery hazardous. In larger doses, depressants can cause unconsciousness by reducing breathing and heart rate. A person’s speech may become slurred and his or her movements sluggish and uncoordinated. Other effects of larger doses include nausea, vomiting, and in extreme cases, death. When taken in combination, depressants increase their effects and increase the danger of overdose.

In contrast to depressant drugs, stimulant drugs speed up the functions of the central nervous system. People use the following stimulants every
Drugs

369
day: caffeine (most coffee, tea, and cola drinks contain caffeine, which is a mild stimulant), nicotine (the nicotine in tobacco is a stimulant, despite many smokers using it to relax), and ephedrine (used in medicines for bronchitis, hay fever, and asthma). Stronger stimulant drugs include amphetamines and methamphetamines, also known as speed, ice, and crystal meth; cocaine, also known as coke and snow; slimming tablets, for example, Duromine and Tenuate; and dexamphetamine, prescribed to treat attention deficit disorder in children and narcolepsy, which is an uncontrollable urge to fall asleep. Stimulants speed up or stimulate the central nervous system and can make the users feel more awake, alert, or confident. Stimulants increase heart rate, body temperature, and blood pressure. Other physical effects include reduced appetite, dilated pupils, talkativeness, agitation, and sleep disturbance. Higher doses of stimulants can overstimulate the users, causing anxiety, panic, seizures, headaches, stomach cramps, aggression, and paranoia. They can also cause heart problems such as arrhythmia. Prolonged or sustained use of strong stimulants can also cause these effects. Strong stimulants can mask the effects of depressant drugs, such as alcohol. This can increase the potential for aggression and poses an obvious hazard if the person is driving.

Hallucinogenic drugs distort the user's perceptions of reality. These drugs include lysergic acid diethylamide (LSD), also known as trips, acid, and microdots; magic mushrooms (psilocybin), also known as mushies; mescaline (peyote cactus); and ecstasy (methylene dioxyamphetamine [MDMA]), also known as E, XTC, and Eccies and produces a combination of hallucinogenic and stimulant effects; and ketamine, also known as K and Special K.

The main physical effects of hallucinogenic drugs are dilation of pupils, loss of appetite, increased activity, talking or laughing, jaw clenching, sweating, and sometimes stomach cramps or nausea. Drug effects can include a sense of emotional and psychological euphoria and well-being. Visual, auditory, and tactile hallucinations may occur, causing users to see or hear things that do not actually exist. The effects of hallucinogens are not easy to predict, and the person may behave in ways that appear irrational or bizarre. Psychological effects often depend on the mood of the users and the context of use. Negative effects of hallucinogens can include panic, paranoia, and loss of contact with reality. In extreme cases, this can result in dangerous behavior that can put the user and others at great risk. Driving while under the influence of hallucinogens is extremely hazardous. It is common for users to take minor tranquilizers or marijuana to help them come down from a hallucinogenic drug.

Drug Abuse or Drug Misuse
Drug abuse is the act of taking a drug that harms or has the ability to harm the physical or mental health or social well-being of an individual or other individuals or society at large or that is illegal, for instance, taking any drugs such as heroin, cocaine, hallucinogens, cannabis, ecstasy, ketamine, injectable drugs, and methamphetamines. There is confusion about the following terms on drug abuse or misuse.

Drug addiction is having an overwhelming desire or need to continue taking a drug and to obtain it by any means. It is psychic and has psychological influence with detrimental effect on the individual and on the society.

Drug dependence is a psychic or psychological and sometimes a physical state resulting from the interaction between a person and a drug, characterized by behavioral and other responses that always include a compulsion to take the drug on a continuous or periodic basis in order to experience its psychic effect and sometimes to avoid the discomfort of its absence. Tolerance may or may not be present. An individual may be dependent on more than one drug.

Drug tolerance is an adaptive state characterized by diminished response to the same quantity of drug or by the fact that a large dose is required to produce the same degree of pharmacodynamic effect or response. Dependence drugs include opioids, sedatives, cannabis, stimulants, hallucinogens, and volatile inhalants.

Rational Drug Use
This implies that an appropriate drug is prescribed, that it is available at the right time at an affordable price, that it is dispensed correctly, and that it is taken in the right dose at the right interval and for the right length of time. “Rational” stands for accordance with reason or principle or understanding and not upon simple experience. Its elements include appropriate diagnosis, appropriate drugs,
appropriate dose or dosage, appropriate usage and
duration of usage, and appropriate cost. There are
three major targets for rational drug use, and they
include the prescribers or physicians, the pharma-
cists, and the patients or recipients.

Irrational Use of Drugs
This is the use of nonessential pharmaceuticals,
drugs with doubtful efficacy, wrong or unsafe drugs,
correct dosages and routes of administration,
self-medication, over-prescribing, and other wrong
practices with drugs. Examples of irrational use
of drugs include over-prescribing, self-medication,
overuse and underuse of antibiotics, use of wrong
drugs, and overuse of injections. These are factors
contributing to irrational use of drugs: deregula-
tion and expansion of the private sector as source
of drugs, de-scheduling of drugs, widespread avail-
ability of prescription drugs from unqualified drug
sellers, increases in advertising of drugs and new
forms of market promotions, lack of political will to
implement programs of rational drug use, and lack
of research into the extent and impact of irrational
drug use.

Impact of Drugs on Society
The negative consequences of drug abuse affect
not only individuals who abuse drugs but also their
families, friends and colleagues, various businesses,
and government resources. Many of these effects
cannot be quantified. The most devastating drug-
related harm to the community is the death toll fol-
lowed by morbidity. Drug use causes around one
in 15 of all deaths all over the world. It is a factor
in about one in seven of all deaths of men between
25 and 54 years old. Recent figures indicate that
approximately 3,000 to 4,500 of all deaths in Nige-
ria, for example, in 2011 were attributable to drug
use or alcohol use. On top of this, many more people
died from diseases or causes associated with drugs
or alcohol. The majority of these costs relate to lost
productivity, crime, and health care. There are a
range of other harms that can result from excessive
or inappropriate use of psychoactive substances.
Loss of life is one extreme and tragic possibility.

Negative health effects, family and social prob-
lems, psychological and emotional difficulties, and
legal and financial problems are more common
experiences. It should be stated that many people
start and then continue to use drugs to find relief or
escape from these types of problems. There is a pre-
vailing community fear that, if a person uses drugs,
he or she will become dependent or addicted. No
drug leads to an immediate physical or psychological
dependence. However, drug-related harm can hap-
pen at all levels of use, including experimental, recre-
ational, and dependent use. The most obvious effects
of drug abuse—which are manifested in the individ-
uals who abuse drugs—include ill health, sickness,
and ultimately, death. Particularly devastating to an
abuser’s health is the contraction of needle-borne ill-
nesses including hepatitis and human immunodefi-
ciency virus/acquired immune deficiency syndrome
(HIV/AIDS) through injection drug use.

Children of individuals who abuse drugs often
are abused or neglected as a result of the individu-
als’ preoccupation with drugs. It is also shown that
parents who abuse drugs often put their need to
obtain and abuse drugs before the health and welfare
of their children. Children whose parents and other
family members abuse drugs often are physically or
emotionally abused and often lack proper immuni-
zations, medical care, dental care, and necessities
such as food, water, and shelter. The risk to children
is even greater when their parents or guardians manu-
facture illicit drugs such as methamphetamine.
Methamphetamine abusers often produce the drug
in their own homes and apartments, using hazard-
ous chemicals such as hydriodic acid, iodine, and
anhydrous ammonia. Children who inhabit such
homes often inhale dangerous chemical fumes and
gases or ingest toxic chemicals or illicit drugs. These
children commonly test positive for methamphet-
amine and suffer from both short- and long-term
health consequences. Moreover, because many
methamphetamine producers also abuse the drug,
children commonly suffer from neglect that leads to
psychological and developmental problems.

The economic impact of drug abuse on businesses
whose employees abuse drugs can be significant.
While many drug abusers are unable to attain or hold
full-time employment, those who do work put oth-
ers at risk, particularly when employed in positions
where even a minor degree of impairment could be
catastrophic; airline pilots, air traffic controllers,
train operators, and bus drivers are just a few exam-
pies. Economically, businesses often are affected
because employees who abuse drugs sometimes
steal cash or supplies, equipment, and products that
can be sold to get money to buy drugs. Moreover,
absenteeism, lost productivity, and increased use of medical and insurance benefits by employees who abuse drugs affect a business financially.

The economic consequences of drug abuse severely burden federal, state, and local government resources and, ultimately, the taxpayer. This effect is most evident with methamphetamine. Clandestine methamphetamine laboratories jeopardize the safety of citizens and adversely affect the environment. Children, law enforcement personnel, emergency responders, and those who live at or near methamphetamine production sites have been seriously injured or killed as a result of methamphetamine production.

Methamphetamine users often require extensive medical treatment; some abuse, neglect, and abandon their children, adding to social services costs; some also commit a host of other crimes including domestic violence, assault, burglary, and identity theft. Methamphetamine producers tax strained law enforcement resources and budgets as a result of the staggering costs associated with the remediation of laboratory sites. For instance, the average cost to clean up a methamphetamine production laboratory is $1,900.

**Drug Regulatory Authorities**
Regulatory authorities continually deal with issues such as drug administration and control, increased responsibilities from expansion of the market, and the improvement and sophistication of products. Each country regulates and controls the import, export, manufacture, advertisement, distribution, sale and use of food, drugs, cosmetics, medical devices, packaged water, and use of chemicals. For instance, in Nigeria, there are the National Agency for Food and Drug Administration and Control (NAFDAC), the Pharmacist Council of Nigeria (PCN), and the National Drug Law Enforcement Agency (NDLEA). These drug agencies adopt measures to identify, trace, freeze, confiscate, or seize goods from drug-related offences. They also eradicate illicit cultivation of narcotic plants and use of narcotic and psychotropic substances such as cocaine, morphine, and others.

**Recommendations**
Governments should invest in policies and programs designed to reduce drug abuse and misuse, cancer risks associated with environmental factors, and unhealthy behaviors. Regardless of socioeconomic status, individuals from racial and ethnic minority populations experience a myriad of stressors in the context of their social locations. The effects of social location are mediated by lifetime exposure to social and environment factors as well as individually modifiable drug behavioral risks. Such social and individual-level exposures translate into differential health care quality and access.

Public and private-based organizations should address drug behavioral risk factors such as physical inactivity, obesity, heavy alcohol consumption, a diet high in red or processed meats, a diet that lacks fruits and vegetables, a diet high in animal fat, smoking, and environmental hazards such as radon, asbestos, air pollution, and certain metals (chromium, cadmium, and arsenic). Community-level interventions are also warranted. At the community level, such interventions might address community norms and lifestyles that promote adverse drug-related health outcomes.

There is also need for better research data. Drug registries should collect socioeconomic data (income, education, and health insurance status). To make use of existing registry data to compute survival and mortality rates, drug registries should be linked to social security records. This will permit the computation of trends in incidence, survival, and mortality.

Duke Cancer Institute

The Duke Cancer Institute (DCI), formerly the Duke Comprehensive Cancer Center, is located on the Duke University campus in Durham, North Carolina. The DCI is one of 41 centers in the country designated by the National Cancer Institute as a comprehensive cancer center. It serves nearly 6,000 new cancer patients each year and is ranked as the top cancer hospital in the south by U.S. News & World Report. The DCI treats patients from a range of ages, ethnic and racial backgrounds, socioeconomic statuses, and from rural and urban settings in North Carolina and the larger region as well as from across the country. While the DCI offers care for patients with every form of cancer, it is nationally recognized for its brain tumor and blood and marrow transplantation programs. Patients at the DCI receive care across the cancer continuum, from prevention and diagnosis to treatment and survivorship.

Duke has made a $400 million investment in the DCI, including construction of a new 267,000-square-foot DCI building that opened in early 2012, expansion of clinical services, and investment in state-of-the-art technologies. The DCI includes more than 300 researchers and physicians and 500 clinical staff dedicated to a broad spectrum of cancer research and the translation of that research into the latest in patient care. It offers hundreds of clinical trials for the treatment and prevention of many forms of cancer.

The DCI also supports numerous shared resources that provide access to technologies, services, and scientific consultation that enhance scientific interaction and productivity. These shared resources include, but are not limited to, bioinformatics, biospecimen repository and processing core, biostatistics, flow cytometry, high-resolution nuclear magnetic resonance spectroscopy, integrative cancer genomics, pharmaceutical research, and proteomics. The DCI is also home to a variety of research programs and groups, including 10 disease-site groups and nine NCI-designated programs. Each disease-site group has leaders representing clinical care, clinical research, and basic research who work collaboratively to address the various needs of cancer patients. The nine NCI-designated programs at the DCI, supported by the shared resources, are multidisciplinary in nature and designed to address research opportunities impacting cancer care through basic, clinical, and translational research. Researchers at the DCI are also involved in quality and outcomes research. Specifically, the Duke Cancer Care Research Program is a team of clinical scientists whose research efforts focus on improving health-related, emotional, and psychosocial outcomes for cancer patients.

The DCI has demonstrated a consistent record of state-of-the-art patient care and positive patient outcomes. In 2011, the DCI served more than 45,000 individuals with cancer and was recognized by the Joint Commission as an exemplar in performance on key quality measures. The DCI provides treatment for several types of cancer, including breast, genitourinary, gastrointestinal, and gynecologic cancer in addition to leukemia and lymphoma, brain tumors and neuro-oncology, thoracic cancer, adult bone marrow cancer and stem cell transplant, sarcomas, and melanomas. However, the most commonly treated cancers at the DCI are uncommon types of cancer. The treatment capacity of the DCI is largely attributable to the numerous clinical trials that are housed with the institute. Approximately 900 open trials at the DCI provide patients with access to the most innovative treatments, many of which are not widely available at other hospitals.

For example, pioneering research led by the Preston Robert Tisch Brain Tumor Center continues to demonstrate the utility of bevacizumab and temozolomide for the treatment of brain tumors. This ongoing research contributed to the accelerated approval by the Food and Drug Administration of
bevacizumab for glioblastoma multiforme. As a result of this research, patients with brain tumors at the DCI are provided with this innovative and effective treatment, despite its relative scarcity in other cancer treatment centers. Similarly, breast cancer patients at the DCI are experiencing substantial improvements in survival rates based on research examining the effectiveness of a new treatment protocol: lapatinib and trastuzumab. The DCI also offers cutting-edge treatment options for other forms of cancer, such as stem cell transplants from mismatched family or unrelated donors for central nervous system (CNS) tumors, rotationplasty for sarcoma patients, and endocrine therapy for breast cancer patients.

The DCI offers an array of comprehensive and multidisciplinary resources for patients and their families in the areas of: individual and family counseling, support groups, self-image resources, cancer patient education resources, physical and occupational therapy, pharmaceutical counseling, social work, and nutrition counseling. One such support service is the Duke Cancer Patient Support Program (DCPSP). The DCPSP is an established psychosocial support program with providers specializing in psychology, psychiatry, and medical family therapy. The DCPSP provides services and resources, at no charge, to help support patients and their loved ones throughout their experience with cancer. Also housed within the DCI is the multidisciplinary psychosocial oncology team, which includes psychology, psychiatry, medical family therapy, oncology recreation therapy, occupational therapy, social work, and child life specialists. The recently founded Duke Center for Cancer Survivorship is another multidisciplinary resource that coordinates resources for support, care, education, and research for men and women surviving cancer. Finally, Duke’s Cancer Patient Education Program, which includes a resource center and a variety of education classes, uses a multimedia approach to assist DCI patients and their families with obtaining disease and treatment-related information, gaining resources for health decision making, managing the effects of cancer and its treatment, and advocating for themselves. Through providing an array of multidisciplinary support services and survivorship resources, the DCI aims to improve patient outcomes and decrease cancer burden.

The DCI is one of the first comprehensive cancer centers in the United States. Since 1973, it has continued to lead the nation in cancer prevention, treatment, education, and research. Currently, the DCI provides multidisciplinary, individualized care to more than 45,000 local, national, and international patients. The DCI also leads the field of oncology in the development of new techniques, treatments, and approaches to cancer treatment through numerous clinical trials and research protocols. Thus, the DCI serves as a model for the provision of innovative, comprehensive cancer treatment through both clinical and research activities.

Dyes and Pigments

Dyes and pigments are ubiquitous in modern society, from food and clothing to magazines, tattoo ink, hair colorants and other beauty products, and host of other consumer goods. Research has shown...
that some dyes and pigments are associated with an increased risk for cancer. Among the cancers related to dyes and pigments are bladder cancer, lymphocytic leukemia, breast cancer, and Hodgkin's lymphoma.

Dyes and pigments are both colorants but differ in several ways. Their classification is related to a variety of factors, including their composition, method of application, dyeing properties, and origin, such as organic and synthetic dyes. Most dyes dissolve in water and create color through chemical or physical reactions. They are used to dye a variety of materials, including cloth and other porous material, such as hair.

Pigments are particles of color that can leave residues. They usually come in the form of an insoluble powder mixed into other materials, such as water, oil, and resins. They are used to make paint, tattoo inks, and other products.

At least 13 common chemicals in dye and pigments have been related to increased cancer risk. These include the azo dyes (benzidine and benzidine congener-based dyes, including the benzidine derivative o-diansisidine) and the aromatic azines originating from azo dyes, such as (analine, o-tulidine, and n-methylaniline). Both the Occupational Safety and Health Administration (OSHA) and the National Institute for Occupational Safety and Health (NIOSH) have concluded that benzidine-based dyes increase risk for cancer, and the National Cancer Institute (NCI) has noted several azo dyes in general as being carcinogenic. Azo dyes are synthetic dyes known for their bright colors. They are used for a variety of goods, including cosmetics, foods, carpets, clothes, leather and textiles.

Many azo dyes are safe to eat, while others have been associated, primarily with bladder cancer. Some azo dyes can form aromatic amines when broken down. In European Union countries, aromatic amines are banned from both the manufacture and sale of consumer goods.

OSHA banned the production of benzidine dyes in the United States in 1973. Although importing the dyes is banned now also, products containing benzidine-based dyes can still be imported to the United States. Epidemiologic studies show an increased risk of bladder cancer due to occupational exposure, and animal studies have found tumors in various sites due to benzidine exposure, including oral and inhalation exposure. The Environmental Protection Agency (EPA) classifies benzidine as a Group A, a known human carcinogen. The risk for cancer associated with benzidine was substantially increased when dosages occurred in early life.

Aromatic amines exposure from various sources has been linked to cancer, from occupational settings to smoking. Aromatic amines are typically found in the plastic and chemical industries and also as by-products during the manufacturing of a wide variety of products, including dyes, pharmaceuticals, and polyurethane foams. Studies have found that various classes of the aromatic amines are connected with an increased risk for cancer.

For example, female rubber-factory workers have been shown to have an increased risk of breast cancer due to exposure to aromatic amines; and a lifetime consumption of grilled meats and fish, which contain these amines, was connected with an increased risk of postmenopausal breast cancer. Aromatic amines in hair dyes have been associated with bladder cancer.

Food

Food dyes were at one time synthesized from coal tar but are now produced from petroleum products. Many food dyes have been banned due to animal studies. The U.S. Food and Drug Administration (FDA) has established limits for dye contaminants that may be carcinogenic. Banned food dyes that studies have shown to be carcinogenic include Green 1, Red 1, Red 2, Sudan 1, and Violet 1. FDA limits are calculated to limit the lifetime risk of getting cancer to no greater than one cancer per 1 million people.

Controversy continues concerning food dyes. An estimated 15 million pounds of dyes are used in the food supply each year, including three that carry known carcinogens. Studies have shown that seven food dyes have been associated with cancer in animal studies, including colon cancer and brain and testicular tumors as well as DNA mutations. It was estimated that Americans consumed 17.8 million pounds of these dyes in 2005. These dyes are found in food products such as some sodas, popsicles, candy, baked goods, ice cream, maraschino cherries, and snack foods, as well as most pet food.

Overall, since 1955, food dye consumption per person has increased fivefold in the United States. Furthermore, artificial dyes derived from petroleum
are in numerous other foods aimed at children, including breakfast cereals and even vitamins. The dyes Red 40, Yellow 5, and Yellow 6 make up 90 percent of the dyes used in foods.

Groups concerned about food dyes and their toxicities have noted that these dyes are not necessary from a nutrition standpoint. They are only used to enhance a food's appearance and do nothing to improve the nutritional quality or safety of foods. Some contend that dyes still used have been inadequately tested for cancer and other toxicities. Thus, they are an unnecessary risk, especially for young children.

One such group, the Center for Science in the Public Interest (CSPI), petitioned the FDA in 2008 to ban artificial food dyes. This request was made primarily on studies showing a relationship between food dyes and childhood behavioral problems. In 2010, CSPI published “Food Dyes: A Rainbow of Risks,” which pointed to nine artificial dyes approved in the United States that are likely to be carcinogenic or have other serious health consequences.

The report pointed out that benzidine is found in Red 40, Yellow 5, and Yellow 6 food dyes. The FDA has calculated that the ingestion of free benzidine does not raise cancer risk to the threshold of concern. Nevertheless, bound benzidine has been found in greater amounts than those in free benzidine, which is the only type of benzidine the FDA has traditionally tested for in food products. Concerns also focus on higher exposure rates from benzidine in food because intestinal enzymes release bound benzidine.

Hair Dye and Cosmetics

Scientists first noted health risks associated with hair dyes in the late 1970s, focusing initially on a link to breast cancer. For example, a 1976 study found that 87 of 100 breast cancer patients studied had used hair dye for many years. A 1979 study provided further evidence of a relationship between breast cancer and the frequency and duration of hair dye use. The greatest risk was found in women 50 to 79 years of age who had used hair dye for decades. Other links between hair dye and breast cancer included a greater risk of developing breast cancer in women with a history of benign breast disease who also dyed their hair and a greater risk for breast cancer in women dying their hair to change color rather than to remove gray hair only.

Japanese and Scandinavian studies in the 1990s found a correlation between hair dye use and leukemia and ovarian cancer. Another study conducted at Harvard University in the 1990s found a link between hair dyes used one to four times a year with a 70 percent increase in the risk for ovarian cancer. In addition, twice the risk of developing ovarian cancer was found in women who dyed their hair four times a year or more than in women who never dyed their hair.

The FDA is charged with regulating cosmetic product safety. In 1976, the Cosmetic, Toiletry, and Fragrance Association (CTFA) established the Cosmetic Ingredient Review (CIR) program, now known as the Personal Care Products Council. The council is charged with assessing personal care product safety.

Many colorants used in cosmetics are coal tar dyes. Coal tar is made from petroleum-based chemicals and is considered a human carcinogen. These dyes may also have low levels of heavy metal contamination. In addition some are mixed with an aluminum substrate. Both heavy metals and aluminum metals are associated with neurotoxicity.

Permanent synthetic hair dyes and intermediates contain a wide range of substances, including ammonia, diaminobenzenes, phenylenediamines, resorcinol, and phenols. Phenylenediamines are the most common ingredient found in hair dyes today. P-phenylenediamine is a coal-tar-based colorant used in many hair dyes. Generally, darker, permanent hair dyes have more phenylenediamine than lighter hair dyes. Animal studies conducted by the NCI have linked p-phenylenediamine to tumors. Another study found that hair dyes containing p-phenylenediamine and used over a long period of time increased the risk for non-Hodgkin's lymphoma (NHL).

It should be noted that toxic dye ingredients such as diaminotoulene and diaminotoluene were banned in the early 1990s. These ingredients have been linked to breast cancer, and scientists believe it is likely that the past use of these dyes may have led to some modern-day cases of breast cancer. Although modern-day hair dye ingredients have been found to cause mutation in DNA and fetal abnormalities in some animal studies, they are not required to appear on warning labels. In the United States, dyes containing 4-methoxy-m-phenylenediamine are required to include a warning about irritant effects.
and studies showing a relationship to cancer in animal studies.

A 2013 epidemiological review study found what it called "alarming data." It showed that the evidence linking hair dye with most human cancers was inconclusive because of mixed results. The study found that the strongest evidence pointed to an increased risk for NHL, leading the researchers to caution people with a family history of NHL in using hair dyes because of a possible cumulative risk. The study also found evidence of link between pregnant women's use of hair dye and the development of several childhood malignancies in their children, including neuroblastoma and brain tumors. Researchers have noted that the development of these cancers suggest that the harm may occur in utero. As a result, the researchers noted that concerned women might want to avoid using hair dye.

Although the use of hair dyes has been associated with an increased risk for several types of cancer, studies have yet to conclusively confirm that these dyes directly cause cancer. Nevertheless, some precautions are recommended. Because the carcinogenic components of many hair dyes penetrate human skin, one is to rub a petroleum-based ointment onto the scalp to reduce cutaneous exposure to the dye. In addition, people who dye their hair can reduce application time by 25 percent. Nevertheless, these are anecdotal practices that have not been studied for effectiveness.

Some dyes not approved as food additives are still used in cosmetics, such as lipstick and moisturizers, both of which can seep into the skin. Several natural colors used in lipstick include trace amounts of lead, which according to the National Institutes of Health (NIH) is a likely human carcinogen. The FDA, however, has stated that lipstick containing lead is not a human health safety problem because it is only ingested in small quantities.

**Tattoos**

Tattoo inks are made with various pigments, some of which contain toxic substances associated with cancer. Red inks can contain mercury, which has been found to cause cancer in rats. Cobalt can be found in green and blue inks and has been connected with cancer in animals. Black ink includes the polycyclic aromatic hydrocarbon called benzo(a)pyrene, which is found in coal tar and has been connected to skin cancers in petroleum workers.

Some pigments used in tattoo ink also contain nanoparticles (ultramicroscopic particles), which can enter the bloodstream and accumulate in organs, including the kidneys and spleen, which filter impurities. In a preliminary study conducted in Great Britain, researchers studied tattoos at the nano-level have shown that tattoos are reactive histologically. They found that the process of tattooing remodels the body’s main connective tissue (collagen), which helps dye constituents enter other parts of the body.

Scientists have found evidence that some nanoparticles can have toxic effects on the brain and may be carcinogenic in nature. A 2011 study found nanoparticles in tattoo ink. Except for white inks, researchers found that most tattoo inks included nanoparticles. Black ink is most associated with potential dangerous toxicity due to nanoparticles.

There is some concern that black inks are potentially carcinogenic and may cause DNA damage. They may also contain the known carcinogen benzo(a)pyrene. Significant amounts of nanoparticles in black ink may lead to easier and greater absorption of benzo(a)pyrene. In addition, research has uncovered a potential relationship between tattoos and skin cancer, although such a relationship has yet to be substantiated.

Research into tattoo inks and cancer is still in the early stages, and there is no definitive evidence that they cause cancer. Concerns about tattoo inks and cancer are based primarily on evidence linking certain carcinogenic substances found in pigments and other substances used to make the ink. One concern is that pigments from tattoos may reach the body’s lymph nodes. In addition, alcohol is used to disinfect the skin before a tattoo. Alcohol is known to make the skin more permeable, which could lead to more pigments entering the body.

Although the FDA has the power to regulate the contents of pigments, the agency has noted that a lack of strong evidence has led them to create few regulations for these colorants. However, the National Center for Toxicological Research is conducting studies of tattoo pigments. In addition to the safety of tattoo inks and pigments, these studies focus on the chemical composition of the inks, their breakdown in the human body, and their reaction in humans when exposed to light and magnetism. Such studies are pertinent considering the tremendous increase in getting tattoos among the general population.
Occupational Exposure
Studies have found that hairdressers are at a higher risk for cancer. A 2001 study showed that hairdressers who worked for 10 more years in the field had a fivefold higher risk of bladder cancer than the general population. In addition to bladder cancer, evidence has been found that they may also suffer from an increased risk for ovarian cancer.

The NCI notes that permanent hair dyes are the most dangerous to hairdressers. In addition, these dyes work with the aid of hydrogen peroxide, which can cause chemical reactions between aromatic amines and dye couplers used in chromatic photography film. The result is the formation of pigment molecules. Another study found that hairdressers were exposed to the confirmed carcinogen o-toulidine. Higher concentrations of carcinogens were also found in hairdressers who performed higher numbers of hair-dyeing or hair-waving treatments.

Various studies have produced significant medical evidence that working with dyes and pigments in the printing industry is associated with an increased risk of bladder cancer, including a 1.5 percent increased risk of this cancer among typographers. Studies have also consistently showed a higher risk for ovarian cancer in female workers in the printing industries. Another study garnered data showing that the highest risk for cancer due to ink exposure occurs in people exposed before they are 20 years old.

Several studies have found an increase in bladder cancer incidence in workers in dye-manufacturing facilities. A 1985 occupational analysis of chemical dye workers in England found that these workers had a twofold to threefold increased risk for bladder cancer, even after accounting for work age and factors such as smoking. The study also found an association between increased risk and the number of years people worked in the facilities.

A NIOSH study of employees working in dye-manufacturing plants between 1940 and 1972 found that these workers had a significant increase in the risk for bladder cancers. The risk was higher for those employed for 10 years or more in these plants. Workers also had an increased risk for esophagus cancer, and deaths from lung cancer and prostate cancer increased. Dyehouse workers, such as those who work in yarn-dyeing plants, have also been shown to have twice the expected mortality rate for esophageal cancer.

The FDA has acknowledged a growing body of evidence indicating that dyes and pigments used in consumer products and manufacturing may be related to numerous health risks, including cancer. As more studies are focusing on the health effects of dyes and pigments, future restrictions on dye use and manufacturing are likely. For example, a study published in 2014 discovered that yellow dye found in clothing and paper contains PCB-11, which can be found in yellow dyes and pigments.

Polychlorinated biphenyls (PCBs) were banned in the United States in the 1970s because of their environmental impact and their link to cancer. They can build up in the human body and have been linked to cancer. Although PCB-11 is not known to build up in the body, there is still concern, especially when PCB-11 is found in children’s clothing. PCB-11 is an unintentional by-product of pigment manufacturing. As a result, PCB-11 found in consumer products is exempt from U.S. laws regulating compounds in consumer products. The EPA has begun a study to review potential risks of PCB-11’s presence in clothing and other consumer goods.

Ecuador

The northwestern South American nation officially termed the Republic of Ecuador has been the historical site of several empires, conquests, and peoples. In antiquity, the country was the home of the Inca civilization. The modern state of Ecuador was formed in 1811, when Ecuadoran citizens in the capital of Quito declared their independence from Spain. The nation is home to more than 15 million citizens and has the highest diversity of flora and fauna in the world.

In the past 20 years, Ecuador has some of the lowest rates of male cancer incidences in all of South America. However, incidence rates have been relatively stable in both the nation’s male and female populations over the same period of time. Also, researchers have observed the unique trend of Ecuadoran females having higher levels of the alcohol- and tobacco-instigated bowel and lung cancers, whereas in the vast majority of the world, the opposite trend is true. Furthermore, the country is noted to have some of the most incidences of cervical cancer in all of South America.

Ecuador has a regional cancer dilemma in the Amazonian portion of the country. The situation was apparently caused over the past 40 years as a result of environmental pollution produced by Texaco during its operational tenure in the nation. From 1967 to 1992, Texaco operated numerous oil-drilling operations in the nation’s Amazonian region. During this period and beyond, researchers have documented how cancer incidences in the regions in which Texaco worked have skyrocketed, and the affected residents claim this is a result of the pollutants that Texaco procured and disseminated during their operations. In the area in which Texaco worked, researchers have observed the rates of cancer incidences of the Ecuadorans living there to be 150 percent greater than in the nonaffected parts of the country. Also, leukemia incidences in adolescents also skyrocketed in the affected portion of the nation. Since 1992, numerous studies have appeared in respectable medical journals detailing the scope and trends of the remarkable increase of cancers in the Ecuadoran Amazon. The situation appears to be a domestic medical crisis that the country will continue to deal with in the coming decades.

Though Ecuador has only one active cancer treatment facility in the country, the nation is the location of promising new research that could provide a revolutionary breakthrough in modern cancer treatment. For an unrelated medical project, a researcher named Arlen Rosenbloom was visiting Ecuador to offer temporary treatment services to patients. During his time there, he observed a region of the country that was home to an unusually large portion of citizens who suffered from a rare type of extreme dwarfism called Laron syndrome. Arlen Rosebloom teamed up with fellow peer Jaime
Guevarra-Aguirre to study this unique group of Ecuadoran dwarfs. After a great deal of study, the two researchers deduced that this population of Laron dwarfs seemed to have no cancer incidences whatsoever as a result of a unique aspect of their Laron syndrome: a complete lack of the hormone IGF-1 in their bodies. In various studies, an over- abundance of IGF-1 hormones within the human body has been tangibly correlated to higher levels of bowel, breast, prostate, and other cancer incidences. Scientists are now studying these Ecuadoran Laron dwarfs in an attempt to replicate the anticancerous mechanism of their syndrome.

In recent years, the most dominant forms of cancer in Ecuador have been breast, bladder, blood, cervical, and stomach cancer. Bladder, blood, and stomach cancers have been the most common forms of cancer incidences in males in the nation, while breast, cervical, and stomach cancers are the most prevalent incidences of cancer in females there. Over the past decade, incidences of the most-prevalent cancers in Ecuador have generally stayed level, though certain cancers like cervical cancer have steadily increased in incidences.

Presently, Ecuador is regarded as needing to do more to ascertain effective pathways to treatment for domestic cancer patients. Cancer incidences in the rural portions of the country usually go untreated, and even in urban parts of the nation, there are few facilities capable of advanced cancer care. If Ecuador is to deal with its domestic cancer burden in the coming decades, the nation will need to invest in the creation of more cancer treatment facilities and in the training of more domestic oncologists.

Education

Cancer education is an important component of efforts associated with prevention, detection, and management of the disease. Whereas individuals may be impacted physically, emotionally, and economically, the costs to society are substantial.
In the United States, the cost of cancer to the economy exceeded $200 billion in 2009, thus timely and effective education can have a positive impact on individuals and society. Although cancer may be caused by genetic, environmental, and lifestyle factors, or certain types of infections, an estimated two-thirds of all cases may have been prevented by lifestyle choices. Cancer education is therefore a vital component in efforts to reduce morbidity, mortality, and disability burdens. The main lifestyle factors that are addressed through cancer education include tobacco use, exposure to sun, physical activity, and diet.

**Purposes and Importance of Cancer Education**

Cancer education may be specifically geared toward prevention, early detection, treatment, and management of symptoms, side effects, comorbidities, and rehabilitation. Each of these areas may be targeted toward the general public, cancer patients, and health professionals. Prevention education is primarily focused around lifestyle choices, including tobacco use, sun exposure, diet, and physical activity.

**Tobacco Use**

Besides general advertising and smoking cessation promotional campaigns, the surgeon general’s reports have consistently highlighted the effects of tobacco use and exposure to secondhand smoke on cancer risk. These reports have sought to educate the public about the importance of not being exposed to secondhand smoke in cars, at work or home, or in enclosed public places. Evidence is building about the effect of what is now termed thirdhand smoke—residual particles from tobacco that is smoked indoors. This is an area of cancer education that is expected to develop further in the near future. Agencies such as the American Cancer Society (ACS), the Environmental Protection Agency (EPA), and the American Chemical Society are currently involved in thirdhand smoke education.

**Sun Exposure**

Skin cancer education is imperative. There are more cases of skin cancer diagnosis per year than diagnoses of all other cancers combined. Educating the public about the simple preventative steps that can be taken to avoid overexposure to UV rays from either the sun or tanning beds is the primary method used for education of skin cancer. Educational information on sun exposure and skin cancer may be obtained from the American Academy of Dermatology (AAD), the EPA, and the Melanoma Research Foundation. Educational campaigns from agencies such as the Skin Cancer Foundation are targeted to medical professionals and the public and focus on prevention, early detection, and treatment. Information is provided on sun-protective products, steps in skin protection, and the visible warning signs of skin cancer. Audiovisual material, manuals, newsletters, brochures, posters, and books are distributed via the Internet, health fairs, screening clinics, wellness programs, and grassroots educational campaigns.

**Physical Activity and Diet**

Various institutions have focused on increasing awareness of the roles of physical activity, diet, and body weight in the prevention and treatment of cancer. For example, the American Institute for Cancer Research (AICR) provides peer-reviewed materials that help medical professionals to advise patients on weight, physical activity, and diet issues. AICR also helps to keep the public well-advised by providing facts for journalists and by putting journalists in touch with researchers, clinicians, dietitians, and other experts. As another example, the National Cancer Institute (NCI) hosts Web sites that include nutritional and physical activity facts and recommendations, such as types, frequency, and duration of exercise. NCI Web sites also present information on the relationships among physical activity, nutrition, and risk for various types of cancer, prognosis, and survivorship.

**Cancer Education Challenges: Patient-Centered Education**

Recent work in the area of patient-centered education has led to the development of patient-centered communication in cancer care. The domains include: information exchange, fostering of healing relationships, recognizing and responding to emotions, managing uncertainty, making decisions, and enabling patient self-management. These domains underscored the importance of collaboration and interaction between physician and patient (inclusive of family members), support systems, trusting and culturally sensitive partnerships among all members of the health care team, along with
Education

involvement of the patient in decision making regarding managing day-to-day aspects of cancer illness and patient well-being. Other work on holistic, patient-centered cancer education also has included the concept of care communities, which include the patient, family, oncologists, surgeons, nurses, therapists, radiologists, and clergy. Providers must become competent in framing the information in light of what the patient has already received from other sources. This is necessary to achieve the goal of patient-centered education—making it easier for patients to understand how all information about cancer fits together.

Cancer Disparities
Morbidity, mortality, and disability-related education are influenced by factors associated with populations, medical practitioners, and cancer-reduction advocates. Educating the general population about the importance of early detection, for example, has the potential to positively impact cancer prognosis. This is even more crucial for ethnic or racial minority groups and for those who are considered lacking in health literacy and are therefore unable to adequately source, process, and understand information about screening, risk, and symptoms associated with cancer. They may therefore be unable to make prudent health-related decisions. These groups may live within medically underserved communities, where cancer is disproportionately distributed. To help reduce the impact of literacy disparities, health care providers should adapt their communication to the level of patients; this is easier than for patients to adapt to the level of providers. Customized videos and community-based collaborations and outreach programs that provide culturally and linguistically competent education and access to early detection services have been found to be particularly successful in these communities.

Practitioners and Advocates
Patient-provider communication is a key source of information about the association between early diagnosis of cancer and prognosis or survival. What, and how much, information is provided, however, has become a question of much debate. The passage of the Affordable Care Act (ACA), which now allows for some routine screenings to be covered by health insurance, has fueled dialogues pertaining to early detection and patient education. There have been concerns about what messages are disseminated to the public regarding routine screening for breast cancer. One reason behind the concerns is the claim that increased screening and the attendant increased incidence of early detection have not been accompanied by the expected decrease in late stage presentations and overall mortality. One recommendation that has been proposed to address this issue is that physicians inform patients about both sides of the screening controversy. This provides opportunities for practitioners to have case-by-case discussions with their patients, helping them to arrive at the best decision for each case rather than making screening decisions based on routine policy recommendations.

The Future of Cancer Education
Continued immigration from various cultures around the world has further diversified the U.S. population. To continue providing meaningful information to members of the entire population, providers will need to account for the differences that exist among immigrant residents in designing culturally appropriate educational material.

Finally, the pace of technological advancement presents both opportunities and challenges for cancer education. Computer technology is well poised to facilitate creative educational sources. For example, computer games, such as the Cancer Game (http://cancergame.org) and HopeLab (http://hopelab.org) have been developed to help in cancer-related medication adherence and living with cancer. Those who, because of socioeconomic or other disadvantages, are not able to keep pace with technological development may have less and less access to cancer education. Cancer education professionals must therefore be mindful to consider the disadvantaged as educational programs are developed in a fast-changing technological environment.

Cancer education sources include the following:

- American Cancer Society (http://www.cancer.org), where education focuses on prevention, and screening
- American Association for Cancer Education (AACE), which provides education on treatment guidelines, training, and information to those who educate groups
concerned with the early detection of cancer, early multimodality therapy, rehabilitation, and support for cancer patients

- National Cancer Institute’s (NCI) Cancer Information Service (CIS), which provides information to professionals and the public and is also involved in the development of research programs—timely information is provided to the public through various channels, including telephone (1-800-4-CANCER) and online (http://www.cancer.gov); the NCI also provides counseling services the cessation of smoking (1-877-44U-QUIT)
- The Agency for Healthcare Research and Quality’s Web site called the National Guideline Clearinghouse (http://www.guideline.gov), which is a database of cancer-related abstracts and guidelines, listed as neoplasms
- The National Comprehensive Cancer Network (http://www.nccn.org) Web site, which contains practice guidelines for clinic practices relating to most of the oncological tumors
- Center for Advancement in Cancer Education, a U.S. federally approved, not-for-profit information, counseling, and referral agency providing education on cancer prevention and support during and after treatment to individuals and health professionals worldwide (http://www.naturallifestyle.net/profiles/The-Center-for-Advancement-in-Cancer-Education-135)

Egypt

The Arab Republic of Egypt is a lower middle-income country with a population of approximately 80 million. Most of the population lives in the Nile Valley, with a roughly even division between those living in densely populated urban centers and rural areas. Urban life in Egypt is associated with a higher risk for cancer, perhaps due to greater exposure to environmental pollutants and more sedentary, urban lifestyles. Urban diets consist of a higher proportion of meat and fat as opposed to vegetables, and over a third of Egyptian adults are obese, which is a risk factor for some cancers.

For all cancers common to both genders, Egyptian men show a higher prevalence of cancer than women. In 2010, 35 percent of men used tobacco on a daily basis, while the comparable figure for women was only 0.2 percent, largely because of social stigma. However, the 2005 Global Youth Tobacco Smoking Survey indicated that smoking rates among 13- to 15-year-olds was closer: 16 percent for boys and 7.6 percent for girls. This indicates that smoking among women may increase in coming decades.

Smoking is permitted in most workplaces, restaurants, and private homes, so secondhand smoke represents a threat to nonsmokers and youth. Public advertising of tobacco products is not permitted, but other forms of marketing are allowed. Consumption taxes are approximately 65 percent of retail cost, but tobacco prices remain low, ranging between $0.50 per pack for domestic brands to $1.50 per pack for imported brands. In recent years, there has been a trend toward water pipe smoking, which is perceived as culturally authentic, natural, and less damaging to health than cigarette smoking.

Bladder cancer is the most prevalent cancer among Egyptian males, with a mortality rate (16.3 per
100,000 population, or around 8,000 deaths annually) that is twice as high as the highest European rates and more than four times as high as in the United States.

Bladder cancer in Egypt has typically been squamous cell carcinoma, associated with a history of *Schistosoma haematobium* parasite infection from unclean water. Several decades of interventions aimed at reducing schistosomiasis have reduced the occurrence of squamous cell carcinoma. However, prevalence of transitional cell carcinoma bladder cancer has increased. The cause of this increase is unclear but may be due to exposure to environmental pollutants and tobacco use. Despite the prevalence of bladder cancer in Egypt, there is no comprehensive screening program in place.

Breast cancer is the most common cancer among Egyptian women, representing 18.9 percent of total reported cancer cases (35.1 percent in women and 2.2 percent in men), occurring at a rate of 49.6 cases per 100,000 individuals. After the first symptoms appear, patients often wait more than 3.5 years before seeking treatment, and total mastectomy is the most common treatment for locally advanced malignancy. Small-scale efforts at screening have been promising in terms of early diagnosis and treatment, but population based screening programs do not exist. Mortality from the disease is significantly higher among women with lower socioeconomic profiles, including education, occupation, and income. This difference is likely a result of reduced health awareness and agency in seeking treatment. Women in rural areas have a higher mortality compared to women in urban areas, perhaps due to access to screening and treatment facilities.

Colorectal cancer is typically less prevalent in developing countries compared to Western countries, and though it is the third-most common cancer among Egyptian men, it is also relatively rare, representing only 3 percent of malignancies. There are troubling indications, however, that colorectal cancer may become a more significant health threat in the future. Since the 1990s, one-third of colorectal cancer cases have been in patients under the age of 40, though there is no indication of a hereditary predisposition. Adoption of a Westernized diet may contribute to this unusual age distribution, but exposure to agricultural and industrial chemicals and a history of eating food directly from farms has also been shown to be associated with an increased risk for colorectal cancer in Egypt.

Further Readings

**Eisai (Japan)**

Eisai is a Japanese corporation with 10,419 employees worldwide including subsidiaries as of early 2014. Eisai ended up as number five in Japan and as number 25 in on a global basis in the Medical Care & the Pharmaceutical Industry 2013 overview of pharmaceutical corporations’ sales. Eisai integrates a whole range of pharmaceuticals and health care products within its portfolio, except for veterinary medicines. A majority of the products are sold overseas. One main product for a number of years was Aricept (donepezil) for Alzheimer’s disease, approved by the U.S. Food and Drug Administration (FDA) in 1996. It was developed by Eisai but subsequently co-marketed with Pfizer. The product lost U.S. market exclusivity in 2012, and there is currently competition from a generic version. More recent products include the breast cancer treatment Halaven (eribulin mesylate), approved by the FDA in 2010, and the receptor antagonist Fycompa for epilepsy, approved by the FDA in 2012. These were both developed in-house and are considered to be two of Eisai’s future core products. The anti-obesity agent Belviq was in addition launched in the United States in 2013.

**Eisai’s Oncology Segment**

Eisai has increased its presence within the oncology field, with oncology-related products increasing from 10 to 18 percent during 2010 to 2012. As of 2013, the plan was to increase oncology to 22 percent by 2015. Halaven’s eribulin is a synthetic derivative of halichondrin B, which is a natural marine product derived from a sea sponge. It is a new anticancer treatment in the sense that it acts against tumors by suppressing the growth of microtubules. Halaven was, as of 2013, also in a phase III study investigating the potential for use in non–small cell lung cancer treatment, and phase II studies are underway in Japan in order to investigate the agent as a potential treatment for sarcoma. Another drug, Lenatinib, has been designated an orphan drug for thyroid cancer in Japan (2012) and Europe (2013), and there are several other projects underway.

