Pneumonia can be classified either according to the organism responsible for infection or by the site of disease; *Pneumococcus* is the commonest cause overall; however, in 30–50% cases no organisms is identifiable while in about 20% of cases more than one organism is present. Infection can be localized with the whole of one or more lobes affected (‘lobar pneumonia’) or diffuse, when the lobules of the lung are mainly affected, often due to infection centred on the bronchi and bronchioles (‘bronchopneumonia’).

Pathophysiology
Several different microorganisms commonly cause CAP. Infection is spread by respiratory droplets. Both the clinical presentation and the range of causative organisms vary with age and with the effectiveness of the host’s immune response and innate defence mechanisms. Factors which increase the risk of developing CAP are shown in Box 15.5.

Other causes of pneumonitis are listed below:
- **Chemical insult**, such as in the aspiration of vomit (see p. 838)
- **Radiotherapy** (see p. 838)
- **Allergic mechanisms** (see p. 852).

Clinical features of CAP
The clinical presentation varies according to the immune state of the patient and the infecting agent.
- **Cough:** this may be dry or productive and haemoptysis can occur. In pneumococcal pneumonia, sputum is characteristically rust-coloured.

### Box 15.5 Risk factors for community-acquired pneumonia

- **Age:** <16 or >65 years
- **Co-morbidities:** HIV infection, diabetes mellitus, chronic kidney disease, malnutrition, recent viral respiratory infection
- **Other respiratory conditions:** cystic fibrosis, bronchiectasis, COPD, obstructing lesion (endoluminal cancer, inhaled foreign body)
- **Lifestyle:** cigarette smoking, excess alcohol, intravenous drug use
- **Iatrogenic:** immunosuppressant therapy (including prolonged corticosteroids)

---

**PNEUMONIA**

Pneumonia is defined as inflammation of the substance of the lungs. It is usually caused by bacteria but can also be caused by viruses and fungi. Clinically, it usually presents as an acute illness with cough, purulent sputum, breathlessness and fever together with physical signs or radiological changes compatible with consolidation of the lung (Fig. 15.33), However, it can present with more subtle symptoms, particularly in the elderly. About 50% of pneumonia is pneumococcal.

**Figure 15.33** Chest X-ray showing lobar pneumonia.
- **Breathlessness**: the alveoli become filled with pus and debris, impairing gas exchange. Coarse crackles are often heard on auscultation, due to consolidation of the lung parenchyma. Bronchial breath sounds may be heard over areas of consolidated lung.

- **Fever**: this can be as high as 39.5–40°C. If swinging fevers are present this often indicates empyema (see **Complications**).

- **Chest pain**: this is commonly pleuritic in nature and is due to inflammation of the pleura. A pleural rub may be heard early on in the illness.

- **Extrapulmonary features** (Box 15.6): these are more common in certain infections and are not universal. Sometimes the presence of these symptoms gives a clinical clue as to the aetiology.
  - Haemolysis due to cold agglutinins occurs in approximately 50% cases of *Mycoplasma pneumoniae*. Thrombocytopenia is relatively common.

- **Other features**: in the elderly, CAP can present with confusion or nonspecific symptoms such as recurrent falls. CAP should always be considered in the differential diagnosis of sick elderly patients given their frequently atypical presentation.

- Where symptoms have been present for several weeks or have failed to respond to standard antibiotics, the possibility of *tuberculosis* should always be remembered.

### Investigation and management of CAP

The clinical presentation varies between different causative organisms, but there is considerable overlap. *Streptococcus pneumoniae* (pneumococcus) is the commonest single cause, and all treatment and investigation strategies need to cover this. The most likely causative pathogens must be treated while considering alternative less common infectious causes (such as tuberculosis) or an alternative pathology (e.g., lung cancer). The treatment plan can always be refined and focused later. Pneumonia caused by endobronchial obstruction due to lung cancer is the main underlying problem.

### Initial assessment

The type and extent of investigation depends on the severity of the illness, which also guides where the patient should be managed and predicts their outcome. Diagnostic microbiological tests are not needed in mild infection, which should be treated at home with standard antibiotics (amoxicillin or clarithromycin for those with a history of penicillin allergy). Where patients have mild disease, chest X-ray is not routinely recommended unless they fail to improve after 48–72 hours. Antibiotics can be administered orally.

Severity is commonly assessed by CURB-65 or the CRB-65 score (Box 15.7). These give a guide to the likely risk of fatal outcome but they are not mandatory and antibiotic choice must always be tempered by clinical assessment and judgement, taking into account other factors associated with increased rates of mortality (Box 15.8). The CRB-65 score is used in the community where the serum urea level is not usually available (Fig. 15.34). Other severity scores are available to predict mortality and where a patient should be cared for such as the Pneumonia Severity Index (PSI), which is used more widely in the USA. Figure 15.34 illustrates a suggested diagnostic and treatment algorithm in CAP. It incorporates treatment recommendations extracted both from the British Thoracic Society Guidance for the management of CAP (2009) and the Infectious Diseases Society of America/American Thoracic Society Guidance 2007.

### Investigations

All patients admitted to hospital should have a chest X-ray, blood tests and microbiological tests.

#### Chest X-ray

This must be repeated 6 weeks after discharge unless complications occur to rule out an underlying bronchial malignancy predisposing to pneumonia by causing obstruction.

- **Strep. pneumoniae**. Consolidation with air bronchograms, effusions and collapse due to retention of secretions can all be seen. Radiological abnormalities can lag behind clinical signs. A normal chest X-ray on presentation should be repeated after 2–3 days where CAP is suspected.

- **Mycoplasma**. Usually one lobe is involved but infection can be bilateral and extensive.

- **Legionella**. There is lobar and then multi-lobar shadowing, with the occasional small pleural effusion. Cavitation is rare.

### Box 15.7 CURB-65 score

| C: confusion present (abbreviated mental test score <8/10) | U: (plasma) urea level >7 mmol/L |
| R: respiratory rate >30/min | B: systolic BP <90 mmHg; diastolic BP <60 mmHg |
| Age >65 | 1 point for each of the above: |

- Score 0: Treat as outpatient
- Score 1: Admit to hospital
- Score 3+: Often require ICU care
- Mortality rates increase with increasing score.

### Box 15.6 Extrapulmonary features of community-acquired pneumonia

- Myalgia, arthralgia and malaise are common, particularly in infections caused by *Legionella* and *Mycoplasma*
- Myocarditis and pericarditis are cardiac manifestations of infection, most commonly in *Mycoplasma pneumoniae*
- Headache is common in *Legionella pneumonia*. Meningoencephalitis and other neurological abnormalities also occur but are much less common
- Abdominal pain, diarrhoea and vomiting are common.
- Hepatitis can be a feature of *Legionella pneumonia*
- Labial herpes simplex reactivation is relatively common in pneumococcal pneumonia
- Other skin rashes such as erythema multiforma and erythema nodosum are found in *Mycoplasma pneumoniae*
- Stevens–Johnson syndrome (p. 1231) is a rare and potentially life-threatening complication of pneumonia

### Box 15.8 Other markers of severe community-acquired pneumonia

- Chest X-ray: more than one lobe involved
- P_{O_2} <8 kPa
- Low albumin (<35 g/L)
- White cell count (<4×10^{9}/L or >20×10^{9}/L)
- Blood culture – positive
- Other co-morbidities
- Absence of fever in the elderly
**Blood tests**

Full blood count, urea and electrolytes, biochemistry and C-reactive protein are helpful.

- **Strep. pneumoniae**. White cell count is $>15\times10^9$/L (90% polymorphonuclear leucocytosis); inflammatory markers significantly elevated: ESR $>100$ mm/hour; CRP $>100$ mg/L.

- **Mycoplasma**. White cell count is usually normal. In the presence of anaemia, haemolysis should be ruled out (direct Coombs’ test and measurement of cold agglutinins).

- **Legionella**. There is lymphopenia without marked leucocytosis, hyponatraemia, hypoalbuminaemia and high serum levels of liver aminotransferases.

**Other tests**

The causative organism must be identified:

- Sputum culture and Gram-stain are required for all patients:
  - **S. pneumoniae**: Gram-positive diplococci
  - **S. aureus**: Gram-positive organisms commonly in clusters like a bunch of grapes

- Also diagnostic in infections caused by **S. aureus**, **H. influenzae**, **M. catarrhalis**, Gram-negative organisms

- Blood culture should be done for all patients who have moderate to severe CAP, ideally before antibiotics are administered. In **S. pneumoniae** infection, positive blood culture indicates more severe disease with greater mortality.

**Table 15.14** highlights more specific diagnostic tests used to identify the causative organism in patients with moderate to severe CAP.

**Pulse oximetry and arterial blood gas analysis** is necessary if oxygen saturation is below 94%.

**HIV testing**: since pneumonia is a common initial presenting illness in patients with previously undiagnosed HIV infection, a test should be offered to all patients with pneumonia unless the patient is unable to give consent or comfort measures alone are implemented due to poor prognosis.

**General management of pneumonia**

- **Oxygen**. Supplemental oxygen should be administered to maintain saturations between 94% and 98% provided the patient is not at risk of carbon dioxide retention,
Table 15.14  Specific diagnostic tests in patients with moderate to severe community-acquired pneumonia (CAP)

<table>

<tr>
<th>Organism</th>
<th>Diagnostic confirmatory test</th>
</tr>
</thead>
<tbody>
<tr>
<td>Streptococcus pneumoniaiae</td>
<td>Counter-immunoelectrophoresis (CIE) of sputum, urine and serum is 3–4 times more sensitive than sputum or blood cultures. Urinary antigen test detects C-polysaccharide. This is rapid and unaffected by antibiotics; sensitivity is 65–80% and specificity about 80%. Pneumococcal PCR (not routinely recommended as inferior to blood cultures and low sensitivity).</td>
</tr>
<tr>
<td>Mycoplasma pneumoniae</td>
<td>PCR of respiratory tract samples (throat swab/sputum/BAL fluid) – higher detection rates than serological assays. PCR on serum under assessment and likely to become more available. Complement fixation test (CFT) (though sensitivity and specificity low) – measure paired samples 10–14 days apart and look for rising titres or single level approximately 7 days after onset of illness.</td>
</tr>
<tr>
<td>Legionella spp. (also termed Legionnaire’s disease)</td>
<td>Urinary antigen test detects only serogroup 1, which accounts for most of these infections. Sensitivity (~80%) and specificity are high (almost 99%). Direct immunofluorescent staining of organism in the pleural fluid, sputum or bronchial washings is carried out. Serum antibodies are less reliable. Paired serum antibody titres 10–14 days apart (or single level 7 days after onset of illness) Culture on special media is possible but takes up to 3 weeks. This gives valuable information on antibiotic sensitivity and should be performed if urinary antigen positive Legionella is not visible on Gram-staining.</td>
</tr>
<tr>
<td>Chlamyphila pneumoniae</td>
<td>Paired serum antibody titres 10–14 days apart Antigen detection (DIF) on throat swabs/respiratory samples CFT usually only weakly positive and less reliable than in C. psittaci.</td>
</tr>
<tr>
<td>Chlamyphila psittaci</td>
<td>Paired serum antibody titres 10–14 days apart Antigen detection (DIF) not available for C. psittaci.</td>