The increased ratio of oncology is partly due to acquisitions as well as new research and development (R&D) efforts. Eisai acquired Morphotek, Pennsylvania (2008), MGI Pharma, Minnesota (2007), and AkaRx, New Jersey (2010). Morphotek had been established in 2000, based on the invention of the company’s legacy technology called morphogenics, which is a platform technology regulating the ability of a host organism to repair mutations that occur during DNA replication.

Morphotek has got several monoclonal antibodies for cancer and inflammatory disease in clinical development. Morphotek, Inc. continues to exist as a subsidiary. MGI Pharma had been founded in 1979, focusing on products for oncology and acute care applications. AkaRx had been developing a therapeutic agent for thrombocytopenia (relative decrease of platelets in blood), a condition that may be a side effect of chemotherapy. In addition, H3 Biomedicine Inc. was established as a research subsidiary in Cambridge, Massachusetts, in 2010 and aims at discovering drugs based on using genetic information from cancer patients. If successful, this can shorten the R&D process and reduce the scale of clinical trials. The genetic information can help identifying what types of drugs could be most effective, thereby allowing fewer trial subjects in the clinical R&D process.

**History of Eisai**

Eisai was founded as Nihon Eisai Co. Ltd. in 1941 by Toyoji Naito, a former employee of an existing pharmaceutical corporation. At 57 years of age, he started Eisai, which eventually merged with the company Sakuragaoka Research Laboratory in 1944 and was listed on the stock exchanges in 1961. Key products in the first years included Vitamin E and health care products. Then the corporation announced a much-publicized innovation declaration in 1988 and started a series of five-year development plans. From 1987 to 1991, the focus was to strengthen domestic marketing, from 1992 to 1996 to focus on globalization with a special emphasis on the U.S. market, from 1997 to 2001 to focus on expansion, and from 2001 to 2007 to focus on the implementation of a millennium plan. Then, due to certain imminent developments such as the expiration of market exclusivity of key products such as Aricept, the focus from 2007 to 2011 was on implementing a
dramatic replanning. These corporate developments have attracted the attention of renowned management theorists Nonaka, Peltokorpi, and Strebel. The veterinary business was divested in 2003, whereas, as mentioned, the Pennsylvania-based monoclonal antibodies company Morphotek as well as the Minnesota-based oncology-focused MGI Pharma were acquired in 2007, and AkaRx, based in New Jersey, was acquired in 2010.

Corporate Philosophy and Recent Strategy
Eisai’s R&D expenditures in relation to sales were 21 percent in fiscal year 2012, and the corporate slogan is Human Health Care (HHC). As of 2012, the corporation was present in a total of 73 countries, and the plan has been to reach 114 countries by 2015. After the founder’s death, the presidency has continued to be in the Naito family. The corporation has, however, implemented a broad structure where a majority of the members are external, including for example, university professors and lawyers. Eisai tries to operate according to a performing better with fewer resources concept, which means to enhance product creation capabilities, generate innovation, and fundamentally strengthen marketing capabilities. The corporation also strives to improve access to medicines in emerging and developing countries, for example, through a so-called 4P mix strategy, which consists of a differentiated pricing policy, utilizing the benefits of production also overseas, maintaining products that may ensure full-scale entry to markets in emerging countries and pursuit of differentiated partnerships. The corporation’s special incentive system allows awards to exceptional individual employees. After the development success of Aricept, for example, several employees received such awards.

El Salvador

The central American nation officially termed the Republic of El Salvador was established in 1992 after the conclusion of a civil war in the nation. Since then, the nation has developed and industrialized quickly. El Salvador is now home to close to 6 million citizens, and it is currently one of the most compactly populated nations in all of the Americas.

El Salvador has a unique national cancer situation as its female population experiences more cancer incidences than its male population, which is the opposite of the global trend of males generally experiencing higher cancer rates. Fortunately, a study conducted by the Fifth Annual Cancer Control Congress in 2013 ascertained that El Salvador has a tangibly declining cancer mortality rate, even in the cancers that are large domestic problems such as breast, cervical, and stomach cancers. Researchers estimate that there are up to 7,000 new cases of cancer occurring in El Salvador every year, and they have also determined that cancer of the stomach is presently the leading cause of cancer mortalities in both the nation’s female and male populations.
In line with El Salvadoran females experiencing higher rates of cancer than their male counterparts, breast and cervical cancers are one of the most substantial health problems in the country. Unfortunately, these two diseases are largely preventable, and their high levels of incidence in El Salvador correlate with various obstacles to diagnosis. To start, many El Salvadorans do not have access to even basic health care facilities, much less cancer treatment centers. El Salvador is a developing country, and thus the distribution of health information in the nation’s rural areas is inadequate, and many El Salvadoran females are wholly unaware that early screening for breast and cervical cancers can provide an effective path to warding off the diseases. Culturally, and also due to the lack of regular physician visits in which trust is built, El Salvadoran women are averse to having their reproductive organs examined for cancer. Furthermore, and like numerous other developing nations around the world, the El Salvadoran population is not informed enough regarding what cancer is and how the disease is developed. Several organizations and governmental departments are working to overcome these treatment obstacles, but it may take a decade or two to substantially negate these impediments.

Currently, there is a crisis in El Salvador regarding the lack of effective management for pain derived from cancer. Researchers estimate that more than 80 percent of all terminal cancer patients will experience severe pain at some point during their affliction, and El Salvador has been observed to have astonishingly low amounts of painkillers available for palliative treatment. Medical experts believe that El Salvador needs to have up to 40 kilograms of morphine in its domestic medicine supply in order to sufficiently manage the severe pain of its terminal cancer patients, but in 2007, the nation had and used less than half a kilogram of morphine on all its medical patients. Even if such a small amount of morphine was used exclusively on the nation’s cancer patients, it would only account for 1 percent of the El Salvadoran terminal cancer patients. Access and availability to effective avenues of pain treatment will need to drastically improve in El Salvador in the coming years as the nation currently has the lowest rate of morphine availability out of all the countries of North, Central, and Latin Americas.

In the past several years, the most prevalent forms of cancer in El Salvador have been breast, bladder, blood, cervical, and stomach cancer. Bladder, blood, and stomach cancers are the most common forms of cancer incidences in males in the nation, while breast, cervical, and stomach cancers are the most common incidences of cancer in females there. Over the past decade, incidences of bladder, blood, and stomach cancers have been consistently increasing nationwide in both El Salvador’s male and female populations, while occurrences of cervical and breast cancer have been consistently declining.

Sadly, many citizens of El Salvador have suffered from cancer throughout the nation’s history. The El Salvadoran ex-president Jose Napoleon Duarte Fuentes died as a result of stomach cancer after having struggled with the disease for several years. Rafael Menjivar Ochoa, the critically acclaimed El Salvadoran writer and journalist, passed away in 2011 after succumbing to his fight with colon cancer. Moreover, Roberto D’Aubuisson, the infamous leader of Salvadoran death squads in the nation’s civil war during the 1980s, died from his bout with esophageal cancer in 1992.

Electrical Industry

Thomas Edison developed the light bulb in 1880 and electrical companies sprang up in urban areas by 1890. Regulation of utility companies began in 1907 and two-thirds of the urban areas in the United States possessed street and home lights by 1920. Since the beginning of commercial electricity, over a century of high-voltage electricity use transpired in the industrialized world. When mentioning the electrical industry, discussions about cancer often arise. The visible, health-associated problems to electricity initially consisted of fire, explosions, and electrocutions. Only toward the later part of the 20th century did research into biological effects of electricity appear.

Electric and Magnetic Fields

Some studies carried out in the 1960s found that invisible electromagnetic fields (EMF) created by high-voltage utility lines demonstrate a link to cancers in adults and children. Power lines generate both electric and magnetic fields. Because the body acts as an electrical conductor, the electric field goes down in magnitude within the human body and, in fact, the electric fields from power lines exist at a lower level than the electric field in the body.

A Swedish study by S. Tornqvist, S. Norell, A. Ahlbom, and B. Knave on 3,358 power lines workers and 6,703 power station operators between 1961 and 1979 showed no consistent risk of cancer, especially leukemia and brain tumors. The groups displayed no elevated risk of cancer of the urinary tract.

Magnetic fields remain as a possible source of deleterious health in the human body. Yet even magnetic fields from power lines remain very small. The Earth's magnetic field exists at between 300 to 500 milliGauss, compared to the power line source of 2 milliGauss. Initial studies in the 1970s and 1980s conducted by Nancy Wertheimer and Ed Leeper alleged that electric power lines generated an increased incidence of childhood leukemia, but the research turned out to be flawed. J. G. Davis and colleagues published a review in 1992 that discussed in detail the problems with the earlier research on power lines and cancer.

G. Zeman from the Health Physics Society reported no known health risks arise from living next to high-voltage power lines but stated that science cannot prove that low levels of electromagnetic fields remain risk free. Consequently, scientists continue research to ascertain any health risks, but most believe that, if risks are present, the risk represents a small contribution to developing cancer. Later research shows some effects.

C. Sermage-Faure and colleagues studied the association of living next to high-voltage overhead power lines (HVOLs) and childhood acute leukemia in France from 2002 to 2007. Children living within 50 meters of a HVOL showed a small elevated risk of developing acute leukemia. The study supports similar findings in other international sites.

A study by C. F. Robinson, M. Petersen, S. Palu, and J. P. Sestito calculated the mortality of a large cohort of electrical workers from the United States for the years 1982 to 1987. The research confirmed the presence of lung cancer from asbestos exposure in male workers but indicated the need for more research to relate leukemia and melanoma skin cancer to electrical work. The outside environment of electrical industry workers causes their skin to be overexposed to ultraviolet (UV) radiation. The overexposure can produce skin cancers and melanomas.

Wireless Telecommunication Technologies

M. Roosli and K. Hug performed a literature review on the association of radiofrequency electromagnetic field (RF-EMF) exposure and health problems. The authors found nine randomized trials that found no association between RF-EMF and health problems from 2007 to 2011. Two observation studies looked at the effect of RF-EMF on quality of life and found no adverse effects. The reviews stated
that the researchers followed the exposures for short periods of time, and longer-term studies are needed to accurately determine any associations to health problems.

S. Sadetzki and colleagues designed an international study to determine the possible health effects of exposure to radiofrequency (RF) and extremely low frequency (ELF) electromagnetic fields in children and adolescents using mobile phones. The multinational case-control study will investigate the exposure of EMF in 14 countries on children ages 10 to 24 years old.

Electricity Fields
J. Aoun, N. Saleh, M. Waked, J. Salame, and P. Salameh describe their study of lung cancer and a sample of Lebanese adults. The case control study on lung cancer found risk factors of cigarette smoking, living near an electricity generator, a family history of cancer, and consuming low quantities of fruits and vegetables. The authors advise further study to confirm these findings. This study did show an effect of an association between lung cancer and living near an electricity generator.

Polychlorinated Biphenyl
The electrical industry began using polychlorinated biphenyl (PCB) in 1929 as a cooling and insulating fluid for industrial transformers and capacitors as well as for stabilizing additives in the production of coating for electrical wiring and electronic components. As early as 1936, the toxicity associated with PCB came to light when family members developed pustules on the skin from exposure to the electrical workers’ clothing. By 1947, R. M. Brown published a report on PCBs being “objectionably toxic” and described a maximum permissible concentration of 1 microgram per meter cubed for an eight-hour day. However, the use of PCBs persisted with few restrictions until the 1970s.

When studies about the carcinogenic properties of PCBs arose in the 1970s, outcries to stop using PCBs arose. A ban on open sources of PCBs went into effect in the 1970s, but unfortunately, PCBs endure in the environment due to PCBs being allowed in totally enclosed uses like transformers and capacitors. If the enclosure fails, the PCB can leak, catch fire, or explode. When the substance leaks from the transformers on the electrical poles, it contaminates the soil below the utility pole.

PCBs generate mutagenic consequences by disturbing the hormones in the body. The PCB can both impede and mimic estradiol, the primary sex hormone in females. Mimicking estrogen can fuel breast cancer cells and possibly other cancers, like uterine or cervical.

Multiple routes of contact with PCBs exist. A person can breathe in air contaminated with PCB, consume PCB-tainted food, or absorb PCB though the skin via contact with old electrical equipment. Once a person becomes exposed, certain PCBs change in the body to other chemicals. So chemically changed and unchanged PCBs may be passed by way of feces or can stay in the body fat or other organs for months. PCBs, in milk fat, can be passed to infants during breast-feeding.

A. M. Ruder, M. J. Hein, N. B. Hopf, and M. A. Waters assessed the mortality of 24,865 electrical capacitor workers exposed to PCBs at plants in Indiana, Massachusetts, and New York over 10 years, ending in 2008. The study showed an association between cumulative PCB exposure and cancers of the stomach, uterine, and prostate as well as multiple myeloma. These results demonstrate cancer’s relationship to PCBs in this longitudinal study.

A study completed by A. C. Pesatori and colleagues in an Italian cohort present different cancers occurring in electrical capacitor production. The cancers suggested from exposure to PCB included the digestive system, brain, and lymphohemopoietic tissue. The authors stated the sample size limited the ability to make a definitive statement.

K. Mallin and colleagues studied 2,885 workers at an electrical capacitor plant between 1944 and 1977. The authors found females possessed significantly elevated rates of liver or biliary cancer and intestinal cancer, whereas males demonstrated significant elevations in stomach cancer and thyroid cancer.

Electrical Lighting and Breast Cancer Risk
Light during the night suppresses melatonin, and it disrupts circadian rhythms. R. G. Stevens describes a theory, proposed in 1987, purporting an increase in the use of electricity at night to light streets and inside homes accounts in part for the elevated risk of breast cancer worldwide. R. G. Stevens, G. Brainard, D. E. Blask, S. W. Lockley, and M. E. Motta reviewed the evidence for electric lighting disrupting circadian rhythm and causing breast cancer but found a paucity of data to link
this association. More research will be needed to determine the association of breast cancer and circadian disruption.

**Biologically Closed Electric Circuits**

The book on BCEC describes a new theory on carcinogenesis and a novel method of treatment against cancer. The innovative theory proposes using electric currents against inflammatory states, fractures, atheromas, and neurologic complications of disease. He basically proposes a new approach to electrophysiology, indicating that fluctuating electrical potentials arise from within cancers and could affect the extracellular fluid dynamics around a tumor. Unfortunately, this novel theory will require testing from other scientists before electrical currents can be used to treat human disease.

**Bioelectrical Impedance**

All living cells contain electrical capability and even create electric currents. E. Hondroulis, S. J. Melnick, X. Zhang, Z. Z. Wu, and C. Z. Li describe a laboratory study showing the electrical properties of cancer cells differ from the body's normal cells. The researchers used ovarian cancer cells in comparison to normal ovarian cells. By applying alternating electric fields to both cell groups, the scientists showed how the electric fields slowed the growth of the cancer cells. The study indicates the possible effects of alternating electric field therapy to future applications in clinical and drug treatments.

A group of researchers in Poland consisting of T. Malecka-Massalska, A. Smolen, and K. Smorshed used bioelectrical impedance analysis (an ImpediMed bioimpedance analysis machine) in a case-control study of breast cancer patients and health subjects. Significantly higher levels ($p = 0.0031$) of reactance and resistance at 50 kHz occurred in the breast cancer patients over healthy subjects. This preliminary observation appears to be in line with the research carried out by Nordenstrom, but further research is needed in larger patient groups to validate these initial findings.

Malecka-Massalska and colleagues further studied a group of patients with squamous cell carcinoma in head and neck tumors in a cross-sectional study using bioelectrical impedance analysis.

The results showed significantly higher levels ($p = 0.0002$) of resistance in the patients with the head and neck cancer than the control group. Further observations in head and neck cancer are needed to confirm results.

Previous results show a significant electrical property difference between malignant and benign prostate tissue. V. Mishra and colleagues evaluated an electric property-sensing biopsy needle to determine the effectiveness of the needle in biopsies of malignant and normal prostate tissue. The study found higher resistive and reactive electrical components in the malignant prostate tissue. By sensing the malignant prostate tissue in real time, the device improves the accuracy of cancer during biopsy procedures.

**Conclusion**

Despite the widespread existence of electricity since the 1920s, only a few characteristics of the electrical industry show a direct relationship to the development of cancer. Electric workers develop cancer from PCB used in capacitors and from asbestos used in the insulation. Due to the strong association of cancers and PCB, regulators banned open sources of PCB in 1979, but electric workers still come in contact with the closed sources. Research on high-voltage overhead power lines in the last decade confirmed an association to childhood acute leukemia. The electric lighting at night and breast cancer has yet to be confirmed.

More recently, the electrical activity of cells came under study from the original work of Nordenstrom. The last 10 years have demonstrated the need for more research on electrical currents present in cancer cells. This research shows that cancer cells show higher levels of electrical activity than normal cells. The future will surely demonstrate more use of measuring electric currents in cells to diagnose and treat cancer.

There are a wide variety of legitimate reasons for considering an association between electronics and cancer as a societal issue. There are ongoing debates in scientific communities, for example, on the extent to which electromagnetic energy is a risk factor or associated cause of cancer. There is no shortage of publications on technology use and suspected negative effects on human health. These discussions often focus on whether there is a link between magnetic field exposure and cancer in the home or at work. There is an interest in the risk of leukemia or breast cancer (for men and women) that may be associated with various levels of exposure to electromagnetic fields (EMFs). Some of these discussions have even made their way
into popular media, for example, the concern over mobile telephone use and cancer risk. Most recently, discussions have also focused on the increasing popularity and prevalence of electric cigarette use and the possible risk for cancer in high-risk individuals. However, despite these legitimate concerns, there are equally viable uses of electronics and electronic technology associated with health and healing.

Electronic communication and access to electronic media may increase health awareness and is associated with healthier lifestyle choices and reduced risk of cancer or other illnesses or disease. Another modern use of electronic technology that is indirectly related to health and healing includes electronic data sharing of health information. This includes access to medical records and patient information between physicians and possibly health systems. Some countries have developed electronic surveillance systems for use in the early detection of possible epidemics. It is conceivable that these systems might also be useful for tracking possible risk factors for certain types of cancer or monitoring the health conditions of individuals or communities at higher risk for some types of cancer. Finally, an essay on the association between electronics and cancer in society would be incomplete without mention of the many direct uses of electronics in cancer treatment.

**Does Electromagnetic Energy Cause Cancer?**

Research has looked into the electromagnetic radiation (EMR) produced by electricity in the home and from overhead power lines as a possible cause of cancer. EMR can be categorized into two types: ionizing (e.g., X-rays, radon, and cosmic rays) and nonionizing (e.g., radiofrequency and extremely low-frequency or power frequency). No conclusive link has been found so far between EMR and the incidence of cancer. The most recent research studies seem to show that low levels of electromagnetic energy do not increase the risk of cancer.

Studies have looked mainly at EMFs and the risk for leukemia and breast cancer. In 2001, the National
Radiation Protection Board (NRPB) reported that there might be a very slight increased risk for leukemia in children. The EMR exposure investigated in this report was mostly from domestic use of electricity. A study from England in 2005 found that children who lived within 200 meters from high-voltage power lines at birth had an increased risk for leukemia. In 2012, the Advisory Group on Non Ionising Radiation (AGNIR), within the Health Protection Agency in UK, reported on electromagnetic radiation and breast cancer risk. The belief was that exposure to EMFs could lower the levels of a hormone called melatonin and that this could increase the risk of breast cancer. After looking at the available evidence, the group reported that exposure to EMFs did not appear to increase the risk of breast cancer. They also reported that EMF exposure did not appear to influence melatonin levels.

A Danish review of studies published in 2008 reported that long-term exposure to EMFs among children does seem to be associated with an increased risk for leukemia. Yet, the explanation is not clear, and researchers suggested that the observed relationship could be due to chance. Studies from Australia in 1996, and from Italy in 2002, have reported childhood leukemia clusters close to high-power television and radio broadcast transmitters. However, large, systematic studies in South Korea and Germany show no association between exposure to radio frequency EMFs from broadcast towers and childhood leukemia. A report in February 2014 from the Childhood Cancer Research Group at the University of Oxford found that children who live near overhead power lines in early life do not have a greater risk of developing childhood leukemia. Therefore, research is likely to continue, but existing evidence suggests that it is unlikely that electromagnetic fields cause cancer.

What About Mobile Phones and Cancer?
Mobile phones transmit radiofrequency energy. Radiofrequency energy is a form of nonionizing electromagnetic radiation. Human skin and underlying tissues nearest to where the phone is held can absorb this energy. Currently, there is no consistent evidence that nonionizing radiation from mobile phones increases the risk of cancer. The World Health Organization (WHO) says that the EMFs produced by mobile phones are classified by the International Agency for Research on Cancer as possibly a carcinogen in humans. They also say that studies are ongoing to fully assess the potential long-term effects of mobile phone use.

The WHO reports that, over the past 20 years, no adverse health effects have been found across a large number of studies that have been done to assess whether mobile phones pose a potential health risk. Mobile phones were not used widely until the early 1990s, so longer-term effects are not yet known. However, animal studies of long-term exposure to electromagnetic fields have not shown any increased cancer risk.

**Technology Use and Human Health**
Some social media sites and other electronic sources that increase health awareness may include recommendations for physical exercise and prevention diets that may reduce the risk for certain types of cancer. Electronic access to readily available information also provides a level of insight into symptoms and possible treatment options that previous generations did not have. Likewise, the rise of social media and electronic social networks allows countless individuals to discuss health issues with other people around the world without leaving their homes. Originally, the Internet was mostly a large repository of information that could be tapped in increasingly clever ways, but the transfer of information was mostly unidirectional (from the World Wide Web to the end user). Since the beginning of the 21st century, though, the Internet has become a two-way information highway, where the uploading of personal information has become as common as the downloading of information. This behavior evolved into the formation of online social networks on Web sites like Myspace, Facebook, Twitter YouTube, and Tumblr as well as professional networking sites like LinkedIn. This nascent use of electronic communications by the common layperson, therefore, has the potential to improve general health conditions through public health awareness.

Another interesting development in the connection between electronics, technology use, and cancer risk is the increasing popularity of telework. Electronics technology enables companies to seek opportunities for employees to work from home or other remote locations—telework. Telecommuting, or telework, can reduce required transportation to work and any associated environmental pollution that may be linked to increased risks or incidence of cancer in society.
A more direct use of electronics and public health is the Electronic Surveillance System for the Early Notification of Community-Based Epidemics (ESSENCE). Public health surveillance can be defined as the systematic collection, analysis, interpretation, and dissemination of health-related data. The purpose of an electronic health surveillance system is to prevent or control disease or injury and to improve health or to improve a health program or service, including cancer registries.

Finally, there are many direct uses of electronics in cancer treatment. Cancer treatment research has demonstrated that low-intensity electric fields can disrupt the division of cancer cells and slow the growth of brain tumors with little danger to normal brain tissue. This noninvasive procedure uses a small device with alternating electrical fields to disrupt the rapid cell division exhibited by cancer cells in some malignant tumors. A similar technique called transcutaneous electrical nerve stimulation (TENS) has been shown effective as a method of relieving acute and chronic pain caused by cancer as well as other problems such as surgery, childbirth, migraine headaches, and so on. Some practitioners believe that the low-voltage electrical impulses stimulate the production of endorphins, the body’s natural painkillers.

Eli Lilly & Company (United States)

Eli Lilly & Company (Lilly) researches, develops, manufactures, and sells pharmaceuticals. With products sold in approximately 130 countries, Lilly has manufacturing and distribution facilities in 17 other countries in addition to the United States. Lilly also includes the Lilly Oncology division, which focuses on innovative cancer drugs and on improving outcomes for patients.

Founded in 1876 by a pharmaceutical chemist and Civil War veteran Colonel Eli Lilly, the company remained under Lilly family management until 1953. Lilly began a concerted effort in the 1960s to find solutions for cancer. In the 1970s, it began marketing Eldisine (vindesine sulphate) for the treatment of leukemia. The drug’s use would eventually be expanded to include breast cancer, non–small cell lung cancer, and melanoma.

On September 13, 2007, following three clinical trials, the FDA approved Lilly’s raloxifene hydrochloride tablets (Evista) for reduction in the risk of invasive breast cancer in postmenopausal women with osteoporosis and in postmenopausal women at high risk for invasive breast cancer. Raloxifene is not prescribed to decrease the risk of developing non-invasive cancer. Raloxifene, which is also used to prevent and treat osteoporosis, reduces the risk of developing invasive breast cancer by preventing the female hormone estrogen from affecting breast tissue, thus reducing the chance of tumors developing that need estrogen to grow. Raloxifene does not completely prevent breast cancer, and women who take the drug are instructed to continue to receive regular breast examinations.

Lilly got approval from the U.S. Food and Drug Administration (FDA) in 1996 for Gemzar (gemcitabine) to treat pancreatic cancer. Gemzar is also used to treat non–small cell lung cancer. Other chemotherapies produced by Lilly include Alimta (pemetrexed) for pleural mesothelioma and non–small cell lung cancer and Erbitux (cetuximab) for metastatic colorectal cancer and head and neck cancer.
The cancer drug Cyramza (ramucirumab), which the company acquired via acquisition of ImClone Systems in 2008, became the first FDA-approved treatment for advanced gastric cancer after prior chemotherapy. The drug was also approved to treat gastroesophageal junction adenocarcinoma, a cancer located at the junction between the esophagus and stomach. However, in July 2014, phase 3 clinical trials of the drug for use as a secondary treatment for patients with liver cancer did not produce statistically significant data that these patients had longer survival rates.

The Lilly Oncology unit was formed in 2009 as part of a company restructuring designed to improve Lilly’s success of getting experimental drug therapies approved for marketing. A major focus of the effort was the idea of developing drugs tailored to specific strains of cancer. In the case of breast cancer, for example, it is actually a myriad of different diseases influenced by a woman’s genetic makeup.

The oncology unit is conducting research in several areas. Research on cancer signaling revolves around cancer cells’ ability to sustain chronic proliferation. Investigations revolve primarily around cell cycle regulation. The research is a genetics-based effort to develop drugs that could target aberrant cell-signaling pathways.

Another area of research is cancer angiogenesis (blood vessel sprouting). Lilly’s efforts focus on identifying and developing new antiangiogenic agents with an emphasis on discovering agents for specific tumor types or for cancers that do not respond to current chemotherapies. Other areas of research include cancer metabolism, tumor immunotherapy, and epigenetics.

The company also conducts research into supportive care. One research area focuses on toxicities often associated with cancer and cancer therapies, such as anemia and muscle wasting. Ongoing research focuses on using antibodies to target regulators of muscle metabolism and iron homeostasis.

The company is also conducting phase 1, 2, or 3 clinical trials on a number of cancer-fighting agents. These trials focus on agents for early development cancers and for breast, gastrointestinal, genitourinary, hematologic, lung, and neurologic cancers as well as soft tissue sarcoma and melanoma supportive care. In 2014, Lilly announced that it had formed an agreement with UK Biotech to develop new cancer drugs.

The Lilly Oncology division also runs several initiatives concerned with helping physicians better manage cancer cases and communication with patients. There are also several patient-based initiatives. PACE is a Lilly Oncology initiative and stands for Patient Access to Cancer Care Excellence. The Global initiative focuses on encouraging public polices and other health care decisions that foster the development of new medicines, enhanced learning from cancer cases, and better response to cancer treatment and care.

Lilly has also created mobile applications (apps) for oncologists to run via their mobile devices, such as smartphones and tablet computers. The Oncology Pipeline app provides health care professions access to the Lilly Oncology Clinical Development program. The app includes information on drug discovery platforms in development and molecules under research. The Lilly Oncology Clinical Trials Resource app includes free access to clinical trial information, including trials for various types of cancer.

Lilly has developed a number of programs and resources for clinicians and other health care professionals directly related to patient care. The company’s app called the Cancer Companion was developed for health care professionals to learn more about cancer treatment and care, especially in terms of information that they can then pass on to their patients. Other apps include the MDLinx Oncology app, which provides the latest oncology journal articles for review on mobile devices.

Lilly also provides online, interactive lung and colorectal staging galleries for use by health care professionals. These galleries help health care providers better discuss with their patients various issues concerning their cancer and its treatment. The IASLC Staging Atlas for Thoracic Oncology smartphone app provides updated staging information for non–small cell lung cancer. (IASLC stands for International Association for the Study of Lung Cancer.)

Lilly also has developed a number of programs that focus on better communication between health care professionals and patients. For example, the company has an interactive educational speaker program that helps providers improve patient care through better communication. It also has information on promoting health behavior for cancer survivors who are recovering.

Lilly’s Taking Back Control video targets patients and focuses on the difficulties they face after being diagnosed with cancer. The Lilly Oncology on Canvas art competition, cosponsored by the National Coalition for Cancer Survivorship, promotes anyone in the
United States and Puerto Rico to express through artwork or writing their experiences with cancer with a focus on life-affirming changes in their lives. The program is open not only to patients but also to caregivers, family members, friends, and health care professionals.

The Lilly Patient One program is for health care providers who have patients who may be experiencing financial and insurance coverage issues. For patients prescribed a Lilly Oncology product, their health care providers can find out information to help patients gain access to financial assistance or reimbursement assistance programs and services. In addition to offering information on insurance issues, such as payer policy information and payment methodologies, the program can help in the evaluation of other funding options, drug replacement options, possible reimbursement assistance, and appeals assistance when insurance claims are denied.

Embalming Fluids

More than 5 million gallons of embalming fluid are used every year in the United States in order to sanitize, disinfect, and preserve human and animal cadavers, whether for funerals and burial or for scientific study. The main components of embalming fluid are formaldehyde and methanol in combination with other solvents and numerous additives. Embalming fluids have been linked to cancer rates and other health risks faced by embalmers.

Embalming is the practice of treating the remains of the deceased—especially humans, but animal remains are preserved for scientific study and to teach dissection and anatomy—in order to preserve or restore them. With human remains, the principal purpose is to display the remains, such as at a wake or viewing before the burial. As such, preventing the deterioration, putrefaction, and odor of dead tissues is paramount.

The following are the five stages of embalming:

1. In the pre-embalming preparations, the corpse is washed with antibacterial and germicidal solutions, and rigor mortis (a postmortem effect that stiffens the limbs beginning a few hours after death) is relieved by bending and massaging the arms and legs. The corpse is posed in a process called setting the features, consisting of arranging the face so that it appears to have a calm expression of being at rest. This is performed even if the corpse is going to be cremated or if there is no viewing planned as a gesture of respect for the deceased.
Setting the features involves using eye caps to keep the eyes shut, and using sutures, adhesives, or wires injected by needle in order to manipulate the mouth, lips, and jawbone. In some cases, some amount of facial reconstruction may be necessary. Specialized techniques and tools have been developed purely for the mortuary industry. Male corpses are also shaved of any visible stubble.

2. Embalming chemicals are injected into the body, traditionally through the right common carotid artery. Blood and other fluids are displaced and expelled from the body through a tube injected into the right jugular vein. The body is massaged in order to break up clots and distribute embalming fluids, and if circulation

Embalming Fluids

More than 5 million gallons of embalming fluid are used every year in the United States in order to
remains poor, multiple injection points at other arteries are used.

3. The internal fluids inside body cavities are similarly displaced during cavity embalming, in which an incision is made in the navel so that a trocar can be inserted into the chest and stomach cavities in order to aspirate the contents of hollow organs. A formaldehyde-heavy mixture is pumped in to fill the space.

4. In hypodermic embalming, tissues are injected with embalming fluids by syringe on an as-needed basis.

5. Surface embalming preserves the skin’s surface and deals with damage from accidents, decomposition, or cancerous growths.

Additional steps are needed for many organ donors because of the complications of preparing a body after a long-bone donation or skin donation. If an autopsy was performed, this also complicates the procedure. Embalming takes several hours at a minimum. After the embalming, the body is washed to remove the smell and appearance of embalming fluids, dried, moisturized, and cosmetics are applied to improve the color of the skin. (Warm-toned lighting is usually used during the viewing as well.)

Embalming chemicals include a wide variety for various purposes. Formaldehyde is usually the key ingredient because of its preservative properties. About three gallons of embalming fluid are used for an adult corpse.

Embalming fluids also include anti-edemic chemicals that draw excessive fluid from bodies, humectants that restore the tissues of dehydrated bodies, cell conditioners that help prepare cells to absorb fluid from the arteries, dyes to restore natural coloration, and disinfectants. The cavity embalming fluid is a separate mixture, usually an undiluted formaldehyde-heavy solution.

Formaldehyde is the most important carcinogen in embalming fluids, not only because it constitutes a large percentage of the fluid preparation but because, despite its classification as a class 1 carcinogen, the industry has resisted pressures to adopt an alternative. This is in part because a good alternative with the same properties has simply not presented itself. Similar chemicals tend to be disinfectants rather than actual preservatives that can maintain the body’s appearance postmortem—and prevent the smell of decay as perfectly as formaldehyde does. Instead, embalming facilities depend on adequate ventilation to protect their workers, along with gloves and masks. Ventilation ducts are ideally placed at table level rather than the older system of ceiling ducts, which caused fumes to be carried past workers’ faces before being removed from the room.

Formaldehyde is highly toxic. A single ounce—half a shot glass—of formaldehyde in the concentration used in the funeral industry is sufficient to kill an adult male. Even formaldehyde resins, used in construction materials, can result in chronic headaches, asthma-like symptoms, and respiratory problems among workers in workplaces where the resins decompose. Formaldehyde has been suspected as a carcinogen since 1978 and classified as such since the 1980s. In 2006, the International Agency for Research on Cancer (IARC) formally reclassified it as a known human carcinogen. Its links to nasal sinus cancer and nasopharyngeal cancer are known, especially through inhalation in the workplace. More recently, its link to leukemia has been established.

Though the industry as a whole has continued to embrace formaldehyde, individual embalmers have not always done so. In 2012, a New Jersey mortician diagnosed with acute promyelocytic leukemia filed a lawsuit against his employer and the manufacturers of the embalming fluids blamed for his illness. He also alleged that, after returning to his job after a nine-month disability leave, his employer denied his request to improve ventilation or transfer him to a second, newer, and better ventilated, facility.

According to a 2009 study of funeral industry professionals who died between 1960 and 1986, death from myeloid leukemia—associated with formaldehyde—was statistically significantly more likely than in the rest of the population, and that this risk was elevated for subjects who performed more than 500 embalmings in their lives, compared to those who performed fewer. The study concluded that membership in and duration of association with the embalming profession were positively correlated with risk of death from myeloid leukemia. No link to brain cancer could be established. Separate studies found increased risk among embalmers of death from brain tumors, colon cancer, cirrhosis of the liver, and arteriosclerotic heart disease, without
positively correlating these risks to formaldehyde exposure specifically.

Embalming fluids also contain methanol, which is not carcinogenic but is highly toxic in sufficient doses, both because it depresses the central nervous system and because it metabolizes to formic acid, which causes cellular hypoxia.

The practice of green burial or natural burial is interment of the body in soil without preserving it against decomposition in the long term. In some green burials, conventional embalming is actually still used—the primary difference is in the type of coffin used, moving away from the trend in recent decades toward using coffins that resist degrading longer. In other green burials, the body is either not embalmed or alternative, nonformaldehyde preparations are used. Sometimes, for this reason, there is no viewing of the body offered.

independent prognostic factor. However, although high endogenous levels of unopposed estrogen are related to increased risk of endometrial cancer, their independence from other risk factors is inconsistent with being a common underlying biologic pathway through which all risk factors for endometrial cancer operate. An increased incidence of endometrial cancer also has been associated with tamoxifen treatment of breast cancer, reports R. F. van Leeuwen and colleagues. Researchers studied 813 cases of endometrial cancer and concluded that there is an increased risk of the cancer associated with tamoxifen treatment extending beyond five years. Other risk factors include obesity, hypertension, and diabetes mellitus. Cardiovascular disease is the most common cause of death in patients diagnosed with endometrial cancer.

The pattern of endometrial cancer is partially dependent on the degree of cellular differentiation. Well-differentiated tumors usually limit their spread to the surface of the endometrium; myometrial extension is less common. In cases with poorly differentiated tumors, myometrial invasion occurs more frequently. Myometrial invasion is frequently associated with lymph node involvement and distant metastases and is often independent of the degree of differentiation.

Metastatic spread occurs in a characteristic pattern: to the pelvic and para-aortic nodes. When distant metastasis occurs, it most commonly involves the lungs, inguinal and supraclavicular nodes, liver, bones, brain, and vagina. M. Hanson and colleagues found another factor that correlates with extraterine and nodal spread to be involvement of the capillary-lymphatic space.

Three prognostic groupings of clinical stage I disease have been identified: Diagnoses with grade 1 tumors involving only endometrium and no evidence of intraperitoneal disease have a low risk (less than 5 percent) of nodal involvement. Cases with grade 2 or 3 tumors and invasion of less than 50 percent of the myometrium and no intraperitoneal disease have a 5 to 9 percent incidence of pelvic node involvement and a 4 percent incidence of positive para-aortic nodes. Cases with deep muscle invasion and high-grade tumors or intraperitoneal disease have a 20 to 60 percent risk of spread to pelvic nodes and a 10 to 30 percent risk of spread to para-aortic nodes. C. Tornos and colleagues identified four statistically significant risk factors: myometrial invasion, vascular invasion, eight or more mitoses per 10 high-power fields, and an absence of progesterone receptors.

In cases without extraterine spread, the greatest determinants of recurrence were grade 3 histology and deep myometrial invasion. In this study, the frequency of recurrence increased with positive pelvic nodes, adnexal metastasis, positive peritoneal cytology, capillary space involvement, and involvement of the isthmus.

At the cellular levels, endometrial cancers are classified in one of the following two categories: Type I tumors include tumors of endometrioid histology that are grade 1 or 2; these comprise approximately 80 percent of endometrial carcinomas. These tumors typically have a favorable prognosis, are estrogen responsive, may arise from complex atypical hyperplasia, and are pathogenetically linked to unopposed estrogenic stimulation. Type II tumors account for 10 to 20 percent of endometrial carcinomas. They include grade 3 endometrioid tumors as well as tumors of nonendometrioid histology: serous, clear cell, mucinous, squamous, transitional cell, mesonephric, and undifferentiated. These tumors are often high grade, have a poor prognosis, and are not associated clearly with estrogen stimulation. A precursor lesion is rarely identified.

Four subtypes have been identified that will refine classification and provide prognostic and therapeutic implications.
The most common endometrial cancer cell type is endometrioid adenocarcinoma, which is composed of malignant glandular epithelial elements that may include an admixture of squamous metaplasia. Adenosquamous tumors contain malignant elements of both glandular and squamous epithelium. Clear cell and papillary serous carcinoma of the endometrium are tumors that are histologically similar to those in the ovary and the fallopian tube, and the prognosis is worse for these tumors. Mucinous, squamous, and undifferentiated tumors are rarely encountered. Frequency of endometrial cancer cell types are as follows: endometrioid (75–80 percent); uterine papillary serous (less than 10 percent); mucinous (1 percent); clear cell (4 percent); squamous cell (less than 1 percent); mixed (10 percent), and undifferentiated.

Prognoses for cases with endometrial cancer that have localized disease are significantly good with hysterectomy or hysterectomy and adjuvant radiation therapy. Results of two randomized trials on the use of external-beam radiation therapy (EBRT) in patients with stage I disease did not show improved survival but did show reduced local-regional recurrence (3–4 percent vs. 12–14 percent after 5–6 years’ median follow-up, \( P < .001 \)) with an increase in side effects, reports the National Cancer Institute. Some patients have regional and distant metastases that, though occasionally responsive to standard hormone therapy, are rarely curable. For these patients, adjuvant chemotherapy is a consideration.

Uterine serous histologies have higher rates of recurrence than do other stage I endometrioid carcinomas. The outcomes in institutional case series utilize a policy of adjuvant carboplatin plus paclitaxel, occasionally including radiation therapy. If there is cervical involvement, options include radical hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymph node dissection. If the cervix is not involved but extension to the cervix is documented on postoperative, radiation therapy should be considered.

Patients with stage III endometrial cancer are treated with surgery, followed by chemotherapy or radiation therapy, or both. For years, radiation therapy was the standard adjuvant treatment for patients with endometrial cancer. However, several randomized trials have confirmed improved survival when adjuvant chemotherapy is used instead of radiation therapy. In a trial conducted in a subset of patients with stage III or IV disease with residual tumors smaller than 2 centimeters and no parenchymal organ involvement, the use of the combination of cisplatin and doxorubicin resulted in improved overall survival (OS) compared with whole-abdominal radiation therapy (adjusted hazard ratio, 0.68; 95 percent confidence interval limits, 0.52–0.89; \( P = 0.02 \); five-year survival rates of 55 versus 42 percent). In some studies, cisplatin, doxorubicin, and paclitaxel may be a superior treatment, however, may result in peripheral neuropathy.

When possible, patients with stage IV endometrial cancer are treated with surgery, followed by chemotherapy or radiation therapy, or both. Treatment of patients with stage IV endometrial cancer is determined by the site of metastatic disease and site-specific symptoms. For bulky pelvic disease, radiation therapy consisting of a
combination of intracavitary and EBRT is used. When distant metastases, especially pulmonary metastases, are present, hormonal therapy is indicated and useful. Observational studies support maximal cytoreductive surgery for patients with stage IV disease, although these conclusions need to be interpreted with care because of the small number of cases and likely selection bias. Hormonal treatment of progestational agents, have produced good antitumor responses in as many as 15 to 30 percent of patients.

An inoperable disease caused by tumor that extends to the pelvic wall may be treated with a combination of chemotherapy and radiation therapy. The usual approach is to use a combination of intracavitary radiation therapy and EBRT. When patients are neither candidates for either surgery or radiation therapy, they may be treated with progestational agents. A high rate of failure for distant metastases in the upper abdominal and extra-abdominal sites have been found, and for this reason, patients with stage III disease may be considered for innovative clinical trials.

Progestational agents have been evaluated as adjuvant therapy in a randomized clinical trial of stage I disease and have been shown to be of no benefit. These studies, however, were not stratified according to level of progesterone receptor in the primary tumor. No trials of adjuvant progestins in more advanced disease have been reported. Determination of progesterone receptors in the primary tumor is encouraged, and entry onto an appropriate adjuvant trial (if receptor levels are high) should be considered. If no trial is available, data from receptors on the primary tumor may help guide therapy if disease recurs.

A recent review by F. Lin and colleagues compared laparoscopically assisted surgery (LAS) and open surgery in endometrial cancer patients. LAS had fewer intraoperative complications, lower incidence of transfusion, less blood loss, and shorter hospital stays, but longer surgical times. The conclusions regarding safety were cautious due to concerns in validity evaluation and the small number of studies analyzed, and they might not be reliable.

Environmental Justice and Cancer

Even though cancer is caused by mutations in human genes, factors outside the human body, including environmental factors, cannot be ruled out. The relationship between environmental exposures and cancer has been established, giving proof to the argument that cancer is an environmental as
well as lifestyle disease. When considered broadly, environmental factors account for about 67 percent of all cancer cases; specifically, tobacco is known to cause about 29 to 31 percent of all cancer deaths, diet accounts for 20 to 50 percent of cancer deaths, bacterial and viral infections account for 10 to 20 percent, ionizing and ultraviolet (UV) lights account for 5 to 7 percent, occupation exposures account for 2 to 4 percent, while pollution in the air, water, and food account for 1 to 5 percent of all cancer deaths.

Environmental justice is a concept that addresses civil rights, antitoxicity, environmental sustainability, fair and just labor practices, and related issues of sustainable human and earth rights. Environmental justice also intersects with environmental racism in the commitment of fair treatment and meaningful involvement of all people regardless of ethnicity, national origin, or income to fair and just development, implementation, and enforcement of environmental laws, regulations, and policies. Persons in developing nations, and poorer regions in the United States, Europe, and other industrialized nations, are far more likely to live in proximity to industrial areas, nuclear plants, landfills, pollution from ground transportation, water-quality problems, and other related environmental concerns. All persons should have a fair and just level of protection from environmental and health hazards and equal access to the decision-making process to have a healthy environment in which to live, learn, and work. Goals of environmental justice include protecting health in communities overburdened by pollution; empowering communities to take action to improve their health and environment; establishing collaborative partnerships with local, state, tribal, federal, national, and international organizations to achieve healthy and sustainable communities.

Environmental Justice and Occupational Cancer Risks
One key commitment of environmental justice advocates is upholding the right of all workers to safe and healthy work environments without being forced to choose between an unsafe livelihood and unemployment. Chemical exposures may be responsible for the elevated incidences of cancer of workers in numerous industries including, but certainly not limited to, the chemical, plastics, and coal mining industries. For example, the plasticizer contamination of firefighters’ protective clothing has been found to increase health risks. Research has found that firefighters are exposed to high levels di-(2-ethylhexyl) phthalate (DEHP), a plasticizer and probable human carcinogen, which is added to polyvinyl chloride (PVC) to enhance the flexibility of firefighters’ protective clothing.

Environmental causes of cancer can be modified or prevented with changes in lifestyle choices or choices of type and location of employment. Approximately one-third of cancer cases can be prevented by a change in lifestyle. Cancer cases have depended on how long a person has been exposed to particular environmental factors in addition to the person’s genetic makeup, age, and other factors.

Environmental justice advocates aim to uphold the right of those who work at home to be free from environmental hazards in their domestic environments. Advocates and researchers are informed by the International Agency for Research
Environmental Justice and Cancer

403

on Cancer’s classification of environmental agents into groups of one to three depending whether they are carcinogenic (Group 1), probably carcinogenic (Group 2A), possible carcinogenic (Group 2B), or not classifiable (Group 3).