</table>

Table 15.15  Causes of slow resolving pneumonia

| Incorrect or incomplete antimicrobial treatment | Underlying antibiotic resistance |
| Non-adherence | Malabsorption |
| Complication of CAP | Parapneumonic pleural effusion |
| (exudative) | Empyema |
| Lung abscess |
| Underlying neoplastic lesion or other lung disease | Obstructing lesion |
| Bronchoalveolar cell carcinoma |
| Bronchiectasis |
| Alternative diagnosis | Pulmonary thromboembolic disease |
| Cryptogenic organizing pneumonia |
| Eosinophilic pneumonia |
| Pulmonary haemorrhage |

Analgesia. Simple analgesia such as paracetamol or non-steroidal anti-inflammatory medication helps treat pleuritic pain, thereby reducing the risk of further complications due to restricted breathing because of pain (e.g. sputum retention, atelectasis or secondary infection).

Complications

Complications of pneumonia must be excluded, especially if the patient does not respond quickly to initial treatment (see Table 15.17).

Prevention of further episodes

Cigarette smoking is an independent risk factor for CAP; if the patient still smokes, cessation advice and support should be given.

due to loss of hypoxic drive in COPD. In patients with known COPD, oxygen saturations should be maintained between 88% and 92%; normally with controlled oxygen via fixed percentage delivery mask.

Intravenous fluids. Required in hypotensive patients showing any evidence of volume depletion.

Antibiotics. The first dose of antibiotic should be administered within 4 hours of presentation in hospital and treatment should not be delayed while investigations are awaited.

- Parenteral antibiotics should be switched to oral once the temperature has settled for a period of 24 hours, provided there is no contraindication to oral therapy.
- If patients fail to respond to initial treatment, microbiological advice should be sought and alternative diagnoses considered (e.g. S. aureus pneumonia, which requires addition of flucloxacillin/fusidic acid, and possibly cover for MRSA infection. Causes of failure are shown in Table 15.15.
- The antibiotic regimen should be adjusted specifically once culture and sensitivity results are available. There is an increased incidence of Clostridium difficile associated diarrhoea (CDAD) associated with some antibiotics, e.g. cephalosporins, which should be avoided if possible. The risk of MRSA increases with antibiotic overuse.

Thromboprophylaxis. If admitted for >12 hours subcutaneous low molecular weight heparin should be prescribed unless contraindications exist and TED (thromboembolus deterrent) stockings fitted.

Physiotherapy. Chest physiotherapy is not needed unless sputum retention is an issue.

Nutritional supplementation. The need for this is assessed, particularly in severe disease, by a dietician.
Vaccination against influenza is recommended for at-risk groups. All patients over the age of 65 who have not previously been vaccinated and are admitted with CAP should have the pneumococcal vaccine before discharge from hospital.

**Types of pneumonia** *(Table 15.16)*

The clinical presentation of pneumonia varies according to the causative organism but there is considerable overlap. Pneumococcal disease is typically acute in onset, with prominent respiratory symptoms and a high fever. Pneumonia due to the so-called atypical pathogens (*Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Legionella pneumophila*) tends to have a slower onset, often with more prominent extrapulmonary symptoms and complications.

**Complications of pneumonia** *(Table 15.17)*

**Parapneumonic effusion and empyema**

Effusions commonly occur with pneumonia and complicate around one-third to a half of cases of CAP. The majority of these are simple exudative effusions but empyema may also develop (where purulent fluid collects in the pleural space). Early indications of empyema are ongoing fever, and rising or persistently elevated inflammatory markers, despite appropriate antibiotic therapy.