Occupational pollutants can contribute to cancer incidence. Cancer incidence as a result of occupation-related chemical exposures (occupational cancers) accounts for about 15 to 20 percent of cancer cases in men. Chemicals in products such as paints, dyes, and solvents and some petroleum products also have been linked to occupational cancer incidence. For instance, some phthalates, which are used in cosmetics and some medical devices, are noted to cause sterility in men. A unique set of occupational cancer risks is found in the textile and leather industries. For example, while ancient practices in the leather tanneries in such locations as Fez, Morocco, used natural dyes, more current practices tend to incorporate synthetic dyes. Environmental impact assessments have been made to evaluate the potentially carcinogenic metabolites of these synthetic dyes as well as chemicals that are known to be lethal, most notably Chromium 3.

Radiation can induce cancers such as leukemia and lymphoma, thyroid cancers, skin cancers, some sarcomas, and some lung and breast cancers; radiation can be ionizing or nonionizing. An example of nonionizing radiation is UV rays; exposure to UV rays could be artificial in the form use of sun beds or tanning beds and natural through depletion of the ozone layer. UV rays as a cancer risk factor depend on the amount of exposure (dose). Radiation could be in the form of occupational exposures such as chemicals radiation technologists, uranium miners, and workers in nuclear plants who are exposed in their workplaces; exposures to atomic bombs; and patients treated by radiotherapy or chemotherapy. Additionally, exposure to radon and radon decay products has been found to be responsible for about 10 percent of lung cancer causes. Exposure to very low frequency (VLF) and extremely low frequency (ELF) electromagnetic fields (EMFs), including power lines, transformers, and electric train engines, among others, also has been known to induce cancer. Indeed, recent studies have established an association between long-term use of cellular phones and brain tumors; however, this finding has been contested by other studies. Some X-ray imaging and magnetic resonance imagining (MRI) can also cause certain cancers.

Different environmental exposures are linked to different types of cancers. For instance, exposure to asbestos can lead to lung cancer, while exposure to benzidine has been shown to cause bladder cancer. In fact, in the United States, talcum products for use in the home have since the 1970s been required by law to be asbestos-free; this is based on the relationship between asbestos and certain types of cancer. Asbestos has also been banned in the United Kingdom. Incidence of leukemia was twice as likely in workers who have had both 10 or more years of exposure to formaldehyde and 20 years or more since their first exposure to formaldehyde. In addition, research has linked formaldehyde exposure with cancer of the nasal cavities, nasopharynx, prostate, lung, and pancreas among industrial workers.

Carcinogenic Ingredients in Domestic Products

There is a growing body of research in the area of toxic and carcinogenic ingredients in various products that most persons use on a daily basis. The documentary Plastic Planet (2008), written and directed by Werner Boote, an Austrian filmmaker and grandson of a plastics industry executive, draws attention to the nearly 1,000 scientific studies that have found carcinogenic, toxic, and other problematic causes of various plastics used in industry and consumer goods.

Numerous studies have found certain consumer products (including cosmetics and other health and beauty or personal care products) may be linked to various cancers, most notably breast cancer. The International Agency for Research for Cancer has classified numerous cosmetic ingredients including, but not limited to, ethylene oxide as carcinogenic and mutagenic to humans, with sufficient evidence of carcinogenicity for breast cancer. Of further concern, in the United States, major loopholes in federal law allow the cosmetics industry to put thousands of synthetic chemicals into personal care products, even if those chemicals are linked to cancer, infertility, or birth defects. For example, the U.S. Centers for Disease Control and Prevention reports male reproductive problems have doubled between 1970 and 1993. There is a correlation between reproductive problems and environmental chemicals and toxins.
As untested chemicals have been steadily introduced into the environment, breast cancer incidence has risen dramatically. In one study on teens’ exposures to cosmetic use, conducted by researchers with the Environmental Working Group, which includes researchers in environmental toxicology at Cornell University and in chemistry at Northwestern University, results revealed the presence of 16 chemicals in the bodies of U.S. teenage girls age 14 to 19. The 16 chemicals were from the phthalates, triclosan, musks, and parabens families, all commonly used in cosmetics and body care products. They have been determined as capable of disrupting the hormone system, according to laboratory tests. More biomonitoring research is needed, as is awareness-raising efforts about the environmental and health implications of many cosmetics and personal care products, particularly concerning their use by girls and young women. The European Cancer Registries reports incidence of breast cancer, the most common cancer among women, has increased not only in postmenopausal but also in very young women.

Research on compounds of toxicological concern in household exposures are particularly relevant as persons spend up to 90 percent of their time indoors, often at home, where household environments and household products have not been adequately assessed. More research is needed to inform public health efforts regarding exposure reduction of toxicological compounds. Of further concern is how parents’ exposure to occupational pollutants can increase the risk of cancer in their children. Outdoor pollution in the form of smoke, vehicle exhaust, and indoor pollution all contain chemicals such as polycyclic aromatic hydrocarbons (PAH), biocides, and formaldehyde, which are known to induce cancer. Pesticides and food additives also can cause cancer. Exposure to arsenic oxides and other metals such as lead, hexavalent, nickel, and mercury can induce cancers in the lung, bladder, liver, and kidney, among others.

Increasing collaboration among scientific researchers, community advocates, and activists is emerging. The experiences of patients, survivors of breast cancer, and their family help to inform research findings, for example, concerning breast cancer, for ethnic minority women in industrialized nations. Assessment initiatives, such as the U.S. National-Scale Air Toxics Assessment, have been utilized to evaluate correlations between environmental pollutants that have been linked to breast cancer and to health problems inherent in lower-income, minority communities in industrialized nations. For example, toxicological compounds that have been found to affect breast cancer are in the industrial category of oil combustion and refining. Such compounds from emissions from oil refineries are known to affect the lower-income communities situated within geographic proximity.

The U.S. National Institute of Environmental Health Sciences has established an environmental justice grant program to support community-based participatory research collaboration. Key partners include Communities for a Better Environment and the Silent Spring Institute, whose mission addresses women’s health, particularly breast cancer.

Similar collaborative efforts are emerging in developing nations. For example, l’Institut de Presse et des Sciences de l’Information (IPSI) at l’Université de la Manouba, in Tunisia, l’Institut de Communication et des Sciences de l’Information (ISIC) at the Faculty of Political and Information Sciences of the University of Algiers, and the School of Media and Communication at Bowling Green State University have established a partnership with North African civil society organizations including, but not limited to, le Centre International des Technologies de l’Environnement de Tunis (CITET), the Arid Lands Institute (IRA), in Sousse, Tunisia, le Centre d’Études Maghrébines en Algérie (CEMA), and l’Association pour la Recherche sur le Climat et l’Environnement (ARCE) both located in Oran, Algeria, with consultation by the Ministry of the Environment and Sustainable Development of the Republic of Tunisia. Such collaborative partnerships seek to bring together practitioners to assess environmental concerns and raise awareness among citizens, organizations, and governing bodies with oversight for public health efforts regarding exposure reduction of toxicological compounds in homes and communities.

More effort from collaborative partnerships and biomonitoring experts and activists is needed to assess environmental factors that can influence cancer rates and risks, particularly as they differ by region within nations, and regions of the world. It is important to note that environmental exposures...
alone do not cause cancer; they need to interact with certain gene mutations in the body, lifestyle choices, and proximity to sources of exposure, among other considerations. Such diverse combinations of factors often result in various people who are exposed to the same environmental factors being diagnosed with cancer. Unfortunately, this can make it very challenging to enact litigation against corporations that have been deemed to be emitting toxins into the environment.

Environmental Tobacco Smoke

The ill effects of smoking on a person’s health are well documented, dating back to 1964 and the first report of the U.S. Surgeon General’s Advisory Committee on Smoking and Health. The toxic and carcinogenic aspects of environmental tobacco smoke (ETS) would not be firmly established until much later. Nevertheless, substantial research has shown that ETS increases the risk of lung cancer, causing the disease in approximately 3,400
Environmental Tobacco Smoke

nonsmokers each year. Subsequent research has linked ETS with lymphoma, leukemia, and brain tumors in children and cancers of the larynx, pharynx, nasal sinuses, brain, bladder, rectum, stomach, and breast in adults who do not smoke.

ETS refers to exposure to tobacco smoke that originates from someone else smoking. Breathing in ETS is also called passive smoking, secondhand smoke, and involuntary smoking. According to the American Cancer Society, there are two sources of ETS: sidestream smoke coming from cigarette, pipe, or cigar smoke and mainstream smoke exhaled from the smoker.

Sidestream is considered more dangerous to people’s health because it has higher levels of carcinogens and is more toxic than mainstream smoke. Scientists have shown that sidestream smoke has smaller particles that enter more easily into the lung and cells of those exposed to it. Nonsmokers who are exposed to ETS inhale nicotine and toxic chemicals that reach higher levels the more they are exposed to ETS in terms of amount and duration. Overall, ETS contains more than 7,000 chemical compounds, 250 of which are known to adversely affect human health and 69 are known to be carcinogens.

Since the first 1964 surgeon general’s report on smoking, more than 30 subsequent reports from the surgeon general’s office have addressed in some manner the harmful effects of ETS. The surgeon general, who is the top public health official in the United States, first addressed the issue in a 1972. The report noted that tobacco smoke in the air often caused discomfort in nonsmokers and could possibly harm people with chronic heart or lung disease. Another report in 1975 also noted the annoyance smoking caused to some nonsmokers and included data that elevated nicotine levels in nonsmokers could be the cause of atherosclerotic disease.

Scientists and public health officials were not the only people raising the alarm about secondhand smoke. In the 1970s, nonsmokers began complaining more and more that they suffered headaches and found themselves coughing and gagging when exposed to ETS. Furthermore, people with respiratory illnesses began pointing out that they could not enter certain places of business because of ETS, from bars to trains and airplanes. Employees started to complain about workplace smoking as well. These complaints eventually led to the formation of community groups targeting public smoking, such as the Group Against Smoking Pollution (GASP) in California.

The U.S. surgeon general’s office continued to put out reports that contained warnings about ETS. A 1979 report recommended further studies about the issue due to the limited amount of scientific data available on ETS. Another report in 1982 discussed three studies that had noted a potential link between ETS and lung cancer in nonsmokers.

The first major report in the United States that ETS can increase definitively the risk of developing lung cancer in nonsmokers came in 1986, when the U.S. surgeon general published the first report dedicated entirely to the health effects of secondhand smoke, “The Health Consequences of Involuntary Smoking.” Among the findings reported was conclusive evidence that secondhand smoke can cause lung cancer in nonsmokers. Furthermore, it noted that it might not be enough to protect smokers merely by separating them from nonsmokers in the same room or area. That same year, the International Agency for Research on Cancer, part of the World Health Organization, noted that data was connecting ETS to increased risk of cancer in some nonsmokers, and the National Research Council estimated that a nonsmoker married to a smoker increases his or her risk of getting lung cancer by 25 percent.

In 1992, the U.S. Environmental Protection Agency (EPA) released its report on secondhand smoke, titled “The Respiratory Health Effects of Passive Smoking: Lung Cancer and Other Disorders.” The report concluded that ETS exposure in the United States was a serious public health problem that caused approximately 3,000 lung cancer deaths each year in U.S. nonsmokers. The report also cited ETS as being especially dangerous for children.

In 2005, the EPA released a report that updated scientific findings concerning ETS. The report noted that, among other health problems, ETS played a role in approximately 9,000 deaths in the United States each year due to lung cancer and other respiratory disorders. The following year, the 2006 surgeon general’s report, “Health Consequences of Involuntary Exposure to Tobacco Smoke,” definitively stated that the scientific community had reached a consensus on the dangers of ETS.

The 2006 surgeon general’s report stated that ETS has far-reaching health implications for nonsmokers. It noted conclusive biologic, epidemiologic,
behavioral, and pharmacologic evidence of its harmful effects, which include not only cancer but also coronary and lung disease and premature death in adults. The report also noted that ETS was likely associated with other cancers in adults and children as well as diseases such as chronic obstructive pulmonary disease (COPD) and asthma. The report concluded that there were no acceptable levels of exposure to ETS. The 2014 surgeon's report restated that secondhand smoke has been causally linked to cancer and other diseases.

**How ETS Causes Cancer**

Scientists have determined that, among the 7,000 chemicals that occur in secondhand tobacco smoke, approximately 250 are known to be harmful to human health. In addition, 69 of these chemicals are known to cause cancer, including arsenic, benzene, beryllium (a toxic metal), 1,3-butadiene (a gas), cadmium, chromium (a metallic element), ethylene oxide, nickel (a metallic element), polonium-210 (a radioactive chemical element), and vinyl chloride. Scientists are also concerned about the potential of other chemicals in the smoke to cause cancer, including formaldehyde, Benzo[α]pyrene, and toluene.

The various chemicals in ETS can adversely affect nonsmokers’ immune systems, weakening them to the point that they have difficulty fending off the spread of cancer cells. Some of these chemicals damage a nonsmoker’s DNA, which controls normal cell growth and function. Damaged DNA can lead to uncontrolled cell growth, resulting in the creation of a cancerous tumor.

Other biological pathways also contribute to carcinogenesis due to ETS. For example, chemical compounds called nitrosamines are specific to nicotine and tobacco and bind to various cellular receptors in the body, leading to activation of biologic pathways that can lead to cytogenetic changes, resulting in cell proliferation and transformation. Scientists also have produced evidence that even noncarcinogenic compounds in ETS enhance tobacco smoke’s carcinogenicity via the stimulation of cell proliferation.

**Tobacco Companies Respond**

The tobacco industry is a big business in the United States, with the U.S. market bringing in approximately $66 billion in 2013. The tobacco industry has sponsored various studies questioning the negative health effects of ETS. For example, a 2003 study sponsored by the industry and published in the *British Medical Journal* reported that data proving the harmful health effects of passive smoking were greatly exaggerated. The article also noted that many studies about ETS were not statistically significant to prove a definitive relationship between smoking and lung cancer. The American Cancer Institute responded by objecting that the study had numerous flaws in how it was conducted and data analyzed.

The industry also started a public relations campaign in the early 1990s to dispute the scientific evidence that ETS was harmful. The industry campaigns also have focused on issues such as personal rights and freedoms. As a part of its campaign efforts, the tobacco industry funded various think tanks, such as the Cato Institute, which criticized growing efforts in policy to restrict exposure to secondhand smoke. As early as 1994, the EPA...
stated that attacks on the scientific research were unfounded and that secondhand smoke was a preventable health risk. The EPA noted that its Science Advisory Board, made up of independent scientific experts, had reputed virtually every argument against ETS increasing the risk of lung cancer in nonsmokers.

Nevertheless, some rigorously conducted studies have questioned just how serious ETS is in causing lung cancer in nonsmokers. A 2013 study conducted at Stanford University and published in peer-reviewed *Journal of the National Cancer Institute* confirmed a strong link between lung cancer and people who smoke but found no statistically significant association between lung cancer and secondhand smoke.

Tracking more than 76,000 women for more than a decade, the Stanford study found that the only statistically significant relationship between ETS and lung cancer in nonsmokers occurred in women who had lived with a smoker for 30 years or more. Nevertheless, the researchers have noted that it was too early to conclude that passive smoking had absolutely no role in causing lung cancer in some nonsmokers. Furthermore, ETS also has other adverse effects on the lungs and circulatory system.

**ETS Laws and Society**

Substantial efforts to limit ETS exposure has taken place since the 1980s, including various laws on the state and local levels to prohibit smoking in public and workplaces. Employers and businesses also have taken voluntary actions to limit or eliminate exposure to ETS. On the federal level, smoking restrictions laws and regulations have been limited. They largely target airplanes, federally owned buildings and facilities, and facilities that provide services to children and receive federal funds.

The most comprehensive laws concerning ETS occur at the local level, from the state to city and town ordinances and laws. Initially, city and town governments played the most important role in restricting smoking in public as they responded to growing antismoking sentiments among the local citizens. The first state law to establish nonsmoking restrictions took place in 1993, when the Vermont state government enacted a law outlawing smoking in restaurants. Nevertheless, nonsmoking efforts still are strongest at the local level, where as of July 2014, there were 4,036 municipalities with laws restricting where people can smoke. On the international level, more than 90 countries have laws and ordinances restricting smoking in public and work environments.

**Ependymoma, Childhood**

Ependymoma comprises roughly 5 percent of brain tumors occurring in children and is often diagnosed at age 4 or younger. For a couple of decades, childhood ependymoma has been treated with the
total removal or gross resection of the affected brain tissue, followed by irradiation. Approximately 75 percent of cases that underwent this treatment approach showed a three-year disease-free survival rate. Despite the promising outcomes in terms of cancer recurrence in children, this technique has also resulted in other treatment-related outcomes, including damage to various epithelial and vascular tissues as well as disorders involving the endocrine system. However, the most significant impact of irradiation is on cognitive skills, such as lower intelligence quotients (IQs) and poor academic performance.

Several studies have thus been performed in order to identify specific approaches in reducing these treatment-related effects involving cognitive functions in pediatric patients. Previous reports have shown that children who underwent treatment for ependymoma such as surgery, irradiation, and chemotherapy are at an elevated risk for late-onset cognitive problems, including a general decline in intellectual capabilities and academic performance. These effects also could be further carried forward in the adult years, often resulting in poorer quality of life and difficulty in performing daily tasks without the assistance of a family member or caregiver.

The high incidence of cognitive side effects among pediatric ependymoma patients has thus prompted clinicians to conduct investigations that would identify the specific causative factors that were responsible for lower IQ scores and decline in functional abilities. These extensive studies have thus far identified various factors that influence the degree of cognitive decline among pediatric ependymoma patients. The information gathered from these studies may also help in designing personalized treatment schemes for patients.

A clinical study conducted by Kelli Netson and colleagues showed that one of the main causative factors responsible for cognitive decline after ependymoma treatment is the radiation dose applied to the brain. Their report described an inverse correlation between the radiation dose and the level of cognitive decline. Thus, a higher radiation dose applied to a pediatric ependymoma patient would result in a lower IQ postirradiation. However, pediatric ependymoma patients who received focal irradiation using modulated intensities showed a higher chance of maintaining their IQ scores compared to those who underwent irradiation of the entire craniospinal region. These patients also were spared from deterioration in verbal learning as well as in academic skills such as mathematics and spelling, thus suggesting that this specific treatment approach reduced the development of cognitive side effects in pediatric ependymoma patients.

In an attempt to determine the progress of cognitive skills in children who underwent focal irradiation using modulated intensities, the research team of Netson examined a total of 123 pediatric patients diagnosed with intracranial ependymoma. The mean age of the children at irradiation was approximately 4.6 years. A series of neurocognitive assessments such as age-appropriate measurements of IQ as well as Vineland Adaptive Behavior Scales (VABS) were employed at baseline (prior to irradiation), six months posttreatment, and annually for the next five years. The VABS tool allows the assessment of adaptive behaviors among children, including communication, socialization, skills required in daily living, and motor functions. These efforts generated approximately 579 neurocognitive assessments that were included in the analysis. The results of the study showed that the IQ and VABS scores of the pediatric patients at baseline and during the next five years were generally stable and within the normal range, except for the VABS score for communication, which significantly deteriorated. The results of their study indicated that focal irradiation using modulated intensities spared the children from a massive decline in IQ and cognitive skills, except for the ability to communicate.

In another study led by Karen Kuhlthau, the quality of life of 142 children diagnosed with brain tumors such as ependymoma, medulloblastoma, and glioma were assessed after treatment with proton radiation. The use of proton radiotherapy was based on earlier observations that this procedure utilizes a significantly lower amount of dose than the classical technique of using external-beam photons. This novel technique may thus serve as an alternative treatment scheme for brain tumors that would result in lower levels of toxicity and minimal reduction in cognitive functions. To determine the quality of life of the pediatric patients after proton radiotherapy, a self-report assessment was conducted. In cases wherein the pediatric patient was unable to respond to the questions in the assessment tool, the parents served as proxy in answering each item on the questionnaire. The results of
this investigation showed that proton radiotherapy resulted in a better quality of life compared to patients who underwent global craniospinal irradiation. Furthermore, the quality of life of pediatric patients after irradiation were strongly influenced by the type of brain tumor and the intensity of the proton treatment. Thus, pediatric patients with medulloblastoma experienced a worse quality of life after proton radiotherapy compared to those with ependymoma.

A research team led by Katja von Hoff also conducted an assessment of the quality of life of pediatric ependymoma patients who underwent surgery and irradiation of the posterior fossa. A total of 23 pediatric patients with an age range of 0.3 to 14 years at ependymoma diagnosis were subjected to neuropsychological assessment after irradiation using a dose of 54 Gy. The assessment of quality of life was conducted for an average of 4.5 years, with a monitoring range of one to 15.5 years after radiation treatment. The results of the study showed that all the pediatric patients showed difficulties in cognitive functions such as reading, memory, and attention span. However, the IQ levels of the pediatric patients remained the same. The study also identified a correlation between the detection of cerebellar deficits and a deterioration of IQ after irradiation therapy. Pediatric ependymoma patients who underwent surgery and chemotherapy before the age of four also showed a worse deterioration in IQ after treatment. Furthermore, pediatric ependymoma patients who did not develop a hydrocephalus prior to radiation treatment were more likely to undergo better cognitive functions after radiotherapy.

Eritrea

Eritrea is a country located on the Horn of Africa on the eastern part of the African continent. It is bordered by the Red Sea, Ethiopia, Sudan, and Djibouti. Eritrea has a population of 6 million and is ethnically diverse. Like many African countries, cancer rates go underreported in Eritrea. Decades of war with neighboring Ethiopia depleted health care facilities and services during the second half of the 20th century. Subsequently, the Eritrean government has invested heavily in a primary health care infrastructure throughout the country, although specialized cancer treatment facilities remain limited.

Beginning in the 1st or 2nd centuries c.e., Eritrea and its neighbor Ethiopia both belonged to the kingdom of Aksum. The Eritrean people adopted the Christian religion during this period. In the medieval period, current-day Eritrea was divided into the Medri Bahri kingdom and the Hamasien republic. From 1890 to 1941, Eritrea was an Italian colony. The Federation of Ethiopia and Eritrea was formed in 1947, following a period of British occupation that began during World War II. The federation dissolved shortly thereafter, when Ethiopia annexed Eritrea, beginning several decades of war. Eritrea became an independent nation in 1991, although border disputes with Ethiopia are ongoing. Long-term military conflicts devastated the Eritrean economy and national infrastructure. Poverty is widespread in Eritrea, where the majority of the population is engaged in agricultural work, fishing, or mining.

European missionaries and Italian colonizers introduced modern health care services in Eritrea at the end of the 19th century. Italians established the first Eritrean hospital in Asmara during this period.
Prior to the creation of the Federation of Ethiopia and Eritrea, health services in the region were relatively advanced for the time. The Eritrean War of Independence effectively destroyed the health care infrastructure as well as the economy and the environment. Following independence in 1991, the Eritrean Ministry of Health (MOH) has worked to rebuild medical facilities, train health care professionals, and restore drug supplies and medical equipment.

The majority of health care facilities is owned by the Eritrean government and are available to everyone in the nation. The MOH oversees 23 hospitals in Eritrea as well as 52 health centers and 225 local health stations. Since 1991, the number of Eritrean hospitals has increased by 50 percent. The number of health centers and health stations has increased by 100 percent since independence. In addition, there are a small number of public–private partnership facilities available. Access to health care facilities is better in the central and south highlands of Eritrea than in the lowlands, constituting a geographical disparity. While Eritrean health care facilities are widespread through the country, most are devoted to primary care and basic health services.

In Eritrea, as in many African countries, malnutrition, infant mortality, and infectious diseases receive the most attention and funding support from governments and nongovernmental organizations. Although rates of cancer incidence in Eritrea are similar to those in more developed countries, these tend to go underreported and undertreated in Africa. Infectious diseases like human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS) and malaria receive more support for treatment and prevention. This disparity can result not only in a lack of services for cancer patients but also can lead indirectly to higher rates of cancer incidence. For example, exposure to dichlorodiphenyltrichloroethane (DDT) and other pesticides used to control the mosquito populations that spread malaria in Eritrea can increase the risk of leukemia, pancreatic cancer, and breast cancer.

In Eritrean men, prostate and colorectal cancers are responsible for the majority of cancer deaths, followed by non-Hodgkin's lymphoma. Each year approximately 125 men are diagnosed with prostate cancer in Eritrea, although many cases go undiagnosed.

Breast cancer constitutes the highest rate of cancer mortality for women in Eritrea, followed by cervical cancer. Studies have shown that the majority of Eritrean women who present with breast cancer symptoms are under 50 years of age. Women do not tend to present until reaching the later stages of the disease, and there are no standard protocols for managing and treating breast cancer in Eritrea. There is no human papillomavirus (HPV) vaccine program in Eritrea. The ICO Information Centre on HPV and Cancer estimates that, every year, 265 Eritrean women are diagnosed with cervical cancer, and 189 women die of the disease. There is a lack of reliable information on cancer incidence, treatment, and mortality rates in Eritrea due to the absence of a cancer registry and other resources.

Many women are skeptical about Western medicine and choose traditional methods of healing instead. These traditional Eritrean health care practices include herbal remedies as well as spiritual healing techniques that involve the cutting and burning of the body. Although traditional medical treatments tend to have inconsistent results and can sometimes be counterproductive, they continue to be widely practiced in Eritrea.

Esophageal Cancer

Esophageal cancer is a malignancy in the muscular tube that connects the throat to the stomach. There are two common forms (histologic subtypes) of esophageal cancers; these include squamous cell carcinoma and adenocarcinoma. Squamous cell carcinoma forms in the squamous cells of the esophagus and mainly occurs in the upper two-thirds of the esophagus. Adenocarcinoma forms in the glandular cells of the esophagus and usually occurs in the lower third of the esophagus near the stomach. These histologic subtypes have differing global trends and their own sets of risk factors. However, signs and symptoms, diagnosis, and conventional treatment options are similar and are dependent on the stage of cancer at diagnosis rather than the histologic subtype.

Global Trends and Risk Factors

In 2012, Globocan estimates that esophageal cancer is the eighth-most common cancer worldwide and the sixth-most common cause of death from cancer. Its incidence varies greatly globally, with the highest rates found in eastern Asia, southern Africa, and eastern Africa and the lowest rates found in Central America and western Africa, consistently affecting males at a higher rate than females. The occurrence of esophageal cancer is uncommon before the age of 40, and most esophageal cancers that occur in the world are squamous cell carcinoma.

A region of the world with some of the highest rates of esophageal squamous cell carcinoma is known as the esophageal cancer belt. This geographical area spans eastward from Iran through Turkmenistan, northern Afghanistan, Uzbekistan, and Kazakhstan into northern China and Mongolia and extends southwest to Quetta, Balochistan, located in Pakistan. Within this high-risk region, males and females are affected at similar rates, and risk factors reported for esophageal squamous cell carcinoma are different from those reported in North America. Some of these risk factors include: poor nutritional intake, consumption of dietary carcinogens, and chronic irritation and inflammation of the esophagus (e.g., the result of consuming extremely hot mate tea, use of opium or opium dross, consumption of silica-contaminated flour, and exposure to polycyclic aromatic hydrocarbons).

Studies conducted within the United States show higher incidence of esophageal squamous cell carcinoma among black people and those of low socioeconomic status. These racial and social disparities likely act as surrogates for other underlying and documented risk factors for esophageal squamous cell carcinoma, such as those relating to lifestyle (e.g., alcohol and tobacco use) and environmental factors and workplace hazards (e.g., exposure to air pollutants via certain chemicals and dusts).

Esophageal cancer trends within North America and parts of Europe have changed over the past few decades. The incidence of adenocarcinoma has surpassed the once-higher incidence of squamous cell carcinoma. In North America, the United States and Canada have reported some of the highest rates of esophageal adenocarcinoma. The most common risk factors for esophageal adenocarcinoma include: high body mass index (obesity), severe and frequent gastroesophageal reflux disease (GERD, the backflow of stomach acid into the esophagus), esophagitis (an inflammation of the esophagus), an increase in the use of medication that contributes to reduced sphincter pressure, and Barrett’s esophagus (a metaplastic change of the lining of the esophagus and a precursor for esophageal adenocarcinoma).

There are other important documented risk factors for esophageal cancer that are also worth noting. These include but are not limited to: family history, poor oral health, chronic lye strictures, achalasia (an esophageal motility disorder), tylosis (a genetic disorder), Plummer–Vinson syndrome (a complex vitamin deficiency), caustic injury to the esophagus, exposure to radiation, history of gastric surgery, genetics, environmental and occupational factors (e.g., the use of certain dry-cleaning agents,
with workers exposed to combustion products) as well as various esophageal disorders and conditions and certain diseases and viruses. Some of these risk factors are applicable to only one histologic subtype, while others are linked to both.

**Signs and Symptoms**

Some of the most common signs and symptoms of esophageal cancer include: dysphagia (difficulty swallowing foods or liquids), significant weight loss, hoarseness and cough, indigestion and heartburn, and chest pain. When esophageal cancer is at a more-advanced stage, odynophagia (painful swallowing) and regurgitation are often the result of a large tumor obstructing the esophagus. Esophageal cancer is associated with a poor prognosis and a low five-year survival probability because symptoms are not usually apparent until the disease has progressed to a later stage.

**Diagnosis, Staging, and Treatment**

There are a number of different diagnostic tests that could be performed to detect esophageal cancer. The most common include some combination of: a medical history and physical exam, complete blood count, blood test, barium swallow (a special type of X-ray that outlines the upper gastrointestinal tract when barium is swallowed), endoscopy (the examination of the upper gastrointestinal tract via the use of a lighted, flexible instrument called an endoscope), and biopsy (the removal and examination of a sample of tissue).

Esophageal cancer can be classified from stage 0 (precancerous) to stage IV (invasive and inoperable). Prior to 2010, the TMN (tumor, node, metastases) system, whose rankings within each of these were grouped together, was used to determine the stage of esophageal cancer. In 2010, the American Joint Committee on Cancer refined and made specific changes to how esophageal and esophagogastric junction tumors are staged by pathologists. Esophageal squamous cell carcinoma and adenocarcinoma used to be staged according to the same principles, but this is no longer the case. Some categories within the TMN system have been redefined and extended, and a new category G has been added, which takes into account the grade of the tumor. Now, staging indicates the type of data used to inform the staging (i.e., clinical or pathological data). Also, esophagogastric junction tumors and proximal five centimeters of the stomach are now staged as esophageal adenocarcinoma rather than stomach cancer.

Understanding the stage of disease, alongside an individual’s overall health is important in determining a treatment plan. There are a number of treatment options for esophageal cancer. These range from any combination of surgery, chemotherapy, radiation, endoscopic treatments and procedures (i.e., endoscopic mucosal resection, photodynamic therapy, laser surgery, radiofrequency ablation, electrocoagulation or plasma coagulation, and palliative endoscopic procedures), and clinical trials. These conventional treatment options are often determined by a team of specialists.

**Conclusion**

Esophageal cancer has a poor prognosis given that, by the time symptoms appear, the disease is already at an advanced stage. Its global trends differ according to histological subtype as do its risk factors. The risk factors associated with developing esophageal squamous cell carcinoma vary depending on geographical location. Consideration to wider social and environmental dimensions can help shed light on why these differences exist. There are several diagnostic tests used to identify esophageal cancer. Once staged by a pathologist, treatment options are targeted as a means of palliative (to alleviate symptoms relating to the disease) or curative (to eliminate disease) treatment of disease.

Esophageal Cancer, Childhood

Esophageal cancer is one of the 10 most common cancers worldwide, although it occurs at a less frequent incidence in the United States (3.2 per 100,000 in persons younger than 80 years of age). The two principal subtypes of esophageal cancer are esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EAC). In adults, these subtypes differ markedly in tumor development, risk factors, and outcomes. Alcohol and smoking, particularly when used concomitantly, are the greatest risk factors for ESCC, which is more prevalent in developing countries. EAC is associated with chronic reflux disease and intestinal metaplasia (Barrett’s Esophagus [BE]) and is more prevalent in developed countries such as the United States. Increased age (greater than 60) and male sex are risk factors for both subtypes. Because symptoms often do not present until the cancer has progressed to an advanced stage, both subtypes have a poor prognosis (10–25 percent five-year survival rates). Esophageal cancer in both adults and children most often presents as dysphagia and weight loss, although other symptoms may include hoarseness, voice changes, aspiration, nausea, and vomiting. Surgery is generally indicated if the cancer is resectable, and chemotherapy is often included as adjuvant therapy before or after surgery. If the tumor is not indicated, then platinum-based chemotherapy is the treatment of choice.

The carcinogenesis of both ESCC and EAC are related to the development of dysplastic and metaplastic lesions due to chronic irritation over a long period of time. Due to the chronic nature of the events that eventually lead to esophageal cancer, it is rarely diagnosed in childhood. Most of the literature on esophageal cancer in childhood is limited to case reports. Nonetheless, it is clear that esophageal cancer in childhood has a similar poor prognosis when compared to esophageal cancer in adults. In a study reviewing 10 case reports of children diagnosed with ESCC, two died within 14 months of diagnosis, four were alive after limited follow-up (less than 14 months), and four were lost to follow-up. The same study reviewed 14 case reports of children with EAC and, of the 14, only three were alive after case report follow-up (at 11, 12, and 36 months). Of the six cases of AEC that reported time from diagnosis until death, the average time was less than eight months. Research evaluating the efficacy of different treatment modalities in treating childhood esophageal cancer is almost nonexistent due to the rare nature of the cancer, a major obstacle in improving outcomes in pediatric patients with esophageal carcinoma.

Pediatric Risk Factors

Although there is a limited amount of cases of esophageal cancer available for study, there is a much greater population of pediatric patients with well-known risk factors and precancerous lesions that predispose patients to esophageal cancer at younger ages. This population provides researchers with a means of studying the progression of esophageal cancer in childhood and physicians with the opportunity to prevent cancer in high-risk patients. In a literature review of nine pediatric patients with esophageal carcinoma, seven of the patients had coexisting BE, and the other two’s BE statuses were unknown, although they had factors predisposing them to BE such as gastroesophageal reflux disease (GERD) and hiatal hernia. The prevalence of BE increases with the severity and chronicity of GERD in pediatric patients.

There are a number of conditions that predispose pediatric patients to GERD. These include neurologic impairment, congenital esophageal atresia, cystic fibrosis, family history, congenital syndromes,
obesity, and inflammatory disorders. In a study of children with chronic GERD, intestinal metaplasia of the esophagus was present in 10 percent of children, much higher than the baseline rate for children without GERD. Hiatal hernia is also a significant independent predictor of BE in children. In a study of institutionalized children, GERD was found to be much more frequent and severe in children with scoliosis, cerebral palsy, or a very low IQ. Of that subset, 18 percent of patients who underwent endoscopy were diagnosed with BE. Another subset of children at a higher risk of developing BE are those who suffered from congenital esophageal atresia (EA). A study that followed patients with EA for 36 years revealed that 11 percent of patients developed BE. Cystic fibrosis patients have also been shown to have higher incidences of GERD and BE. Obesity has also been implicated in the development of GERD in both adults and children. Moderately and extremely obese children are more likely to develop GERD than children with normal weight. Although there has been no direct genetic cause identified in GERD or BE, there are many studies that suggest familial clustering of hiatal hernia, GERD, BE, and esophageal adenocarcinoma incidence. Therefore, an unidentified genetic link may exist to the predisposition of esophageal cancer at a younger age.

Conclusion
Esophageal cancer in childhood is a very rare disease, affecting less than two in every million children. Because of its rarity, there are no ongoing clinical trials, and most of the literature only exists as case files. This makes it nearly impossible for pediatric oncologists to develop novel therapies tailored specifically to the treatment of esophageal cancer in children. There must be an increased collaborative effort between both pediatric and adult oncologists and oncologists on an international level to maximize the efficacy of treatment given the limited exposure to the disease. Increased physician awareness of esophageal cancer, GERD, and BE in children and the specific conditions that predispose children to those diseases are important for both prevention and early detection.

Estrogen, Steroidal

Estrogen is a female sex hormone that plays an important role in menstrual and reproductive cycles. Natural estrogens are steroidal hormones, while some synthetic ones are nonsteroidal. This hormone is synthesized in all vertebrates as well as some insects. Their presence in both vertebrates and insects suggests that estrogenic sex hormones have an ancient evolutionary history. Estrogens are used as part of some oral contraceptives, in estrogen replacement therapy for postmenopausal women, and in hormone replacement therapy for transexual women. Estrogen also readily diffuses across the cell membrane as do all other steroidal hormones. Once inside the cell, they bind to and activate estrogen receptors (ERs), which in turn modulate the expression of many genes.

The three major naturally occurring estrogens in women are estrone, estradiol, and estriol. Estradiol is the predominant estrogen during reproductive years both in terms of serum level as well as in terms of estrogenic activity. During menopause, estrone is the predominant circulating estrogen, and during pregnancy, estriol is predominant in terms of serum level. Estradiol is the most important estrogen in nonpregnant females who are between the menarche and menopause stages of life. In females, estrogens are produced primarily by the ovaries and, during pregnancy, by the
placenta. Follicle-stimulating hormones stimulate the ovarian production of estrogens by the granulosa cells of the ovarian follicles and corpora lutea. Some estrogens are produced in smaller amounts by other tissues such as the liver, adrenal glands, and the breasts. These secondary sources of estrogens are especially important in postmenopausal women.

The actions of estrogen are mediated by the ER, a nuclear protein that binds to deoxyribonucleic acid and controls gene expression. Estrogens are present in both men and women, and they are usually present at higher levels in women of reproductive age. They promote the development of female secondary sexual characteristics, such as breasts, and are also involved in the thickening of the endometrium and other aspects of regulating the menstrual cycle. There are several other structural changes induced by estrogen, such as to accelerate metabolism, increase fat stores, stimulate endometrial growth, increase uterine growth, increase vaginal lubrication, thicken the vaginal wall, reduce bone resorption, and increase bone formation.

Scientific studies have found that estrogen is a potent growth stimulus in its target organs such as the uterus, vagina, and some ER-positive breast cancers. However, estrogen is also able to control menopausal symptoms and maintain bone density in postmenopausal women. Until recently, there was also believed to be a link between estrogen and the prevention of cardiovascular disease. For these reasons, hormone therapy (HT) with orally active estrogen and progesterone has been used routinely for more than 50 years to maintain physiologic homeostasis after menopause. Many research studies have found that HT increases the risk of developing breast cancer. Combination estrogen plus progestin significantly increases breast cancer incidence and death—based on data from the Women’s Health Initiative, a randomized, controlled trial. This evidence together with other studies led the International Agency for Research on Cancer (IARC) to classify combination estrogen plus progestin as a breast carcinogen. Evidence strongly indicates that higher circulating levels of endogenous sex hormones are associated with increased breast cancer risk among postmenopausal women.

A meta-analysis of nine prospective studies observed a twofold increase in breast cancer risk in women with estradiol levels in the highest, relative to the lowest, quintile, with similar associations noted for estrone, estrone sulfate, and testosterone. The risk of breast cancer associated with estrogen and progesterone therapy is greatest for postmenopausal women who have the lowest circulating estradiol and estrone levels. Thus, pretreatment determination of estradiol and estrone levels may be helpful in identifying women at particularly elevated risk for breast cancer with combined hormone therapy. P. P. Bao and colleagues proposed after a study of breast cancer in Shanghai that epidemiologic and biologic evidence suggests a pivotal role for estrogen and progesterone in the development of breast cancer. The effects of these hormones are mediated by their respective receptors, ER and
progesterone receptor (PR). ER and PR status are biologic markers considered to be a crucial factor in treatment recommendations. Furthermore, it has been hypothesized that hormone-related risk factors that reflect exposure to estrogen and progesterone may be predominantly associated with breast tumors that express ER and PR but not with tumors that are hormone-receptor negative.

Estrogen is considered to play a significant role in women's mental health. Sudden estrogen withdrawal, fluctuation in estrogen levels, and periods of sustained estrogen at low levels correlate with significant mood lowering. Clinical recovery from postpartum, perimenopause, and postmenopausal depression has been shown to be effective after levels of estrogen were stabilized or restored. According to some recent studies, women suffer less from heart disease due to the vasculo-protective action of estrogen, which helps in preventing atherosclerosis. It also helps in maintaining the delicate balance between fighting infections and protecting arteries from damage, thus lowering the risk of cardiovascular disease and stroke.

There has been increasing concern about the impact of environmental compounds with hormonelike action on human development and reproductive health over the past decades. An alternative but neglected source of hormone action that may be considered in this connection is hormone residues in meat from husbandry animals treated with sex steroid hormones for growth promotion. However, the major source of circulating estrogens among postmenopausal women is from the body's fat cells. Accordingly, being overweight and obesity after menopause are directly related to increased risk for breast cancer and increased risk of dying from breast cancer.

Estrogen has anti-inflammatory properties and helps in mobilization of polymorphonuclear white blood cells or neutrophils. Estrogen is also used in the therapy of vaginal atrophy, hypoestrogenism, amenorrhea, and oligomenorrhea. Estrogen can also be used to suppress lactation after child birth. Researchers have proposed from epidemiological studies that breast cancer characteristics vary among different ethnic groups. Numerous studies have shown that some ethnic groups present with more aggressive disease (higher grade and advanced stage with more ER-negative disease) and worse outcomes when compared with white women. Others have proposed that estrogen contributes to tumors by promoting the proliferation of cells with existing mutations or perhaps by increasing the opportunity for mutations that regulate the growth and differentiation of mammary cells, which may play an important role in the development of breast cancer. Many factors are involved in causing breast cancer. Women with a family history of breast cancer need to be more cautious regarding risks of breast cancer. Estrogen also drives increased risk of endometrial cancer.

In conclusion, estrogen is a sex hormone produced in both men and women but in more significant levels in women. Estrogen plays an important role in menstrual and menopausal cycles. Estrogen promotes the development of female secondary sexual characteristics, such as breasts, and is also involved in the thickening of the endometrial and other aspects of regulating the menstrual cycle. There are several other functions induced by estrogen such as protein synthesis, coagulation, increases in high-density lipoprotein, decreases in low-density lipoprotein, changes in fluid balance, reduction in bowel motility, and support for hormone-sensitive breast cancers.

Estrogen and other hormones are given to postmenopausal women in order to prevent osteoporosis as well as treat the symptoms of menopause, such as hot flashes, vaginal dryness, urinary stress incontinence, chilly sensations, dizziness, fatigue, irritability, and sweating. Long-term use of unopposed estrogen increases risk of endometrial cancer and likely breast cancer. Combination estrogen plus progestin therapy (for women who still have a uterus) increases the risk of breast cancer and death from breast cancer. IARC classifies combination estrogen plus progestin as a breast carcinogen.

Bao, P. P., et al. "Association of Hormone-Related Characteristics and Breast Cancer Risk by Estrogen Receptor/Progesterone Receptor Status in the
Ethiopia

Ethiopia is one of Africa’s oldest independent nations and home to more than 84 million people. It is the second-most populous African country (Nigeria is larger) and is expected to become the ninth-most populous country in the world by 2050. There are more than 85 separately categorized ethnic communities, with the Oromo, Amhara, and Tigre being the largest. Ethiopia’s population has traditionally been located in the highlands, with no endemic malaria or other severe vector borne diseases. Internal disruptions, including a civil war lasting three decades and recurrent famine every year during the period of 1958 to 1992 have resulted in epidemics and put a strain on health care. Communicable diseases, which have traditionally been the focus of health care, are on the decline; however, cancer incidence and mortality are expected to double in Africa by 2030.

Ethiopia’s use of modern medicine has a long history, dating back to Emperor Libne Dingel (1508–40). Emperor Menelik II (1889–1913) invited missionaries and diplomats to introduce medicines and provide medical services mainly in the capital Addis Ababa. Emperor Haile Sellassie (1930–74) introduced the country’s first national health services with the creation of the Ministry of Public Health in 1947. Throughout the 1950s, various nongovernmental organizations (NGOs) and the international community helped in developing hospitals and provided essential technical assistance to the Ethiopian government. Because of various interests by the World Health Organization (WHO), UN International Children’s Emergency Fund (UNICEF), and U.S. Agency for International Development (USAID), coordinating programs along Ministry of Health objectives proved difficult.

Community-based health programs were successful, and more were planned, but by 1967, one-third of Ethiopia’s 8,740 hospital beds and all but six of the 65 Ethiopian physicians were in Addis Ababa.

Following the revolution in 1974, the Mengistu Haile Mariam (Derg) period (1974–91) the nation’s first health plan was developed exclusively by Ethiopians. These programs were initially held in high regard but later contributed to the inequitable distribution of health resources to large cities.

Following several decades of war, the Transitional Government of Ethiopia (TGE) gained power in 1991, inheriting damage to 1,221 stations, 108 health centers, 33 hospitals, and several diseases at epidemic rates. The TGE decentralized the Ministry of Health, putting it over issuing policies, setting targets, and monitoring programs. Regional health departments in newly formed states became responsible for planning, implementation, and monitoring their respective health programs. These policies pushed for the extension of health services to pastoralists and other rural populations but not without cultural, political, and systemic challenges.

The Ethiopian government is the country’s main health care provider, with 138 hospitals and 635 health centers. Resources in these facilities are oftentimes lacking, and appropriate care is hard to obtain. The doctor- and nurse-to-population ratio is 1:42,700 and 1:4200, respectively, and their distribution throughout the country is unequal. Access to radiotherapy or chemotherapy is also limited as
Ethiopia only has only two cobalt units. A comprehensive cancer registration is yet to be completed in Ethiopia, so statistics on the country's cancer burden vary depending on the source. Clinical records from Tikur Anbessa (the Black Lion Hospital) Radiotherapy Center estimate that there are 120,500 new cancer cases per year, although Globocan estimates are much lower, at 51,000 per year and a 41,600 mortality rate per year. The prevalence from 2003 to 2008 was 224.2 per 100,000, and less than 1 percent of patients receive specialist treatment.

In 1987, biopsies of 1,154 southern Ethiopia patients were outlined. Among men, hepatic carcinoma, lymphomas, and superficial malignancies were the most common. Among women, cervical, breast, and ovarian cancers predominated. Hodgkin's disease and Burkitt's lymphoma were most common among childhood lymphomas, whereas non-Hodgkin's lymphomas of other types were found in adults. Cancer of the stomach was the second-most common internal malignancy among both men and women. Recently, the government reported that the most common types of cancer seen in hospitals for children are leukemia, lymphoma, retinoblastoma, Wilms's tumor, and bone and soft tissue sarcomas.