### Table 15.16  Types of pneumonia and their clinical features

<table>
<thead>
<tr>
<th>Organism</th>
<th>Features</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>Streptococcus pneumoniae</em></td>
<td>Acute onset, often preceded by flu-like symptoms. Cough with rust coloured sputum. High fevers and pleuritic chest pain common. Bacteraemia more common in females, excess alcohol, dry cough and COPD, diabetes or HIV infection.</td>
</tr>
<tr>
<td><em>Mycoplasma pneumoniae</em></td>
<td>Usually mild disease in young patient; occurs in cycles every 3–4 years. Usually prominent extrapulmonary symptoms (headache, malaise, myalgia); complications common: haemolytic anaemia, erythema multiforme, hepatitis, meningoencephalitis.</td>
</tr>
<tr>
<td><em>Legionella spp.</em> <em>(Legionnaire’s disease)</em></td>
<td>Usually <em>Legionella pneumophila</em> but other species implicated in around 10% of cases. Causes more severe disease with need for early intensive care. Usually acquired by inhaling water mist containing bacteria. Neurological symptoms frequently seen, along with GI involvement and deranged liver enzymes, elevated creatine kinase. More common in smokers, males and in young people with no co-morbidities.</td>
</tr>
<tr>
<td><em>Staphylococcus aureus</em></td>
<td>Evidence of recent influenza found in up to around 40–50% patients (increasing frequency with greater severity disease). Usually meticillin-sensitive strains (MSSA) but increasing incidence of meticillin-resistant disease (MRSA) which can produce Panton Valentine leucocidin (PVL) and result in necrotizing cavitating pneumonia and bilateral infiltrates.</td>
</tr>
<tr>
<td><em>Chlamydia pneumoniae</em></td>
<td>Unclear whether this is a causative or associated organism. Generally causes mild disease but with prolonged prodrome.</td>
</tr>
<tr>
<td><em>Haemophilus influenzae; Moraxella catarrhalis</em></td>
<td>More common in pre-existing structural lung disease (CF, bronchiectasis, COPD) and the elderly.</td>
</tr>
<tr>
<td><em>Chlamydia psittaci</em></td>
<td>Acquired from birds (only 20% have positive history). Can be person-to-person spread; usually mild illness.</td>
</tr>
<tr>
<td><em>Coxiella burnetti</em> <em>(Q fever)</em></td>
<td>Tends to occur more commonly in young men. History of dry cough and high fever. Recognized cause of endocarditis.</td>
</tr>
<tr>
<td>Gram-negative organisms</td>
<td></td>
</tr>
<tr>
<td><em>Klebsiella pneumonia</em></td>
<td>More common in men and those with history of excess alcohol (bacteraemia more likely), poor dental hygiene, diabetes and other co-morbidities; often present with low platelet and white cell count. Systemic upset is usual; high mortality.</td>
</tr>
<tr>
<td><em>Pseudomonas aeruginosa</em></td>
<td>Cavitation and abscess formation seen. Infection is associated with underlying lung disease (cystic fibrosis, bronchiectasis, COPD) or immune suppression.</td>
</tr>
<tr>
<td>All respiratory viruses</td>
<td></td>
</tr>
<tr>
<td><em>Varicella zoster</em></td>
<td>Infection more likely in elderly with subsequent staphylococcal pneumonia. Usually causes mild disease; not admitted to hospital. Causes pneumonitis which heals leaving characteristic small calcified or non-calcified nodules.</td>
</tr>
<tr>
<td><em>Influenza A and B</em></td>
<td>Approximately 10% of adults with confirmed influenza infection have coincident S. aureus disease. Fever, malaise and myalgia common.</td>
</tr>
<tr>
<td>Other</td>
<td></td>
</tr>
</tbody>
</table>
Thoracocentesis should be performed to make a diagnosis. Fluid should be aspirated under ultrasound guidance and sent for Gram-stain, culture, protein, glucose and LDH (with comparison to serum levels). Light’s criteria (see p. 863) can be applied to assess whether an effusion is transudative or exudative. An exudative effusion with pleural fluid pH < 7.2 is strongly suggestive of empyema. Pathogens are often detectable; sensitivity analysis will help guide antimicrobial therapy.

If an empyema develops, the fluid should be urgently drained to prevent further complications such as development of a thick pleural rind or prolonged hospital admission. The presence of empyema further increases mortality risk. The duration of antibiotic administration will usually need to be extended. Whenever possible, the choice of antimicrobial should be guided by the results of cultures. Thoracic surgical intervention is necessary in severe cases.

### Lung abscess

This term is used to describe severe localized suppuration within the lung associated with cavity formation visible on the chest X-ray or CT scan, often with a fluid level (which always indicates an air-liquid interface).

There are several causes of lung abscess (Box 15.9).

- **Aspiration pneumonia**: rarely, abscesses develop as a complication of aspiration pneumonia. A history of excessive alcohol consumption or impaired swallowing in a patient with pneumonia suggests aspiration.
- **Tuberculosis**: see pages 839–841.
- **Pneumonia caused by certain species**, particularly *Staphylococcus aureus* or *Klebsiella pneumoniae*.
- **Septic emboli usually containing staphylococcus**: these can cause multiple lung abscesses. The presence of multiple lung abscesses in an injecting drug user should prompt investigation for infective endocarditis of the tricuspid (or rarely pulmonary) valves. Infarcted areas of lung (due to pulmonary embolism) occasionally cavitate and become infected.
- **Spread from an amebic liver abscess**: amoebic lung abscesses occasionally develop in the right lower lobe following transdiaphragmatic spread.
- **Bronchial obstruction by an endoluminal cancer**
- **Foreign body inhalation**.

**Box 15.9 Common causative organisms in lung abscess**

- Klebsiella pneumonia
- *Staphylococcus aureus*
- Gram-negative enteric bacilli
- *Mycobacterium tuberculosis*
- *Streptococcus milleri*
- Anaerobic bacteria (post aspiration)
- *Haemophilus influenzae*

**Box 15.10 Organisms implicated in hospital-acquired pneumonia**

- Gram-negative bacteria (*Pseudomonas* spp., *Escherichia* spp., *Klebsiella* spp.)
- Anaerobic bacteria (*Enterobacter* spp.)
- *Staphylococcus aureus* (including MRSA)
- *Acinetobacter* spp.

In the latter two, a fibreoptic bronchoscopy and CT scan are performed. Chronic or subacute lung abscesses may follow inadequate treatment of pneumonia.

**Clinical features**

The clinical features are usually persisting or worsening pneumonia associated with the production of large quantities of sputum, which is often foul-smelling owing to the growth of anaerobic organisms. There is usually a swinging fever; malaise and weight loss frequently occur. On examination, there may be little to find in the chest. Clubbing occurs in chronic suppuration. Patients have a normocytic anaemia and/or raised inflammatory markers (ESR/CRP).

**Treatment**

Treatment should be guided by available culture results or clinical judgement and is often prolonged (4–6 weeks). Surgical drainage is sometimes necessary.

**Pneumonia in other settings**

**Hospital-acquired pneumonia (HAP)**

This is defined as new onset of cough with purulent sputum along with a compatible X-ray demonstrating consolidation, in patients who are beyond 2 days of their initial admission to hospital or who have been in a healthcare setting within the last 3 months (including nursing/residential homes as well as acute care facilities such as hospitals). HAP is the second most common form of hospital-acquired infection after urinary tract and carries a significant mortality risk, particularly in the elderly or those with co-morbidities such as stroke, respiratory disease or diabetes. In HAP, the causative organisms differ from those causing CAP (Box 15.10). Viral or fungal pathogens are not responsible in immunocompetent hosts. Aerobic Gram-negative bacilli are commonly involved (e.g. *P. aeruginosa*, *E. coli*, *Klebsiella pneumoniae* and *Acinetobacter* species). *Staphylococcus aureus* is increasingly recognized in HAP, particularly meticillin-resistant *S. aureus* (MRSA), both in Europe and the USA. HAP due to *S. aureus* is more common in patients with diabetes mellitus, head trauma, and patients in intensive care units. Empirical antimicrobial therapy should be tailored accordingly. Other conditions should be excluded, including aspiration of gastric contents due to impaired swallowing or bulbar weakness.

Elderly residents of long-term care facilities who develop pneumonia have a similar range of pathogens to those found in HAP. In the USA, *S. aureus*, Gram-negative rods, *Pseudomonas* species are the commonest causes of pneumonia acquired in nursing homes. Pneumonia associated with ventilation has the same range of organisms as other forms of HAP (p. 894). Piperacillin-tazobactam is commonly used in severe HAP.

**Aspiration pneumonia**

Acute aspiration of gastric contents into the lungs can produce an extremely severe and sometimes fatal illness.
owing to the intense destructiveness of gastric acid. This can complicate anaesthesia, particularly during pregnancy (Mendelson’s syndrome). Because of the bronchial anatomy, the most usual sites for aspirated material to end up are the right middle lobe and apical or posterior segments of the right lower lobe. The persistent pneumonia is often due to anaerobes and progresses to lung abscess or even bronchiectasis if protracted. It is vital to identify any underlying problem, since without appropriate corrective measures aspiration will recur.

Tuberculosis

**Epidemiology**

It is estimated that one-third of the world’s population are infected with tuberculosis (see also p. 135). The World Health Organization (WHO) declared TB a world emergency in 1993. There were almost 9 million new and relapsed cases of TB worldwide in 2010. Its incidence had been increasing by around 1% per year to a peak in 2005, but since then the global incidence per capita has started to slowly decline. The majority of cases (around 65%) are seen in Africa and Asia (India and China). Co-infection with HIV remains a problem, not only because this is a huge health burden on resource-poor nations, but also because of the growing incidence of multi- and extremely-drug resistant strains and the high mortality of the two co-existent diseases. TB was responsible for 1.4 million deaths in 2010 and a quarter of these were in HIV co-infected individuals. There are a number of factors affecting the prevalence and risk of developing TB (Box 15.11).

**Pathophysiology**

Tuberculosis is caused by four main mycobacterial species collectively termed *Mycobacterium tuberculosis complex (MTb)*:

- *Mycobacterium tuberculosis*
- *Mycobacterium bovis*
- *Mycobacterium africanum*
- *Mycobacterium microti*.

These are obligate aerobes and facultative intracellular pathogens, usually infecting mononuclear phagocytes. They are slow growing with a generation time of 12–18 hours. Due to high lipid content in the cell wall, they are relatively impermeable and stain only weakly with Gram-stain. Where stained with dye combined with phenol and washed with acidic acid, they become ‘acid-fast bacilli’.

**Pathogenesis**

Tuberculosis is an airborne infection spread via respiratory droplets. Only a small number of bacteria need to be inhaled to develop infection but not all those who are infected develop active disease. The outcome of exposure is dictated

---

**Box 15.11 Factors affecting the prevalence and risk of developing tuberculosis in the developed world**

- Contact with high-risk groups:
  - Originated from a high incidence country (defined as >40/100 000)
  - Frequent travel to high incidence areas
- Immune deficiency
  - HIV infection
  - Corticosteroids or immunosuppressant therapy
  - Chemotherapeutic drugs
  - Nutritional deficiency (vitamin D)
  - Diabetes mellitus
  - Chronic kidney disease
  - Malnutrition/body weight >10% below ideal body weight
- Lifestyle factors:
  - Drug/alcohol misuse
  - Homelessness/hostels/overcrowding
  - Prison inmates
- Genetic susceptibility (twin studies of gene polymorphisms)

---

**Further Reading**

by a number of factors including the host’s immune response (Fig. 15.35).

**Primary tuberculosis**

‘Primary tuberculosis’ describes the first infection with MTb. Once inhaled into the lung, alveolar macrophages ingest the bacteria; the bacilli then proliferate inside the macrophages and cause the release of neutrophil chemoattractants and cytokines, resulting in an inflammatory cell infiltrate reaching the lung and draining hilar lymph nodes. Macrophages present the antigen to the T lymphocytes with the development of a cellular immune response. A delayed hypersensitivity-type reaction occurs, resulting in tissue necrosis and formation of a granuloma.

Granulomatous lesions consist of a central area of necrotic material called caseation, surrounded by epithelioid cells and Langhans’ giant cells with multiple nuclei, both cells being derived from the macrophage. Lymphocytes are present and there is a varying degree of fibrosis. Subsequently, the caseated areas heal completely and many become calcified. Some of these calcified nodules contain bacteria, which are contained by the immune system (and the hypoxic acidic environment created within the granuloma) and are capable of lying dormant for many years. The initial focus of disease is termed the ‘Ghon focus’.

On a chest X-ray, the Ghon focus is evident as a small calcified nodule often within the upper parts of the lower lobes or the lower parts of the upper lobes, seen in the midzone. A focus can also develop within the regional draining lymph node (primary complex of Ranke).

Upon initial contact with infection <5% of patients develop active disease. This percentage increases to 10% within the first year of exposure.