The most common cancers occurring in adults include breast cancer, cervical cancer, head and neck cancer, esophageal cancer, sarcoma, colorectal cancer, liver cancer, non-Hodgkin's lymphoma, and skin cancer. Both studies note that inaccessible cancer such as liver, gastric, and pancreatic are less likely to be diagnosed because of nonspecific presentation and hospitals' lack of necessary imaging technologies. Late presentations, limited resources, low awareness of symptoms, lengthy referral processes, and traditional beliefs contribute to Ethiopia's having a high mortality rate of cancer.

Tikur Anbessa hospital in Addis Ababa has 600 beds, of which 18 are for cancer treatment. There are 201 physicians at the hospital, with only four medical oncologists, two surgical, and one pediatric. There also are two hematologists, four radiotherapists, and three palliative pain specialists. Tikur Anbessa allocates only 26 of their 627 nurses to oncology and has the nation's only computed tomography (CT) scanner and magnetic resonance imaging (MRI). In 2010, the hospital saw more than 2,000 adults and more than 200 children with cancer, providing treatment with anticancer drugs, surgery, and radiotherapy. Clinical guidelines for cancer treatment have been developed at Tikur Anbessa and distributed to other university hospitals.

Hospice Ethiopia in Addis Ababa is the first professional palliative care unit in Ethiopia, founded in 2003 by Sister Tsigerada Yiswafossen in a room in her home with the help of 20 volunteers. Volunteers were trained by the local Community Health Bureau. African partners, such as Uganda's Hospice Africa, have been supportive and aided in the organization's growth. The most common sources for referrals are from Black Lion University Hospital and St. Paul's Millennium Hospital; however, referrals also come from private clinics, health centers, volunteer organizations, and charities, along with self-referrals by patients and their families.

In 2005, Ethiopia partnered with AstraZeneca and successfully developed a program to improve the support infrastructure for the management of patients with breast cancer in Tikur Anbessa. With limited investment, this program showed considerable improvement in low-resource environments. The program has provided tamoxifen freely to staff and patients to promote adherence to a well-defined protocol of care, continuous audit of patients, and cross-departmental patient management groups, as well as other methods.

Information and communications technologies and applications, including the development of specialized content, have a low cost and can be an important source of international support. Health research directly relevant to Ethiopia and cancer may be unrepresented as research conducted locally may be published in developing country journals and absent in literature searches. Language is another barrier as most of the literature and materials are in English.

An example of a successful tool and program is HealthNet, which is a knowledge network created to assist Ethiopia and several other African nations with the potential to provide health data collection and information resources through the use of personal digital assistants.

Europa Donna, the European Breast Cancer Coalition

The European Breast Cancer Coalition is an independent, nonprofit organization whose members are affiliated with groups from countries throughout Europe. The coalition works to raise awareness of breast cancer and to mobilize the support of European women in pressing for improved breast cancer education, appropriate screening, optimal treatment and care, and increased funding for research. Europa Donna represents the interests of European women regarding breast cancer to local and national authorities as well as to institutions of the European Union (EU). Europa Donna was founded in 1994 and now has 46 fora (national country organizations) across Europe.

Europa Donna Goals

- To promote the dissemination and exchange of factual, up-to-date information on breast cancer throughout Europe
- To promote breast awareness
- To emphasise the need for appropriate screening and early detection
- To campaign for the provision of optimum treatment
- To ensure provision of quality supportive care throughout and after treatment
- To advocate appropriate training for health professionals
- To acknowledge good practice and promote its development
- To demand regular quality assessment of medical equipment
- To ensure that all women understand fully any proposed treatment options, including entry into clinical trials and their right to a second opinion
- To promote the advancement of breast cancer research

As Europe’s breast cancer advocacy organization, Europa Donna has identified seven main priorities for its European breast cancer advocacy work. These are: establishing population-based mammography screening programs in all countries set up according to the EU guidelines for quality assurance in breast cancer screening and diagnosis, establishing specialist breast units in all countries set up according to these EU guidelines, ensuring an appropriate EU-wide accreditation program is developed to ensure quality standards across all countries for breast services, developing national breast cancer registries, and furthering breast cancer research, breast cancer prevention, and survivorship.

The coalition consists of a 9-person board elected from among Europa Donna’s 46-member countries. The head office of the coalition is located in Milan, Italy, and is responsible for carrying out coalition projects in the areas of information, education, and public affairs.

Europa Donna provides information that is evidenced-based in various publications, newsletters, Web sites, and social networking sites. In 2006, the European guidelines for quality assurance in breast cancer screening and diagnosis were published. This document forms the basis for much of our advocacy work as it outlines the breast cancer services that all women should have a right to receive. Europa Donna has published a short guide to these guidelines to enable women
and the lay public to understand the main points contained in this scientific document. These can be downloaded from www.europadonna.org and have been translated into 17 languages.

Breast Health Day is Europa Donna’s prevention program held annually on October 15; it provides information to women and girls about lifestyle changes that can help prevent a diagnosis of breast cancer in the future. Breast Health Day publications and campaign materials can be viewed at www.breasthealthday.org.

The Europa Donna Pan-European Conference is the only conference in Europe that is conducted for breast cancer advocates and survivors. The 11th Europa Donna Pan European Conference was held in Prague, Czech Republic, in October 2013, and the next conference will be held in Paris in October 2015. Topics of current interest are covered such as: the EU accreditation scheme for breast services, new study results on lifestyle factors, updates on progress in research, advocacy for women with metastatic breast cancer, and the challenges of survivorship. There are still vast differences in the breast services available in different countries, and the organization seeks to help national groups overcome obstacles to gain access to appropriate services.

Europa Donna is co-organizer with the European Society of Breast Specialists (EUSOMA) and the European Organisation for Research and Treatment of Cancer (EORTC) of this unique conference that brings together more than 3,500 researchers, clinicians scientists, and advocates in one arena; it is held every two years.

The European Breast Cancer Advocacy Training Course is a two-and-a-half-day training course for breast cancer advocates that is conducted annually in Milan; here, members from 46 countries learn how to initiate and carry out advocacy programs in their own countries. The course covers the biology of breast cancer, early detection, best practices in treatment of breast cancer, the EU guidelines that have been developed, and communications skills training.

The Europa Donna Advocacy Leader Conference is a new program provided for the national representatives and key leaders of member countries to discuss issues and topics of common concern and provide sessions for them to improve management and development of their local organizations.

Europa Donna is an active participant in several scientific research programs in Europe. The organization has representation on the scientific committee of Breast International Group (BIG) and serve on committees of the MINDACT trial and the new AURORA study. Europa Donna has conducted training programs for advocates concerning trials and has published two booklets “Breast Cancer and Clinical Trials” and “The Advocates Guide to Understanding Breast Cancer Research” to increase understanding of clinical trials among nonscientists.

**Public Affairs**

Europa Donna is constantly engaged in bringing about positive policy change at the European level. It has held numerous European Parliament Information meetings and exhibits resulting in two European Parliament Resolutions on breast cancer in 2003 and 2006 and the Written Declaration against
breast cancer in the EU in 2010. These form the basis of much of our work to promote change nationally. Information on these activities as well as various publications, the annual newsletter, and e-news can be found on the Web site at www.europadonna.org.

**Conclusion**

Europa Donna advocates for all women in Europe to have access to accurate, up-to-date information concerning breast cancer and to have equal access to state-of-the-art services for early detection, diagnosis, treatment, and follow-up for this disease. The strength of the organization lies in uniting women of many countries and cultures to achieve common goals based on scientific evidence.

**European Association for Cancer Research**

The European Association for Cancer Research (EACR) was founded in 1968 with the aim of advancing cancer research and undertakes a variety of responsibilities in research funding and training. The EACR registered office is located in England and Wales. EACR has the largest membership of cancer researchers in Europe, with more than 9,000 current members. EACR has strong associations with other cancer societies in Europe and is one of the founding members of the European CanCer Organisation (ECCO), which works toward creating awareness of cancer patients’ needs and wishes and encourages progressive thought in cancer policy, training, and education. As a founding member of ECCO, EACR makes a valuable contribution to the biennial ECCO–European Society for Medical Oncology multidisciplinary congress and is intimately involved in the development of the charter for the scientific program of the meeting.

EACR provides educational training, opportunities for scientific meetings and conferences, and facilitates cooperation and collaboration among member cancer researchers by providing a platform for scientific interactions and exchanges between basic research scientists, translational researchers, and clinical scientists and physician researchers, covering all aspects of oncology. It also nurtures and encourages the professional development of young researchers by awarding fellowships and promotes knowledge sharing through technical exchange and training for specific techniques. EACR also advocates for persistent economic and political support for cancer research in Europe.

EACR is an inclusive organization with members from multidisciplinary fields. It encourages researchers in the field of cancer research to join the association. The costs to become an EACR member are deliberately kept low so that the cost factor does not deter membership applications. EACR also provides reduced membership rates for postgraduate students and postdoctoral fellows with less than four years of postdoctoral experience. Researchers affiliated with the national cancer societies in Britain, Belgium, Croatia, Denmark, France, Germany, Hungary, Ireland, Israel, Italy, Portugal, Serbia, Spain, and Turkey are automatically assigned membership to EACR.

EACR has the *European Journal of Cancer* (EJC) as its official international journal on oncology, covering multidisciplinary research areas. The EJC publishes 18 issues yearly on topics related to oncology, covering basic research, preclinical trials, translational research, clinical oncology, and epidemiology and cancer prevention. The articles published in the EJC undergo a rigorous peer-review process before publication and include original research and reviews, editorial comments on basic and preclinical cancer...
research, translational oncology, clinical oncology, cancer epidemiology, and prevention. EJC can be accessed as a digital or print version.

EACR also grants recognition for pioneering work on cancer research through awards. The Mike Price Gold Medal and the Pezcoller Foundation—EACR Cancer Researcher Award are among the most prestigious awards. The Mike Price Gold Medal is awarded to exceptional senior researchers contributing to cancer research in Europe. It was initiated the first time in 2012 at the EACR biennial congress in Barcelona. The Pezcoller Foundation—EACR Cancer Researcher Award recognizes academic achievements in the field of cancer research from European cancer researchers with less than 15 years of postdoctoral experience.

Additionally, EACR provides researchers with the opportunity to work across Europe at a center of excellence of their choice or to participate in practical workshops and courses by covering the travel costs through numerous travel fellowships. These travel fellowships are jointly supported by the EACR and the Association for International Cancer Research (AICR). Apart from these awards, EACR also has a Meeting Bursary scheme designed to provide economic support toward cost of travel and accommodation to the members of EACR so as to attend the Association’s Biennial Congress.

The Education Committee of EACR encourages special conferences on highly focused topics by responding to the calls from members of EACR. EACR also supports and organizes meetings such as the annual meeting of Progress in Vaccination Against Cancer, besides participating in the organization of a number of courses in partnership with other organizations, a recent example being the training course on the molecular pathology approach to cancer, jointly organized by EACR and the Organization of the European Cancer Institutes. EACR also plans to have a joint special conference with the American Association for Cancer Research (AACR) and Società Italiana di Cancerologia (SIC) on Anticancer Drug Action and Drug Resistance to be held in June 2015 in Florence, Italy, and is expected to attract global audience.

EACR partnered in the Eurocancercoms project, a two-year project funded by the European Commission with the aim of providing a proof of concept to establish an efficient network for cancer communication in Europe. The primary aim of the project was to use the World Wide Web as a one-stop information exchange platform to integrate, provide access, and share information among patients, policy makers, research scientists, and physicians. The vast scope of this project covered everything from information on the patients to educational tools for clinical scientists.

The project also included access to the latest bioinformatics tools for cancer biologists working in the laboratories. The role of EACR in this project involved collating the collective knowledge of the member researchers and identifying their information needs, attitudes, and ideas. Three Europe-wide member surveys were conducted on communication and use of the Web, usage of National Cancer Institute’s caBIG bioinformatics tools, as well as views on open access publishing. The findings of these projects have been made accessible to the public on the EACR Web site.

European CanCer Organisation

The European CanCer Organisation (ECCO) is a not-for-profit international association, which was previously known as the Federation of European Cancer Societies (FECS). FECS was founded in the early 1980s by visionary researchers working on various aspects of oncology when multidisciplinary cancer care was a novel concept. FECS was founded with the aim of devising a coordinated, multidisciplinary approach toward cancer treatment. The members of FECS looked at oncology with a broader perspective and worked toward bringing together the major players in cancer research, cancer prevention, diagnosis, treatment, and care. The society also spearheaded the program to create awareness of patients’ wishes and needs and to encourage progressive thought in cancer policy. FECS, as an organization, also encouraged exchange of scientific ideas via multidisciplinary conference meetings.

In September 2007, after a consultation with experts in the field of oncology, FECS was renamed as ECCO at the European Cancer Conference in Barcelona Spain. Since its formation, ECCO continues to expand its outreach in research, education, as well as training to professionals covering multidisciplinary aspects of oncology through a biennial series of conferences. Educational programs such as the ECCO e-Learning and an online patient information section are some of the programs initiated by ECCO under the dedicated leadership of specialists and experts in the form of official committees. Currently, ECCO is headed by the president, Martine Piccart (2014–2015) and serves the interests of more than 60,000 professionals associated with oncology through its 24 member organizations.

ECCO strives to uphold the rights of all European cancer patients such that they have access to the best possible treatment and care. ECCO promotes interaction between associated cancer societies in Europe and creates awareness of patients’ needs and wishes, encouraging progressive thinking in cancer policy, training, and education and promoting European cancer research, prevention, diagnosis, treatment, and care through the organization of international multidisciplinary meetings.

ECCO has members of the founding member societies, the full member societies, and the advisory member societies. The founding member societies include the European Association of Cancer Research (EACR), European Society for Medical Oncology (ESMO), European Society for Radiotherapy and Oncology (ESTRO), European Oncology Nursing Society (EONS), European Society for Surgical Oncology (ESSO), and the European Society for Pediatric Oncology (SIOP Europe). The full member societies include the European Association of Neuro-Oncology (EANO), European Organization for Research and Treatment of Cancer (EORTC), European School of Oncology (ESO), European Society of Breast Cancer Specialists (EUSOMA), European Association of Urology (EAU), European Society of Gynecological Oncology (ESGO), and European Society of Oncology Pharmacy (ESOP).

ECCO is advised by members of a council that includes representatives from all voting member societies. In addition, there are also the advisory members who are representatives from other European and international organizations, with objectives consistent with the mission of ECCO. The ECCO Council of Members formally meets once a year.

ECCO is uniquely positioned to represent the consensus of oncology professionals in Europe and to engage with the European policy makers, ensuring adequate attention to cancer research, training, and patient care as a priority in the European Union (EU).

The public affairs arm of ECCO engages in Oncopolicy, which involves a coordinated and sustained effort of interaction with the policy makers in the EU as well as third-party stakeholders in shaping an effective cancer health and research policy for the EU member countries. The public affairs policy of ECCO has specific objectives that include: raising a collective voice on wider policy issues; engaging stakeholders in cancer research, innovation, treatment, care, and education; coordinating the EU oncology community under a single umbrella; and fostering a proactive approach to cancer in Europe.

ECCO is committed to engage advocates of cancer patients to uphold the rights of cancer patients in getting the best patient care in Europe. In 2009, the European Cancer Congresses started a special theme called the Patient Advocacy Track.
dedicated entirely to cancer patients. The Patient Advocacy Track has been developed by the experts from the ECCO Patient Advisory Committee (ECCO PAC). It focuses on the better understanding of cancer patients’ desires rather than their perceived needs.

Since 1999, ECCO, in collaboration with other cancer societies, organizes an annual workshop on Methods in Clinical Cancer Research, which is an introductory educational program for junior clinical oncologists and concentrates on the principles of good clinical trial design. This workshop is held yearly in the last week of June in the town of Flims in Switzerland with the goal of developing young researchers into well-trained, experienced researchers capable of designing better clinical trial and incorporating the methods for cancer therapy and prevention into everyday practice and health care.

ECCO acts as the coordinating organization for the EU-funded project Oncovideos. The project has an online video collection of 24 videos on standard procedures in different oncology disciplines filmed at 18 teaching partner institutions. The primary purpose of the Oncovideos project is to assist in the medical education of health professionals who want to further develop and acquire practical vocational skills in oncology.

ECCO is also a partner organization of the European Journal of Cancer (EJC), the monthly scientific journal with news, reviews, editorial comments, and research on experimental oncology, clinical oncology, and translational oncology. ECCO is one of the four founding members of the Web-based, open-access cancer journal ecanercmedicalsience, initiated by the European Institute of Oncology. ECCO is also a part of the online project eurocancercoms, funded by the European Commission, with the aim of integrating information resources on cancer using modern technology to provide a unique platform providing information on cancer to public, patients, as well as the medical community.

European Cancer Prevention

The European Cancer Prevention organization (ECP) was established in 1981 by the founders Professor Michael Hill (United Kingdom), Professor Paul Mainguet (Belgium), Professor Attilio Giacosa (Italy), and many other clinical physicians. The aim of ECP is to promote collaborations and intellectual exchange among scientists from Europe and to study the primary causatives of cancer in European populations. ECP acts as an authority on information on the causes of cancer and prevention for European governments, health care professionals, and the media.

The majority of initial work by ECP concentrated on the comparative analysis of incidences of cancer in southern Europe, with primarily Mediterranean diet and nutrition with that of the Scandinavian countries. Attempts were also made to integrate epidemiological findings as a tool for cancer prevention in Europe. Cancer prevention by alteration of dietary intake and exercise emerged as one of the priorities that could decide the fate of cancer prevalence.

ECP is governed by a general assembly, which is selected by the board from the members of the society. The general assembly conducts meetings once a year, while the board members are elected by the members every three years. ECP has a president (Professor Jaak Ph Janssens from Belgium) and a treasurer (Dr. Belinda Johnston from the UK). The overall scientific program of ECP is managed by the scientific committee, which constitutes the
heads of all working groups of ECP as well as distinguished scientists who are experts in their chosen fields. The administrative arm of ECP carries out work at different country headquarters and is responsible for extensive communication among the members of ECP. The administrative headquarters are also responsible for organization of scientific projects, financial support, and international conferences.

One important goal of ECP includes prevention of cancer cases in developing eastern European countries, which appear to be taking the same path in the number of cancer cases as the developed world in the 20th century. A second aim of ECP is to intensify cancer prevention programs and, at the same time, promote healthy lifestyles. ECP also plans to concentrate on the screening methodologies for different forms of cancer for early detection of the disease as current evidence suggests a drop in mortality with better screening for disease.

The organization also provides funding in the form of research grants for the development of better endoscopic screening and imaging tools as well as research on genetic factors such as polymorphisms along with developments of methods for patient friendly tissue harvesting.

The *European Journal of Cancer Prevention*, the official journal of ECP, was started in 1992 to provide a dedicated platform furthering the publication of research conducted by numerous scientific research groups at ECP. The journal was started with the aim to raise awareness regarding all aspects of cancer prevention and to facilitate exchange of intellectual ideas.

The *European Journal of Cancer Prevention* covers a broad range of topics related to cancer prevention. These include topics covering descriptive and metabolic epidemiology, biochemical and molecular biological pathways important in cancer prevention and progression of the disease, histopathology as a tool for detecting cancers, clinical sciences, interventional trials and public education programs, and basic laboratory studies and special group studies concentrating on focused topics in cancer prevention.

Although the journal is based in Europe, it addresses all important aspects associated with cancer prevention internationally. Professor Jaak Ph. Janssens, from Hasselt, Belgium, and Professor Carlo La Vecchia from Milan, Italy, have served as the editors of the *European Journal of Cancer Prevention*. The *European Journal of Cancer Prevention* works in collaboration with the International Agency of Cancer Registration to combine the national and regional registries of cancer patients in European countries. This publication serves as a reliable and robust source of epidemiological data and is further used to classify the national and regional differences in the incidences of cancer in Europe.

The *European Journal of Cancer Prevention* serves as a major platform to integrate, evaluate, and publish scientific findings on cancer prevention tools and strategies. ECP informs the population of the role of lifestyle and diet and the risk of cancer through a variety of channels and media. It also fosters exchange of knowledge and research ideas by organizing international meetings and bringing together people with different disciplines, including basic research scientists, clinical researchers, pharmaceutical companies, and policy makers.

ECP encourages young researchers with no more than five years of postdoctoral experience to apply for travel grants. The selection process chooses a candidate for the award based on his or her outstanding work in cancer prevention who wishes to establish a career in the field. The award funds travel costs and visits to established scientists in the field of cancer prevention.

Another specific area where ECP is actively involved is the identification of new threats toward the development of cancer, especially in eastern Europe. The incidence of cancer is rising in the eastern European countries, in contrast to western Europe, as improved lifestyles and an adoption of Western-style diets increase the risk of obesity, which can further manifest into other diseases like type 2 diabetes and cancer. In the future, ECP plans to prioritize the efforts of cancer prevention in developing eastern European countries to minimize the new cases of cancer.

ECP also works to ensure the availability of vaccines against certain types of cancer. This is especially relevant for cervical cancer. Cervical Cancer Update was the theme of the 2013 annual ECP meeting held in Antwerp, Belgium, and ECP undertakes collaborative efforts with the pharmaceutical industry to identify regions and target
women who are at the highest risk of developing cervical cancer.

Further Readings

European School of Oncology

The European School of Oncology (ESO) is an independent not-for-profit organization established in 1983 to improve the standards of treatment and care for cancer patients across Europe. Founded by the renowned Italian cancer surgeon Umberto Veronesi, together with international leaders in cancer surgery, radiotherapy and medical oncology, its mission is “to contribute through education to reducing the number of cancer deaths and to ensuring early diagnosis, optimal treatment, and holistic patient care.” ESO remains one of the only providers of oncology courses not tied to commercial interests. It has been able to steer its own course in pursuit of its mission thanks to generous backing from independent donors.

Educational Courses
In its early days, the concept of continuing medical education (CME) was virtually unknown in Europe, so ESO sought and gained accreditation for its courses from the American Medical Association. The school was a key player in introducing a CME system in Europe, drawing up a report to the European Commission in 1994, and then working with the Union of European Medical Specialists to lay down a framework.

Today ESO runs 20 to 25 courses a year on different cancers and aspects of treatment and care, in addition to its flagship, weeklong Masterclass in Clinical Oncology. Courses are taught by leading oncologists who are committed to student-focused teaching and patient-centered care and provide their services for free. Students come primarily from European countries and are selected on a competitive basis. The school also runs an e-ESO program of fortnightly e-grand rounds. Presented by international experts and broadcast live, these webcasts can be accessed by anyone in the world, and the audience can pose questions by e-mail before or during the session.

To help fill gaps in provision of more in-depth learning for oncologists around the world, ESO is collaborating with the University of Ulm, in Germany, to provide courses that run over 14 months, using a distance learning format.

The school also runs conferences, meetings, and symposia that provide expert overviews of key developments or hot topics. Its signature conferences focus on advanced breast cancer (the only professional conference to address the treatment and care needs of people with advanced cancer), active surveillance for low-risk prostate cancer, and breast cancer in young women.

A Multidisciplinary Organization
ESO was founded as a multidisciplinary organization at a time when medical oncology was still emerging as a specialty in its own right. As scientific director of the Istituto Nazionale dei Tumori in Milan, ESO’s founder, Veronesi, hosted the first trials of adjuvant chemotherapy in 1972, which were being boycotted by surgical departments in the United States. In 1982, he published a landmark paper showing that quadrantectomy—a technique he pioneered for breast-conserving surgery—was safe if used in combination with radiotherapy. The school remains one of the few providers of oncology education to use multidisciplinary faculties.
ESO played a key role in setting up the multidisciplinary European Society of Breast Cancer Specialists (EUSOMA) in 1986. Together with the patient advocacy group Europa Donna, EUSOMA developed, defined, and advocated for the concept of specialist multidisciplinary breast units as the best way to organize breast cancer services. The concept was adopted as policy by the European Parliament in 2003 and has influenced the way services have developed in many European countries. ESO is now backing calls from many prostate cancer specialists and patient advocates for a similar organizational model to be adopted for prostate cancer.

**A Focus on Patient Care**

ESO decided from the outset to teach all courses from the perspective of caring for the patient rather than treating the disease. While rejecting traditional paternalistic attitudes, the school sought to promote a distinctive, compassionate, European approach to patients in contrast to what it saw as a rather bleak interpretation of the truth telling then practiced in the United States.

ESO established a psycho-oncology task force in the late 1980s, at a time when the specialism was emerging in the United States. By 1989, ESO was integrating psycho-oncology into its courses. The school was also quick to recognize the importance of specialist cancer nursing and to integrate nursing into their courses. ESO has been funding training courses for nurses, designed and delivered jointly with the European Oncology Nursing Society, since 1996.

ESO sponsored the establishment of European patient advocacy groups, including the European Breast Cancer Coalition, Europa Donna, in 1994; the European Prostate Cancer Coalition, Europa Uomo, in 2002; and the European Cancer Patient Coalition (ECPC), in 2003.

**A Policy Agenda**

ESO looks for opportunities to engage with governments, policy makers, and administrators regarding policies and practices that impact on patient outcomes.

In 1985, ESO drew up the blueprint for Europe Against Cancer—Europe’s biggest ever coordinated health program—which ran between 1987 and 2000. The school also played an important role in carrying out many aspects of the program, including formulating the European Code Against Cancer, developing training courses for primary care health professionals, defining minimum standards for oncology training in universities, and convincing heads of government to back tough legislation on tobacco.

In 2012, ESO brought together leading clinicians, researchers, epidemiologists, advocates, policy makers, and industry representatives at the first World Oncology Forum, organized in collaboration with the *Lancet* “to evaluate progress in the war against cancer.” The conference issued a statement, Stop Cancer Now!, which called on world governments to implement a 10-point strategy to speed up progress in the prevention, delivery of treatment and care, and development of effective affordable therapies.

**Cancer World and the Media Service**

ESO publishes *Cancer World*, a bimonthly magazine for cancer professionals, policy makers, administrators, and advocates, which addresses social, cultural, political, economic, and organizational factors that impact patient experiences and outcomes.

The ESO Media Service promotes critical reporting of cancer issues in the European mass media through awards and grants for journalists. It also runs training courses for journalists to better equip them to report on all aspects of cancer and provides media training for clinicians and other cancer professionals to help them interact more effectively with the media.

European Society for Therapeutic Radiology and Oncology

The European Society for Therapeutic Radiology and Oncology (ESTRO) was founded in 1980 by the founding fathers Maurice Tubiana, Jerzy Einhorn, Klaas Breur, Michael Peckham, and notably Emmanuel van der Schueren. The aim of the society was to establish radiation oncology as an independent specialty within a broader field of multidisciplinary oncology.

ESTRO is a nonprofit organization fostering improved patient care using multimodality treatments for cancer. ESTRO primarily focuses on the betterment of methods used in radiation oncology. ESTRO has more than 5,000 members from around the world. ESTRO provides economic as well as educational support to all professionals in the field of radiation oncology. This includes professionals in their daily practice, including radiation oncologists, medical physicists, radiobiologists, and radiation therapists. ESTRO's mission includes developing and promoting the standards of practice and education in radiotherapy and clinical oncology and encouraging cooperation between societies representing radiotherapy, clinical oncology, and related subjects within Europe and globally. ESTRO also spearheads research and development activities in clinical oncology, radiotherapy, and other allied fields.

ESTRO held its first annual congress in 1982 in London and was a success with the participation of around 500 delegates. The theme of the first congress was to integrate basic fundamentals of radiation oncology with clinical applications. At present, apart from the ESTRO conference, the association also partners in joint conferences with other societies and associations to promote networking and research initiatives striving for excellence in patient care.

ESTRO pioneered and prioritized dedicated education and training in the field of radiation oncology in Europe. The Education and Training Committee was established in 1985 and was chaired by Jens Overgaard during the Stockholm congress. ESTRO subsequently held its first training course in physics in Leuven, the Netherlands, in 1985. The teaching course was inspired by outcomes of research by physicists Andrée Dutreix (Paris, France), Ben Mijnheer (Amsterdam, the Netherlands), and Hans Svensson (Umea, Sweden), who demonstrated the large variations in standards at different radiation oncology centers. Since the first course, ESTRO regularly offers training courses and modules in Europe on a variety of topics related to radiation oncology.

ESTRO launched its official journal, the Green Journal, in August 1983, with Emmanuel van der Schueren as the editor. The European journal became one of the two leading journals in the field of radiation oncology. ESTRO also releases a bimonthly, open-access, digital newsletter highlighting current topics of interest to the community of radiation oncologists. The newsletter publishes the latest advancements, conference summaries, and other research relevant to the field.

During the past 20 years, ESTRO supported more than 40 European research projects and is recognized as an international leader in education and research-based training of professionals in the field of radiation oncology. Some of the current projects of ESTRO include development of innovative radiation treatments to improve patient outcomes, using stem cells to evaluate the risk of cancer from neutrons in comparison to photons and the induction of secondary malignant neoplasms following radiation therapy in pediatric patients.

The primary vision strategy for ESTRO, as stated during the 30th anniversary of ESTRO, held in Brussels, Belgium, is to link the development of optimal patient care to patient access to state-of-the-art radiation therapy. ESTRO aims to provide optimal, individualized patient care to every cancer patient in Europe through collaborative efforts with current and future organizations collectively involved in the development of multidisciplinary treatment modalities for cancer care. ESTRO also works in tandem with the appropriate scientific and professional societies, international agencies, national representative groups, collaborative clinical trials groups, and patient advocacy groups.
One of the future aims of ESTRO is to develop new areas of engagement with regulatory authorities within Europe, which include the European Union (EU), European Economic Area (EEA), and national regulatory agencies as well as the nongovernmental organizations.

ESTRO’s mission is to promote innovation, research, and dissemination of science through its congresses, special meetings, educational courses, and publications. The ESTRO also provides financial and material support facilitating the PhD student exchange programs and research fellowship. It also assists junior fellows to apply for EU grants to support participation in research studies and scientific meetings.

In 2010, ESTRO launched the project Health Economics in Radiation Oncology (HERO), with the aims of consolidating a knowledge base and creating a model for the evaluation of health economics of radiation therapy in Europe. The HERO project addresses questions on the accessibility versus the need for radiotherapy in Europe. The project aims to establish a cost-versus-effectiveness and cost-versus-utility program for radiotherapy treatments in Europe. ESTRO launched the ESTRO Cancer Foundation (ECF) in 2012 as a Belgian public interest foundation with the vision of improving the roles and perceptions of radiation oncology as an economical contributor toward cancer treatment modalities. The project promotes radiation oncology to patients and decision makers. The foundation can be regarded as the ESTRO arm that tangibly enforces its vision statement on the ground.

From its central position, ESTRO has developed a broad network of contacts with international, regional, and national societies as well as professional bodies and industry partners in the field of radiation oncology.

European Society of Mastology

The European Society of Mastology (EUSOMA), otherwise known as European Society of Breast Cancer Specialists, was established in 1986 by a group of physicians who specialized in breast cancer to collaborate on solutions for the issues and needs that existed in the area of breast cancer. For the period between 1986 and 1990, EUSOMA’s members conducted discussions about different aspects of breast disease; the meetings were informal during this time, and the discussions did not result in any publications.

The society’s formal activities began in 1991. Starting at this time and for the next few years, the society organized conferences and scientific discussions that led to the publication of articles. Since 1998, the society has organized multidisciplinary workshops where experts collaborate to discuss their experiences and opinions as well as drawing up reference documents on different facets of breast disease. These documents resulted in the publishing of guidelines in the *European Journal of Cancer*. EUSOMA is one of three entities that organize the European breast cancer conferences that convene every other year.

Further Readings

The *European Journal of Cancer* is the official journal of EUSOMA. The journal is an oncology journal that takes a multidisciplinary approach, publishing research, reviews, and comments by the editor on basic as well as preclinical research, clinical oncology, translational oncology, and medical, radiation, pediatric, and surgical oncology, along with cancer epidemiology and methods of prevention.

After the European breast cancer conference in 1998, a working team was established to consider a Europe-wide standard, high-quality, specialist breast service. EUSOMA gave an official opinion on the standards that made up high-quality breast cancer units Europe-wide. Many facets of care and quality were considered when the statement was made regarding the guidelines, including the facility’s size, the provisions of the unit, the services offered, and much more. The hope was that the resulting standards for high-quality breast cancer care will inspire improvement in diagnostics, treatment, and care for patients suffering from breast cancer Europe-wide. EUSOMA also created a quality treatment system for auditing breast cancer facilities. The metrics used include screening, surgery, pathology, assessment, hormone therapy, chemotherapy, follow-up, and other categories.

The society has established that diagnosis and treatment of breast diseases, especially breast cancer, have wide and varying approaches across the European region. In addition, the society identified an urgent need for provision of a channel for a wider diffusion of basic research programs either by way of screening the population or through education and information. Based on these essential insights, the society established four core objectives, which have for the period of time the society has been in existence, informed and guided their operations.

Since the inception of EUSOMA, its objectives have been to promote scientific research and increase contacts between scientists and health care professionals interested in breast diseases and in particular in breast cancer and to improve and standardize the ways how patients are treated with appropriate screening and support solutions. This is for making it available for all women in Europe though a state-of-the-art treatment solution; supporting standards for managing different issues and different certification needs for offering the best solutions possible; bringing these to the attention of the appropriate authorities; and fostering training...
and postgraduate programs in breast disease at national and international levels.

The society organizes the European breast cancer conference every two years. The conferences provide platforms for the various European-based professionals in the area of breast cancer, among them doctors, nurses, health practitioners, care givers, and researchers, to meet and discuss the various key issues in the research, treatment, prevention, and advocacy of breast cancer. The objective of this activity is to reach a final consensus on the topic.

In addition to the conference held once every two years, the society organizes workshops on a regular basis. These workshops are on the different aspects of breast diseases, and the specialists from the field of oncology who attend discuss and come up with documents that are meant to provide quality assurance in the diagnosis and treatment of breast cancer.

The scope covered by the society is wide. Even though it is in the areas of breast diseases and in particular breast cancer, the society covers aspects of biology and immunology of cancer, diagnosis and screening, epidemiology and prevention, loco-regional and systemic treatment, genetics and pathology, reconstruction, patient support, and rehabilitation.

Toward these objectives, the society has made considerable achievements through the European breast cancer conferences that the society organizes together with organizations devoted to the research of cancer and how it develops. The solutions are designed to promote help for the body at large.

Other achievements by EUSOMA include the documents that are drawn up during the regular workshops organized by the society. These documents, which are developed by specialists in oncology, have helped to increase the standards in breast health care throughout Europe because they are adopted as guidelines. In addition to the documents, other scientific articles have been published by scientists after attending the workshops as well as consensus conferences and scientific meetings that have been organized by the society.

The work by the society has helped to improve the methods used in the management of not only breast cancer but also breast diseases.

European Society of Surgical Oncology

Established in 1981, the goal of the European Society of Surgical Oncology (ESSO) is to advance the art, science, and practice of oncological surgery, which is surgery specifically used in the treatment of cancer. ESSO’s mission is aimed at supporting the overall health and well-being of cancer patients through multidisciplinary educational and research efforts. The guiding philosophy for ESSO is to create a system of surgical oncology within Europe’s medical establishment that focuses on a patient-centered approach rather than a disease-focused approach. This, ESSO says, helps patients become clear partners in their treatment, ultimately improving the patient’s quality of life and providing for a higher rate of survivorship.

ESSO operates under a set of core principles and goals that supports patient advocacy and multidisciplinary expertise for the field of oncology. These include education, cooperation, science and investigation, oncopolicy, and communication.

Touting a membership of 20,000 worldwide—to include individuals, groups, and corporations—ESSO members span multiple disciplines that are either directly involved or related to in the practical application, research, and care and treatment associated with surgical oncology in Europe. ESSO believes that creating a collaborative, multidisciplinary educational and research environment for
those involved in this field will help propel cancer treatment forward and help surgeons serve a crucial role in the care and treatment of cancer patients. ESSO provides standardized training and education on topics ranging from innovative surgical techniques to advising and counseling patients, to cutting-edge therapies.

As a result, ESSO does not focus solely on the technical aspects of surgical oncology; instead, ESSO supports collaboration with other specialties involved in cancer treatments, like radiologists and geneticists. This collaboration provides ESSO members with a well-rounded perspective, possible cancer treatments and research areas and connects medical professionals from a variety of disciplines and subdisciplines through shared knowledge and expertise that might otherwise have operated as disparate communities. Some examples of these multidisciplinary areas include robotic surgery, minimally invasive laparoscopic surgery for cancer patients, intraoperative chemotherapy and radiation therapy, reconstructive surgeries, and recovery programs.

ESSO is also a founding member of the European CanCer Organisation (ECCO), which is a nonprofit federation focused on the patient rights and advocacy. As of 2014, ECCO is made up of 24 other multidisciplined oncology societies and organizations in Europe. Through ECCO, the member organizations work to create awareness of patient’s rights, needs, and wishes during cancer treatment programs and advocates for progressive cancer policies, especially in the areas of training, education, cancer research, care, and treatment.

ESSO is governed by an overall general assembly, which meets once a year and gathers the ESSO members to discuss issues of strategic importance, elect members to serve on the organization’s executive committee, and approve the daily operations functions, such as budgets and changes to the organizations guiding charter. In addition to the general assembly, ESSO’s governance includes an executive committee. This committee is charged with carrying out the overall operations of the organization and is tasked with implementing any activities that support the overall goals of the organization and its members. Other governing bodies include a steering committee, which is comprised of the organization’s officers, who take care of the organization’s day-to-day operations, an education and training committee, which focuses on the development of a strategic training plan for ESSO, to include projects and activities for members, and the editorial committee, which focuses on ESSO’s communications objectives and publication of its scholarly journal.

In order to accomplish its overall goals, ESSO partners with various other organizations and cancer societies. These partner organizations include the European CanCer Organisation, the European Society for Radiotherapy and Oncology, the European Society for Medical Oncology, the Society of Surgical Oncology, the European School of Oncology, the European Society of Breast Cancer Specialists, the International Society of Geriatric Oncology, and the European Association of Urology. These partnerships enable ESSO to leverage resources, expertise, knowledge, and funding.

ESSO’s official publication is the European Journal of Surgical Oncology, a joint scholarly journal produced with the British Association of Surgical Oncologists (BASO), an association of cancer surgery. Through this publication, ESSO provides education and information on a monthly basis in the form of, but not limited to, original scientific articles, news articles, peer reviews, and clinical trials on a variety of cancer surgery subdisciplines and specialties, such as epidemiology, preventative oncology techniques, new applications and surgical treatments, and results assessments. The journal is published and distributed internationally through both print and electronic formats. Additionally, ESSO is supported, in part, through educational grants from the Genomic Health and Nutricia.

Ewing’s Family of Tumors

Ewing’s family of tumors (EFT) is a group of cancers that arise in bone or soft tissues of mainly children and adolescents. This group comprises of four main tumor types:

(1) Ewing’s sarcoma of bone (ES) was first described by James Ewing in 1921 as a diffuse endothelioma of the bone. It is the second-most common bone cancer that affects children after osteosarcoma. ES occurs mainly in the pelvis, lower extremity, upper extremity, chest wall, and spine.

(2) Extraosseous Ewing’s sarcoma (EOE) acts and looks very much like ES but occurs in soft tissues around bones. The tumors can occur anywhere including the trunk, extremities, head and neck region, and retroperitoneum.

(3) Peripheral primitive neuroectodermal tumor (pPNET) is a rare tumor that occurs in bones and soft tissues and shares features with ES and EOE.

(4) Askin’s tumor is a pPNET of the chest.

The cells that make up the tumors in this group have the same unique genetic abnormalities that are not found in other cancer types. Due to this unique characteristic, there is a strong likelihood that these cancers originate from the same cell. Hence, they are all grouped as EFT and receive the same treatment. About 25 percent of patients have metastatic disease at diagnosis. While the five-year survival for patients with localized tumors is 75 percent, it is only 20 percent for patients with metastatic disease.

Epidemiology

The overall incidence of ES sarcoma is approximately three cases per 1 million per year and has remained unchanged for 30 years per data from the U.S. National Cancer Institute’s Surveillance, Epidemiology, and End Results registries. The cancer occurs most frequently in teenagers and young adults, although it can occur at any time during childhood. It is very rarely seen in adults over the age of 30. About 225 new cases of EFT are diagnosed each year in North America. The probability of Caucasians being affected is almost nine times greater than African Americans.

Diagnosis

Definitive diagnosis is based on histologic findings and immunopathology coupled with molecular pathology. On histology, ES and EOE appear as small, round cell tumors with clear cytoplasm with abundant glycogen. Neuroendocrine differentiation may be prominent in pPNET. Tumors are positive for MIC2 gene product CD99, which is a cell membrane protein. However, MIC2 positivity is not unique to ES as it is found in several other tumors, including synovial sarcoma, non-Hodgkin's lymphoma, and gastrointestinal stromal tumors. Hence, histopathological findings need to be confirmed molecularly by fluorescent in-situ hybridization-based detection or by polymerase chain reaction (PCR)-based amplification of a chimeric gene, EWS-FLI1 that results from a chromosomal translocation t(11;22)(q24;q12). This genetic feature is a molecular hallmark for this disease as it is present in approximately 90 percent of EFT cases. The remaining few cases could have lesser common translocations between the EWSR1 gene and a member of the ETS family such as ERG, ETV1, or E1AF. Rarely, other TET family members can substitute for EWS. In addition to aiding in diagnosis, PCR enables the detection of submicroscopic metastatic disease in the blood (circulating tumor cells) or bone marrow.

Tumor Staging

Pretreatment staging is important for understanding tumor extent and spread. For EFT, a localized tumor is defined as one where there is no spread beyond the primary site and no regional lymph node...
involvement by clinical and imaging techniques. Continuous extension into adjacent soft tissues may occur. Imaging guidelines from the Children’s Oncology Group bone tumor committee states that magnetic resonance imaging is the current standard of care for primary tumor assessment. Spiral computed tomography (CT) is more sensitive than traditional thin-cut CT for detection of metastasis. Additional studies should include bone scans, chest CT, and bone marrow aspiration and biopsy. Molecular analysis of bone marrow for the presence of chromosomal translocation will help detect advanced disease spread, but this staging modality is not commonly used. Results from the EURO-E.W.I.N.G. 99 clinical trial suggests that positron emission tomography (PET) using fluorodeoxyglucose and conventional imaging are both equally efficient in detecting a primary tumor, but PET alone has better detection rates for lymph node involvement and bony metastases.

**Prognosis**
The prognosis for EFT patients depends on pretreatment factors as well as therapeutic response. Pretreatment factors such as patient age, sex, and tumor features along with extent of spread influence outcomes. Younger patients (less than 15 years old) with disease and girls have a better prognosis. Cancer occurring in distal extremities performs better than tumors located proximally. Large tumors along with metastatic disease respond poorly to treatment. Primary cancer that is genetically stable with less-complex karyotype has good prognosis. Molecular biomarkers linked with aggressive tumor behavior or drug resistance are associated with inferior outcomes. Therapeutic response factors include presurgical chemotherapy response and postsurgical tumor volume. Patients with poor response to preoperative chemotherapy have an increased risk for local recurrence, while those with minimal or no residual viable tumor after presurgical chemotherapy have a significantly better chance for event-free survival. In patients with advanced disease, decreased PET scan uptake following chemotherapy correlates with good histologic response and better outcomes.

**Treatment**
The complete treatment of patients with EFT requires systemic chemotherapy together with surgery or radiation therapy for local tumor control. Most patients with metastatic disease have a good initial response to preoperative chemotherapy. However, for most, the disease is only partially controlled with a high recurrence risk. Patients with only lung metastasis have a relatively better prognosis than patients with metastases to bone or bone marrow. Treatment lengths depend on tumor location and stage of disease at diagnosis. The surgical resection may involve limb salvage or amputation. Although EFTs are radiation sensitive, radiotherapy alone for localized disease is rarely considered due to radiation-related morbidity as well as advances in orthopedic surgery. Multidrug neoadjuvant systemic chemotherapy for EFT includes vincristine, doxorubicin, cyclophosphamide with ifosfamide, and etoposide. Addition of the latter two drugs has markedly improved overall and event-free survival for patients with localized disease but does little for patients with metastasis. Increasing chemotherapy doses for metastatic disease increases acute toxicity and risk of secondary cancers. Recent clinical trials in the United States and Europe are concentrating efforts on chemotherapy regimens termed megatherapy for metastatic disease. Megatherapy involves myeloablative high-dose chemotherapy (busulphan-melphalan) with or without total-body irradiation followed by rescue with marrow or peripheral hematopoietic stem cells. Benefits of megatherapy are still uncertain for those with advanced disease. Clinical trials in the United States and Europe are underway to improve the overall survival outcomes for this aggressive disease.

**Ongoing Research**
Genomics and proteomics are being used by various researchers to identify disease-specific molecular targets that can lead to the development of novel therapeutic drugs. This may ultimately help change future treatment strategies for ES patients with improved survival without increasing drug toxicity.

Exercise

Over the past 20 years, there is a vast body of research exploring the relationship between exercise and cancer. This research explores how exercise, or physical activity, is associated with cancer risk, prevention, and survival. While evidence from epidemiological studies documents the benefits of exercise in reducing cancer mortality, there is also extensive research summarized by the International Agency for Research on Cancer (IARC) relating higher levels of exercise to reduced risk of many cancers. This entry explains the biological mechanisms that link exercise and cancers, describes the characteristics of exercise frequently studied in relation to cancer, and summarizes current epidemiological research studying the association between exercise (or the lack of it) and various cancers.

The biological mechanisms that influence the impact of exercise on cancer include a number of pathways such as the positive outcomes of exercise on reduction of body fat, improving insulin sensitivity, and improving pulmonary function. Exercise, a modifiable behavior, is known to decrease body fat, which consequently lowers levels of inflammatory markers, reduces the production of sex hormones (estrogen and testosterone), and increases levels of sex hormone binding globulin (SHBG). Moreover, reduced body fat is linked with improving insulin sensitivity and lowering plasma insulin and glucose levels. Thus, exercise may reduce the risk of certain hormone-related cancers such as postmenopausal breast, colon, endometrium, ovarian, and prostate cancers. Exercise also lowers the concentration of carcinogenic material in the lungs, which decreases lung cancer risk.

Research has studied numerous features of exercise that may be related to the development of cancer. These features or characteristics include type of exercise (leisure, household, or occupational), duration of exercise, frequency (number of days per week), intensity (low, moderate, or high), and age at which exercise started. Exercise is related to or results in other factors that are studied in relation to cancer, such as body mass index (BMI) and weight.

The link between exercise and cancer is examined and reviewed by several national and international organizations as well as individual researchers. Foremost among these is the IARC, which uses consistent systemic methods to summarize evidence and classify exposures according to their potential to cause (or prevent) cancer. The evidence shows that the strength and consistency of this association varies based on the site of cancer; that is, one cannot generalize evidence from one cancer to all cancers. Further, the findings can be classified as convincingly associated, possibly associated, and null or insufficient findings.

**Convincingly Associated With Exercise: Reduction in Colon Cancer**

More than 60 studies have been conducted across the world on the relationship between exercise and the risk of colon or colorectal cancers. These studies show that exercise results in decreasing the risk of colon cancer among men and women by 20 to 25 percent. Research found that both occupational (22 percent) and recreational (23 percent) exercise resulted in nearly the same levels of risk reduction. The evidence from studies of recreational or leisure activities suggests that 30 to 60 minutes of moderate to vigorous exercise per day can significantly decrease colon cancer risk.

**Probably Associated With Exercise Reduction in Breast Cancer.** More than 73 studies have been conducted worldwide on the link between exercise and breast cancer risk. Three-quarters of these studies have reported a positive relationship, showing a risk reduction of 25 percent. While all types of exercise were found to be beneficial in decreasing breast cancer risk, studies show that household and leisure activities reduced the risk by 21 percent, walking or cycling by 18 percent, and occupational activity by 13 percent. Research also found that, although exercise performed at any age contributed to reducing the risk of breast cancer, exercise...
done after the age of 50 had a stronger impact than exercise done when younger. The benefits of exercise were greater for postmenopausal women and women with normal BMI.

Reduction in Endometrial Cancer. A systematic review of 20 studies reported that exercise was related to a 20 to 30 percent decreased risk of endometrial cancer. While studies show that any type of physical activity reduced endometrial cancer risk, recent research evidences that a sedentary lifestyle that includes more than five hours of sitting is associated with increased risk of endometrial cancer. Indeed, emerging research suggests that moderate-intensity exercise for approximately one hour per day reduces endometrial cancer risk.

Possibly Associated With Exercise
Reduction in Lung Cancer. Most of the 20 studies conducted to investigate the relationship between lung cancer risk and exercise reported a decreased risk ranging from 20 to 40 percent. Owing to the causal link between smoking behaviors in the development of lung cancer, controlling for the effects of smoking or investigating the risk for nonsmokers is important when considering this site of cancer. Interestingly, the effects of exercise on nonsmokers is reported to be null or weakened among studies that take into account individual smoking status. Similarly, research that did not control for smoking found that exercise was a strong predictor of reduced lung cancer risk, highlighting the protective nature of exercise for this particular cancer. This effect is stronger for leisure (versus occupational) activity, is stronger in men (versus women), but is consistent across various histological (i.e., type of tissue where the cancer originates) subtypes.

Reduction in Prostate Cancer. The relationship between exercise and reduced prostate cancer risk ranges from 10 to 20 percent. However, these findings are inconsistent, lacking clarity on type of exercise, time periods in life that make exercise most beneficial for risk reduction, and duration of exercise. A methodological issue that one needs to consider is that this cancer is dormant, resulting in most men dying with undiagnosed prostate cancer. Hence, it may be problematic to identify a difference in the effects of exercise between individuals with cancer and “healthy” individuals who may be having dormant, nondetectable prostate cancer because the two groups may be too similar.

Reduction in Ovarian Cancer. Of the 20 studies conducted in exercise and ovarian cancer risk, the findings were found to be inconsistent as half the studies noted positive effects of exercise, half reported no effects, and one study observed an increased risk. A meta-analysis conducted in 2007 found that recreational activity was related to ovarian cancer risk reduction by 20 percent. Two studies reported sedentary behavior to be a risk factor for ovarian cancer, with a 55 percent risk increase when a person is sitting for six or more hours per day.

Null or Insufficient Association With Exercise
Findings from studies examining the relationship between exercise and non-Hodgkin’s lymphoma (NHL), Hodgkin’s lymphoma, leukemia, and multiple myeloma were limited due to small sample sizes. Exercise can reduce body fat, and reduced body fat is linked with improving insulin sensitivity and lowering plasma insulin and glucose levels. Thus, exercise may reduce the risk of certain hormone-related cancers such as postmenopausal breast, colon, endometrium, ovarian, and prostate cancers. (National Cancer Institute/Bill Branson)
sizes, inadequate assessments of exercise, and not controlling for confounding variables.

Few studies have investigated the association between exercise and cervical cancer risk, reporting inconsistent findings, with some studies showing increased risk and some decreased risk. Further, there is insufficient evidence for the link between exercise and various cancer sites, namely pancreatic, kidney, testicular, and bladder cancers.

There are several risk factors for cancer, with research evidence suggesting exercise to be a significant risk factor especially in the case of colon, breast, and endometrial cancers. Further research is needed to confirm the exercise—cancer risk relationship for cancers such as lung, prostate, ovarian, hematological, and other genitourinary cancers. Considering the impact of physical activity on less-researched cancer sites will add to the overall scientific knowledge of exercise as a risk factor of cancer. This information will, consequently, help develop public health interventions for physical activity, such as planning exercise programs and setting up exercise awareness initiatives.

The current World Health Organization (WHO) global recommendation for physical activity for adults between 18 and 64 years is 150 minutes of moderate-intensity aerobic exercise per week. However, understanding the role of psychosocial factors that contribute to physical activity (e.g., culture, economic status, and education) can further inform such international health recommendations on exercise.

Experimental Cancer Drugs

Cancer is the term used for all the malignant tumors. A malignant tumor is defined as “an abnormal mass the growth of which exceeds and is uncoordinated with that of the surrounding tissues.” Cancer is described as human consumption even in this era of unprecedented medical advancement. In 2012, there were about 8.2 million cancer-related deaths worldwide, with lung cancer accounting for the greatest number of deaths (estimated at 1.6 million), followed by liver cancer (745,000 deaths), stomach cancer (723,000 deaths), colorectal cancer (694,000) and breast cancer (521,000). This made oncology—that is, the study of cancer—one of the most attractive fields for research workers. New advances were made to seek its remedy.

Chemotherapy, Hormones, and Enzymes
Chemotherapy is the use of drugs for the treatment of diseases. Cancer chemotherapy targets one or more of the steps involved in tumor development—that is, excessive proliferation, or anaplasia (lack of differentiation), local invasion, or metastasis (development of secondary cancer at anatomically distinct sites).

The current drugs mostly act through molecular targets to inhibit the excessive proliferation of neoplastic cells. The newer classes of drugs include hormone antagonists, enzyme inhibitors, growth factor inhibitors, antiangiogenic factors, pro-angiogenic factors, and drugs that promote the body’s immune system.

Various classes of hormone antagonists are used to suppress the growth of hormone-responsive tumors. A good example is carcinoma of the breast. Two of the most striking classes of drugs for this carcinoma are selective estrogen receptor modulators (SERMs) and aromatase inhibitors.
SERMs inhibit the action of estradiol on estrogen receptors in tumor tissues of the breast and endometrium. They block the activation of genes required for cellular proliferation without interfering with the desirable effects of estrogen on bones and low-density lipoproteins (LDL) levels. Aromatase complex is responsible for the final step of estrogen synthesis. Aromatase inhibitors like aminogluthethemide inhibit cyp-450 through the interaction of nitrogen atoms of the drug with haem iron of the enzyme. Similarly acting agents with aza heterocycles in their structures are under investigation.

Estrone-3-O-sulfamate (EMATE, a steroidal sulfatase inhibitor) is an irreversible active site-directed inhibitor. It is very potent but has not been able to make its mark in the treatment of breast cancer so far. Nonsteroidal sulfatase inhibitor 667 COUMATE is in phase I trial. The results of a follow-up on phase II trial will establish its efficacy. A dual aromatase and sulfatase inhibitor compound A is expected to be more efficacious.

Prostate cancer is another example of hormone-responsive tumors that can be treated along similar lines. Signals by testosterone are required for continued proliferation of prostate cells, while 5 alpha reductase is an essential enzyme for the synthesis of testosterone. Finasteride is a potent irreversible inhibitor of 5 alpha reductase type II. It reduces the dihydrotestosterone levels incompletely, which is due to noninhibition of 5 alpha reductase type I. This led research workers to try for the development of dual inhibitors of 5 alpha reductase I and II. The Glaxo Company developed a dual inhibitor Dutasteride, which is in clinical trial phase III.

Cytochrome P17 is another enzyme for the synthesis of androgens in testes and adrenals. Liarozole is a good inhibitor of rat cytochrome P17. In humans, it reduced the plasma testosterone concentration by 80 percent. It is in phase III clinical trials. YM 116 and BW 19 act similarly and are under clinical evaluation.

Several 17-pyridyl steroids have also been tested for cytochrome P17 inhibition. One of them is a highly selective inhibitor abiraterone. The profile of this drug in phase I trial has been very promising. It reduced the testosterone plasma levels without affecting the cortisol levels. Sa 40, a compound derived from abiraterone, is even more active. More recently, compounds like MH_54, L_39, which are dual inhibitors of 5 alpha reductase and cytochrome P17, are being tested.

The use of enzymes and their inhibitors is not new to physicians. Imatinib is an inhibitor of tyrosine kinase domain of Bcr_Abl oncoprotein. The inhibition of tyrosine kinase prevents the oncoprotein from causing unlimited proliferation.

Telomerase is an enzyme that prevents the cells from senescence—that is, aging. Normal cells age after a certain period of time and undergo apoptosis. Cancer cells escape this phenomenon through continued telomerase production. A number of research projects have been carried out regarding the use of telomerase inhibitors to promote the aging and death of tumor cells.

Antiangiogenic Drugs in Chemotherapy

Every solid tumor needs to generate blood vessels to survive once it reaches a certain size. Angiostatic-based treatment prevents angiogenesis. Bevacizumab is being investigated for metastatic colorectal cancer therapy. It is a humanized monoclonal antibody directed against vascular endothelial growth factors secreted by the tumor. It inhibits its interaction with its receptors VEGFR-1 and VEGFR-2. The normal function of VEGF is the formation of blood vessels and regulation of their permeability and inhibition of apoptosis of new blood vessels. The interruption of these functions by bevacizumab kills the tumor. In a research trial carried out by Duke University Medical Center, patients who received bevacizumab along with the standard chemotherapy showed a five-month life extension.

Thalidomide is an old agent that is being exploited for multiple myeloma due to its antiangiogenic and immunomodulatory effects. Although the exact antiangiogenic mechanism has not been elucidated, several preclinical studies prove its efficacy.

Some drugs inhibit angiogenesis by a different mechanism. Gefitinib is a small molecule inhibitor of tyrosine kinase domain of epidermal growth factor receptor. It inhibits the angiogenesis caused by epidermal growth factor. Loss of blood supply starves the tumor. ZD6474 acts by plugging up small pockets inside the cell where adenosine triphosphate (ATP) would normally dock and enable the growth factors to activate. In the presence of ZD6474, the activation of vascular endothelial growth factor (VEGF) is prevented. A newer
Experimental Cancer Drugs

approach is to increase the formation of blood vessels in the tumor so that the tumor is choked. This approach has not yet proved to be as effective as antiangiogenic therapy.

Immunotherapy

Immunotherapy means to enhance the body’s immune system; it utilizes the natural components of the immune system or synthetic analogs for this purpose. The immune system of the body is suppressed in cancer patients and its enhancement would help overcome neoplasia. Immunotherapy utilizes monoclonal antibodies, cytokines and interferons, and cancer vaccines. Monoclonal antibodies are specifically directed against the antigens on the surface of tumor cells. This helps the destruction of tumor cells. Many have been developed like rituximab and trastuzumab, and many like cetuximab are being evaluated for various types of cancers. They are being used in combination with cytotoxic drugs and toxins to carry them to their targets so, in this case, these monoclonal antibodies are being used as guided missiles.

Interleukins are small proteins that enhance the T-cell immune response e.g. IL-2 activates; lymphokines activate killer cells (LAK cells). LAK cells destroy the tumor cells and benefit the patients with renal carcinoma, melanoma, and non-Hodgkin’s lymphoma.

Vaccines, Bacteria, and Viruses

Attempts have been made to develop effective vaccines to prevent cancer or treat cancerous patients. Cancer vaccines consist of a source of cancer-associated material (antigens) along with other components to stimulate the immune response against that antigen.

For example, in malignant lymphoma, a vaccine using lymphoma-associated protein called idio-type can stimulate the immune system and resist the development of lymphomas. Similarly, dendritic cell vaccines are being tried for melanomas where dendritic cells switch on the immune response.

Generally, engineered bacteria are also being used to enhance the immune system, for example, mycobacterium segments. Another study is being carried out to use anaerobic bacteria, such as Clostridium novyi, to consume the interior of oxygen-poor tumors. They do not consume the oxygen-rich side, so they are combined with chemotherapy.

T-cells may be isolated from the cancer patients and modified by induction of viruses into them that carry the receptor genes. When the modified T-cells are transfused into the patient, the receptor genes obtained from the virus enable them to attack the tumor cells with specificity. This approach has been tested for malignant melanoma.

The Duke University Medical Center developed a drug that uses targeting RNA to enter the cells and silencing RNA to stop the expression of those proteins that keep the cells alive. This drug has undergone many successful clinical trials (for prostate cancer). Attempts are being made to transform silencing RNA into natural anticancer drugs.

The University of California, San Francisco discovered an experimental anticancer drug called onyx-015. It is a genetically modified version of adenovirus (cold virus). In normal, healthy cells, the P-53 gene prevents tumor formation—that is, it checks the growth rate of cells. This virus can replicate only in those cells in which the P-53 gene is suppressed, which is the case in 60 percent of tumor cells. It also acts against the cells with intact P-53 genes but with defective P14 ARF that is located upstream in the tumor suppression pathway. The loss of P14 ARF inhibits P-53, which removes the restriction on adenovirus replication.

In contrast to P-53, Bcl-2 is a proto-oncogene that inhibits apoptosis by inhibiting the pro-death signals. Drugs like ABT-737 have been developed to release the pro-death signals from the inhibition caused by Bcl-2, which enhances the self-destruction of tumor cells.

Insulin and Gene Therapy

Insulin potentiation therapy is an unproven alternative cancer treatment. The cancer cells consume more glucose than healthy cells, so they are more susceptible to hypoglycemia caused by insulin. The chemotherapy after the injection of insulin will result in increased efficacy and decreased incidence of adverse effects because lower doses of drugs are required. However, this therapy has its own demerits.

A relatively newer approach to combat cancer is gene therapy. Genes are isolated from human cells, cloned, and altered. These genes could be put into cancer cells and then activated to produce a poison or toxin that kills the cells to make the cells more susceptible to the body’s immune system,
replace the damaged genes, or improve the effect of chemotherapy.

Further Readings

Explosives

Explosives, or explosive materials, are reactive substances (solids, liquids, or a mixture of substances) that, when measured in given quantities, or charges, release potential energy through a chemical reaction under certain conditions of light, heat, sound, or pressure.

Historically, explosives have been used by the military in warfare but have also been used for industrial mining, quarrying, construction, and demolition. In 1867, Alfred Nobel, a Swedish chemist and engineer, patented dynamite in both England and Sweden. Dynamite consists of sodium carbonate, diatomaceous earth, and nitroglycerin (ND). Although Nobel attempted tight control over these patents, Americans engineered a slightly different formula, trinitrotoluene (TNT).

Later, military-grade dynamite was engineered without using the highly unstable and sensitive nitroglycerin and instead using the chemical composition of cyclotrimethylene-trinitramine or cyclonite or hexahydro-1,3,5-trinitro-1,3,5-triazine, also known as the Royal Demolition eXplosive (RDX), which was used extensively in Germany during World War II.

In the process of demilitarizing off-specification, obsolete, or otherwise unserviceable munitions bases from 1940 through the 1970s, the U.S. Department of Defense began to recover TNT and TNT-containing fillers from explosives left over from the enormous quantities of RDX manufactured in World War II. According to the Environmental Protection Agency (EPA), this process allowed significant quantities of chemicals to contaminate soil and groundwater, the first report of which was in the 1980s.

Although RDX is not commercially produced in the United States, it is still widely used in commercial applications and U.S. military munitions, accounting for a large part of contamination around U.S. military installations. According to the Agency for Toxic Substances and Disease Registry (ATSDR), RDX has been identified by the EPA in at least 31 of the proposed hazardous waste sites for inclusion on the National Priorities List, 1,699, of which are targeted for long-term federal cleanup activities.

Within the new millennium, Dense Inert Metal Explosive (DIME) is a new breed of experimental military weaponry developed by the U.S. Air Force, combining RDX and a heavy metal tungsten alloy (HMTA) mixture. Tungsten is an inert metal, meaning it is not active in the chemical reaction causing the explosion but, upon detonation, acts like micro-shrapnel, embedding itself in the body's tissue and is extremely lethal within a four- to 15-meter range. DIME mixtures were used in military actions after 2000, primarily in Gaza throughout the various Israeli sieges in Palestine. While DIME technology has been lauded for its precision, accuracy, and ability to decrease the potential for collateral damage, physicians treating patients in Gaza in 2006 criticized DIME technology for causing “abnormally serious” physical injuries. Norwegian physicians Dr. Mags Gilbert and Dr. Erik Fosse have been at the forefront in bringing attention to the serious injuries incurred by Palestinians at al Shifa Hospital in Gaza City.

Many chemicals and substances used in the manufacturing or detonation of explosives are considered carcinogenic, meaning they have cancer-causing potential. Such carcinogens may directly affect DNA, leading to cancer, or could increase the likelihood that DNA changes will occur with varying levels of cancer-causing potential dependent on the degree,
limited or prolonged exposure, the intensity of those exposures, and a person’s unique genetic makeup.

Many of the substances, either on their own or in combination with other chemicals, are either grouped as carcinogenic to humans (Group 1), probably carcinogenic to humans (Group 2A), or possibly carcinogenic to humans (Group 2B), according to the classification developed by the International Agency for Research on Cancer (IARC). The U.S. National Toxicology Program (NTP) identifies these agents as known to be carcinogenic or reasonably anticipated to cause cancer.

The Occupational Safety and Health Administration (OSHA) recognizes both the evaluation of the IARC Group 1 and Group 2A carcinogens as well as the list of known and potential carcinogens published in the Annual Report on Carcinogens by the NTP as criteria for regulated carcinogens under the Hazard Communication Standard. OSHA requires all manufacturers of chemicals and mixtures to disclose the potential hazards when handling chemicals and compounds on a Material Safety Data Sheet (MSDS), which include any information regarding the carcinogenic nature of the material listed as well as allowable limits of exposure and potential health risks posed by exposure.

The most common explosives listed as carcinogens with governmental regulations are discussed in the remainder of this entry.

NT or o-NT, chemically known as nitrotoluene or ortho-nitrotoluene, may be used in the manufacturing of explosives, agricultural chemicals and pesticides, as well as the petrochemical, pharmaceutical, and rubber industries. The Report on Carcinogens (RoC) cited that o-NT be “reasonably anticipated to be a human carcinogen” based on animal studies and the IARC notes that o-NT is “probably carcinogenic in humans” in similar studies where laboratory rats were exposed to high doses for extended periods of time. Human exposure is most likely through contaminated groundwater near munitions-manufacturing facilities and military grounds and can result from ingesting orally, absorbing through the skin, or inhaling airborne particulates.

OSHA has set a permissible exposure limit (PEL) of five parts per million (ppm) and 30 milligrams per cubic meter (mg/m³) of workplace air within an eight-hour workday for a 40-hour workweek. NIOSH holds a recommended exposure limit (REL) of 0.5 mg/m³, while ACGIH recommended a more stringent TLV of 0.1 mg/m³ of workplace air within an eight hour workday for a 40-hour workweek.

RDX (chemical name: hexahydro-1,3,5-trinitro-1,3,5-triazine) has been classified as a Group C, possible human carcinogen, by the EPA based on a study wherein mice ingested RDX between one and two years, leading to the presentation of liver tumors. The ACGIH has classified RDX as not classifiable as a human carcinogen, or Group A4.

Potential routes of human exposure are through the skin or inhalation as well as ingestion of contaminated drinking water around hazardous waste sites. RDX targets the nervous system, causing seizures, nausea, and vomiting.

According to the Integrated Risk Information System (IRIS), the EPA’s database of chemical risk values, which includes health risk assessment and toxicity benchmarks, RDX was assigned a chronic oral reference dose (RfD) of $3 \times 10^{-3}$ milligrams per kilogram per day (mg/kg/day). The EPA assigned an oral slope factor for carcinogenic risk of 0.11 mg/kg/day, and the drinking water unit risk is $3.1 \times 10^{-6}$ micrograms per liter (μg/L). The EPA has issued a drinking water health advisory for RDX at varying concentrations of RDX contamination with a lifetime health advisory guidance level of 0.0002 mg/L.

The ATSDR established a minimal risk level (MRL) for varying durations of oral exposure to RDX: 0.2 mg/kg/day for acute-duration (14 days or
Extracranial germ cell tumors occur outside the brain. Germ cell tumors are abnormal growths...
Extracranial Germ Cell Tumor, Childhood

that are derived from germ cells, the cells that differentiate into the sex cells, eggs, and sperm (in contrast, the cells forming the rest of the body are called somatic cells). Tumors typically are classified in reference to the cell type from which they develop, with germ cell tumors originating in germ cells, sarcomas in nonhematopoietic mesenchymal tissue, leukemias and lymphomas in hematopoietic cells, and carcinomas in epithelial cells. Extracranial germ cell tumors may be either benign or malignant (cancerous), though even benign tumors can cause medical problems. Often, they originate as birth defects caused during embryonic development.

Extracranial germ cell tumors are classified as two types—extragonadal and gonadal, according to whether or not they are located in the gonads. This classification is in part because extragonadal germ cell tumors were originally believed to be metastasized carcinomas originating in the gonads before it was understood how common benign extragonadal germ cell tumors (many of which are called teratomas) are.

Another way to express the division between the two types of extracranial germ cell tumors is as that between germinomatous and nongerminomatous. The germinomatous germ cell tumors include germinoma of the brain, developing from the pineal gland (not discussed here, as it is not extracranial), dysgerminoma, developing in the ovary, and seminoma, developing in the testis. Nongerminomatous germ cell tumors are extragonadal.

Gonadal germ cell tumors are either testicular or ovarian. Testicular germ cell tumors usually occur during one of two windows: before age four or during adolescence. Though adolescents with gonadal germ cell tumors are often treated in pediatric cancer centers, their cancer is actually virtually the same as adult testicular cancer and develops differently than childhood gonadal germ cell tumors.

Seminoma produces hormones called beta-human chorionic gonadotropin. Testicular tumors may present as a painless lump in the testicles. Despite being difficult to diagnose until they develop more-painful symptoms, the survival rate is very high. One testicle may need to be removed surgically, but the patient will remain fertile. Childhood seminoma is unusual; germ cell testicular tumors are usually found in teenagers and young men. In about 10 percent of cases, rather than a lump presenting, testicular atrophy occurs. Lower back pain may present and is usually a sign of metastasis. The tumor may sometimes be detected by a blood test for placental alkaline phosphatase, especially if the patient has never smoked, which also increases placental alkaline phosphatase (PLAP). Often, the nature of the tumor is not certain until surgery has been performed and a biopsy can be done.

Testicular germ cell tumors can present an additional complication in the form of intratesticular masses, which need to be removed by inguinal orchiectomy.

Spermatocytic seminoma is a type of testicular germ cell tumor, constituting only about 1 percent of all testicular germ cell tumors. It is extremely rare but not unheard of as a childhood cancer, more commonly occurring in men over 50. It presents as slow and painless testicular enlargement in one or both testicles, and the tumors may sometimes show sarcomatoid differentiation. This cancer rarely metastasizes and so is fairly easily dealt with surgically. Chemotherapy and radiotherapy are rarely required.

Dysgerminoma forms in the egg-making cells of the ovary and are more common in adolescent girls. Ovarian tumors may present a lump in the abdomen, accompanied by pain, fever, or constipation as well as unusual bleeding from the vagina or, in adolescent girls, cessation of menstruation. Only about 5 percent of dysgerminoma cases occur during childhood. In 10 percent of patients, tumors occur in both ovaries. Having abnormal gonads due to androgen insensitivity syndrome or gonadal dysgenesis increases the risk of developing dysgerminoma. Tumors are usually smooth and knobby on the outside and soft and gray, pink, tan, or cream-colored on the inside. If they metastasize, they usually do so in the lymph nodes.

Certain hereditary disorders, notably Swyer syndrome, increases the odds of developing gonadal germ cell tumors, as does having an undescended testicle. The tumors are identified by physical examination, imaging including X-rays, ultrasounds, and computed tomography (CT) scans, or blood tests.

Prognosis depends on the malignancy of the tumor, the patient's age and health, and whether it has metastasized. A nonmetastatic tumor can usually be successfully removed, malignant or not. The prognosis is generally good for childhood gonadal germ cell tumors and slightly better in girls.
Chemotherapy and radiotherapy are both exceptionally effective with both ovarian and testicular childhood germ cell tumors.

Extragonadal Germ Cell Tumor

Extragonadal germ cell tumors originate outside the gonads. Germ cell tumors are neoplasms (abnormal growths) derived from germ cells, the cells that differentiate into eggs and sperm (all other cells in the body are called somatic cells). Tumors are neoplasms that have formed a lump, but not all neoplasms are tumors in that sense, even if they are malignant. Tumors often are classified according to the type of tissue from which they developed—sarcomas develop from nonhematopoietic mesenchymal tissue, carcinomas from epithelial tissue, leukemias and lymphomas from hematopoietic cells, and germ cell tumors from germ cells. Not all are cancerous, and they may originate as birth defects caused during the development of the embryo.

It was once believed that extragonadal germ cell tumors were carcinomas that had metastasized beyond the gonads, but it is now understood that many extragonadal germ cell tumors are in fact benign. About half of them are sacrococcygeal teratomas, located at the base of the coccyx. Teratomas are tumors with components that resemble the normal derivatives of two or more germ layers. They are most familiar to the layperson from their rarest example, fetiform teratoma, which consists of a mature teratoma that includes tissues resembling a poorly formed fetus, including not only hair, bone, or epidermis but partially or fully formed hands, feet, and eyes. There is a theory that fetiform teratoma is the result of a fetus that began development within its twin before being arrested, but this is not at all a certainty, and the mechanism is in any case unknown.

It is just as likely that these fetal features developed as a birth defect, not as a separate fetus, in the same way that a fetus may develop with a six-fingered hand or cleft palate. Other mature teratomas may be either solid or cystic, often including skin or hair, and sometimes bone. Sometimes tissues associated with organs like the liver, brain, or kidney will be present but not fully formed. Mature teratomas are almost always benign and are usually found in women. Immature teratomas, without these developed tissues, are more often found in men and are more often malignant.

Teratomas are graded 0 (mature and benign), 1 (immature and probably benign), 2 (immature and possibly malignant), or 3 (malignant) and classified according to whether they are solid (containing only tissues and the complex structures of mature teratomas), cystic (containing only pockets of fluid, like sebum, fat, or cerebrospinal fluid), or mixed, containing both. Any teratoma has the potential to become malignant, and any malignant teratoma has the potential to metastasize. Seemingly benign teratomas may become malignant in unexpected ways, such as cystic teratomas containing squamous cell carcinoma that is not discovered until surgery.
Though present before birth, teratomas are usually not diagnosed until much later—sometimes during childhood, if the tumor is large, but more often in adulthood. Even fetiform teratomas may go undetected for decades. In some cases, the teratoma is detected in a prenatal magnetic resonance imaging (MRI), and some larger teratomas are responsible for the death of a fetus or require emergency intervention, usually fetal surgery. This is particularly true if the teratoma is large enough that the fetus’s blood flow is redirected to it.

Some benign teratomas can cause difficulty simply through their physical presence, either because of obstructing some important process in the body or by stimulating antibodies or secretions. Ovarian teratomas can result in a serious illness called anti-N-methyl-D-aspartate (NMDA) receptor encephalitis, in which patients develop psychosis and memory troubles, followed by seizures, language difficulty, and finally a near-catatonic state characterized by unsteady breathing and abnormal movements. Other teratomas in both men and women can cause chest pain or breathing difficulty because they are pressing down on the lungs.

Sacrococcygeal teratomas, located at the base of the tailbone, occur in roughly one in every 35,000 people and are more likely than other teratomas to be identified in babies and children. Prenatal ultrasounds nearly always will reveal their presence. In rare cases, they may grow larger than the fetus, jeopardizing its life as previously discussed. They are found more often in girls than boys by a ratio of about four to one. Those that are not found on ultrasound or in the newborn often are discovered shortly after the child learns to talk, especially during toilet training, as the teratoma may be detectable as a periodic physical sensation that the child articulates as fecal urgency.

Teratomas are usually treated with surgery and are relatively easy to resect from surrounding tissues. This is often recommended because of the possibility of becoming malignant or of concealing malignant tissue within it. Malignant teratomas (which become adenocarcinomas) are subjected to follow-up chemotherapy. With sacrococcygeal teratomas, although it is relatively simple to remove the malignant tumor in its entirety, some functional disability is often a side effect.

Family Size

Family size is the number of members that make up a family unit. There are many different definitions of family, somewhat complicating research, but in the United States, it typically means those who are tied through blood or marriage, or who live together in the same household.

Research has identified some relationships between family size and risk for cancer. However, much of the research is preliminary, and this topic warrants much further in-depth research to find concrete patterns between the two. Research on the relationship between family size and cancer is complicated by the fact that family size may correlate with other risk factors such as socioeconomic status and also that the number of children a women bears directly influences her risk for reproductive cancers (breast, ovary, and endometrium).

As the definition of a family is variable, so is the definition of what constitutes a “large” versus a “small” family. The lack of consistency across studies in defining a small and a large family is a further complication in studying this relationship, although many studies count four or more children as a large family and three or less as a small family. To advance insights from research, a more consistent application of definitions will help.

Large Family Size

One study found that individuals from larger families were less likely to develop melanoma of the skin. The study, conducted in a northern region, offered the possible explanation that larger families typically could not afford vacations to sunny climates, from their homes in the north to the south, and therefore were less likely to experience prolonged sun exposure, which has been linked to melanoma (skin cancer). Obesity, which increases risk for various cancers such as liver, breast, esophageal, colorectal, kidney, and endometrial cancer, has been linked to large family size, but this relationship is complicated by the fact that in current U.S. population surveys, poverty is related to both obesity and large family size.

Large families can also contribute to an increased risk for stomach cancer because of greater exposure to the bacterium Helicobacter pylori. Younger siblings are at the greatest risk for stomach cancer from H. pylori because they may be exposed to the bacterium at a very young age from their older siblings. Being exposed to the bacterium while one’s immune system is still developing can cause long-term effects. The bacterium will have already had a “head start” in a younger person, compared with a genetically similar older person (e.g., a younger sibling compared with an older sibling), and can attack
the younger sibling in a stronger, more disastrous way. The bacterium also has the potential to have adapted to the family's genes and can easily compromise a younger sibling's immune system, causing stomach cancer later in life.

Other cancers with infectious and viral origins also have a higher prevalence in larger families. This may be due to the fact that infections may spread more readily through a large family than through unrelated individuals because family members live in close proximity to one another. This ease of disease spread can lead to compromised immune systems and a higher likelihood of certain cancers including certain lymphomas.

In contrast, some cancers are less common in members of large families. For instance, glioma brain cancer is less prevalent in larger families, and having siblings is associated with a reduced risk of developing glioma as an adult. Unlike the case of stomach cancer, being exposed to infection at a young age from siblings actually lowers the risk for glioma, as it can stimulate the immune system and prepare the body better to fight off infection that could have led to glioma as an adult.

Small Family Size
Small families are associated with more educated women and higher socioeconomic status, and they are also associated with higher parental age at conception. Due to risks associated with having children at an older age, the last-born child may be at a higher risk of developing both childhood cancers as well as cancers later in life. These cancers can vary as there are myriad health concerns for children born to older mothers. Later age at childbirth and fewer children increase the risk for breast cancer in mothers, and fewer children is directly related to increased risk for ovarian cancer. Since the onset of industrialization, family size is becoming smaller, and an unintended consequence is higher risk for some cancers among women.

Family size has also been linked to breast cancer. A genetic breast cancer study found that women with fewer than two first- or second-degree family members living past 45 years were more likely to develop genetic breast cancer. Having a smaller gene pool from which to have potentially inherited hereditary cancer may raise the risk for cancer, but it also makes tracking the family history simpler. However, this research is complicated by the fact that though small family size makes it easier to track family history and records from small families may be more accurate, some observed results may be due to the differential quality of data from families of different sizes.

Family size has been linked to cancer risk in another way, because the number of children borne by a woman has been related to differing risks for some types of cancer. Women who have more than two children have a higher risk for cervical cancer. Yet having no children puts women at a higher risk for endometrial and ovarian cancers. Pregnancy serves as a protection for women against breast and ovarian cancer. During pregnancy and subsequent breastfeeding, women have a much lower risk of developing breast or ovarian cancer.

Prevention and Support
Family size also plays a role in norms around prevention behaviors for cancer, such as smoking, exercise, choice of diet, and getting health screenings. These behaviors may be learned from and influenced by the behavior of other family members, and the family environment may be more or less welcoming to behaviors identified as increasing cancer risk or reducing cancer risk. Of course, many of these behaviors are also related to other factors that are related to family size, such as socioeconomic status. Differing family dynamics may also play a role in the practice of health behaviors: For instance, some health risk behaviors (e.g., smoking) may be more likely to pass unnoticed in a large family than in a small one.

In some cases, the term family can include the extended family, such as grandparents living under the same roof as their children and grandchildren. Creating a multigenerational family, which may tend to be larger than a nuclear family, has been shown to increase the likelihood of following preventative measures to avoid cancer. Living with one's grandparents makes it easier to gather information about family history, and older generations are more likely to promote cancer screenings for the family in hereditary cancer cases. Older family members who have experienced cancer may understand both the medical and the social aspects of the disease better than younger family members.

They are also able to offer guidance and support to younger generations in the family if everyone lives under the same roof.
Family size can also play an important role in support systems. A diagnosis of cancer creates a very vulnerable and fearful time in one’s life, one that is best handled in a supportive environment. Two aspects of social support are network size (how many family members and friends one has) and perceived adequacy of the support to the patient. The larger the support network size, the less likely patients are to show depressed symptoms. High perceived adequacy of that support aids in lowering depression too. Coming from a larger family can automatically grant someone a higher network size, thus leading to lower levels of depression. However, even when coming from a large family, as people age, their social network diminishes in size, leading to higher incidences of depression in elderly cancer patients. This is especially true for people who do not have any or many children.

Preliminary research shows that family size can be a medical predictor of cancer incidence, as well as aid in the understanding of social support after a cancer diagnosis. Continued research into the many different types of cancers as well as the many different types of families will yield information vital for cancer research.

Finland

The Republic of Finland is a Nordic nation bordered by Sweden to the north, Russia to the west, Estonia to the south, and the Gulf of Finland to the west. With a population of 5.5 million, Finland is one of the more sparsely populated members of the European Union as well as one of the most prosperous. Most of Finland’s health care system is funded by the government and is the responsibility of Finland’s Ministry of Social Affairs and Health. Research regarding various diseases and health conditions, including cancer, is provided by Finland’s National Institute for Health and Welfare.

Beginning in the 12th century, Sweden controlled most of what is present-day Finland, continuing its hegemony over the area until 1809, when Finland became a grand duchy of the Russian Empire. Achieving independence in 1918, Finland remained a mostly rural, agrarian society until after World War II. Joining the United Nations in 1955, Finland has maintained its neutrality since that time, partially in deference to concerns of the Soviet Union, now the Russian Republic. After 1950, Finland rapidly industrialized, with the majority of its citizens now living in urban areas. Economic growth was rapid, and Finland’s gross domestic product (GDP) and per-capita income were among the globe’s highest by the mid-1970s. After an economic depression during the early 1980s, Finland again enjoyed rapid economic
Finland has adopted the Nordic model of government, which combines free markets with strong social welfare programs. The first nation to grant universal suffrage to all citizens, Finland strives to provide for the educational and economic well-being of all. To do so, Finland has established a system of legal rights, including that to health care. In 1929, the Finnish government established a committee that examined the status of the nation’s health care system. At that time, it was determined that Finland was sorely lacking in access to health care. The decision was consequently made to establish a system of publicly funded hospitals, which have served as the base of the modern Finnish health system.

Government health policies are established through the Ministry of Social Affairs and Health and subsequently approved by the Finnish parliament. Each municipality is charged with offering health care services to its residents. These health care services are often provided through municipal health care centers. Local health care centers, which employ general practitioners and nurses, provide primary care, which encompasses most day-to-day medical services. Primary care health centers also specialize in health promotion activities. The primary care centers serve as gatekeepers for more-specialized services in the secondary and tertiary care sectors, and a referral from a patient’s primary care provider is needed for him or her to receive care on the secondary and tertiary levels. When secondary care is needed, it is provided through district hospitals, where more specialists are available. Tertiary care is provided by Finland’s network of five university teaching hospitals, which provide the most advanced medical equipment and facilities. Municipalities also fund both secondary and tertiary care, although the national government does assist with the cost of medical training. Tertiary care facilities are located in Helsinki, Kuopio, Oulu, Tampere, and Turku. The health care system is funded both through general tax revenues and user fees.

Finland’s Ministry of Social Affairs and Health also funds medical research, including that involving cancer, through the National Institute for Health and Welfare. The National Institute for Health and Welfare works to find solutions to certain health problems facing the Finnish public and also to affect the health services provided those citizens. With an annual budget of €100 million, the National Institute for Health and Welfare focuses upon the following:

- Promoting the health and welfare of Finns
- Preventing diseases and other social problems that threaten Finland’s health
- Developing health care and social activities and programs

As such, the National Institute for Health and Welfare works to reduce the incidence of cancer in Finland, seeking both to alter certain behaviors of the population (i.e., reducing tobacco usage) while also sponsoring research that assists in treatment of the disease. It also works with international organizations to translate research findings from abroad into improved treatment options for Finns facing cancer.

Cancer Research

The National Institute for Health and Welfare and the Cancer Society of Finland jointly sponsor the Finnish Cancer Registry, also known as the Institute for Statistical and Epidemiological Cancer Research. The Finnish Cancer Registry has since 1953 maintained a database of all incidents of cancer in Finland. This has permitted researchers and scientists to examine how rates of cancer have changed over time. Examination of this data permits policy makers and health care providers to explore why the incidence of certain types of cancer may have increased or declined over time and to take appropriate steps to deal with these changes. Alcohol consumption among Finns increased by approximately 33 percent between 1985 and 2010, with a concurrent increase in liver cancer and other alcohol-related diseases. As a result, policy efforts have begun to decrease the rate of alcohol successfully, including tax increases and a public awareness campaign.

The Finnish Cancer Registry also undertakes basic research, resulting in the publication of approximately 100 scholarly articles per year. The research funded by the Finnish Cancer Registry is broad and varied. Examples of recent research includes Marianne Hinkula’s examination of the relationship between childbearing and reproductive organ cancer incidence; Hinkula’s study found
that women who bore five or more children had a statistically significant lower chance of cancer of the breast, ovaries, or endometrium, while the incidence of cervical cancer increased for the same population.

These findings have led to further studies examining how hormonal therapy might reduce the incidence of these cancers. Another study conducted by Timo Timonen, Simo Näyhä, and Eero Pukkala examined the interaction between sunlight deprivation, influenza, and leukemia. Sunlight deprivation is of particular interest in Finland, where exposure to sunlight is severely restricted during winter months. The study found that the incidence of acute leukemia increased during the winter months, as did the incidence of influenza. The researchers posited that this occurred as a result of the dark season, which itself caused a substantial proportion of Finns to suffer from a deficiency of vitamin D. Further studies are being conducted to examine how vitamin D supplements will affect this deficiency. As a result of this and other research, the survival rate of Finns diagnosed with cancer has increased dramatically over the past 50 years.

Flame Retardant

Designed to suppress, delay, inhibit, or otherwise prevent the spread of flames, flame retardants are minerals added to base materials (additive) or chemically bonded compounds applied as surface finish and coatings (reactive) in manufactured goods that might be combustible.

The two classes of flame retardants, additive and reactive, are further subdivided into families of minerals (aluminum hydroxide, hydrates, borates, etc.), organohalogen compounds (polymeric brominated compounds, brominated polystyrenes, organochlorines, organobromines, etc.), and organophosphorus compounds (organophosphates, brominated tris, chlorinated tris, and halogenated phosphates).

Coupling with a rise in global safety standards, the worldwide use of flammable materials in consumer products, including electronic, aviation and automotive components as well as insulation, roofing, clothing, upholstery, and textiles, has encouraged the use of flame retardants. There are risks of exposure through direct contact with such products, dust and airborne particles, as well as post-combustion inhalation.

Studies indicate that flame-retardant chemicals pose a health risk during combustion, emitting large amounts of carcinogenic dioxins and furans released in the smoke and dust. Inhaling, ingesting, or absorbing these toxic by-products puts firefighters at a higher risk. In a California study, incidences of breast cancer among female firefighters age 40 to 50 had six times the national average, which may be linked to the state’s early adoption of California Technical Bulletin 117 (TB 117) standards. Subsequent studies show firefighters of both genders developing cancer, including rare forms of transitional cell carcinoma typical of chemical industry workers, at higher rates than the general public.

TB 117 was enacted in 1975, requiring polyurethane foam to meet the basic flammability standard of withstanding a small open flame for at least 12 seconds. Because California represents such a large percentage of the market, the majority of furniture manufacturers met these standards in products distributed throughout the United States, using halogenated organic flame retardants. By the turn of the millennium, 80 percent of the furniture treated in the United States met TB-117 standards.

Despite their pervasive use, worldwide numerous studies have shown that flame retardants are not necessarily effective in delaying combustion or preventing the spread of flames. Testing has shown that bioaccumulation, the buildup of these
toxic chemicals in the human body as well as animals over a lifetime, never reduces, causing serious health impacts including cancer. Regulations allow for the discontinuation or ban of one chemical only to be replaced by its equivalent.

A recent *Chicago Tribune* investigative report linked the introduction of halogenated flame retardants in the United States to a 1920s strategy employed by the tobacco industry aimed at redirecting public pressure on self-extinguishing cigarettes to flame-retardant requirements in response to a rise in deaths, identifying indoor cigarette smoking where the smoker fell asleep smoking in an upholstered chair or bed.

The data collected by the *Chicago Tribune* suggested that the tobacco industry allied with various fire safety groups, inventing the National Association of State Fire Marshals, to push for fire-retardant furniture and upholstery requirements, contributing to the passage of TB 117. The campaign was effective in delaying the introduction of the self-extinguishing cigarette almost a century after the first self-extinguishing cigarette was developed.

A 1977 study explored the use of fire retardants (polybrominated biphenyls [PBBs], polychlorinated biphenyls [PCBs], and tris-[2,3-dibromopropyl] phosphate [tris-BP]) in children’s pajamas, which were added due to the Flammable Fabrics Act of 1943 to protect the public from “unreasonable risk” of fire. It suggested a more prudent alternative to using toxic chemical fire retardants in clothing would be self-extinguishing cigarettes as the cause of 30 to 50 percent of U.S. 12,000 fire deaths per year could be attributed to the use of tobacco products.

This study, among others in the 1970s, contributed to the ban of tris-BP in children’s pajamas, citing a 1973 study by the National Cancer Institute (NCI) where 50 percent of female laboratory rates developed adenocarcinomas. Effective January 2014, the flammability standard was replaced by the smolder test, such that upholstery and furniture need to withstand a smoldering cigarette rather than an open flame, expecting to reduce the use of flame retardants.

Among the earliest of flame retardants, PCBs were used as heat transfer fluids in transformers and capacitors and banned in the United States in 1977. In 1979, the U.S. Congress banned the manufacture of PCBs and later, the Environmental Protection Agency (EPA) classified PCBs as known animal carcinogens and probably human carcinogens based on animal testing.

Use of PCBs was replaced by brominated flame retardants (BFR), including trambromobisphenol A (TBBPA), hexabromocyclododecane (HBCD), and the most frequently cited polybrominated-diphenyl ethers (PBDEs). In studies where rats and mice ingested decabromodiphenyl ether (decaPBE)-laced food for the duration of their lives, they developed liver tumors, and as a result, the EPA has classified decaBPE as a possible human carcinogen.

Widely used in furniture manufacturing as an additive in furniture foam until 2000, penta-bromodiphenyl ether (pentaBDE) has been the source of growing concern for both environmental and public health risks. The EPA has partnered with the Furniture Flame Retardancy Partnership (FFRP) since 2003 to access viable alternatives to pentaBDE. PBDEs with fewer bromine atoms, such as pentaBDE and octabromodiphenyl ether (octaBDE), are not classifiable as carcinogens according to the Agency for Toxic Substances and
Disease Registry (ATSDR). This does not necessarily mean these compounds are safe or not carcinogenic but demonstrate a void of research necessitating further study. In 2001, the Stockholm Convention, an international environmental treaty, listed 22 organohalogenics and three BFRs as persistent organic pollutants (POPs).