**Latent tuberculosis**

In the majority of people who are infected by *Mycobacterium* spp., the immune system contains the infection and the patient develops cell-mediated immune memory to the bacteria. This is termed *latent tuberculosis*.

**Reactivation tuberculosis**

The majority of TB cases are due to reactivation of latent infection. The initial contact usually occurred many years or decades earlier. In patients with HIV infection newly acquired TB infection is also common. There are several factors implicated in the development of active disease. (Box 15.12). The clinical features of latent and reactivation TB are contrasted in Table 15.18.

**Clinical features and diagnosis**

Any of the manifestations of disease shown in Table 15.19 occur in primary or reactivation disease but extrapulmonary involvement is far less common in primary disease and is usually only seen in regions of high endemnicity.

In all cases of suspected TB, substantial effort should be made to obtain tissue or fluid for microscopy, smear and culture to obtain information on sensitivities. Tissue samples should also be sent for histopathological examination.

**Pulmonary TB**

Patients are frequently symptomatic with a productive cough and occasionally haemoptysis along with systemic symptoms of weight loss, fevers and sweats (commonly at the end
of the day and through the night). Where there is laryngeal involvement, hoarse voice and a severe cough are found. If disease involves the pleura, then pleuritic pain is a frequent presenting complaint.

The chest X-ray (Fig. 15.36) demonstrates several findings: consolidation with or without cavitation, pleural effusion or thickening or widening of the mediastinum caused by hilar or paratracheal adenopathy.

**Lymph node TB**
The next commonest site for infection is lymph node TB. Extrathoracic nodes are more commonly involved than intrathoracic or mediastinal. Usually this presents as a firm non-tender enlargement of a cervical or supraclavicular node. The node becomes necrotic centrally and can liquefy and be fluctuant if peripheral. The overlying skin is frequently indurated or there can be sinus tract formation with purulent discharge but characteristically there is no erythema (cold abscess formation). Nodes typically can be enlarged for several months prior to diagnosis. On CT imaging, the central area appears necrotic (see image).

**Other forms of TB**

**Gastrointestinal**
See page .833

**TB of bone and spine**
See pages 533 and 534

**Miliary TB**
- **Miliary disease** occurs through haematogenous spread of the bacilli to multiple sites, including the central nervous system in 20% cases.
- Systemic upset is the rule, with respiratory symptoms in the majority. Other findings are liver and splenic microabscesses with deranged liver enzymes or cholestasis and GI symptoms.
- The chest X-ray demonstrates multiple nodules which appear like millet seeds, hence the term 'miliary'.

**Central nervous system TB**
See this chapter.

**Pericardial TB**
See page 774.

**Skin**
See page 1198.

**Sampling of other involved organs often necessary**

**CSF lymphocytosis**
Microbiological diagnosis

Rapid identification of the presence of bacteria by immediate stains is essential and should be performed within 24 hours; culture of the sample allows determination of the antibiotic sensitivity of the infecting strain.

**Stains**

Auramine-rhodamine staining is more sensitive (though less specific) than Ziehl–Neelsen; as a result it is more widely used. It requires fluorescence microscopy and highlights bacilli as yellow-orange on a green background.

**Culture**

The majority of the developed world uses liquid/broth culture of mycobacteria in addition to solid media (Lowenstein–Jensen slopes or Middlebrook agar) as time to culture is shorter than for solid culture (1–3 weeks compared with 3–8 weeks). Using liquid culture in the presence of anti-mycobacterial drugs (usually first-line therapy initially) establishes the drug sensitivity for that strain and usually takes approximately 3 weeks).

The use of microscopic-observation drug-sensitivity (MODS) assay allows detection of bacteria and susceptibility rapidly by comparing growth in multiple wells with anti-mycobacterial drugs within liquid media. This technique has the advantage of being relatively inexpensive (although labour-intensive and operator dependent) and is therefore more widely used in resource-poor areas.

**Nucleic acid amplification (NAA)**

NAA is increasingly used for rapid identification of MTb complex and is useful in differentiating between MTb and non-tuberculosis mycobacteria (NTM) as well as identifying TB in smear-negative sputum specimens. Culture and staining is still necessary and should not be replaced by PCR. PCR is only useful at the initial stage of diagnosis as it frequently remains positive despite treatment due to the detection of dead organisms. This test has a high specificity and moderate sensitivity on cerebrospinal fluid and should be routinely looked for in suspected CNS TB.

The identification of mycobacterial DNA is becoming increasingly useful in facilitating rapid commencement of treatment and also rapid identification of drug resistance. Genetic mutations in bacterial DNA conferring rifampicin-resistance are highly predictive of multi-drug resistance. The development of a highly specific probe designed to detect this mutation thereby allows rapid identification of resistant disease and appropriate therapy to be commenced sooner than waiting for cultures to complete (may take up to 8 weeks).

Molecular testing for drug resistance has also become possible using PCR to detect genetic mutations associated with rifampicin resistance.

Management

Patients with fully sensitive TB require 6 months of treatment, excluding TB of the central nervous system, for which the recommended duration is at least 12 months. Shorter duration courses are being studied, aiming at reducing the duration of treatment and increasing the armamentarium against resistant strains. In CNS and pericardial disease, corticosteroids are used as an adjunct at treatment initiation to reduce long-term complications. Table 15.20 summarizes standard recommended regimens.