In 2004, the only U.S. manufacturer of pentaBDE and octaBDE voluntarily ceased manufacturing the chemicals, and by 2009, the primary manufacturer of decaBDE committed to end the production, import, and sale of decaBDE by the end of 2013, although it is possible that pentaBDE continues to be used in other countries and enters the United States through imported goods.

A group of 145 prominent scientists, representing 22 countries, signed the landmark San Antonio Statement on Brominated and Chlorinated Flame Retardants 2010, the goal of which is to advocate for widespread policy changes in the use of flame retardants. The first consensus statement against flame retardants citing documented health hazards linked to high levels of flame retardant chemicals in consumer products and furniture, it questioned the usefulness of using flame retardants given the limited safety benefits and serious impacts on human health.

According to a 2014 market study performed by Ceresana Research, 2 million tons of flame retardants were used, generating projected revenue in the United States of $7.15 billion by 2021. This same study recognizes a downward trend in BFRs as well as chlorinated and halogenated flame retardants.

Because of heavy exposure of the BFRs and PBDEs over several decades, it is assumed that most people have bioaccumulated toxins as a result of exposure in furniture, infant products, electronics, computers, and foam insulation. Studies show that people living in the United States are exposed at a rate 10 to 40 times higher than their European or Asian counterparts.

The EPA has issued a proposed rule in 2012 to stop the import of products containing PBDEs, including pentaBDE, octaBDE, and decaBDE, and has formed the Design for the Environment (DfE), an EPA partnership with industries aimed at identifying safer alternatives to PBDEs, HBCDs, and other chemical flame retardants in response to human health and environmental concerns and evidence of increasing body burden in the general population.

PBDEs largely have been replaced in consumer products by tris(1,3-dichloro-2-propyl) phosphate (TDCPP) and are used in polyurethane foam padding applied to furniture and automobiles. In a 2013 survey of 101 products for infants and toddlers, TDCPP was found to be the most frequently used flame retardant.

Because TDCPP is not chemically bonded to the foam, it poses a risk of exposure through dust. Recent studies also documented the presence of the flame retardant in accumulated dust in homes, offices, and automobiles, where levels of exposure were seen to be higher than in people's homes. Two complementary studies demonstrated alarmingly high exposure to TDCPP. Unlike PBDEs, which can linger in the body for years, TDCPP is believed to have a half-life of hours or days.

The National Research Council reported TDCPP to be linked to cancer in rats. Further studies indicate that TDCPP is neurotoxic, an endocrine disruptor, and a reproductive toxicant. Although TDCPP is on California's Proposition 65 list of substances known to cause cancer, its potential carcinogenicity has not yet been classified by the EPA, International Agency for Research on Cancer (IARC) or National Toxicology Program (NTP). As of June 2014, the EPA will be assessing more than 20 flame retardants to determine the level of risk.

Another organophosphate flame retardant chemical similar to TDCPP and used to replace PBDEs, Firemaster 550, has been used in foam furniture and children's products. Firemaster 550 contains TBB, or 2-ethylhexyl-2,3,4,5-tetrabromobenzoate, and TBPH, or 2-ethylhexyl-2,3,4,5-tetrabromophthalate. The carcinogenicity and toxicity of Firemaster 550 has not yet been determined, although a recent study showed a detected presence in 96 percent of the dust samples. Detectable levels of Firemaster 550 have been found in the tissues of baby harbor seals, indicating contamination of the ocean environment and wildlife.

Flavoring Agents

The connection between health, taste, and flavoring agents is a complex one, colored by many factors. By description, flavorings are often complex mixtures of natural and man-made substances. Some flavorings are simple and composed of only one chemical, while many others are complex mixtures of several substances. When properly combined, such mixtures can provide the aroma and taste of a specific flavor, such as butter or strawberry. This entry discusses what flavorings are in greater detail, where they come from and how they are made, potential health issues and risks surrounding them, and why they will likely continue to pose some risk to those especially who manufacture them.

The Manufacturing and Labeling of Flavoring Agents

To begin, flavoring agents are ubiquitous in the modern food supply. In fact, there are more than 2,000 substances used in flavoring manufacturing for food products today. Typically, in the United States, the Food and Drug Administration (FDA) regulates flavorings to ensure they are safe when they are eaten (but not necessarily inhaled). Any liquid extracts, essences, and flavors that are added to foods to enhance their taste and aroma are evaluated for safety and toxicity typically, regardless if naturally or synthetically derived. There are a wide number of original sources of flavorings such as: essential oils, in the cases of almond, lemon, and vanilla; fresh fruits obtained by expression methods; ginger obtained by extraction methods; mixtures of essential oils and synthetic organic chemicals or entirely from synthetic chemicals, with the aid of various solvents such as alcohol, glycerol, and propylene glycol used alone or in combination. In the manufacturing process of making the agents, water is often added as well as certified food coloring. To be precise, extracts, essences, and flavors employing only natural flavoring agents are called pure flavorings. Contrarily, those employing
synthetics (in part or entirely) are called imitation, or artificial, flavorings.

It is important to note that nearly all of these organic chemicals have been artificially synthesized as well, and it is these synthetics that are used in the manufacture of imitation flavorings. In sum, flavorings are focused on altering the flavors of natural, whole foods such as meats and vegetables, or creating flavor for food products that do not have the desired flavors as determined by manufacturers, such as candies and other snacks. Most types of flavorings are focused on enhancing the scent and taste of the product.

Depending on which country and its respective laws you examine, each country may slightly alter their definition and categorization of flavorings. For instance, in the United States, the U.S. Code of Federal Regulations describes a natural flavorant as “the essential oil, oleoresin, essence or extractive, protein hydrolysate, distillate, or any product of roasting, heating or enzymolysis, which contains the flavoring constituents derived from a spice, fruit or fruit juice, vegetable or vegetable juice, edible yeast, herb, bark, bud, root, leaf or any other edible portions of a plant, meat, seafood, poultry, eggs, dairy products, or fermentation products thereof, whose primary function in food is flavoring rather than nutritional.” The European Union’s (EU’s) guidelines for natural flavorants differ slightly. In this instance, certain artificial flavorants are given an E number, which may be included on food labels, whereas United Kingdom food law defines a natural flavor as “a flavoring substance (or flavoring substances) which is (or are) obtained, by physical, enzymatic or microbiological processes, from material of vegetable or animal origin which material is either raw or has been subjected to a process normally used in preparing food for human consumption and to no process other than one normally so used.”

**Unique Characteristics of Artificial Flavorings**

Most artificial flavors are highly specific and often complex mixtures of singular, naturally occurring flavor compounds combined together to either imitate or enhance a natural flavor. These mixtures are formulated by flavorists (i.e., flavor chemists) to accomplish a number of things including (1) to give a food product a unique flavor; (2) to maintain flavor consistency between different product batches; and (3) to maintain flavor consistency after recipe changes. The list of known flavoring agents in food manufacturing includes thousands of molecular compounds, and the flavorist often can mix these together to produce many of the common flavors found in many natural, whole foods. For instance, many flavorants consist of esters, which are often described as being sweet or fruity, which are typically highly desired flavors in many foods. However, what is considered a flavorant or not can be somewhat discretionary. Such is the case with organic acids that may enhance sour taste, such as acetic acid and citric acid, which are not regulated as flavorants by law.

Compounds used to produce artificial flavors are almost identical to those that occur naturally. Ironically, it has been suggested by some testing authorities that artificial flavors may be safer to consume than natural flavors due to the standards of purity and mixture consistency that are enforced either by the manufacturing company or by law.

Examples of artificial flavors include the chemical compound diacetyl (used to make artificial butter flavor), isoamyl acetate (used to make banana flavor), cinnamic aldehydes (used to mimic cinnamon), and benzaldehyde (which can mimic the flavor of bitter almonds).

**Safety and Health Issues Surrounding Flavoring Agents**

To begin, many flavorings have been in use for many years and are classified by the FDA as generally recognized as safe (GRAS) for oral consumption. However, the FDA does not require testing for other routes of exposure, such as inhalation, and this is where other data in a number of studies has suggested otherwise when it comes to their safety.

For example, the National Institute for Occupational Safety and Health (NIOSH) investigated the occurrence of severe lung disease in workers at a microwave popcorn packaging plant. Eight former workers at this plant developed an illness characterized by fixed airway obstruction on lung function tests linked to diacetyl exposure (i.e., artificial butter flavor) through respiration. Similar fixed, obstructive lung disease has also occurred in workers at other plants that use or manufacture flavorings, and furthermore, in animal tests, inhaling vapors from a heated butter flavoring used in microwave popcorn production caused severe injury to airways.
In general, flavoring chemicals are very volatile, making them readily able to evaporate into the air from their liquid or solid form, thus leading to likely inhalation. They also can be inhaled in the form of a powder if airborne dust is created in the production process (such as in food manufacturing plants). Many of these chemicals in studies have been shown to be highly irritating to the eyes, respiratory tract, and skin.

At flavoring and microwave popcorn production plants, where workers developed the severe lung disease, workers routinely handled or were exposed to open vessels containing flavorings or their chemical ingredients. In addition to microwave popcorn and flavorings plants, other food industries of note with potential exposure to butter flavoring chemicals include (1) snack foods (e.g., chips and pretzels); (2) commercial and retail bakeries (e.g., cakes, cookies, and bread); (3) retail baking mix production; (4) margarine and other vegetable oil–based cooking products; (5) butter and other dairy products; (6) and candy manufacturers. Furthermore, the use of butter-flavored cooking oil products to prepare meals in restaurants also may lead to worker exposure in such venues. While exposures in the flavoring industry and in microwave popcorn production have caused severe lung disease in some workers, the degree of risk to workers from exposures in other settings is currently unknown and will likely remain a risk factor for the foreseeable future due to a lack of regulatory guidelines and enforcement on such exposures.

Given the complexity of flavoring mixtures and the lack of health data for many of the component materials, identifying the relative contributions and risks of individual substances to causing flavoring-induced lung disease is very difficult. The flavorings industry has estimated that more than 1,000 flavoring ingredients have the potential to be respiratory hazards due to possible volatility and irritant properties (e.g., alpha, beta-unsaturated aldehydes and ketones, aliphatic aldehydes, aliphatic carboxylic acids, aliphatic amines, and aliphatic aromatic thiols and sulfides). Some of the most closely examined flavoring agents and their connections to potential health issues include the following: diacetyl (related to artificial butter typically); 2,3-pentanedione; 2,3 hexanedione; 2,3 heptanedione; acetoacetin (acyl methyl carbinol); and acetaldehyde.

By far, the overwhelming concern with flavoring agents primarily relates to respiratory damage and lung disease sequelae (such as bronchiolitis obliterans). This is also primarily via respiratory inhalation, not oral consumption of such agents, research suggests. The initial signs and symptoms of flavoring-related fixed airways obstruction may be subtle. These signs and symptoms seen in affected workers include cough, fatigue, and shortness of breath with exertion. Such signs and symptoms generally do not improve on weekends, brief respites, or vacations, and these same signs and symptoms may have a gradual onset. In some cases, however, severe signs and symptoms have occurred suddenly with rapid progression of lung disease. Accordingly, because of a lack of general knowledge and awareness of the risks associated with flavoring agent exposure by the medical profession, workers may be misdiagnosed with other lung diseases such as asthma or chronic obstructive pulmonary disease (which in some cases may increase the risk for certain types of lung cancer).

It may take months or years before, potentially, the real causes and issues are later revealed. Once diagnosed, unfortunately, studies have not suggested a good prognosis. Workers with flavoring-related fixed airways obstruction, including bronchiolitis obliterans, largely have not demonstrated any improved lung function with medical treatment in clinical studies. Studies also indicate that, while a small percentage of individuals have noted gradual improvement in their cough, several years after flavoring agent exposure, their pulmonary function generally has not improved. In extreme cases, individuals have developed severe, disabling lung disease requiring that they receive a lung transplant.

In addition to the plethora of lung disease problems linked to flavoring agent exposure, exposed individuals have also experienced irritation of the eyes, nose, and throat. For example, in the NIOSH study examining the popcorn manufacturing site, researchers found that nearly half of the current production and office workers and all current laboratory and warehouse workers reported having experienced nasal irritation. Furthermore, approximately half of the then-current office workers and
warehouse workers and approximately 80 percent of production and laboratory workers reported experiencing eye irritation. Lastly, skin problems were most common in current production workers (36 percent), especially in workers who made mostly liquid flavorings (60 percent).

**Conclusion**
As has been detailed, flavoring chemicals are very volatile, so they easily evaporate and can be readily inhaled. They can also be inhaled in the form of a powder if airborne dust is created in the production process. Many of these chemicals are highly irritating to the eyes, respiratory tract, and skin and can be linked to chronic and progressive lung diseases. Thus, for as long as we continue to use them in the food manufacturing process and also not require proper ventilation and protection for workers and office staff in food manufacturing and preparation sites, health risks and lung disease in particular will continue to be issues for those chronically exposed.

**Food Additives**

Any substance added to food to preserve the color, flavor, texture, or appearance or to extend the shelf life of a food product for storage can be considered a food additive regardless of whether it is natural (caffeine, vanilla, etc.) or artificial (yellow dye #5, aspartame, etc.).

Within the second half of the 20th century, factory-processed foods have introduced more than 3,000 food additives, both natural and artificial, to the global food supply and have significantly changed the standard American diet, raising concerns about the adverse impact that these food additives may have on human health.

The Food and Drug Administration (FDA) regulates the safety of food and responds to petitions by companies requesting approval for new chemical ingredients and food additives. After the review process, the FDA will either deny the petition or approve the request, granting the label generally recognized as safe (GRAS), with recommendations on the terms of use within food.

The GRAS designation was established in the Food Additives Amendment of 1958, an amendment to the Food, Drugs and Cosmetic Act of 1938. Under the Delaney Clause of the 1958 amendment, new food additives (pesticides, chemical ingredients, and organic compounds) must be tested, and if found to be carcinogenic in humans or animals, the law requires the FDA to ban the usage of such additives.

Several ingredients that have been banned in other countries have been granted approval by the FDA, including various food dyes, azodicarbonamide, potassium bromate (brominated flour), artificial sweeteners, nitrates and nitrites, acrylamides, butylated hydroxanisole (BHA), and butylated hydroxytoluene (BHT).

Azodicarbonamide is the latest food additive to come under speculation. Used in bread as a food additive, and industrially for yoga mats and shoe soles, azodicarbonamide breaks down and forms high levels of urethane, a known carcinogen. Even though it has been approved for use in food not to exceed 0.0045 percent by weight of the flour used in bread, the FDA recommends manufacturers voluntarily remove the ingredient. In 2014, the food chain Subway voluntarily discontinued use of azodicarbonamide under public pressure.
Potassium bromate, also used in bread making, is classified as a Group 2B possible carcinogen by the International Agency for Research on Cancer (IARC) based on studies of exposed rats that developed renal cancer. Although the European Union, Canada, and several other countries have banned potassium bromate, the FDA sanctioned its use prior to the Delaney Clause and has asked bakers to voluntarily discontinue its use.

Artificial sweeteners have received a great deal of attention as possible carcinogens, historically. The prevalence of their usage throughout the world, marketed as sugar-free products to diabetics and as a lower-calorie substitutes for weight watchers, has raised questions about the allowable limits of daily and lifetime consumption and the links to cancer.

In 1969, the FDA banned the use of cyclamate as a result of studies on laboratory rats that demonstrated an increased risk of bladder cancer in humans. Even though this study was reevaluated by the Office of Food Additive Safety (OFAS), determining that cyclamate was not carcinogenic, the petition for reapproval with the FDA is being held in abeyance, a category which includes petitions found to be deficient, and as of March 2014, the status of the petition shows no new evidence to satisfy the deficiency.

Drawing much concern and attention to artificial sweeteners, studies performed in 1977 on laboratory rats linked saccharin (Sweet ‘N Low) to the development of bladder cancer. Subsequent studies showed that these results only apply to rats and not humans. Epidemiological studies show that there are no consistent patterns of evidence that would support incidences of cancer in human beings, and in 2000, saccharin was taken off the list as reasonably anticipated to be a human carcinogen, published in the “11th Report on Carcinogens” (RoC) by the U.S. National Toxicological Program (NTP).

Aspartame is another artificial sweetener composed primarily of two common amino acids, aspartic acid and phenylalanine. Although aspartame (NutraSweet and Equal) was approved by the FDA in 1981, a 1996 report linking an increase of brain tumors between 1975 and 1992 with the introduction of aspartame renewed concerns in the link between artificial sweeteners and cancer. After further analysis, the report failed to show conclusive evidence that the overall rise in brain tumors could be attributed to the introduction of aspartame.

In 2005, the European Food Safety Authority (EFSA) released a statement declaring aspartame carcinogenic based on long-term studies performed by the European Ramazzini Foundation (ERF) where laboratory rats fed high doses of aspartame developed lymphoma and leukemia. The FDA evaluated the findings and, upon completion of its review in 2007, reported the ERF’s findings unsupported and insufficient in evidence for the FDA to change its conclusion that aspartame is safe for human consumption, a conclusion based on more than 100 toxicological and clinical studies.

In addition to saccharin and aspartame, four other artificial sweeteners are currently approved by the FDA for use in food:

- Acesulfame potassium (Sweet One) was approved in 1988 for use in specific food and beverage categories and was later approved as a general-purpose sweetener (except in meat and poultry) in 2002.
- Sucralose (Splenda) was approved as a tabletop sweetener in 1998, followed by approval as a general-purpose sweetener in 1999.
- Neotame was approved as a general-purpose sweetener (except in meat and poultry) in 2002.
- Advantame was approved as a general-purpose sweetener (except in meat and poultry) in 2014 based on findings from more than 37 animal and human studies failing to demonstrate any clear evidence of a cancer risk.

Sodium nitrate and sodium nitrite are added as preservatives to delay the growth of botulinal toxins, which cause botulism, and to enhance the color as well as flavor of processed meats. Nitrites and nitrates are also found in some vegetables and even baby food.

A 1971 study raised concern that nitrites have the potential to form N-nitrosamines when the nitrites are heated and combined with amines, the natural by-product of the breakdown of protein, to form N-nitrosamine, a known carcinogen in animals. In 1972, the FDA approved nitrites and nitrates as GRAS, stating that meats containing high levels of nitrates and nitrites are not carcinogenic but that N-nitrosamines still poses a human health hazard.
In 1982, the National Academy of Sciences requested additional evaluation, and the FDA nominated nitrites for NTP study, which was completed and reviewed, and the findings were reported in 2001. The proposed conclusion was such that no evidence of carcinogenic activity was found in male mice, and equivocal evidence of carcinogenic activity was found in female mice.

In 2006, the IARC conducted a working group of epidemiologists and toxicologists to perform another review of the carcinogenicity of nitrite and nitrates, resulting in their classification as probably carcinogenic to humans based on an extensive review that links consumption to bowel cancer and places high on the priority of sodium nitrates and sodium nitrites for consideration as possibly carcinogenic for human beings.

Citing the conflicting evidence in the link between nitrates and nitrites and cancer, the EPA regulates the amount sodium nitrate to no more than 500 parts per million (ppm) in finished meat products and the amount of sodium nitrite to not more than 200 ppm in finished meat products. The World Health Organization recommends eating no more than 3.7 milligrams of nitrates for each 2.2 pounds of body weight.

Acrylamide is a chemical used for industrial purposes in manufacturing paper, dyes, and plastics and in treating both drinking water and sewage. Acrylamides have been found in certain foods (potato chips, French fries, and other fried foods) and tobacco smoke. The NTP and the IARC consider acrylamide to be a probable human carcinogen based on studies in laboratory rodents ingesting acrylamide in drinking water, even though toxicological studies show differing rates of absorption between humans and rodents.

Current case-controlled studies investigating the link between consumption of acrylamides and developing cancers of the oral cavity, pharynx, esophagus, larynx, large bowel, kidney, breast, and ovary have found no excess of tumors associated with acrylamide intake. Because much of the data collected was based on personal interviews, the accuracy is subject to individual recall of exposures. Concerned about the major hazard to human health, the World Health Organization and the Food and Agriculture Organization of the United Nations have called for more research to determine the dietary risk of acrylamide.

Sodium benzoate and benzoic acid are food additives used as preservatives in a wide variety of processed foods and beverages. Listed as a GRAS, the FDA has found no evidence to list these ingredients as hazardous for food consumption after addressing concerns that sodium benzoate in soft drinks reacts with added vitamin C to form benzene, a known carcinogen. In a 2007 study published in *Lancet*, 200 beverages with sodium benzoate and vitamin C were sampled and tested, with four beverages exceeding federal safety standards for benzene levels.

BHA, an antioxidant and preservative in foods, is listed as reasonably anticipated to be a human carcinogen in the 12th Report on Cancer published by the NTP. Another preservative, BHT, has been on the GRAS list since 1959, and NTP studies have been inconclusive in rats or mice, although the FDA has noted concerns that BHT may transform

Potassium bromate, used in bread making, is classified as a Group 2B possible carcinogen by the International Agency for Research on Cancer (IARC). (Photos.com)
Food and Drug Administration

The U.S. Food and Drug Administration (FDA) is a government regulatory agency concerned with protecting the health of Americans. The agency is housed under the Department of Health and Human Services and is responsible for assuring foods, medicines, medical devices, cosmetics, and dietary supplements are safe. It also regulates electronic equipment that produces radiation and tobacco products. This broad responsibility translates into regulatory actions such as reviewing the results of clinical trials and approving new drugs, ensuring consumers are adequately informed of the risks and benefits of new drugs, monitoring approved drugs already on the market to ensure their continued safety and efficacy, assuring food and drug products are adequately and accurately labeled, inspecting manufacturing plants, and ensuring overall compliance with the various acts that pertain to food and drug products.

While the agency’s regulatory function is very broad and extends to the 50 United States, the District of Columbia, the Virgin Islands, Puerto Rico, Guam, American Samoa, and other U.S. territories, it does not regulate all consumer products, and some of its responsibilities are shared by other government departments and agencies. For example, the FDA regulates game meats, such as moose, deer, rabbit, wild ducks, and wild turkeys, but it has no control over other meats and poultry frequently found on the American table. Additionally, it has no jurisdiction over vaccination for infectious animal diseases and shares the responsibility for regulating pesticides with the U.S. Department of Agriculture and the Environmental Protection Agency.

Some critics of the FDA believe its regulatory role is too broad and intrusive, while others believe the role should be expanded and the agency given greater autonomy. The debate about the reach of the FDA is probably most intense in the drug industry, where government control meets science and research.

FDA and Cancer Research

In recent years, the FDA has taken decisive steps to reconcile between maintaining consumer safety and facilitating the speedy development of drugs to treat cancer and other chronic diseases. Researchers in

substances into cancer-causing additives, a concern that warrants further investigation. BHT has been banned in the United Kingdom.

Further Readings

oncology had repeatedly complained that the FDA bureaucracy was stymieing progress in the field; critics charged the FDA was slow and inefficient in reviewing new drugs. In an attempt to improve efficiency, the FDA established in 2005 an Office of Oncology Drug Products (ODP). The move was intended to centralize the review of cancer drugs application and expedite the review process without compromising safety. Prior to 2005, the review of cancer drug applications was shared across different offices in the FDA.

This resulted in reviewers without expertise in oncology making final decisions about cancer drugs and reviews taking an inordinate amount of time. The establishment of ODP has significantly improved this situation. In the first two and a half years of its existence, the office reported approving 50 of the 58 new drugs that were submitted for review. The FDA has also developed expedited drug review programs with the aim to make available as quickly as possible new drugs that demonstrate the potential to address unmet medical needs in the treatment of cancer and other life-threatening diseases. Since the introduction of these programs, almost half of all cancer drugs submitted to the FDA for review have an expedited status categorization, and on average, oncology drugs are reviewed faster than other drugs.

Critics of the expedited review program argue the process is making available to patients drugs that have not been adequately tested and for which the risk and benefits have not been clearly established. New drugs that receive an expedited status are approved based on preliminary clinical evidence and are made available to patients even while clinical tests are still being conducted. Critics argue the FDA is compromising safety in order to facilitate innovation and access. They cite the later withdrawal of some drugs approved under the expedited review process as evidence of the FDA's betrayal of its mandate to ensure drugs sold on the U.S. market are efficacious and safe.

**History of the FDA**

In spite of the criticisms and limitation in some of its oversight capacities, the FDA has helped to significantly improve the quality of America's food and drug supply. Prior to the establishment of the FDA in 1906, the food and drug industries were largely unregulated, and consumers had no protection from corporate greed. Foods were being manufactured under very unsanitary conditions, manufacturers adulterated foods by mixing together anything that would cut their manufacturing cost (e.g., chalk was added to flour and insects were ground up and added to sugar), chemicals were used to disguise rotting foods offered for sale to consumers, labels were nonexistent or misleading, and "medicines" ranged from simple water mixed with alcohol or sulfuric acid to lethal and addictive concoctions made from narcotics and other substances not fit for human consumption.

Drugs were released to unsuspecting consumers without any form of clinical trial or safety mechanism and were often marketed as panaceas for a range of diseases on which they had no positive effect. With no way to verify the claims of the powerful businesses, consumers were left extremely vulnerable. While there is no certainty about the precise number of people who were affected by contaminated foods and deadly drug concoctions, it is believed thousands of adults and children were either killed or permanently maimed.

The free-for-all and corruption in the pharmaceutical and food industry received its first major challenge from Harvey Wiley, a medical doctor and chemist. Wiley was pro-commerce but believed businesses had a responsibility to deal honestly. He was also concerned about adulterated foods and the health effects of chemicals that were being used as preservatives. Through his lobbying, the Pure Food and Drug Act was passed in 1906 under the presidency of Theodore Roosevelt. The food and drug regulatory agency, which was then named the Bureau of Chemistry, was born. The agency was renamed the U.S. Food and Drug Administration in 1930.

Even many years after the FDA was established, it was troubled by corruption, weak regulatory powers, inaction in the face of pressure from powerful business interests, and political manipulation. The Kefauver–Harris bill of 1962 that came in the wake of a near thalidomide drug disaster increased the power of the FDA and demanded the agency adopt a more scientific approach to carrying out its function. Among other mandates, the law demanded drug companies use carefully designed and controlled scientific studies to prove the efficacy and safety of drugs being introduced to consumers. Before 1962, drugs were considered safe and effective based on the "expert testimonies" of doctors.
The FDA Today
The FDA still faces many challenges, some of which existed since its inception. The agency continues to struggle to reconcile maintaining consumer safety and facilitating science and innovation, it lacks adequate funding to fully carry out its regulatory role, and its power is limited by restriction on its legal authority. The globalized context in which the FDA now operates also creates added challenges. A large portion of the U.S. food and drug supply is imported from other countries. This makes monitoring an even more complex and expensive undertaking.

The passing of the Food Safety and Modernization Act (FSMA) of 2011 represents the most recent legislation aimed at aligning the agency’s function and authority with its vastly expanded 21st-century role. The FSMA has been described as a comprehensive reform of food safety laws that takes a risk-based prevention approach to food safety. The aim of FSMA is to prevent food-borne diseases and promote public health.

The act expands both the responsibility and authority of the FDA. Under the new legislation, the FDA is mandated to develop model standards for food safety and disseminate them to international and domestic food suppliers. The agency is also required to increase surveillance of domestic and international food facilities, improve its record keeping and food tracking capacities, and apply a scientific food monitoring and protection system. In addition, the act gives the agency greater access to records pertaining to all stages of food preparation and distribution and gives the FDA the power to order a product recall without prior approval from the court or prohibit the distribution of food from a facility that is deemed unsafe.

Today, the FDA continues to face criticisms about its authority and the way it carries out its role. The question of whether the FDA is overregulating or under-regulating is yet to be decided. In spite of criticisms and challenges, however, most agree the FDA's regulatory function is crucial to the safety of the U.S. food and drug supply.

Forest Labs
(United States)

Forest Laboratories, Inc., headquartered in New York, City, is a specialty pharmaceutical company that researches, develops, manufactures, and sells pharmaceutical products used in the treatment of various diseases and medical conditions in the United States. The company’s pharmaceutical portfolio includes both brand-name and generic drugs developed to treat a variety of illnesses and medical conditions to include, but not limited to, diseases and medical conditions affecting the central nervous and cardiovascular systems; conditions associated with gastroenterology, urology, and women’s health; and the treatment of Alzheimer’s disease. From a cancer treatment perspective, the company primarily develops medications used to treat cancers affecting the thyroid and pituitary glands as well as medications used to prevent infections in patients recovering from other medical treatments such as chemotherapy and radiation. These medications include products such as Armour Thryoid, Thyrolar, and Levothroid, to name a few.

In July 2014, the pharmaceutical company Actavis completed its $25 billion acquisition of Forest Laboratories, Inc., which was first announced in February of the same year. This merger created one of the largest specialty pharmaceutical companies in the United States, with an expected annual revenue amount of more than $15 billion in 2015. The combined company’s business model places emphasis on lower-risk drug development by implementing a flexible manufacturing model that

can be easily adapted to better meet any changing needs the medical community and pharmaceutical industry may encounter as a whole. By leveraging Forest Laboratories, Inc. strong product development options, including nine clinical-stage drugs, the merger will build on both companies’ strong foundations of research and development, poised to serve not only the United States but also to take part in pharmaceutical growth in other areas of the world such as Canada and Latin America. Additionally, the merger will allow Actavis to begin performing some functions in-house that they currently outsource by leveraging existing functions already being performed in Forest Laboratories, resulting in further savings.

In order to support its U.S.-based operations and sales, Forest Laboratories, Inc. has three major subsidiaries located in the United States in addition to the company’s two subsidiaries in Canada and Europe. These U.S. subsidiaries include Forest Pharmaceuticals, Inc., a St. Louis, Missouri-based company; Forest Research Institute, Inc., with operations in both Jersey City, New Jersey, and Long Island, New York; and Cerexa, Inc., located in Oakland, California.

The company’s first U.S. subsidiary—Forest Pharmaceuticals, Inc.—is responsible for the manufacture, sale, and distribution of Forest Laboratories’ name-brand prescription medications and products in the United States. Forest Pharmaceuticals operates by marketing and selling its products directly to U.S. health care networks and the medical industry, to include health care professionals, hospitals, and pharmacies.

The company’s second subsidiary—Forest Research Institute—is a wholly owned subsidiary and is tasked with the research and development mission of Forest Laboratories, Inc., which includes product development, preclinical and clinical trials, and the overall evaluation success of the company’s medications. This research and development arm of Forest Laboratories, Inc. provides the company with an opportunity to invest in scientific research and pharmaceutical development that incorporates the many facets of a drug’s life cycle and helps the company gain appropriate approvals from the U.S. Food and Drug Administration at the appropriate times in a product’s development.

As is the case with the Forest Research Institute, the company’s third subsidiary—Cerexa—is also a wholly owned subsidiary of Forest Laboratories, Inc. Cerexa is a biopharmaceutical company solely focused on the development of an anti-infective therapy portfolio. Founded in 2005, Forest Laboratories, Inc. acquired Cerexa in early 2007.

As with other pharmaceutical companies in the United States, Forest Laboratories, Inc. is required to implement post-marketing requirements (PMRs) as part of its overall drug development initiatives. These PMRs include the company gaining a sponsor for a particular drug after gaining FDA approval and conducting appropriate studies and clinical trials designed to garner information on the product’s safety, efficacy, and use. On the other hand, Forest Laboratories, Inc. also conducts post-marketing commitments (PMCs), which are not required by any statute or FDA regulation but indicate a drug sponsor’s agreement with the FDA to conduct studies or trials to gain information on a drug’s overall safety and use.

In recent years, mainly 2009 through 2010, Forest Laboratories, Inc. suffered from a series of legal complications after being accused by the U.S. Department of Justice of criminal negligence and defrauding the federal government by illegally marketing some of the company’s drugs but namely surrounding the evaluation, promotion, and distribution of the company’s thyroid and antidepressant drugs. The U.S. government alleged that Forest Laboratories, Inc. and Forest Pharmaceuticals, Inc. illegally marketed their products, deliberately slowed manufacturing and availability of other drugs, and essentially provided payments to doctors for prescribing specific drugs to patients—such as promoting Cerexa and Lexapro, which are antidepressants, in unapproved pediatric patients.

These charges led the company and its subsidiary, Forest Pharmaceuticals, Inc., to plead guilty to a number of criminal charges, both felonies and misdemeanors. Other charges alleged the illegal distribution of drugs and therefore a violation of the Food, Drug, and Cosmetic Act. This issue also led to a class-action lawsuit, resulting in the company paying more than $300 million as part of an agreement, both in a civil and federal component of the settlement, in order to rectify the civil and criminal liability charges the government and patients had brought against them. In the end, the federal prosecutors working the case said they gathered the evidence against Forest Laboratories with the help of whistle-blowers.
Despite the legal setbacks and issues Forest Laboratories, Inc. experienced, the company remains a top pharmaceutical company in the United States, and its merger with Actavis poises the company to play a dominant role in the American pharmaceutical industry.

Fox Chase Cancer Center

The Fox Chase Cancer Center is devoted to cancer treatment, prevention, and research. In 1974, the National Cancer Institute designated the center as one of the first comprehensive cancer centers in the United States. Located in Philadelphia, Pennsylvania, Fox Chase is the fourth-largest hospital in the United States dedicated to cancer care. It regularly appears on the America’s Best Hospitals list published by U.S. News & World Report.

The center can trace its history back to 1904 and the founding of the first cancer hospital in the United States, the American Oncologic Hospital. The hospital’s first facility was a west Philadelphia Victorian home. At the time, cancer was widely considered incurable. The hospital would go on to become a leader in radium treatments of cancer. The Fox Chase Cancer Center was established in 1974 via the merger of the American Oncologic Hospital and the Institute for Cancer Research, founded in 1927. Fox Chase remained an independent, nonprofit institution until joining the Temple University Health System in 2012.

The Fox Chase Cancer Center and its precursors have contributed to improved treatments in cancer care. These contributions date back to 1917, when research studies were started to investigate the fundamental biological processes in cancer. Prior to that time, cancer research focused primarily on studies of tumor tissue. Researchers at the American Oncological Hospital, however, were convinced that it was necessary to understand normal cell growth and functioning in order to understand cancer. In 1931, the Marine Experimental Station was established at the hospital to focus on the biological basis of cancer.

By the 1940s, some researchers began focusing on genetics and its relationship to cancer, leading them to establish some of the basic concepts of what would become the discipline of molecular genetics. Hugh P. Creech, Ph.D., joined the staff in 1945 and conducted groundbreaking research on chemotherapy agents over the next three decades. In 1959, two researchers at the institute, David A. Hungerford, then a graduate student at Fox Chase, and a University of Pennsylvania pathologist, Peter C. Nowell, M.D., identified a chromosomal abnormality that led to the first conclusive evidence that cancer is a genetic disorder of the somatic cells.

Other important contributions would also come from Fox Chase, including identifying in 1967 the hepatitis B virus, which is the primary cause of liver cancer. In 1969, Fox Chase researchers developed a vaccine for hepatitis B, thus developing the first vaccine to prevent a human cancer. In 1995, Fox Chase further advanced cancer research as a founding member of the Comprehensive Cancer Network, which includes 21 leading academic cancer centers in the United States.

Fox Chase continues to conduct a wide range of basic and clinical research focusing on the diagnosis, treatment, and prevention of cancer. Overall, the center’s research programs include efforts in cancer biology, prevention and control, immune
cell development and host defense, developmental therapeutics, and women's cancer. Approximately 200 clinical trials are normally underway at the center. These include testing new agents and compounds to prevent cancer in high-risk individuals.

Throughout the years, Fox Chase has also provided clinical care to cancer patients. The center accepts patients with all types of cancers and is known for its treatment of rare and difficult-to-manage tumors. Fox Chase also features special programs in cancer prevention, detection, and survivorship, as well as community outreach programs.

Fox Chase’s 100-bed hospital sees more than 8,400 new patients each year on an inpatient or outpatient basis. It admits approximately 4,800 patients to the hospital each year. Overall, Fox Chase physicians record approximately 88,000 outpatient office visits yearly. Fox Chase is recognized for its programs in medical, radiation, and surgical oncology and for its diagnostic imaging programs. Other areas of special expertise include diagnostic pathology and pain management.

Fox Chase has made several innovations in cancer care, such as its contributions to the development of three-dimensional conformal radiation therapy (3D-CRT). This approach involves shaping beams of radiation to match the tumor’s shape and size. Fox Chase was also the first center in the world to use magnetic resonance imaging (MRI) to help plan for treatments. The center features surgeons who specialize in da Vinci robot-assisted surgery for a broad range of cancers. It is also one of the few centers in the United States to offer advanced minimally invasive surgical techniques for patients with cancers of the lung, gallbladder, liver, pancreas, and bile ducts.

Fox Chase also specializes in the treatment of lung cancer and mesothelioma, including the surgical management of mesothelioma. Fox Chase’s research programs on mesothelioma include studies of new methods for early detection and treatment. Fox Chase researchers are also searching for the genetic roots of the disease.

In 2013, Fox Chase opened its Cancer Genome Institute to provide an innovative clinical service that guides cancer patients’ treatment or their potential to participate in specific new drug trials. The institute features advanced DNA technologies to compare patients’ tumors with a panel of 50 cancer-related genes. The tumors are examined for genetic alterations to determine whether or not they match one or more of the cancer-related genes. The goal is to match patients suffering from advanced cancers to specific gene-altering therapies, either established or experimental.

Fox Chase also heads an outreach program called the American–Russian Cancer Alliance. The alliance is a consortium of cancer research institutes from both countries established to promote increased collaboration among cancer scientists and physicians from the two nations. Fox Chase employs more than 2,000 people, including a staff of 358 physicians and scientists.

France

The western European nation officially termed the French Republic has undergone many political variations in its long and storied history, from
France

In opposition to the monarchy of King Louis XVI, the citizens of France declared the first French Republic in September 1792, and since this date, the nation has experienced several renditions of republican governance, which have led up to the establishment in 1958 of the modern French government, the Fifth Republic.

In 16th-century Europe, the ancient Roman theory that cancer was caused by excessive amounts of bile, or humors, circulating in one's system was still commonly held by practicing physicians, while in the 17th-century, European physicians such as the Italian Gaspare Aselli purported that an incidence of cancer was the result of abnormalities within an individual's lymphatic system. During this time, these theories were consequently espoused in France due to the traffic of ideas on the continent. Another common belief in France during this period was that cancer was contagious; in fact, France's first cancer hospital was forced to move from the city of Reims as late as 1779 because the local populace was anxious that the city would be contaminated.

As the nation entered the 18th century, French physicians such as Claude Deshais Gendron (1653–1750) began to reject these theories in favor of a more modern understanding of the disease. Gendron discerned in his research that cancer arose locally in tissues or organs as a thick, developing mass of cells, which he maintained could not be remedied by drugs but only through surgical removal. Furthermore, later in the 18th century, two French scholars created a new field of research in Pierre and Marie Curie in their lab. The Curies were awarded the Nobel Prize for physics in 1903 for their research regarding radioactivity and their discovery of radium and polonium. Soon after, French scientists made the historic observance that consistent doses of radiation over a series of multiple weeks strongly increased an individual's chance for beating cancer. (Wikimedia Commons)
the campaign against cancer: experimental oncology. Jean Astruc, a physician, and Bernard Peyrilhe, a chemist, began to initiate calculated experiments in a concerted attempt to officially affirm or negate particular theories regarding cancer; in their research, they sought to better understand how cancer progressed and how the disease could be more efficiently diagnosed and treated. In a similar vein of research, the French gynecologist Joseph Recamier intensively studied how cancer cells spread through a person's bloodstream in 1839.

Twentieth-century France experienced many important scientific breakthroughs that became extremely relevant in the global battle against cancer. Pierre and Marie Curie were awarded the Nobel Prize for Physics in 1903 for their research in Paris regarding radioactivity and their discovery of radium and polonium. Soon thereafter, French scientists made the historic observance that consistent doses of radiation over a series of multiple weeks strongly increased an individual's chance for beating the cancer.

In contemporary times, France has the highest survival rates for cancer on the continent. Incidences of cancer have been on the decline for the past two decades. In spite of this fact, France unfortunately has one of the highest rates of male cancer incidences in all of Europe. As stated earlier, though, cancer rates have been steadily waning in the country's male and female populations, and many commentators attribute this to the nation's strong health care system, its effective diagnostic services, its advanced treatment capabilities, and vocal public campaigns that warn against the dangers of smoking and alcohol use with regard to cancer. In recent years, a large amount of domestic institutions has been created in an effort to help combat the disease, such as the Institut National du Cancer in 2004 and the Association Laurette Fugain in 2002.

Currently, though, France does not have a national cancer registration program; information from particular domestic departments has been used to help track the most widespread forms of cancer incidence in the country. Regardless of gender, the most prevalent forms of cancer in France are bowel, breast, lung, oral, and prostate cancer. Bowel, lung, and prostate cancers make up more than one-quarter of all cancer incidences in France, while bowel, breast, and lung cancers account for more than half of all cancer incidences in females there. Moreover, within the past 30 years, certain cancers such as bowel cancer, kidney cancer, leukemias, liver cancer, and prostate cancer have seen a nationwide increase in prevalence, while incidences of cervical cancer and lung cancer have been consistently decreasing.

Sadly, and like the rest of the world, many citizens of France have had cancer. Pierre and Marie Curie, as mentioned earlier, are said to have died from the radiation poison that they acquired during their years of research handling radioactive materials. The once-emperor of France, Napoleon Bonaparte, died in exile on the island of Saint Helena from what was believed to be stomach cancer. Laurent Fignon, who was a two-time winner of the Tour de France cyclist, passed away from lung and intestinal cancer in his Parisian home in 2010.

France is world renowned for being home to as many as 20 cancer specialist centers, each staffed with advanced equipment and highly trained staff. For example, Dr. François Pein, who oversees all research undertaken at the Centre René Gauducheau in Nantes, is a leading expert in the battle against cancer in France. Professor Jean-Yves Blay, who is head of the Medical Oncology Department and the Translational Research Pole at the Centre Léon Bérard in Lyon, received the prestigious Hamilton Fairley Award in 2012 for his research regarding translation issues related to cancer.

Fred & Pamela Buffett Cancer Center

Located in Omaha, Nebraska, the Fred & Pamela Buffett Cancer Center serves a vital role in the mission of the University of Nebraska Medical Center. The Fred & Pamela Buffett Cancer Center, formerly the Eppley Cancer Center, conducts cancer research and provides patient care that includes obtaining information from the patient’s tumor to develop and design a specific cancer treatment for each patient based upon his or her human genome information. This personalized approach at the cancer center undergirds and informs clinical research, patient care, and education programs to facilitate the application of new knowledge regarding the etiology, diagnosis, treatment, and prevention of cancer.

The future of the Fred & Pamela Buffett Cancer Center shines brightly. By 2017, a new facility with an estimated investment of $323 million will house the Fred & Pamela Buffett Cancer Center. This is the largest project ever at the University of Nebraska. The cancer center will consist of three components under one roof: a 10-story, 252,000-square-foot research tower with 98 laboratories; a seven-story, 325,000-square-foot, 108-bed hospital tower; and a multidisciplinary ambulatory care clinic. The cancer center’s multidisciplinary, comprehensive, and translational approach to cancer care will allow researchers to accelerate breakthroughs in the laboratory and clinicians to provide personalized care plans for patients. The new facility represents a key strategy in efforts to achieve status as a National Cancer Institute (NCI) Comprehensive Cancer Center, an achievement by only 41 other centers nationwide by 2014. Director of the cancer center, Dr. Ken Cowan, observed, “The Fred & Pamela Buffett Cancer Center will enhance the already excellent research programs by bringing scientists and clinicians together in the same building to share and exchange ideas.”

Internationally recognized scientists and clinicians at the center study the mechanism of action that causes cancer and translates these findings into new approaches for the prevention and treatment of cancer. Their goal is to pursue innovations to eradicate cancer. There are four basic science, clinical, and translational research programs at the cancer center that provide education and collaborative discussion, which generate further study:

1. Cancer Genes and Molecular Regulation Program
2. Molecular Biochemical Etiology Program
3. Gastrointestinal Cancer Program
4. Cancer Prevention and Control Program

The most notable research at the cancer center includes ongoing scientific inquiry and treatment in the areas of lymphoma and bone marrow transplantation, pancreatic cancer, and breast cancer. The cancer center is also a founding member of the National Comprehensive Cancer Network (NCCN). The NCCN is an alliance that develops standards and sets guidelines for the treatment and prevention of cancer. Throughout their history, the NCI-designated cancer centers have contributed to extraordinary advances in the understanding of cancer mechanics as well as prevention, diagnosis, treatment, and care of diverse populations. A formal academic affiliation agreement has also been secured with Children's Hospital, and as a result, pediatric clinical cancer trials are increasing.

The cancer center is designed as a single-use or one-stop facility, which means that patients only have to go to one place and be seen by the entire oncology team (medical, surgical, and radiation oncology) as well a physical therapists, dieticians,
and social workers for their diagnosis, plan of care, and treatment. The inpatient cancer facility is located next to the cancer outpatient center. With 108 inpatient beds, people can go seamlessly from the clinic to the hospital and back. When a patient is tired from rigorous treatment, saving steps can make a big difference. Likewise, the patient care philosophy at the Fred & Pamela Buffett Cancer Center includes helping patients navigate their health journeys by focusing on wellness and disease prevention while maintaining family and professional support through the continuum of care. This is achieved by the following:

- Focusing on families and individuals
- Restructuring primary care services for personalized care
- Population-based health management based on the latest science
- System integration including seamless research and clinical practice
- Cost containment

The goal is to have each patient receive the right care, in the right place, at the right time, with the right quality, and at the right cost.

The cancer center provides leadership and coordinates regional, national, and international relationships and alliances as well as facilitates outreach education and cancer screening programs.

“JAMA Publication Features Study on Depression and Head and Neck Cancer.” http://esciencenews.com/articles/2008/05/21/jama.publication.features.study.depression.and.head.and.neck.cancer (Accessed September 2014)
prevention. In 1988, scientists from the center started working on the understanding of human immunodeficiency virus (HIV), and the research extended to include other infectious diseases. Presently, the Vaccine and Infectious Disease Division at the center is one of the largest HIV research units in the world. It also acts as a center for HIV Vaccine Trials Network, which is a global initiative to fast-track the development and testing of successful HIV vaccines.

Hutchinson Center has more than 200 research groups, laboratories, and project groups in five scientific divisions, occupying the 15-acre Robert W. Day Campus in Seattle, Washington. In addition to the research laboratories, the Fred Hutchinson Cancer Research Center campus houses core facilities, which are operated by the center's shared resources department. These core facilities provide products, services, and equipment, which are shared amongst researchers.

Fred Hutchinson Cancer Research Center houses biological scientists, clinical scientists, and public health scientists working in tandem to apply the fundamental research toward diagnosis and therapy as well as implementing the new knowledge toward the reduction of deaths in the community from cancer and related diseases. The Hutchinson Center has staff and faculty members in excess of 2,700, working toward the elimination of cancer, HIV, and other related diseases.

In 1982, the Cancer Prevention Program was established at the Fred Hutchinson Cancer Research Center and has made substantial contributions to the current understanding of the role of diet, exercise, and other factors that may be associated with the risk of acquiring cancer and related diseases. Scientists at Fred Hutchinson Cancer Research Center work on diverse aspect of the diseases like cancer and HIV/acquired immune deficiency syndrome (AIDS), covering both the fundamental questions related to the disease as well as clinical treatment options. The most basic aspects of the diseases are investigated at a molecular level and are studied parallel with epidemiological and population-based approaches. These multidisciplinary studies help in unravelling the risks associated with all possible factors affecting the person's likelihood of getting cancer.

Research at Fred Hutchinson Cancer Research Center can be classified broadly into five categories, which include basic sciences, prevention, early detection and diagnostics, treatment and cures, and survivorship, studying the long-term physical, psychological, and social effects of cancer and cancer treatment.

Fred Hutchinson Cancer Research Center considers science education is an essential tool to advancing biomedical research. Apart from its involvement in the training and education of researchers, postdoctoral fellows, graduate students, and high-school fellows, the center also provides opportunities for professional development, internships, and opportunities to gain research experience. Community programs and events creating awareness about the progress in the fight against cancer and related diseases are also organized to raise the awareness of the general public on issues related to cancer. These programs also serve as fund-raising events.

Fred Hutchinson Cancer Research Center works in partnership with numerous other American institutions to further the development of novel therapies and provides the highest quality of health care in the world. As an academic, teaching, and research institution, the interinstitutional relationships allow sharing of ideas, information, as well as resources.

Other scientific initiatives of the Hutchinson Center include the Hutchinson Institute for Cancer Outcomes Research (HICOR), working toward the improvement of the effectiveness of cancer prevention, treatments, and therapy and, at the same time, reducing the costs of cancer care. The Hutch Integrated Data Repository and Archive (HIDRA) is a joint effort of the Fred Hutchinson Cancer Research Center and University of Washington Cancer Consortium, with the aim of the creation of a database enabling scientists and physicians to access information and learn from each new patient. This database is expected to enable the integration of knowledge and application for patient care.

The HIV Vaccine Trials Network (HVTN) is the largest publicly funded international collaboration in the world facilitating vaccine development against HIV/AIDS. The network conducts all phases of clinical trials for safety and efficacy. Project Violet involves researchers developing a new class of anticancer compounds, which are specifically engineered to attack cancer cells. The Solid Tumor Translational Research (STTR) is a
collaborative effort of scientists and physicians at the Fred Hutchinson Cancer Research Center, UW Medicine, and Seattle Cancer Care Alliance with the aim of translating bench research to precise treatment options for solid tumor cancers.

In 1998, the Hutchinson Center joined the University of Washington and Seattle Children’s to form the Seattle Cancer Care Alliance (SCCA), which is a leading cancer treatment center in the United States.

SCCA provides clinical care to patients from the three partner organizations and also acts as the contact center for the Cancer Information Service (CIS) of the National Cancer Institute. The CIS is a cancer education program providing accurate, up-to-date, and reliable information on cancer free of cost by trained information specialists to the people in the United States, Puerto Rico, the U.S. Virgin Islands, and the U.S. Associated Pacific Territories.

In the year 2002, the Hutchinson Center and University of Washington Cancer Consortium was formed to accelerate cancer research at the Hutchinson Center, UW, and Seattle Children’s. The consortium together has more than 400 faculty members with research interests across basic, clinical, and public health sciences related to cancer. The consortium strengthens the collaborative efforts toward fighting cancer while maintaining the autonomy of each institute.

Freon

Freon is the trade name for chemicals (chlorofluorocarbons [CFCs]) developed in the United States in the 1920s and 1930s. Freon has many uses and was labeled a miracle compound at the time of its development. Freon’s history includes remarkable stories of science and their playing out in society and nature.

Freon has several uses, and DuPont sold a majority of Freon for industrial applications, but it was more visible as a refrigerant. This is the story of how humans overcame the limiting effects of summer heat. Prior to the availability of technology to keep cool, people had to accommodate to heat by drinking fluids, staying in the shade, and restricting their physical activity. Fresh food could not be stored or shipped, so families depended on their gardens in the country and on peddlers bringing fresh food into city neighborhoods.

Refrigeration developed in stages in the United States. People have known for millennia that evaporation has a cooling effect, so that, for example, water was stored in a porous clay container to keep it cool to drink. The old fashioned name for household cold storage was ice box, even though it was also called a refrigerator. It literally was a storage place kept cool with a block of ice. There were no machines to produce that ice, so it was a product of the frigid winters of northern regions. The technology of ice storage was to cut ice blocks on frozen rivers and lakes and store them in warehouses insulated with sheets of cork. Then the ice man would bring those blocks of ice to the family home on his daily rounds between the warehouse and the neighborhood.

Late in the 19th century, this ice industry would change with the development of refrigeration technology. The machines that cooled the air and its contents made possible many new industries and contributed to the basis for our modern society. Refrigerated railway cars made it possible to ship fresh meat instead of bringing live animals to the neighborhood butcher. Chicago became the hog butcher of the world as the meat packing industry developed. The availability of a central source of animal by-products led to other industries, such as leatherworks. With home refrigerators, people were not dependent on the daily delivery of ice and could even make their own.
The technology of refrigeration was severely limited by one factor: the chemicals used as refrigerants were dangerous. When they leaked into the air and were breathed in, they caused lung injuries and deaths. Some households kept their refrigerators in the backyard for safety, but this was not convenient, safe, or even possible for large commercial installations, nor for apartment dwellers. This problem opened the way for the introduction of an odorless, colorless, nontoxic, and nonflammable chemical to replace the original refrigerants: Freon. Scientist Thomas Midgley Jr. at the Frigidaire division of General Motors, working with the DuPont chemical corporation developed the miracle compound and patented it in 1928. It replaced other refrigerants when put on the market by DuPont.

Within a few years, the Frigidaire Corporation and others had sold 8 million home refrigerators at the height of the Great Depression. A similar widespread adoption of air-conditioning came after the Carrier Engineering Corporation developed the world’s first self-contained home air-conditioning unit in 1932.

Once Freon became available for the everyday use of air-conditioning, it spread from specialized application in theaters to workplaces, then in homes, and eventually in automobiles. Our modern skyscrapers and even low-rise, modern buildings do not have windows that open for fresh air; temperature-controlled ventilation provides it. Windows in these modern buildings are now window walls. Because ventilating air is filtered and monitored, even in private homes, the air inside is healthier than outside “fresh” air. One consequence is that, if the electric power fails, then the occupants in a modern building will have to evacuate; they no longer can open a window. Thus, we see our dependence upon this modern technology; we cannot live our daily lives without it.

Freon led to human control of the enclosed environments of our buildings and autos. It also supported new applications. Among them was the development of the aerosol spray can. This became the second-most common application of Freon, used to spray all matter of substances, from paint and lubricants to cosmetics and cooking spray. Aerosol cans even were developed to spray air. These cans had the effect of releasing Freon directly into the atmosphere. As aging refrigerators and air-conditioners are discarded, their Freon will eventually make its way into the atmosphere as well.

While Freon had made its appearance as a miracle compound, some scientists became concerned that the chemical had unanticipated effects on the environment. The potential risks of adding this new chemical to the atmosphere in large quantities led to its detailed study. Scientists found that a series of reactions between CFCs and ultraviolet rays led to the release of the element chlorine into the stratosphere. Chlorine is rare as a natural component of the atmosphere and would measurably increase from CFC breakdown. Then it would catalyze the reaction that removes ozone (a form of atmospheric oxygen) from the atmosphere. Scientists calculated that one atom of chlorine would result in the loss of 100,000 molecules of ozone.

Ozone has the property of blocking the passage of high-frequency (energetic) ultraviolet sun rays. These rays are damaging to life through their harm to cells’ DNA and are carcinogenic to skin. Early studies indicated that there would be a significant loss of atmospheric ozone of several percent, a thinning of the Earth’s protective layer of ozone from the expected release of Freon. Even though this reduction would take place several decades in the future, it created alarm. So Freon, introduced as a miracle compound that was completely safe and the basis for the modern industry of refrigeration, had now become unsafe and a threat to life on the planet. Chemists and other scientists concluded that the production of Freon should be reduced and protective measures taken. For example, Freon in refrigerant units could be extracted and recycled rather than be allowed to decay until they were leaking from landfills.

Now a billion-dollar industry involving manufacturing, construction, and people’s private comfort, Freon could not simply be eliminated, unless new, safer chemicals could be substituted for the CFC compounds. What was emerging was a conflict that allied environmentalists and advocates for public health against industry and public indifference. This is the same confrontation that has been repeated as hidden risks have been found in various aspects of modern life.

In the developing confrontation, the DuPont Corporation was in a leading position as the largest manufacturer of Freon. It also had an interest in altering the technology based on Freon. There were several factors in play as found by James Maxwell and Forrest Briscoe in their study of these
developments. The DuPont patent on Freon had ended, so other manufacturers were competing with DuPont. The company was oriented toward an environmentally friendly posture and was questioning its potential contribution to an environmental disaster. DuPont chemists already had replacement chemicals for Freon, although they would be more costly. Nonetheless, if the government were to legislate against Freon, then competitors would not be able to undercut DuPont's more expensive substitutes. By selling those substitutes at a higher price and with renewed patent protection, DuPont would be the beneficiary of laws that banned its own best-selling product. Just as Freon had replaced chemicals found to be hazardous to the public, now Freon was to assume the position of the hazard to be replaced.

What would resolve the Freon problem worldwide would be an international agreement to phase out the chemical with effective enforcements against its manufacture and sale. There had been international concern since laboratory studies by Mario J. Molina and F. Sherwood Rowland found in 1974 that CFCs acted under ultraviolet light to break down ozone catalytically. International meetings and discussions continued without a clear outcome.

The potential for accomplishing this goal came with an international meeting over Freon in Montreal in 1987. The prospects for agreement at this meeting were no better than those from earlier international meetings, although progress was made. The same problem that faces public health and environmental protection in general applied to Freon. An apparently necessary product was opposed by scientists, doctors, and environmentalists. The harm that the experts were forecasting was invisible and in the future. The solution would be costly. The public had not been favorable toward the experts when this kind of situation has arisen. People asked, “Why change,” when the danger only existed “in theory.” Opposition challenging the scientific consensus arises and is included in the media as a “debate” even when the scientific results are already known in situations like this.

This opposition did arise in this case, but it was not effective or large enough to stop the Montreal Protocol of 1987 and its implementation. The reason for this came in part from an unexpected scientific finding that changed public opinion. The second reason is the refusal of DuPont to join other chemical manufacturers in opposing the regulations.

This part of the story begins with the scientific study of the weather, leading to satellite images of the ozone layer over the Antarctic. In 1985, those images disclosed the famous ozone hole. Now, the public could see for themselves the effects of Freon. Scientists also were surprised as the effects were revealed to be more extreme than expected from laboratory studies. In subsequent years, the ozone hole and thinning of the ozone layer elsewhere has been continuously monitored by satellite and ground observations.
The outcome was swayed by DuPont representatives lobbying behind the scenes for enactment of the protocol. The unexpected resolution came from several events coming together to forge the agreement: the various scientific discoveries, the dramatic appearance of the ozone hole that swayed the public, the development of viable (although more costly) alternatives to Freon, and the support of the main Freon producer for phasing out its own product. Thus, the Freon example serves as a model for how to gain international agreement on protecting the environment.

Future of Cancer

In 2010, the World Health Organization (WHO) announced that, for the first time on record, cancer deaths exceeded deaths from ischemic heart disease—making cancer the world’s leading cause of death. In 2009, an article in the *Journal of Clinical Oncology* projected that the incidence of cancer in the United States is likely to increase by 45 percent between 2010 and 2030. The study was based on U.S. Census data and specifically census data projecting a higher rate of cancer among elderly residents and people of color alongside a significant increase in both populations, necessitating new public health initiatives to increase the odds of early diagnosis. This increase in cancer cases is likely to be reflected in developing nations as well, where access to care is even less of a guarantee and more often results in death; according to WHO, wealthy nations, the only nations where a full range of treatment options are available to an average citizen, account for only 28 percent of cancer deaths.

In the coming decades, the incidence of cancer is projected to increase in both the industrialized world and the developing world. Alongside this increase will likely come innovations in experimental cancer treatments, new corporate and regulatory environmental interventions, and vaccinations for oncoviruses, leading to a scenario where cancer will become more prevalent even as the tools used to prevent and treat it will become more sophisticated. Placing these tools in the hands of health providers in developing nations, and making them accessible to low-income cancer patients in the industrialized world, is likely to pose a significant public health challenge.

Prevention

The majority of cancer cases are not preventable using any known mechanism. While this situation is unlikely to change within the near future, some forms of cancer can be traced to known, treatable causes. These include oncoviruses, tobacco use, ultraviolet light exposure, and exposure to known environmental carcinogens.

An estimated 12 percent of cancer cases are caused by eight oncoviruses (HIV, HPV, MCV, HLTV-1, Epstein-Barr, Kaposi’s sarcoma, and hepatitis B and C viruses), all of which are potentially subject to future vaccination efforts. Universal vaccination of children against human papillomavirus (HPV) would prevent cervical cancer in more than 99 percent of cases and could, alongside increased screening efforts, functionally eliminate this particular form of cancer, but universal access to the HPV vaccine is unlikely. Its effectiveness is also reduced when used on patients who already have one or more types of HPV, which is a
demographic that includes more than three-quarters of adults.

Tobacco use is gradually declining in most of the industrialized West, but it remains high in eastern Europe, Asia, and north Africa; the world’s largest market for cigarettes is now China, where an estimated 52.9 percent of adult men smoke tobacco in some form (the majority, 45.4 percent, smoke cigarettes). If ozone depletion continues (and it is projected to do so), ultraviolet light exposure will increase and, with it, the rate of skin cancer; this can be mediated by protection, such as sunscreen, which is (like most mitigating interventions) less available to residents in the developing world than it is to residents of the industrialized world.

The discovery of environmental carcinogens is an ongoing process and, presumably, still a science in its infancy. The degree to which future carcinogens will be discovered, and cancers attributable to the same, is difficult to predict.

Treatment
There have been a wide range of experimental cancer treatments that have achieved some measure of documented success. Two of the most innovative categories of experimental cancer treatments are targeted cell treatments (including photodynamic therapy, bioluminescent-activated destruction, and photoactivated peptides) and the engineering of oncolytic viruses, by which viruses are programmed to target cancer cells while leaving healthy cells intact. With respect to the latter category, scientists have achieved some success using modified forms of human immunodeficiency virus (HIV), HPV, the measles viruses, adenovirus, reovirus, the Newcastle virus, and vaccinia.

Scientists at the University of California, Los Angeles (UCLA) have also achieved some success in starving leukemia cells by pharmacologically blocking their nucleotide pathways, a treatment option that may be applicable to other forms of cancer as well.

Advancements in chemotherapy and cancer surgery may ultimately help these traditional forms of cancer treatment continue to outpace experimental cancer treatment options; new classes of chemotherapy drugs have proven more effective than their predecessors at treating specific types of cancer, and health professionals have successfully mitigated the dangerous side effects of chemotherapy in some cases. Laser microsurgery has also proven effective at treating some forms of cancer that have historically proven inoperable. In principle, nanotechnology is likely to become an effective long-term cancer treatment option. In practice, the science behind nanotechnology is still very young, and it may be decades before nanotechnology becomes an effective routine cancer treatment, even in the industrialized world. The prospects of wide-scale application of nanotechnology in the developing world assume a public health apparatus of unprecedented size and scope.

SAGE was founded in 1965 by Sara Miller McCune to support the dissemination of usable knowledge by publishing innovative and high-quality research and teaching content. Today, we publish more than 850 journals, including those of more than 300 learned societies, more than 800 new books per year, and a growing range of library products including archives, data, case studies, reports, and video. SAGE remains majority-owned by our founder, and after Sara’s lifetime will become owned by a charitable trust that secures our continued independence.

Gallbladder Cancer

The biliary tract cancers are composed of gallbladder cancer, intrahepatic cholangiocarcinoma, and extrahepatic cholangiocarcinoma. Gallbladder cancer is the fifth-most common gastrointestinal (GI) malignancy in the United States and is the most common cancer to arise out of the biliary tract, with an estimated U.S. incidence of 10,650 in 2014 and deaths in 3,630 cases (according to the American Cancer Society). Gallbladder cancers behave very aggressively, and most are unresectable or metastatic at the time of diagnosis. Compared to other biliary tract cancers, gallbladder cancer tends to have early metastatic spread, shorter time to recurrence, and shorter median survival.

Risk Factors

The pathogenesis of gallbladder cancers is felt to be related to chronic inflammation, and several risk factors have been identified. Underlying gallstone disease, gallbladder polyps, and chronic infection with *Salmonella typhi* have been implicated in the development of gallbladder cancer. Other identified risk factors include female gender, obesity, and smoking.

Diagnosis and Workup

Gallbladder cancers are most often diagnosed at an advanced stage. The disease can spread rapidly; however, the diagnosis is often delayed due to presenting symptoms similar to those seen with cholecystitis. Symptoms include biliary colic (abdominal pain especially after fatty meals), development of jaundice, and findings of a mass in the gallbladder on imaging.

The initial workup for gallbladder cancer includes imaging of the abdomen and pelvis (generally computed tomography [CT] or magnetic resonance imaging [MRI]), labs to evaluate liver function, and evaluation for metastatic disease (with additional imaging of the chest). Imaging is also used to determine if cancer appears to be resectable. If the patient has jaundice, then additional workup is needed to determine if placement of a stent is necessary to relieve obstruction.

Other relevant labs that are monitored include the tumor markers carcinoembryonic antigen (CEA) and cancer antigen 19-9 (CA 19-9). Higher levels are suggestive of cancer; however, these tumor markers are nonspecific for gallbladder cancer. They can be elevated in other cancer states and also from benign causes such as inflammation.

Staging and Prognosis

The most common histology is adenocarcinoma (65–90 percent), followed by squamous cell or adenosquamous (10–15 percent), or undifferentiated (5 percent). Staging of gallbladder cancer is done using the 2010 American Joint Committee on
Cancer (AJCC) staging system. Staging consists of examination of the depth of invasion, involvement of surrounding lymph nodes, and invasion into surrounding or distant organs. There are four stages in the AJCC staging. Stage I cancers invade into the muscular layer of the gallbladder without nodal involvement. Stage II cancers invade beyond the muscular layer into the perimuscular connective tissue, without nodal involvement. Stage III cancers invade through the serosa (outer layer of the gallbladder) or invade into surrounding adjacent organs or involve adjacent lymph nodes. Stage IV cancers invade into the vasculature, multiple adjacent organs, distant lymph nodes, or distant organs.

Staging of gallbladder cancer is the most important prognostic factor. Staging is also used to determine whether patients can undergo surgical resection. Estimates of five-year survival rates in more than 10,000 patients diagnosed between 1989 and 1996 were 50 percent, 28 percent, 7 to 8 percent, and 2 to 4 percent, respectively, for stage I, II, III, and IV disease. Another poor prognostic factor is involvement of cancer in the liver at the time of presentation.

TREATMENT: RESECTABLE DISEASE
The only curative treatment for gallbladder cancer is surgical resection. Surgical resectability is determined by degree of vascular involvement, penetration into adjacent organs, degree of nodal involvement, and presence of distant metastatic disease. Staging laparoscopy is sometimes used to evaluate for peritoneal disease as occult disease not seen on imaging is common.

Surgical resection should include complete removal of the gallbladder with limited hepatic resection and removal of the adjacent lymph nodes (including the porta hepatitis, gastrohepatic ligament, and retroduodenal lymph nodes). Negative margins are necessary for cure, and further extensive resection of the liver or bile ducts may be required in order to achieve an R0 resection (defined as surgery with negative margins).

Adjuvant chemotherapy following curative resection has not been clearly defined. There are few prospective clinical trials due to the low incidence of gallbladder cancer, and most of the data has been obtained from retrospective analyses, which are limited by small numbers of patients. The National Comprehensive Cancer Network (NCCN) guidelines provide options for adjuvant treatment, including gemcitabine or fluoropyrimidine chemotherapy or use of chemoradiation (except in stage I disease). However, despite use of adjuvant therapy, rates of recurrence can be up to 80 percent in resected patients.

Surveillance after curative resection is recommended given the high likelihood for disease recurrence, even in early-stage disease. This often will include imaging studies, labs, and exams, typically done every six months for the first two years, with further surveillance dependent upon individual patient cancer characteristics.

UNRESECTABLE OR METASTATIC DISEASE
Due to the insidious nature of the disease, most cases are either unresectable or metastatic at time of presentation. In this setting, biopsy is needed to make a pathologic diagnosis. In cases of disease presenting with jaundice, biliary drainage will be required up front before any chemotherapy and can be done with biliary stent placement via endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous drain placement (PTC).

Cytotoxic chemotherapy remains the mainstay for treatment of unresectable or metastatic disease. The combination of chemotherapy with gemcitabine plus cisplatin is considered to be standard first-line treatment, based upon results of the large, randomized, controlled phase III ABC-02 trial. Alternative active chemotherapy options include combinations of gemcitabine with oxaliplatin or capecitabine, capecitabine with cisplatin or oxaliplatin, fluorouracil with cisplatin or oxaliplatin or single agent fluorouracil, capecitabine, and gemcitabine. Response rates are in the range of less than 10 percent in single-agent therapy to up to 40 percent in combination regimens; however, prognosis is poor, with median overall survival of less than one year. Several ongoing clinical trials are being performed to improve the prognosis in advanced and metastatic gallbladder cancer.

CONCLUSION
Gallbladder cancers are aggressive cancers with an overall poor prognosis. Staging workup is necessary to determine if the disease is resectable. The only curative treatment is surgical resection; however, rates of recurrence remain high. The ability to achieve an R0 resection is the most important
prognostic factor in patients undergoing surgical resection. Advanced disease is treated with cytotoxic chemotherapy; however, median overall survival remains less than one year. Ongoing clinical trials are being performed to improve the outcomes of this aggressive cancer.

**Gasoline**

Commonly referred to as gas, petrol, or motor fluid, gasoline is a pale brown or pink liquid produced from refining petroleum that is extracted from beneath the ground.

Petroleum is extracted by drilling a long hole, or well bore, into the earth with an oil rig or apparatus similar to a mobile crane attached to a drilling auger that drives a rotating drill bit through the ground to an identified petroleum reservoir. After the well bore is created, a steel pipe casing is fitted to maintain the structural integrity of the hole, and crude oil is brought to the surface by regulating the pressure and flow with a complex system of valves.

While there are many stages of petroleum recovery, the end product is the extraction and drainage of all petroleum from the reservoir, which is then distributed through a network of pipelines for storage and processing. For automotive gasoline, processing occurs at a refinery where the crude oil is distilled of impurities and the various petrochemical products (gasoline, kerosene, natural gas, etc.) are separated.

In 1859, Edwin Drake dug the first oil well, distilling kerosene for lighting; the other products, for which he had no use, were waste products. The invention of the automobile in 1892 created a need for suitable automotive fueling alternatives to kerosene and coal tar distillates, but these products caused what is called knocking, a phenomenon whereby fuel compression causes spontaneous ignition after spark ignition, rather than spark plug ignition, resulting in the rapid increase in pressure and engine damage. Several additives, including tetraethyl lead, detergents, ethanol, methanol, and lead, were used to improve the octane rating.

From the 1950s through the 1970s, lead was added to improve engine performance and octane ratings in gasoline. As the apparent health problems of lead emerged, the Environmental Protection Agency (EPA) established standards to phase out lead in gasoline through the 1980s, and by 1995, the U.S. Clean Air Amendment of 1990 banned the use of leaded fuel for automotive vehicles.

In recent years, the EPA has attempted to regulate hazardous air pollutants resulting from the
emissions of automotive gasoline by controlling the content of benzene, 1,3-butadiene, acrolein, and formaldehyde.

According to the Monograph Program of the International Agency for Research on Cancer (IARC), an agency of the World Health Organization specializing in global cancer research, five classification categories exist, ranging from carcinogenic to humans (Group 1), probably carcinogenic to humans (Group 2A), possibly carcinogenic to humans (Group 2B), not classifiable as to its carcinogenicity to humans (Group 3), and probably not carcinogenic to humans (Group 4). The U.S. National Toxicology Program (NTP) identifies these agents as known to be carcinogenic or reasonably anticipated to cause cancer. Many chemicals in gasoline fall in Group 1 through Group 2B or have been identified by the NTP as known to be carcinogenic.

The Occupational Safety and Health Administration (OSHA) recognizes both the evaluation of the IARC Group 1 and Group 2A carcinogens and also the list of known and potential carcinogens published in the Annual Report on Carcinogens by the NTP as criteria for regulated carcinogens under the Hazard Communication Standard. OSHA requires all manufacturers of chemicals and mixtures to disclose the potential hazards when handling chemicals and compounds on a Material Safety Data Sheet (MSDS), which would include any information regarding the carcinogenic nature of the material listed as well as allowable limits of exposure and potential health risks posed by exposure.

Gasoline is a mixture of approximately 150 chemicals depending on the manufacturer. According to the MSDS, the mixture of chemicals in gasoline contains at least 15 hazardous chemicals, including (measured as a percent by volume) benzene (5 percent), toluene (35 percent), napthalene (1 percent), trimethylbenzene (7 percent) and methyl tert-butyl ether (MTBE, 18 percent), as well as 1,3-butadiene, 1,2-dibromoethane, and 1,2-dichloroethane and polycyclic aromatic hydrocarbons (PAHs), or hydrocarbons, organic compounds of carbon and hydrogen, the configuration of which consists of aromatic rings, or rings alternating double and single bonds between carbon atoms. Seven PAHs are classified by the EPA as probably human carcinogens.

The most common exposure to gasoline is through inhaling vapors at a service station when refueling or when using equipment that requires gasoline. Attendants at fueling stations, truck drivers, or those who work with gasoline are at risk for breathing excessive vapors and therefore have an increased risk for negative health impacts. According to the Agency for Toxic Substances and Disease Registry (ATSDR), inhaling vapors at 10,000 to 20,000 parts per million (ppm) or swallowing about 12 ounces can cause death. High concentrations of chronic vapor exposure can cause lung damage, stomach lining irritation, and skin irritation, and swallowing large amounts of gasoline can harm the nervous system.

After long-term exposure (two years) to high concentrations of unleaded gasoline vapors, laboratory animals developed liver and kidney tumors, although the ATSDR does not recognize this as sufficient evidence to determine human carcinogenicity resulting from gasoline exposure. The Department of Health and Human Service (DHHS) has not classified automotive gasoline for carcinogenicity, but the link between automotive gasoline and certain cancers is currently under review.

Studies from 1985 and 1993 suggest that there is no or inadequate epidemiological evidence, consistent with the findings of the IARC that no link between kidney cancer and occupational exposure to gasoline for refinery workers exists.

Benzene naturally occurs in crude oil and gasoline and is a by-product of automotive exhaust; it has industrial uses in oil refineries, chemical plants, and the manufacturing of lubricants, dyes, detergents, drugs, pesticides, and cigarettes. Studies show that lab rodents exposed to benzene developed different types of tumors, supporting the risk of leukemia in humans. The IARC determined that long-term exposure to high levels of benzene may increase the risk of leukemia.

A 2000 study suggested a link between male breast cancer with gasoline and gasoline combustion exposure, concluding that occupational exposure to gasoline vapors may play a role in the increased risk of breast cancer due to benzene, 1,3-butadiene, 1,2-dibromoethane, 1,2-dichloroethane, and PAHs.

Benzene was classified as a known carcinogen by the IARC based on evidence that shows workers exposed to high levels of benzene are found to be at a great risk of acute myeloid leukemia and some
studies suggesting links between benzene exposure and childhood leukemia, acute lymphocytic leukemia, chronic lymphocytic leukemia, non-Hodgkin’s lymphoma, and multiple myeloma (adults).

The IARC designation is supported by the NTP classification of benzene as known to be a human carcinogen, and by the 2007 EPA listing of benzene as a known human carcinogen in the Integrated Risk Information System (IRIS), an electronic database cataloging the human health impacts of environmental exposure to various hazardous substances.

OSHA maintains a recommended exposure limit (REL) to one ppm during an eight-hour workday and a maximum REL of five ppm over a 15-minute period. OSHA also requires employers to provide personal protective equipment (PPE) to workers at risk of exposure, which may include respirators and gloves. The IARC also identifies ethylbenzene, styrene, naphthalene, gasoline, and gasoline engine exhaust as possibly carcinogenic Group 2B materials based on studies in laboratory rodents.

At the 2013 International Scientific Symposium from the IARC, Kurt Straif, M.D., M.P.H., Ph.D., presented the findings of the IARC, citing the difficulty of separating diesel and gasoline exhaust, leading to inadequate evidence to determine carcinogenicity of gasoline engine exhaust. The Working Group, 24 experts from seven different countries, found sufficient evidence through animal experimentation such that they designated gasoline engine exhaust as possibly carcinogenic to humans (Group 2B), publishing their findings in 2012 in The Lancet.

Gene Therapy

Gene therapy is the use of DNA as a disease treatment, one that is administered by delivering DNA to a patient's cells. Typically, healthy, functional DNA is delivered in order to replace a mutated or damaged gene, but there are more complex therapies that use DNA to encode a protein drug that provides treatment. Gene therapy is also used to assist the immune system in recognizing a threat; in cancer patients, because the tumor is composed of the host's own mutated tissue, the immune system is little help against it when left to its own devices. In cancer treatments, the greatest successes with gene therapy have been in treating leukemias and blood cancers.

Gene therapy was conceptualized in 1972, and the first gene therapy clinical trial was approved 18 years later. At the time, gene therapy was seen principally as a potential remedy for hereditary diseases, not cancer (except insofar as several hereditary conditions predispose the patient to cancer). However, gene therapy throughout the 1990s saw few successes, and the field's current growth and confidence dates back only to the mid-2000s, when clinical successes began to flourish in the gene therapy treatment of leukemias, Parkinson's disease, and hemophilia. As of 2014, more than 2,000 clinical trials had been conducted or approved in the gene therapy field. The first gene therapy treatment approved for prescription in the West, alipogene tiparvovec, was approved by the European Medicines Agency in 2012 and was introduced commercially in 2014 under the trade name Glybera.

At $1.6 million for a course of treatment, it is the most expensive medicine in the world. While out of reach for most cancer patients for the moment, recent breakthroughs in clinical trials indicate that gene therapy in the future will join surgery, chemotherapy, immunotherapy, and radiotherapy as a standard oncology therapy. It will be especially welcome for cancer patients who, for one reason or another, are poor candidates for the other standard treatments. In 2014, for instance, Forbes reported on a young girl whose acute lymphoblastic leukemia recurred twice after chemotherapy until a gene therapy treatment using a modified human immunodeficiency virus (HIV) virus; she nearly died from the fever caused by her immune system attacking both the virus and her cancer, but within two weeks, she was cancer free and, for the first time, remained so.

Cancer did not originally seem like a candidate for gene therapy as, in most cases, it results not from the expression of a specific gene but following a complex multistep process in which a variety of somatic genes are altered. Gene therapy seemed not only ineffective in correcting this but too cumbersome because, at first blush, it might appear necessary to correct each of those alterations—not all of which are even known or understood yet—and to restore the original gene function to each cancer cell. Despite these initial and reasonable doubts, as the science of gene therapy matured, cancer turned out to be an ideal subject for it. Treatment strategies augment standard treatments by restoring normal DNA or expressing important proteins rather than rebuilding all of the cancerous cells. (In this sense, though, modern gene therapy as a cancer treatment does differ from the classical conception of gene therapy in that it is not gene-replacement therapy but rather gene therapeutics.)

The first gene therapy approved for use in humans was Gendicine, approved in China to treat head and neck cancers in 2010. Not yet approved in the West—and in order to encourage medical tourism, the Chinese manufacturer Shenzhen SiBiono GeneTech may not be motivated to seek approval overseas—Gendicine uses a recombinant adenovirus as a vector for a treatment for patients with mutated p53 genes. It is administered in conjunction with chemo- and radiotherapy, especially for patients who are resistant to one or both.

Gene therapy is a subset of biologic therapy, which uses biological substances to treat disease. Like other biologics, gene therapies can be either autologous—using the patient's own tissue, which is extracted, modified in the lab, and then returned—or allogenic, using donor tissue. While gene therapy shows promise in treating many different types of diseases, it especially makes sense as a treatment for cancer—the propagation of mutated cells—and hereditary diseases. Cancer treatment strategies using gene therapy include the augmentation of chemotherapy and immunotherapy treatments, such as through drug sensitization with genes for prodrug delivery, the delivery of drug-resistant genes to protect bone marrow during high-dosage chemotherapy, gene replacement for tumor suppressor genes, inactivation of oncogene expression,
and ex vivo and in vivo cytokine gene transfer. Though gene therapy initially focused on delivering a gene that would cause a particular protein to be expressed, a better understanding of nucleases—enzymes in the body—has led to gene therapies that deliver DNA that encodes nucleases into chromosomes. The nucleases then edit the chromosomes and disrupt disease-causing genes.

One of the uses of gene therapy is to deactivate oncogenes. Oncogenes are specific genes that contribute to cancer. Once activated, they cause the cells normally programmed for rapid cell death to survive instead, resulting in cancer’s proliferation. Oncogenes alone rarely cause cancer but are critical to its spread and survival once it has developed. Different oncogenes are associated with different types of cancer. Gene therapy can be used to deactivate these oncogenes or reduce or block their expression. Similarly, gene therapy can be used to restore tumor suppression genes—genes in the body that protect from cancer by preventing cellular mutations, which leave the body vulnerable to cancer when they are themselves mutated. Using gene therapy to replace the mutated tumor suppressor genes with functional healthy tumor suppressor genes is a common strategy.

Gene therapy can also be used to affect the efficacy of chemotherapy and other cancer drugs. Delivering drug-resistant genes to bone marrow or blood-derived stem cells, for instance, helps them survive radiation treatment, which reduces the complications and chances of infection that are attendant to radiotherapy. Drug-sensitivity genes can be delivered in order to enhance the effectiveness of anticancer drugs.

The vector is the package in which DNA is delivered to the patient. Vector development is an important area of gene therapy research, and key areas of study include methods to increase the transduction efficiency of nonviral vectors, identifying the synergy between gene therapies and other therapeutics, vector targeting, and specificity and reducing the toxicity and immunogenicity of viral vectors.

Viral vectors may come from either of the two main types of viruses, lytic and lysogenic. Lytic viruses produce more viruses quickly, spreading infection rapidly. Lysogenic viruses, on the other hand, may remain in the body for years before spreading infection in response to a chemical trigger. Viral vectors are generally safe, the virus having been modified in order to prevent it from replicating. Some viruses pose a stability problem, though, being genetically unstable and capable of rearranging their genomes.

Viral vectors using retroviruses are most subject to the problem of missing the target by inserting the genetic material into the wrong part of a chromosome, which can result in cancer if the disrupted gene happens to regulate cell division. This is the problem that caused a small number of patients in both French and British clinical trials treating X-linked, severe, combined immunodeficiency to develop leukemia, which halted a similar American trial.

Perhaps the greatest drawback to a viral vector, assuming nothing goes wrong, is that it can be used only once on a given patient. There is a limited number of viral vectors to choose from, and once the patient has been exposed to one, he or she develops an immune response that will result in the immune system attacking it if it is used again. If the gene therapy works the first time, this is fine, but many cancer therapies presuppose the possibility of being needed more than once.

Vectors need to be nontoxic in order to avoid side effects as well as destruction by the body’s immune system. Viral vectors have been used traditionally. Viruses like retrovirus, adenovirus, herpes simplex virus, pox virus, and adeno-associated virus can be modified in the lab in order to remove their toxic effects (i.e., using a modified herpes virus to deliver
a gene therapy does not infect the patient with herpes). Viruses have naturally evolved with the ability to transfer their genetic materials to host cells. Indeed, this is the source of cancer in several cases, including liver cancer, cervical cancer, and most Merkel cell carcinomas. Nonviral vectors, though, offer the promise of greater safety. Most are cationic (meaning that, at the molecular level, they possess an active ion with a positive charge), including cationic peptides, cationic liposomes, and cationic polymers like polyethylenimine and poly L-lysine. Cationic lipids, for instance, can condense negatively charged DNA in order to encapsulate it into liposomes for delivery.

The introduction of nucleic acids into cells is called transfection, as opposed to transduction, which is the use of a viral vector to introduce DNA. The simplest form of transfection is an intramuscular injection of naked DNA. In clinical trials, expression as a result of naked DNA injection has been very low, and various methods have been developed to improve on the results. Electroporation, for instance, uses short pulses of high-voltage electricity to transfect DNA across the cell membrane to its target. Electroporation has a high rate of cell death, which makes it inappropriate for some applications. Sonoporation uses ultrasonic bursts instead, which disrupt the cell membrane through acoustic cavitation. Magnetofection, as the name implies, uses magnetic particles to bring DNA into contact with the target cell. And the so-called gene gun uses DNA coated in gold particles with which the target cell is bombarded in a process that leaves the gold behind.

Some studies have used inorganic nanoparticles, such as gold, silica, or calcium phosphates, for gene delivery. Inorganic vectors have a significantly cheaper manufacturing cost (in both materials cost and time), are resistant to microbial attack, and have a low immunogenicity. Quantum dots also have been used. Some hybrid methods of delivery have tried to address the shortcomings of individual methods, such as combining liposomes with a virus to create a virosome that is more efficient at gene transfer than either a viral or liposomal vector.

Laypeople are sometimes confused by the term gene therapy. It does not necessarily involve changing anything about the individual that will be passed on to his or her subsequent offspring through heredity—nor does any treatment used on humans do so, at least not yet. Gene therapy is either somatic or germ line. Somatic gene therapy transfers the therapy to the somatic cells (nonsenes) of the body, and any modifications to the patient’s DNA are limited only to that individual—the DNA encoded in any sex cells (sperm or eggs) remains the same. All gene therapies performed on humans so far have been somatic gene therapy.

However, somatic gene therapy has limitations. No one has yet developed a therapy that replaces multiple genes, for instance, such as the genes that interact in order to cause heart disease, arthritis, diabetes, or Alzheimer’s disease. Germ-line gene therapy could do so. In germ-line gene therapy, which has been performed only on animals, it is the genes of germ cells (sperm or eggs) that are modified in order to correct a genetic disease and prevent it from being expressed by any offspring conceived by those germ cells. Despite the United States’ conservative stance on many forms of medical research, there is actually no legislation preventing this or preventing federal funding for it—federal legislation does not address the difference between somatic and germ-line gene therapy at all, unlike the legislation of several European countries, Canada, and Australia, which ban germ-line therapy for humans. That said, there is as yet no clinical work being done in this area, but a long and justified history of fear of eugenics.

Until the 2000s, most gene therapy had focused on hereditary diseases. In 2006, two significant breakthroughs helped usher in the current age of gene therapy. In May, an Italian team at the San Raffaele Telethon Institute for Gene Therapy overcame the immune rejection problem—whereby the immune system rejects the vector virus or the newly delivered gene—by using microRNA to selectively turn off the identity of the therapeutic gene. In August, a National Institute of Health team in Bethesda, Maryland, treated metastatic melanoma in two patients in one of the first successful uses of gene therapy as a cancer treatment. Five years later, two of three patients in a pilot study were cured of their chronic lymphocytic leukemia by University of Pennsylvania researchers using genetically modified T-cells. The subsequent larger study saw 26 out of 59 patients achieve complete remission. Exciting advances and successes continued to be seen in gene therapy in general.
and gene therapy as a cancer treatment specifically throughout the 2010s.

In the United States, there is no specific gene therapy protocol, but gene therapies are subject to relevant legislation and regulations pertaining to investigational new drug applications, the use of human test subjects, and so on. The National Institute of Health provides additional oversight for federally funded gene therapy research, including a mandatory registry of human genetic engineering research protocols from federally funded projects and a set of guidelines for good practices in the manipulations of genes, prepared by an advisory committee.

Gene therapy poses a number of risks. The immune system may attack a viral vector, which can result not only in failure of the attempted therapy but also in inflammation and other side effects, even including organ failure. In a patient already suffering from the effects of cancer and possibly of other cancer treatments, these side effects can be significant. Virus vectors also may infect the wrong cells, which can lead to effects ranging from mild illness to the growth of a new cancer. Viruses also can recover their original toxicity once in the body. Further, in clinical trials, genes delivered to the wrong part of the DNA have mutated the target gene and created a new tumor instead of helping to eliminate the existing tumor.

Furthermore, three patients have died in gene therapy trials, at least one as a direct result of his trial. (Jesse Gelsinger died in 1999 of organ failure and brain death caused by a massive immune response to the viral vector used in his therapy.)

Closely related to gene therapy is RNA interference as a cancer therapy. RNA interference is the process by which RNA molecules inhibit gene expression, often by destroying specific mRNA molecules. It is a process only recently understood, long thought to consist of several unrelated processes. RNA interference can silence the genes involved in a tumor’s cell division in order to stop its growth or genes implicated in the spread or origin of the cancer. Like gene therapy, RNA interference therapy has relied primarily on viral vectors but is looking further afield. The frequency or result of off-target effects is not yet fully understood, though in one major study of RNA interference to treat liver disease in mice, the death rate from off-target effects was unexpectedly high.

Initial tests suggest that, assuming off-target effects and similar problems are resolved methodologically, RNA interference has great potential as a breast cancer therapy because it has been shown to be effective in targeting the receptors associated with breast cancer proliferation. It also has shown potential in treating chronic myelogenous leukemia and colon adenocarcinoma.

Herper, Matthew. “Is This How We’ll Cure Cancer?” Forbes (May 26, 2014).
Genentech is a biotechnology company that was founded in April 1976 and is headquartered in San Francisco, California. Genentech was founded by Robert A. Swanson and Dr. Herbert Boyer. The company is considered to be the first biotechnology company and, since its inception, has focused on the discovery of drugs that address significant, unmet medical needs. Genentech has multiple products on the market for serious or life-threatening medical conditions, and the organization focuses on basic and applied research in the areas of oncology, immunology, neuroscience, metabolism, and infectious disease. In March 2009, the Roche group acquired Genentech; Genentech now serves as the headquarters for Roche pharmaceutical operations in the United States. Genentech has a number of drugs that are designed to address the needs of cancer patients, including individuals suffering from breast cancer and non-Hodgkin's lymphoma (NHL).

History of Genentech

The idea for the company began in 1973, when Dr. Boyer and a colleague, Stanley Norman Cohen, found that genes from bacteria could be combined with genes from eukaryotes—recombinant DNA. Boyer and Cohen’s discovery opened the door to a new scientific field called recombinant DNA technology. Boyer went on to partner with Robert A. Swanson, a graduate of the Sloan School of Management at the Massachusetts Institute of Technology, and the two left their jobs in order to found Genentech. The duo then formed a partnership with Kleinman, Perkins, Caufield, and Byers, a high-tech venture capital firm also located in the San Francisco area. The group contracted with the City of Hope National Medical Center to conduct their early biomedical research using recombinant DNA.

Genentech pioneered the organizational model that most biotechnology firms would eventually use to grow their businesses: First, create a startup to capitalize on publically funded discoveries that were made by scientists at academic institutions; next, locate venture capital or government funding to develop and test biomedical applications of the research; last, license the rights of the research to a larger pharmaceutical company for the production, marketing, and distribution of the product. In 1977, Genentech used recombinant DNA to produce the first human protein, somatostatin, and one year later, in 1978, it was used in the first genetically engineered, synthetic “human” insulin. By 1982, Genentech partnered with Eli Lilly and Company to become the first biotechnology company to launch a commercial product, biosynthetic human insulin, marketed as Humulin. Today, most of the insulin used throughout the world is a form of biosynthetic recombinant human insulin. Since conception, Genzyme has developed and marketed many other successful biomedical pharmaceuticals, including therapies for breast cancer, colon cancer, lung cancer, non-Hodgkin’s lymphoma, age-related macular degeneration, rheumatoid arthritis, lung cancer, non-Hodgkin’s lymphoma, psoriasis, cystic fibrosis, heart attack, stroke, and growth hormone deficiency.

Genentech Today

Since 1990, the Swiss company Roche has owned a majority of Genentech, and in 2009, the company acquired full ownership of Genentech for $46.8 billion. Roche markets medicines and diagnostic tests in more than 150 countries worldwide. The United States accounts for approximately 42 percent of Roche’s pharmaceutical sales; during 2013, Roche had approximately $18.299 million (CHF 17.428 million) in net sales in the United States, which was a 9 percent increase in sales from 2012.