**Directly observed therapy (DOT)** is widely recommended and employed with an aim to achieve treatment-completion rates of over 85%. DOT is defined as treatment supervised by a healthcare professional or family member where the person is observed swallowing their medication. WHO advocates universal DOT as one of their strategies to reduce the incidence of TB worldwide, partly because the majority of relapsed disease or treatment failure is due to lack of adherence, interrupted therapy or incorrect treatment (Box 15.13). Where used, the dosing frequency may be reduced to threethemepatwise to make DOT more convenient. Success rates are comparable for thrice-weekly DOT as for standard daily unsupervised therapy.

**Unwanted effects of drug treatment**

*Rifampicin* induces liver enzymes, which may be transiently elevated in the serum of many patients. The drug should be stopped only if the serum bilirubin becomes elevated or if transferases are >3 times elevated, which is uncommon. Induction of liver enzymes means that concomitant drug treatment may be made less effective (see Ch. 16). Thrombocytopenia has been reported. Rifampicin stains body secretions pink and the patients should be warned of the change in colour of their urine, tears (contact lens) and sweat. Oral contraception will not be effective, so alternative birth-control methods should be used. Rifabutin, a rifamycin, is similar and is used for prophylaxis against *M. avium-intracellulare* complex infection in HIV patients with CD4 counts <200 mm$^3$.
Isoniazid has very few unwanted effects. At high doses it may produce a polynueopathy due to a B6 deficiency as isoniazid interacts with pyridoxal phosphate. This is extremely rare when the normal dose of 200–300 mg is given daily. Nevertheless, it is customary to prescribe pyridoxine 10 mg daily to prevent this. Occasionally, isoniazid gives rise to allergic reactions, e.g. a skin rash and fever, with hepatitis occurring in fewer than 1% of cases. The latter, however, may be fatal if the drug is continued.

Pyrazinamide may cause hepatic toxicity, though this is much rarer with present dosage schedules. Pyrazinamide reduces the renal excretion of urate and may precipitate hyperuricaemic gout.

Ethambutol can cause a dose-related optic retrobulbar neuritis that presents with colour blindness for green, reduction in visual acuity and a central scotoma (commoner at doses of 25 mg/kg). This usually reverses provided the drug is stopped when symptoms develop; patients should therefore be warned of its effects. All patients prescribed the drug should be seen by an ophthalmologist prior to treatment and doses of 15 mg/kg should be used.

Streptomycin can cause irreversible damage to the vestibular nerve. It is more likely to occur in the elderly and in those with renal impairment. Allergic reactions to streptomycin are more common than to rifampicin, isoniazid or pyrazinamide. This drug is used only if patients are very ill, have multidrug-resistant TB or are not responding adequately to therapy.

Drug resistance
Worldwide, drug resistance is an increasing problem, with an estimated incidence of 444 000 cases in 2008, responsible for around 150 000 deaths (Fig. 15.37). It arises due to incomplete or incorrect drug treatment and can be spread from person to person. In developed countries, the incidence of multi-drug resistance (resistance to both rifampicin and isoniazid, termed MDR-TB) is relatively low (around 1%) and only a handful of extensively drug-resistant (XDR-TB) cases have been seen, though most countries have reported at least one case. XDR-TB is defined as high level resistance to rifampicin, isoniazid, fluoroquinolones and at least one injectable agent such as amikacin, capreomycin or kanamycin. Total drug resistance (TDR) has now been reported from Italy, Iran and Mumbai (India) in a few cases. Mono-resistance is reasonably common, for example the incidence is approximately 10% in the UK. A risk assessment for drug resistance should be routinely performed (Box 15.14).

TB in special situations
HIV co-infection
The increase in TB seen over recent decades has occurred to a considerable extent in association with the incidence of
HIV infection, with high levels seen in Africa (particularly sub-Saharan Africa), the Indian subcontinent and parts of Eastern Europe and Russia. The incidence of HIV infection in TB worldwide is around 15% and TB is responsible for around one-quarter of AIDS-related deaths.

Alongside the increased morbidity and mortality of co-infection, there are specific issues relating to the treatment of TB in HIV: namely, the incidence of drug interactions and intolerability, the increased risk of treatment toxicity and the higher incidence of drug resistance. TB/HIV infection should be managed by experts in TB (respiratory or infectious disease physicians) alongside HIV specialists.

**Chronic kidney disease (CKD)**

CKD is a risk factor for reactivation of latent TB infection due to relative immune paresis. Patients due to undergo renal transplantation may need to be screened for LTBI and need to be given complete chemoprophylaxis if necessary before undergoing their procedure. The presence of chronic kidney disease also complicates the treatment regimen as there is an increased risk of toxicity due to altered pharmacokinetics, which necessitates dosage adjustments and therapeutic drug level monitoring. Management should be undertaken by TB specialists in conjunction with renal physicians.

**Latent TB Infection**

The diagnosis of latent TB infection (LTBI) involves demonstration of immune memory to mycobacterial proteins. Two tests are available.

**Tuberculin skin test (TST)**

A positive result is indicated by a delayed hypersensitivity reaction evident 48–72 hours after the intradermal injection of purified protein derivative (PPD) resulting in:

- A raised indurated lesion >6 mm diameter in non-vaccinated adults
- A raised indurated lesion >15 mm in BCG-vaccinated adults.

False negative (anergic) TSTs are common in immunosuppression due to HIV infection (CD4+ <200/mm³), sarcoidosis, drugs (chemotherapy, anti-TNF therapy, steroids), at the extremes of age and in active disease. False positives occur due to cross-reactivity with non-tuberculous mycobacteria (NTM) and BCG vaccination.