Genentech’s original manufacturing facility was located in South San Francisco, California; however, as demand for Genentech’s expanding product line grew, the company acquired an additional manufacturing facility at a 100-acre site in Vacaville, California. Genentech also has manufacturing and supply facilities in Hillsboro, Oregon, and Singapore. In 2014, Genentech had 35 drugs available on the market with approximately 19 products in the research and development (R&D) pipeline. In 2013, Roche spent about $9.000 million (CHF 8.700 million) in R&D. Genentech employs nearly 13,300 individuals from around the world and is consistently named by Fortune Magazine as one of the 100 best companies to work for.

Controversy

In 1999, Genentech agreed to pay $200 million to the University of California San Francisco (UCSF) to settle a nine-year dispute over a patent
underlying the drug Protropin, a growth hormone used to treat dwarfism. UCSF claimed that Genentech scientists had taken a DNA sample from a lab at the university in 1978 and then used the specimen to develop Protropin; by the end of the 1990s, the drug had generated almost $2 billion in sales. The university asked for $400 million in lost royalties from the theft and other damages. Genentech claimed they had developed the drug independently from UCSF; however, a jury ruled that the university’s patent on the drug was valid but could not determine if Protropin was definitively based on UCSF research. Genentech settled the lawsuit with UCSF, but the controversy left a legal blemish on Genentech’s record.

**Oncology**

Roche is the world’s leading provider of cancer drugs, and about 62 percent of all pharmaceutical sales for Roche derive from the oncology department. Currently, Genentech is focused on several projects related to the understanding and treatment of cancer, including better understanding of complex signaling pathways and critical aspects of the cell cycle, metabolic regulators, the immune response to cancer, and cancer stem cell research. Rituxan is the company’s top-performing oncology drug, and today it has become the standard of care for NHLs and chronic lymphocytic leukemia (CLL). The drug has been used to treat nearly 3 million cancer patients, and in 2013, Genentech received FDA approval for an additional drug, Gazyva, to work with Rituxan to improve cancer treatments. In 2013, Rituxan had $7.298 million in net sales (CHF 6.951 million) and was responsible for 19 percent of all pharmaceutical sales for Roche.

Herceptin is a drug used in metastatic breast cancer patients with tumors that overexpress the HER2 gene. The drug gained FDA approval in 1998 and has subsequently been a key treatment for many breast cancer patients. In 2013, the drug accounted for 16 percent of all Roche pharmaceutical sales and generated $6.383 million in net sales (CHF 6.079 million). Genentech also markets many other key oncology drugs, including Avastin for the treatment of metastatic colorectal cancer, Tarceva for patients with small cell lung and pancreatic cancer, and Erivedge, which is used to treat advanced basal-cell carcinoma. Genentech currently has several additional oncology drugs that are in the R&D pipeline, with several that will undergo the FDA approval process throughout 2014 and 2015.

**Further Readings**

**Genetics**

Genetics involves the science of trait inheritance from parents to progeny, including the hereditary and evolutionary similarities and differences of related organisms, as produced by the interaction of the genes. It pertains to the origins or development of inherited features and characteristics of an organism or group or type of organisms. Because genes are ecumenical to living organisms, genetics is, therefore, applicable to the study of all living systems, including animals, humans, bacteria, and plants. Genetics acts in conjunction with an organism’s environment and experiences to impact development and behavior. Genes principally signify their functional effect through the production of proteins, which are complex molecules responsible for most of the functions in the cell.

Abundant studies that have been devoted to the genetics of human cancer predisposition have supported indications of inheritance as a component of the etiology. Also, sufficient research efforts have been invested in the understanding of the etiology of cancer and of the interaction of genetic and environmental factors that are involved in the disease development. Genes are found in every cell of the human body and control each cell function by
making proteins that have specific functions and act as messengers for the cell.

Changes in genes, referred to as mutations, which occur during a person’s life, either inherited from father and mother or from damage, may contribute to the growth and development of cancer. Cancers commonly begin when one or more genes in a cell are mutated (changed), consequently creating an abnormal protein or no protein at all. It is estimated that there are about 30,000 different genes in each cell, controlling how each cell functions, how quickly it grows, how frequently it divides, and how long it lives. The human body consists of more than a trillion cells, organized into organs, such as the lungs, and organ systems, such as the respiratory system.

Although cancer is prevalently caused by multiple mutations to several different genes, many of the genes that contribute to the development of cancer fall into broad categories. Chromosomes are made up of genes. Humans each have between 20,000 and 25,000 different genes. Genes are composed of deoxyribonucleic acid (DNA), located on 46 chromosomes, which are arranged in pairs. The DNA is created from four chemical compounds known as adenine (A), thymine (T), guanine (G), and cytosine (C). Humans have two sets of 23 chromosomes, one set of which they inherit from their mother and the other from their father. The first 22 chromosome pairs are numbered (chromosome 1, 2, 3, etc.). These chromosomes determine people’s physical features and are called autosomes. The chromosomes of the twenty-third pair, which are referred to as the sex chromosomes, determine whether a person is female or male. These are called the X and Y chromosomes. A human female inherits two copies of the X chromosome, one from each of the parents, constituting an XX pair, while a human male inherits one copy of the X chromosome from the mother and one copy of the Y chromosome from the father, constituting an XY pair.

Cancer can occur in three primary paths: sporadic cancers, familial cancers, and hereditary cancers. Approximately 60 percent of cancers are sporadic. Sporadic cancers occur by chance or occur from environmental exposures, usually over many years, in persons who have no known genetic risk factors and no cancer-relevant family history. Although familial cancers have a tendency to cluster in families, they also tend not to follow the typical rules of inheritance. Commonly, familial cancers are caused by variants in multiple genes working together with environmental factors. A person’s risk of developing cancer is contingent on the number of cancer risk genetic variants that the individual inherits and the environmental factors that come into interaction with those genes. Hereditary cancers are caused in part by gene changes that are passed on from parents to their children. Although not everyone who is born with a gene change will eventually develop cancer, people with inherited gene changes have a 50 percent chance of passing the mutation to each of their offspring. Other blood relatives may share these same gene changes as well. Those individuals who have inherited a gene change may be at a higher risk for developing more than one type of cancer.

In cancer research, the dictation of certain types of genes that contribute to cancer has been an important development in recent times. More than 90 percent of cancers are observed to have some type of genetic alteration. While some of these alterations are inherited, others are sporadic. Two basic types of genetic mutations are acquired and
Germline. The most common types of cancers result from acquired mutations that occur from damage to genes during an individual's life and are not passed from parent to child. These kinds of mutations may result from tobacco use, exposure to ultraviolet (UV) radiation, viruses, and aging factors. On the other hand, cancer caused by germline mutations is referred to as inherited cancer, which makes up approximately 5 to 10 percent of all cancers.

Genetic cancer research has identified three main types of genes that can affect cell accretion and are altered, that is, mutated, in certain types of cancers as oncogenes, tumor suppressor genes, and mismatch-repair genes. Oncogenes are involved in the regulation of the normal growth of cells and can turn a healthy cell into a cancerous cell. Common oncogenes include a specialized protein that controls cancer growth and spread, referred to as HER2, found on some cancer cells, such as breast and ovarian cancer cells, and the RAS family of genes, which make proteins involved in cell communication pathways, cell growth, and cell demise. Genetic cancer scientists usually describe oncogenes to be like a cancer switch that exists in most people's bodies. For some unknown reason, the switch flips to cause these oncogenes to impetuously become unable to control the normal growth cells and allowing abnormal cancer cells to begin to grow.

Tumor-suppressor genes are protective genes. These genes have the capacity to acknowledge abnormal growth and reproduction of damaged cells, or cancer cells, and can interrupt their reproduction until the defect is corrected. Examples of tumor suppressor genes are BRCA1, BRCA2, and p53. Germline mutations in BRCA1 or BRCA2 elevate a woman's risk of developing hereditary breast or ovarian cancers. The most habitually mutated gene in individuals who have cancer is p53, with more than 50 percent of all cancer involving a missing or damaged p53 gene. Mismatch-repair genes are viewed as DNA repair genes that fix mistakes made when DNA is replicated (copied). These genes help in identifying errors when DNA is replicated to produce a new cell. In the event that the DNA does not consummately match, these genes repair the mismatch and correct the error. These genes must be working properly because any errors in DNA can be transmitted to new cells, causing them to become damaged. The number of cells in the human body tissues is tightly regulated so that new cells are made for normal growth and development in addition to replacing dying cells.

Cancer is often referred to as a disease of cells and as a disease of uncontrollable cell proliferation. A cluster of cancer cells in the body is referred to as a tumor. It is also known that not all tumors are cancerous. Tumors are often categorized as benign or malignant. Although benign tumors normally do not threaten the patient's life, benign tumors that develop in the brain can cause grave health effects or even death because of the brain's location within the skull. Furthermore, as the swelling involved in the benign tumor expands, the brain can be damaged because it has nowhere to go to get out of the way of the growth within the skull. Malignant tumors often metastasize to other organs of the body. Metastasis is the spread of cancer to other locations in the body, and the symptoms are dependent on the location of the tumor, which can include enlarged lymph nodes. These symptoms can also be felt or sometimes seen under the skin and are a particularly hard, enlarged liver or enlarged spleen, which can be felt in the abdomen region, pain or fracture of affected bones, and neurological symptoms. Malignant cancer or tumors are serious and will commonly lead to death if not treated promptly. The chances of surviving the disease vary significantly by the types and locations of the cancer and the extent of the disease at the beginning of treatment.

The causes of cancer are diverse, complex, and only partially understood, just as there are so many different cancers that affect humans. There are more than 200 different types of cancers. Cancer can be detected in a number of ways, including recognizing the presence of certain symptoms and signs, screening tests, or imaging. Although cancer symptoms and signs do not commonly appear when the cancer begins, they do appear as the mass continues to grow or ulcerates. Cancer commonly is treated with chemotherapy, radiation therapy, and surgery. Accumulation of genetic information provides resources for identifying those persons who have an increased risk of cancer. Genetic information generation sources include samples of biologic DNA, information gathered from a person's family disease history, diagnostic results from physical examinations, and medical records of the individual and his or her relatives. With conclusive information that indicates that a person is at
increased risk of developing cancer, intervention initiatives can be activated with life-saving management implications that may lead to specific treatment methodologies aimed at ameliorating risk. Such action plans may include tamoxifen for breast cancer, colonoscopy for colon cancer, or risk-reducing Salpingo-oophorectomy for ovarian cancer. Information regarding a person’s genetic predisposition to cancer may also provide a direct health advantage by establishing the absence of an inherited cancer susceptibility. Furthermore, the cognizance of a cancer-predisposing mutation can be informative data for other family members, not only for the individual tested. Genetic information may also provide direction that affects medical and lifestyle decisions.

Genzyme (United States)

Genzyme Corporation is an American biotechnology company headquartered in Cambridge, Massachusetts. The company was founded by George M. Whitesides, Sheridan Snyder, and Henry Blair in 1981 and was originally focused on the discovery of drugs for use with lysosomal storage disorders (LSDs) but today has expanded to other disease areas including renal disease, a range of genetic disorders, cancer, and multiple sclerosis (MS). Genzyme is one of the world’s largest biotechnology companies and employs more than 12,000 people in 40 countries. In 2011, the company was acquired by Sanofi and is a fully owned subsidiary of the organization.

Initially, Genzyme was a small partnership; however, using provisions of the Orphan Drug Act, Genzyme gained exclusive rights to the National Institute of Health (NIH)–discovered replacement enzyme for glucocerebrosidase. In 1991, Ceredase became the first orphan drug developed by Genzyme and Food and Drug Administration (FDA) approved as a replacement therapy for people with Type-1 Gaucher disease. Individuals afflicted by Gaucher disease lack the glucocerebrosidase enzyme, which is responsible for the breakdown of the fat molecule glucocerebroside. Cerezyme replaced Ceredase in 1994 as a treatment for Gaucher disease, and the drug continues to contribute approximately one-third of Genzyme’s annual net sales. Since 1985, Genzyme has branched out into other areas of research, and today, the company runs two business units—MS and rare diseases (RD). The RD unit is focused on LSDs, rare forms of cancer, renal diseases, and genetic cardiovascular diseases known as familial hypercholesterolemia (FH).

In 2013, Genzyme reported $2.944 million net sales (2.142 million euros), a 25.9 percent increase in annual net sales from the previous year. Currently, Genzyme is actively marketing more than eight drugs that have been approved by the FDA and at least eight drugs currently in the Genzyme Research and Development (R&D) pipeline. During 2013, Genzyme invested approximately $580 million (415 million euros) in R&D. Genzyme operates four flagship offices located in Cambridge, Massachusetts; Framingham, Massachusetts; Geel, Belgium; and Waterford, Ireland, with other key operational facilities located at sites around the world that are located near centers of scientific innovation.

Sanofi acquired Genzyme in 2011 for approximately $20.1 billion. The acquisition was an opportunity for Sanofi to grow its specific expertise in rare diseases and also offered the company a presence in
the biotechnology sector. In 2004, Sanofi-Synthé-labo merged with Aventis to become the world’s fifth-largest pharmaceutical company with headquarters located in Paris, France. The company primarily engages in the R&D, manufacturing, and marketing of pharmaceutical drugs available in the prescription market; however, the organization also develops over-the-counter medications. Following the merger, the company officially changed its name to Sanofi in May 2011. The company focuses on seven key areas of medicine: cardiovascular disease, neurology, diabetes, internal medicine, oncology, thrombosis, and vaccines. Today, Genzyme is led by CEO and Chairman of Sanofi Christopher A. Viebacher and David Meeker, M.D., the president and CEO of Genzyme.

**Orphan Drug Act**

In 1983, the U.S. Congress passed the Orphan Drug Act, which designated orphan drugs, vaccines, and other diagnostic agents as those intended to treat rare diseases. Rare diseases are defined as diseases affecting fewer than 200,000 American citizens. The Orphan Drug Act incentivized companies to develop drugs for orphan diseases by providing seven years’ market exclusivity to developers of drugs for rare diseases and tax credits equal to half of the cost of development. At the time when the Orphan Drug Act was passed, Genzyme had already developed a strategy of thinking small, making the company primed to take advantage of the incentives included in the Orphan Drug Act. The opportunity to hold the sole marketing rights of its drugs for seven years made Genzyme an attractive company for many investors. In 1986, Genzyme went public and raised $27 million from investors who saw a valuable opportunity to invest in the company’s orphan drugs for rare diseases.

Since going public, Genzyme’s enzyme replacement therapies for LSDs, including Gaucher disease, remain the company’s biggest source of profit. Correspondingly, the company remains focused on orphan drugs; however, Genzyme has expanded the types of diseases it treats. Other biotechnology companies are trying to re-create the business model that Genzyme perfected, exclusively focusing on rare diseases, even at the expense of a more diversified portfolio. By focusing on small patient populations, the company receives steep reimbursement rates; this demonstrates that leveraging enzyme replacement therapies across multiple rare diseases can be profitable. Genzyme continues to grow through purchases of other companies and has developed and is selling medications for many other areas of medicine. In January 2014, Genzyme announced that it would invest $700 million in Alnylam Pharmaceuticals, a U.S. biotechnology company that develops RNAi therapies.

**Oncology Drugs**

Over the past three decades, health care providers have observed a steady increase in the incidence of thyroid cancer. In order to manage thyroid cancer, oncologists often rely on thyroidectomies or surgeries that partially or completely remove the thyroid gland from the affected individual. Thyroidectomies are often followed by radiiodine ablation and thyroxine therapy. Genzyme’s most successful oncology drug is Thyrogen (thyrotropin alfa for injection), a synthetic product that is similar to the naturally occurring human thyroid-stimulating hormone (TSH) and was developed as an alternative treatment for thyroxin therapy in thyroid cancer patients.

Individuals diagnosed with thyroid cancer and planning to undergo surgery to remove all or part of the thyroid gland may be prescribed Thyrogen prior to surgery in order to continue stimulation of the remaining thyroid tissue. Thyrogen has been used as a thyroid hormone replacement after surgery in order to ameliorate the patient’s quality of life by avoiding thyroid hormone withdrawal. Thyroid hormone withdrawal may include symptoms such as extreme fatigue, depression, and feeling consistently cold and may result in a reduced quality of life. Additionally, Thyrogen has been used successfully as a tool in the identification and diagnosis of thyroid cancer.

In its early history, Georgia was a powerful kingdom, experiencing its peaks in the 10th and 13th centuries. Georgia owes much of its modernization to Russia, including adopting free health care. The country has moved from tax-funded health care to providing health care for the most at-risk citizens (children under 6, elders over 60) and the poor, while those above their poverty line deal with private-sector health insurance companies. The government has also taken steps to provide free cancer screenings for its citizens.

The country of Georgia is geographically located east of the Black Sea and is bordered to the north and northeast by Russia. In the year 1801, Georgia was annexed by the Russian empire, and remained that way until a brief independence in the 1900s. It functioned as an independent state from 1918 to 1921, when it became part of the Soviet Union. From 1921 to 1991, Georgia's health care system was intertwined with the Soviet system. While health care was supposed to be free, some health professionals took illegal, out-of-pocket fees. While it was part of the Soviet Union, Georgia became more advanced and enjoyed greater diversity. Georgians living below the poverty line were provided services including surgery, radiation, chemotherapy, palliative care, and outpatient care. In regard to palliative care, the center ensures that all palliative care employees are instructed at national and international levels. They organize and oversee training in academia at national and international levels for medical practitioners under Tbilisi State University and Tbilisi State Medical University. The staff works with both adult and pediatric individuals.

In the 1990s, Georgia had a health care system that was funded entirely by taxes. Changes in 1995 resulted in a system with social insurance that operated through the State Medical Insurance Company. This covered basic health care. In 2009, primary care costs were paid for mostly by public sources—namely the Ministry of Labor, Health, and Social Affairs for the rural families and the urban population under age six and over age 60.

In 2000, the Cancer Prevention Center (CPC) was founded. The center has legal union status as a nongovernment, nonprofit organization. It provides both medical and teaching programs to patients, doctors, families of the patients, and medical students. CPC's focus is on preventative care as well as early detection techniques and treatment of cancers with known cures. The CPC offers inpatient palliative care, home care, support for those in the early stages, counseling and social support of both the patient and the patient's relatives, and education for both the patients and their families about the illness.

In Georgia, as in many places throughout the world, breast cancer is the main cause of death among women in their reproductive years. This was in part because women tended to get diagnoses in the later stages of cancer when it is harder to treat. In 2005, John Snow, Inc. (JSI) supported Georgia's first-ever walk to raise awareness of the issue, and in 2009, the event became part of the Susan G. Komen Foundation Race for the Cure. The Georgian government set up a national screening center in 2008 and offered free breast cancer screening for the women living in their capital city, Tbilisi. Just two years later in 2010, the government offered this screening nationwide.

In 2009, the rural population had their health care funded through public avenues. The population in urban areas under the age of 6 and over the age of 60 also had their health care funded. Georgians living below the poverty line were provided...
vouchers to purchase private health insurance. Anyone above the poverty line had to pay out of pocket for health insurance or services. In 2010, the Black Sea Countries Coalition on Breast and Cervical Cancer Prevention was held in Tbilisi. The goal of this coalition is to make an agreement to boost early detection and prevention of breast and cervical cancer in the area. The formation of this coalition began with Georgian first lady Sandra Elisabeth Roelofs in 2009, and it is made up of individuals from the health ministries, health policy managers, and clinicians from the area.

In 2013, the Women’s Empowerment Cancer Advocacy Network (WE CAN) and the Georgia National Screening Center held a summit in Tbilisi to raise awareness and promote education on the subject. Dr. Julie Gralow, WE CAN’s founder and director of the breast medical oncology program, Seattle (Washington) Cancer Care Alliance, oversaw the summit.

Georgia has taken great strides in being proactive. Many cancer-related deaths were due to the fact that the cancer had not been screened for, meaning the individuals were being diagnosed when they were in more severe and life-threatening stages.

According to the National Screening Program Web site, the program was started by the Georgian National Council of Reproductive Health. The government now offers free screenings for cervical cancer, bowel cancer, and prostate cancer in addition to breast cancer. For breast cancer, the screenings are free every two years, cervical cancer screenings every three years, and bowel cancer screenings every year for both men and women between the ages of 50 and 70. Prostate screenings are available every year for men ages 50 to 70.

One pitfall of Georgia’s health care system is that it is inaccessible. There are many doctors per capita in Georgia, and in that nation’s capital city of Tbilisi, the number of doctors per capita is three times that of rural locations. Even with the large number of medical professionals, Georgia still sees a low rate of utilization for both in- and outpatient services, including pharmaceutical medications, which suggests that people experience barriers to accessing health care, primarily cost. The poorest are covered by the government, but for anyone above the poverty line, family health emergencies contribute to many families becoming impoverished.

Even with its shortcomings in terms of accessibility, the Georgian government has taken strides to give its people access to cancer screening and the treatment they need. By sponsoring summits in Tbilisi, offering free screenings to its citizens, and giving health care access to the poor, Georgia is improving the quality of life and care of its people. Every step in technology and education for the masses is one step toward a lower rate of cancer mortality.

Germany

The western European nation officially termed the Federal Republic of Germany has ancestral roots stemming all the way back to 962, when King Otto the Great united the various Germanic tribes of Germania to form the Holy Roman Empire. In the centuries that followed, Germany’s humanities and sciences flowered, though war also abounded. In the 20th century and four years after the conclusion of World War II, the modern Federal Republic of Germany was officially founded. In 1990, the previously Soviet-controlled East Germany was reunified with the Federal Republic of Germany, and this has remained as the nation’s modern rendition.

In 19th-century Europe, many European physicians following the lead of the Italian Gaspare Aselli purported that incidences of cancer were the result of anomalies occurring within an individual’s lymphatic system. The German pathologist...
Johannes Muller directly rejected such a theory in 1838. In his studies, he deduced that cancer is constituted by cells and that it is not inherently derived from the lymphatic system; however, he mistakenly also maintained that cancer cells were not derived from regular cells but from the connections between tissues called blastema. In this regard, Muller would later be corrected by one of his students, Rudolph Virchow, who in 1858 ascertained that cancer cells were in fact derived from regular cells. Virchow is now often referred to as the father of cellular pathology, and his work led to breakthroughs regarding how surgery was performed on tumors.

However, even Virchow had mistaken theories. In the second half of the 19th century, he mistakenly proposed that cancer cells were distributed throughout the body as if they were liquid-like in nature. In an attempt to better understand the disease, German surgeon Karl Thiersch negated this notion of Virchow’s throughout the 1860s by demonstrating that cancer cells were distributed by the growth of malignant cells and were not spread through the body by the action of a liquid. Another German surgeon active in the second half of the 19th century was Theodor Billroth, who gained worldwide acclaim for his mastery and innovation of radical surgical techniques on cancerous tumors. Billroth is held in high regard in contemporary medical circles for his pioneering of techniques to effectively remove stomach tumors.

As the German nation entered the 20th century, a German physics professor named Wilhelm Conrad Roentgen was the recipient of the inaugural Nobel Prize in physics for his work in the field of X-ray technologies. Soon after, the first X-ray machines were developed in an attempt to offer more efficient diagnoses. For the rest of the century, treatment capabilities and diagnosis options for the German public advanced. The treatment options in the country were advanced enough that the then-acting United States president Ronald Reagan visited the nation in 1985 to receive treatment for colon cancer from the esteemed German doctor Hans Nieper.

Contemporaneously, Germany is internationally recognized as having some of the best cancer specialists and best cancer treatment centers in the world. In the past several decades, German doctors have pioneered a new form of treating the disease that has been termed hyperthermia therapy, otherwise known as fever therapy, by practitioners in the field; the process is less expensive than other treatment options and involves using a very specialized machine to overheat the specific site of an individual’s tumor, which then consequently stems its growth. Moreover, unlike some other European nations, Germany has a well-established national cancer registry, which was initiated by the Federal Cancer Registry Data Act in August 2009.

In the past decade, the most prevalent incidences of cancer in Germany have been bowel, breast, lung, prostate, and stomach cancer. Intestinal, lung, and prostate cancers are the most prominent cancer incidences in males in Germany, while bowel, breast, and lung cancers are the most prevalent cancer incidences in females there. In the past several years, certain cancers such as gall bladder, liver, and bowel cancer have seen an increase in incidence in Germany, while cases of larynx cancer and cervix cancer are slowly declining.

As around the rest of the globe, many Germans have been affected by cancer. The critically acclaimed and Oscar-winning German actor Ulrich Mühe passed away at his house in Walbeck in 2007 as a result of stomach cancer. The popular comedian and entertainer Dieter Hildebrandt died in 2013 after only recently being diagnosed with prostate cancer. More historically, the German emperor Frederick III died of complications arising from larynx cancer in 1888.

As mentioned earlier, Germany is renowned for its extremely skilled cancer specialists. For example, Dr. Richard P. Baum is the chairman and clinical director of the Department of Nuclear Medicine at the Bad Berka Center of Neuroendocrine Tumors in Bad Berka, Germany, where he oversees interdisciplinary treatment approaches to battling cancer. Another prominent German cancer specialist is Dr. Bertram Wiedenmann, who is currently the chair of hepatology and gastroenterology at Humboldt University in Berlin, Germany, where he specializes in all aspects of gastrointestinal oncology.

Gestational Trophoblastic Tumor

Gestational trophoblastic tumor (GTT), also known as gestational trophoblastic neoplasia, may refer to any of three related types of malignant tumors (i.e., invasive mole, choriocarcinoma, and placental-site trophoblastic tumor), which originate in the placenta. Unlike in a normal pregnancy, wherein placental and trophoblastic cells facilitate the implantation of the fertilized egg into the uterine wall, in a pregnancy affected by GTT, the regulatory mechanisms that typically control the growth of these cells fail, and they develop into invasive, metastatic, and vascular tumors.

The benign premalignant tumor, which along with the aforementioned types of tumors may collectively be referred to as gestational trophoblastic disease, is a hydatidiform mole, in which the chorionic villi cells surrounding the fetus develop improperly and form a benign growth that may be either a complete or partial hydatidiform mole. In the event that a mole develops, the woman is said to be experiencing a molar pregnancy. Complete hydatidiform moles are usually composed completely from the paternal genome and account for around 70 percent of molar pregnancies. Partial moles, however, are comprised of both paternal and maternal genomes.

An invasive mole, or chorioadenoma destructum, begins as a hydatidiform mole, which is by definition restricted to the endometrial cavity but then develops to the point of invading the uterine wall. This type of tumor is seen in 10 to 20 percent of all molar pregnancies.

While invasive moles are composed of placental cells, choriocarcinoma is a cancer composed of only trophoblastic cells, the trophoblast being the membrane that forms the wall of the blastocyst in the early stages of fetal development. Choriocarcinoma can develop subsequent to any type of pregnancy, whereas an invasive mole may only generate from a hydatidiform mole. Around 50 percent of choriocarcinoma cases occur after a hydatidiform mole, 25 percent follow a spontaneous abortion or tubal pregnancy, and the remaining 25 percent occur subsequent to a normal pregnancy.

Placental-site trophoblastic tumors (PSTT) are the rarest of these malignancies, accounting for less than 1 percent of all cases of GTT. PSTTs, which develop at the site where the placenta and uterus join, may develop following a normal pregnancy, abortion, ectopic pregnancy, or molar pregnancy. As opposed to the other types of GTT, in cases of PSTT, the woman’s human chorionic gonadotropin (hCG) levels remain low despite the tumors’ metastasizing. This coupled with the fact that prognostic staging scores are of limited reliability makes detection and diagnosis difficult. In most cases, the tumors affect the uterus only, however, pelvic involvement and metastasis to the lungs and other organs have been documented.

In rare cases, a fetus may coexist with an evident mole, a case referred to as a twin molar pregnancy. There are no clear guidelines for medical
management of these cases. An increased risk of GTT development has been identified for women who continue the pregnancy into the second trimester but who experience complications leading to termination of the pregnancy prior to the stage of fetal viability. Previous recommendations were for the fetus in all twin molar pregnancies to be aborted; however, recent studies have found that around 40 percent of infants born in this scenario experience no significant congenital abnormalities, and so this recommendation is now considered outdated.

**Incidence and Risk Factors**

Worldwide occurrence of GTT is believed to be around 1 in 1,000 pregnancies, with rates perhaps twice as high in some Asian countries, especially in Japan.

Known risk factors associated with GTT include limited consumption of dietary carotene, vitamin A, and animal fat, and either extremely young or very advanced maternal age, specifically in women either younger than 15 or older than 40. Some evidence suggests that advanced paternal age may contribute to risk of complete, but not partial, hydatidiform mole development. Having experienced a prior molar pregnancy additionally has implications for recurrent GTT, with one study reporting that the risk for a second molar pregnancy was one in 76 and that, after two molar pregnancies, the risk for a third was one in 6.5.

**Symptoms and Diagnosis**

The most prominent symptom of complete hydatidiform mole is vaginal bleeding in early pregnancy, which can range from spotting to hemorrhage requiring transfusion. Pain, elevated hCG levels, and rarely, the passage of visible villi tissues may also indicate the presence of GTT. Other medical comorbidities associated with molar pregnancy, including anemia, tachycardia, preeclampsia, hyperemesis, hyperthyroidism, and respiratory distress are now rarely seen, likely due to the now-routine use of ultrasonography to aid in diagnosis of complete hydatidiform mole in the first trimester. Partial hydatidiform moles develop more slowly and are thus not often diagnosed until the second trimester, though vaginal bleeding is still the hallmark symptom of this type of tumor.

Ideally, all products of conception from nonviable pregnancies should be subject to histological examination irrespective of ultrasonographic findings, given that ultrasonography, especially in the first trimester, cannot completely reliably confirm the presence of GTT.

This histological exam, however, is not always performed on evacuation of conception, which can problematically delay the detection of GTT, thus increasing risk for requiring chemotherapy and surgery. Therefore, it is recommended that serum hCG levels be obtained within one week of evacuation, every one to two weeks while levels remain elevated, and then at one- to two-month intervals for up to one year. Most instances of GTT are evident within six months following evacuation, though rare cases of late-developing GTT have been documented.

**Treatment**

For most women experiencing hydatidiform mole or GTT who wish to retain fertility, the preferred evacuation method is suction dilation and evacuation. Some women may elect to undergo a hysterectomy in the event that future pregnancy is desired or that hemorrhagic bleeding is severe. However, it is crucial that women choosing hysterectomy be informed that this procedure prevents only local invasion of tumors but that, given the potential development of metastasizing tumors, it does not negate the need to routinely monitor hCG post-evacuation nor to receive chemotherapy in some cases.

If chemotherapy is recommended following molar evacuation or in response to choriocarcinoma or PSTT development, a typical regimen may include methotrexate, sometimes in conjunction with leucovorin. Dactinomycin may also be used. Effectiveness of treatment is determined through the measurement of hCG levels, and treatment typically concludes following the reduction of hCG levels to expected ranges, though one to two additional chemotherapy cycles may be recommended.

PSTT tumors specifically tend to be less responsive than other subtypes of GTT to chemotherapy, and the highest success rates to date have been found following multi-agent chemotherapy treatments, specifically etoposide, methotrexate, and dactinomycin alternating with cyclophosphamide.
and vincristine (EMA/CO) or etoposide, methotrexate, actinomycin, and cisplatinum (EMA/EP) treatments. The best prognosis is associated with growths localized to the uterus and with an elapsed time of less than two years between diagnosis of PSTT and the antecedent pregnancy.

Some oncologists have assessed whether a prophylactic course of chemotherapy following molar evacuation may reduce the subsequent incidence of GTT. The resulting research indicated that, while incidence was reduced for patients with high-risk moles, those with low-risk moles did not experience a diminishment in GTT development. Furthermore, in cases where GTT developed in spite of preventative chemotherapy treatment, more chemotherapy was required to achieve curative effects, and researchers thus concluded that the development of chemoresistance negated the minimal benefit of prophylactic chemotherapy administration.

Overall, GTT is regarded as the most curable gynecologic malignancy due to recognition of hCG as a tumor marker, the responsiveness of GTT to various chemotherapeutic agents, and the cataloging of risk factors that enable individualization of treatment. Overall cure rates are more than 98 percent with fertility retention, which represents a dramatic improvement over the overwhelming fatality associated with these tumors as little as 60 years ago.

Ghana

The West African country of Ghana is located along the Gulf of Guinea and Atlantic Ocean in the south, bordered by Côte d’Ivoire to the west, Burkina Faso to the north, and Togo to the east. The word Ghana means “warrior king.” The Republic of Ghana is named after the medieval west African Ghana empire. Historically, complex societies have existed in the Ghana (Wagadu) empire, including the region that is now southeastern Mauritania and western Mali, since about 1500 B.C.E. and around Ghana’s core regions since around 300 C.E. Various salient civilizations thrived in the general core region of Ghana until the 13th century. Beginning in the 13th century, the Akan peoples established the next dominant civilization which then was followed by the Ashanti empire, which flourished in the 18th and 19th centuries.

Health care practices in Ghana include the prevention, care, and treatment of diseases, such as cancer and other maladies. Until the introduction of Western medicine by Christian missionaries to the Gold Coast in the 19th century, traditional village healers and clerics were the primary caregivers, providing herbal remedies. In 16th century Ghana, traditional herbalists offered treatment of illnesses that stressed the combination of spiritual and physical healing. A recent 2012 World Health Organization (WHO) statistic has revealed that cancer accounted for 8.2 million deaths globally, more than deaths from human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS), malaria, and tuberculosis (TB) combined. It is projected that, without immediate action, the number of deaths from cancer will increase globally by nearly 80 percent by 2030, with most of the deaths occurring in the world’s developing nations and other low- and middle-income countries. More than 14 million people develop cancer globally each year. While many different types of cancer diseases exist, the two most common and deadly types in the sub-Sahara region of Ghana are breast and prostate cancers.

In Ghana, many cancer patients currently are unable to access curative therapies, state-of-the-art surgery, or expensive cancer drugs that are the mainstay of cancer care in developed nations. The government of Ghana provides most of the health care, which is administered largely by the Ministry
of Health and Ghana Health Services. There are five levels of providers within the health care system: health posts, which are first-level primary care for rural regions, health centers and clinics, district hospitals, regional hospitals, and tertiary hospitals. Funding for these health care programs is provided by the government of Ghana, financial credits, the Internally Generated Fund (IGF), and Donors-Pooled Health Fund. Additional health care services are also provided by the Christian Health Association of Ghana through hospitals and clinics.

Ghanaians living in the urban centers, which contain most of the hospitals, clinics, and pharmacies, are relatively well served by the country’s health care system. Rural areas, however, often lack modern health care technologies, causing patients in these areas either to depend on traditional medicine or to travel long and expensive distances for health care. Ghana currently has a universal health system, the National Health Insurance Scheme (NHIS), which was passed into law in 2003 by former president John Kufour. Until the establishment of the Ghana National Health Insurance, many Ghanaians lost their lives when they became ill because of their inability to pay for their health care needs.

The system of health care that operated before the establishment of the NHIS was commonly known as the cash-and-carry system. Under this system, a patient must make an estimated initial payment before any health care attention will be rendered. The cash-and-carry system was the practice even in emergency situations. It was a requirement that patients needing emergency treatment in hospitals or clinics must pay money before treatment and at every point of service delivery. While overall health care accessibility has improved since the enactment of NHIS, cancer control and care remained a low priority.

The government is ill prepared to combat the dramatically growing cancer burden. Breast cancer is the leading cause of death in Ghana. Despite the efforts devoted to preventing and treating breast cancer, about one-third of individuals diagnosed as having breast cancer die annually. Health professionals in the 2014 World Cancer Day contend that the high rate of death resulting from cancer has been attributed, primarily, to ignorance and delay in reporting the health condition to health agencies for evaluation and treatment. Explanations for the delay in seeking treatment among Ghanaian women also have been documented to include feelings of hopelessness and helplessness and cost of and access to routine screening mammography.

Furthermore, close to 70 percent of the women with breast cancer in Ghana present at hospitals and clinics in the advanced stages of the disease, when a cure is commonly impracticable. Breast cancer accounted for 15.4 percent of all malignancies in 2007 and continues to increase annually. A recent study has indicated that women in Ghana are more likely to be diagnosed with high-grade tumors that are negative for expression of the estrogen receptor, progesterone receptor, and HER2/neu marker. Triple-negative breast tumors are known to be more aggressive and result in higher breast cancer death rates.

Prostate cancer in Ghana and most African societies is the most fearsome and common disease in males after hepatocellular carcinoma. Globally, incidence of prostate cancer is higher among black men than any other male group. Each year, almost 1,000 Ghanaian men are diagnosed with prostate cancer, and about 750 men die of prostate cancer annually. Because prostate cancer is a genetic disease, it is difficult to prevent a man from developing it. A man is commonly at greater risk of developing prostate cancer if his father, grandfather, brother, or uncle had lived with the disease. Although prostate cancer tends to develop in men over the age of 50, recent reports show that it is also becoming more prevalent in Ghanaian men in middle age. In many cases, in men who lack the means and access to receive early diagnosis and adequate or any medical therapy, prostate cancer metastasizes and becomes fatal.

Prostate cancer in its early stage does not present any particular symptoms. Some observable signs may include swelling, needing to urinate often, inability to freely urinate, experiencing weak or interrupted urine flow, difficulty in having an erection, noticing blood in the semen or in the urine, a burning sensation when urinating, pain, abnormal test results, and nausea.

Glass Industry

Glass objects date back to 3500 B.C.E. in Mesopotamia and Syria, with the first stable flat glass industry recorded in 1550 B.C.E. in Egypt. In 650 B.C.E., the practice of glass-making furnaces and glass blowing arose in Syria; then during the Roman Empire in 20 B.C.E., glass objects were documented in Italy, France, Germany, and Switzerland. From 1173 to 1271, Venice started to regulate the glass trade and published guild rules. In the Middle Ages, glass mosaics and stained-glass windows came into vogue.

By 1910, glass was rolled into a sheet between mechanical rollers, and this initiated some automation into the process. Glass windows became common in homes in the early 1900s. Glass windshields also appeared in cars. By 1959, the Float or Pilkington process was initiated for flat glass. The current processes involve automation of much of the process of making flat glass.

Cancer occurs from changes in the cell's DNA in the human body. Environmental factors can cause these changes to the cell's DNA. The production of glass in the workplace, in the home, or in art can produce some of these changes to produce cancer. Cancer also can be generated by prolonged, high-level contact. Individuals possess varying risks of cancer due to exposure to carcinogens, the extent of exposure, and the genetic makeup of the person.

The main organizations classifying carcinogens comprise the World Health Organization's (WHO's) International Agency for Research on Cancer (IARC), the National Toxicology Program in multiple countries, and the Environmental Protection Agency, whereas other agencies (e.g., National Institute for Occupational Safety and Health [NIOSH], the Food and Drug Administration, and the National Cancer Institute) give expert testimony or comments on the substances being classified as carcinogenic.

The glass industry consists of five main manufacturing sectors. The sectors comprise flat glass, container and pressed ware, art glass, special glass (optics or electronics), and fiberglass. The basic phases in producing glass products consist of melting, fining, homogenization, annealing, and forming.

Over the last century, the assembly of flat glass and container glass emerged from traditional batch processes to extremely automated procedures. The current production of flat glass involves substantially automated methods with continuous feeding of ingredients and floating for the forming technique, whereas container and pressed ware use primarily mechanized blowing or pressing of the heated glass. In addition, modern plants for glass production use physical engineering controls (ventilation systems, government-approved respirator masks, and monitoring the size of fibers) to alter exposure to harmful elements. Thus, flat glass and container glass fail to come in contact with humans during the manufacturing process and do not pose a risk to humans.

Art and special glass continue to be made by pot processes that entail manual batch methods. Consequently, art glass manufacturing has changed little over time and even now necessitates blowing the glass by oral breaths. If cutting or grinding of the glass occurs without wearing a particulate mask, lead or borosilicate also can cause cancer. The particulate mask filters the offensive fibers. Arsenic, a metal, may be used in glass production as well. Arsenic possesses an association with skin, lung, bladder, kidney, and liver cancers.

Human exposures transpire in the glass industry to noxious substances (e.g., lead, arsenic, and antimony oxides) when individuals employ traditional, nonautomatic methods with art or crystal glasses. Other possible contact with harmful materials in the glass industry consists of silica, asbestos, other metal oxides, and polycyclic aromatic hydrocarbons.

Glass Production and Cancers
The IARC lists arsenic as known to be a human carcinogen, whereas inorganic lead compounds used
in glass production are listed as probably carcinogenic to humans (Group 2A), and ceramic fibers and glass wool fibers are reasonably anticipated to be human carcinogens.

In the 1980s and 1990s, a cohort study in Finland and a case-control study in Sweden both showed a high incidence of stomach cancer in glass blower workers. Research in the same time frame revealed an increased risk for lung cancer in ceramic and glass workers in Austria, Finland, and Sweden. An Italian cohort study demonstrated an increased risk of laryngeal cancer in glass workers. The Finnish cohort research observed an elevated risk of basal cell carcinoma of the skin in male glass workers.

R. Sankila and colleagues studied workers in Finnish glass factories. The research analyzed all types of cancer but found only significantly elevated risks for lung cancer in men and skin cancer among glass blowers. Previous studies indicated an increased risk of stomach and colon cancer, but this study failed to show any increased risk for these two cancers.

**Glass Fibers**

L. Lipworth and colleagues conducted a meta-analysis of individuals employed in the production of rock wool and glass wool. A small elevation in the relative risk of glass workers involved in man-made vitreous fibers occurred, but the results argue against a carcinogenic effect of man-made vitreous fibers, rock wool, or glass wool in the production workers.

According to T. W. Hesterberg and colleagues, the WHO held a symposium on synthetic vitreous fibers in Copenhagen in 1986. Studies by researchers that covered the period from 1946 to 1982 demonstrated significant increases in deaths in all malignant cancers and lung cancer in employees with more than 20 years working in the fiberglass industry. The highest rates existed for mineral wool workers.

Others have studied the effect of man-made vitreous fibers (MMVF) on the health of glass workers in the United States. No adverse lung effects appeared with exposure to MMVF in this population.
Researchers carried out studies in rats and hamsters to ascertain the effect of glass fibers (e.g., glass wool, continuous glass filaments, rock or stone wool, slag wool, refractory ceramics, and special purpose glass) on carcinogen formation. This study showed only refractory ceramics and special purpose glass with possible human carcinogenic effects. By comparison, all forms of asbestos fibers (actinolite, amosite, anthophyllite, chrysotile, crocidolite, and tremolite) exhibited carcinogenic effects in humans.

In the process of animal research, the scientists found that fiber length and diameter must match human situations. The glass fibers inhaled by humans consisting of a diameter less than three micrometers and a length longer than five micrometers may cause cancers. Studies conducted on animals after the 1990s utilized these measurements. Fiberglass fell into the dimensions that cause lung cancers.

The controlled studies in rats demonstrated carcinogenic capability in the asbestos groups (amosite and rocidolite) and two of the synthetic fiber groups (special purpose E glass and refractory ceramic fiber). The key factor in the rats that produced tumors turned out to be biopersistence. Biopersistence describes the capability of fibers to persist in the lung over prolonged periods of time. Longer fibers produce more toxicity in the body than shorter fibers no matter what the glass substance is.

The European National Toxicology Program conducted a review of all the evidence about the carcinogenesis of glass wool fibers. Their recommendation stated that “glass wool fibers . . . not be classified either as known to be a human carcinogen or reasonably anticipated to be a human carcinogen.”

A 2002 IARC report indicated that a European cohort study of glass fiber workers demonstrated an increased risk of lymphatic and hematopoietic neoplasms in workers with more than 20 years of exposure to styrene. The glass fiber industry employs styrene in the process of making glass fiber-reinforced plastic products.

H. Shannon and colleagues conducted a historical prospective study of 2,557 male subjects working in the glass wool industry in Ontario. The results of the study demonstrated a significant increase in lung cancer mortality in glass wool workers. This study laid the groundwork for later research on the glass industry and lung cancer.

**Glass Protection From Skin Cancer**
Most glass fails to block ultraviolet radiation. Consequently, glass fails to prevent damage from ultraviolet radiation that causes sunburn. Melanoma, basal cell carcinoma, and squamous cell carcinoma can occur from long-term exposure under plain glass.

**Glass Microspheres**
Cancer articles published descriptions of Dr. Delbert Day, Curators’ professor emeritus of materials science and engineering at the Missouri University of Science and Technology, receiving the 2012 Phoenix Award Glass Person of the Year. This award honors a living person for superior contributions to the glass industry. Day performed a critical role in creating radioactive glass microspheres to treat individuals with inoperable liver cancer. He also formed the MO-SCI Corporation for the production of glass microspheres and a variety of glass merchandise for the health care industry. This innovator developed a product to treat cancer using glass.

**Protective Measures in the Glass Industry**
The NIOSH recommends certain protective practices for individuals working in the glass industry. For high exposure areas, practices to reduce worker exposures are implemented. These personal protective equipment recommendations include gloves, long sleeves, long-legged pants, and respirator masks for individuals working in the cutting, cleanup, or releasing containers processes. Glass companies further measure the fibers in the air to determine areas of high exposure to fiber or dust.

The glass industry realized that long-time drivers develop damage to the skin on the side facing the driver-side windows. Transparent ultraviolet filtering film became available for vehicles to reduce the chance of contracting skin cancers. Recently, residential and commercial window films came onto the market. These films block out about 99.9 percent of the ultraviolet rays and prevent skin aging and risks from skin cancer.

**Conclusion**
Research carried out in the glass industry shows only certain areas of production cause individuals to be exposed to high levels of cancer-producing
GlaxoSmithKline (United Kingdom)

The sixth-largest pharmaceutical company in the world, according to 2013 revenue, GlaxoSmithKline (GSK) is a British multinational based in Brentford, London. The company was formed in 2000 with the merger of SmithKline Beecham, which was itself formed through a series of mergers of the Beecham Group with the SmithKline Beckman Corporation formed from the Smith, Beckman, and Kline & French corporations, and Glaxo Wellcome, which had been formed when Glaxo (originally a New Zealand company that relocated to London) acquired Wellcome (founded in London by American pharmacists).