**Interferon-gamma release assays (IGRAs)**

IGRAs detect T-cell secretion of interferon-gamma (IFN-γ) following exposure to *M tuberculosis*-specific antigens (ESAT-6, CFP-10). Where a person has been infected (previously or currently) with TB, activated T cells within their extracted whole-blood secrete quantifiable levels of interferon-gamma in response to re-exposure to TB-specific antigens. The test does not differentiate between active and latent infection. However, it is highly specific compared with the TST and has a similar or better sensitivity.

**Global TB strategy**

Part of the global strategy is an increase in the identification and treatment of latent TB infection (LTBI), thereby reducing the risk of conversion to active disease and transmission to others. In certain groups with LTBI, chemoprophylaxis is offered to reduce the risk of active infection (Box 15.15).

Active case finding forms part of a number of programmes:

**Box 15.15 People who should be treated for latent TB infection (after excluding active TB)**

- People aged ≤35 years with positive TST or IGRAs
- Healthcare workers with positive TST or IGRAs
- Patients commencing anti-TNF therapy with positive IGRAs
- HIV-positive people with positive IGRAs
- People with evidence of previous TB on chest X-ray and inadequate treatment.

**Contact tracing:** carried out after diagnosis of a new case of TB; involves identifying close contacts who are at risk of infection or who may have active infection and not yet sought medical attention

**Screening of healthcare workers:** as part of an occupational health programme, with BCG vaccination of those with no evidence of previous TB exposure

**Screening of new entrants:** those arriving from a country of high incidence of TB should be offered screening for latent or active infection and vaccination if not infected and previously unvaccinated

**Street-homeless or hostel dwellers:** these groups are at increased risk of active TB and should be offered opportunistic screening for active infection

**Immunocompromised people:**
- Patients due to commence monoclonal antibody therapy for autoimmune conditions should be screened for active or latent infection and should be given appropriate treatment before commencing immunosuppressive therapy as they are at a particularly high risk for reactivation of LTBI
- People with HIV infection (see above)
- People with underlying haematological malignancies or solid-organ transplants or undergoing chemotherapy require screening.

**BCG vaccination**

BCG is a live attenuated vaccine derived from *M. bovis* that has lost its virulence. It has variable efficacy but is still recommended in certain situations in developed countries (but not the USA), though no longer offered routinely to all due to the lack of cost-efficacy. It has been shown to reduce the risk of disseminated and CNS TB in babies and children and is therefore used worldwide. There are safety concerns in babies with HIV. Its efficacy in adults is very variable.

**Non-tuberculous mycobacterial infection (NTM)**

NTM occur in soil and water and are not usually pathogenic due to their lack of virulence. However, where there is a breach of the normal host defence mechanisms, certain strains have the potential to become pathogenic (Table 15.21). Factors associated with increased risk of pulmonary NTM infection are shown in Box 15.16. Treatment is suggested if there is a compatible clinical picture and (a) the organism is isolated from an invasive sample or (b) if an NTM is isolated from more than one sputum sample obtained at different times.

Granulomatous lung disease

A granuloma is a mass or nodule composed of chronically inflamed tissue formed by the response of the mononuclear phagocyte system (macrophage/histiocyte) to an insoluble or slowly soluble antigen or irritant. If the foreign substance is inert (e.g. an inhaled dust), the phagocytes turn over slowly; if the substance is toxic or reproducing, the cells turn over faster, producing a granuloma. A granuloma is characterized by epithelioid multinucleate giant cells, as seen in tuberculosis. Granulomas are also seen in other infections, including fungal and helminthic, in sarcoidosis, and in hypersensitivity pneumonitis, and can also be due to foreign bodies (e.g. talc). Granulomatous lung disease with pulmonary vasculitis is discussed on page 847.

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder, commonly affecting young adults and usually presenting with bilateral hilar lymphadenopathy, pulmonary infiltration and skin or eye lesions. Beryllium poisoning can produce a clinical and histological picture identical to sarcoidosis, though contact with this element is now strictly controlled.

Epidemiology and aetiology

Sarcoidosis is a common disease of unknown aetiology that is often detected by routine chest X-ray. There is great geographical variation. The prevalence in the UK is approximately 19/100 000. Sarcoidosis is common in the USA but is uncommon in Japan. The course of the disease is much more severe in American blacks than in whites. The peak incidence is in the 3rd and 4th decades, with a female preponderance. There is no relation with any histocompatibility antigen, but 1st degree relatives (particularly in Caucasians) have an increased risk of developing sarcoidosis. Other proposed aetiological factors are an atypical mycobacterium or fungus, the Epstein–Barr virus, and occupational, genetic, social or other environmental factors (sarcoidosis is commoner in rural than in urban populations). None of these has been substantiated.

Diffuse diseases of the lung parenchyma

Diffuse parenchymal lung disorders (DPLD, also referred to as interstitial lung diseases) are a heterogeneous group of disorders accounting for about 15% of respiratory clinical practice. There is diffuse lung injury and inflammation that can progress to lung fibrosis. The classification is shown in Box 15.17.
**Immunopathology**

- Typical sarcoid granulomas consist of focal accumulations of epithelioid cells, macrophages and lymphocytes, mainly T cells.
- There is depressed cell-mediated reactivity to tuberculin and other antigens such as *Candida albicans*.
- There is overall lymphopenia: circulating T lymphocytes are low but B cells are slightly increased.
- Bronchoalveolar lavage shows a great increase in the number of cells; lymphocytes are greatly increased (particularly CD4+ T-helper cells). The number of alveolar macrophages is increased but they represent a reduced percentage of the total number of bronchoalveolar lavage cells.
- Transbronchial biopsies show infiltration of the alveolar walls and interstitial spaces with leucocytes, mainly T cells, prior to granuloma formation.

It seems likely that the decrease in circulating T lymphocytes and changes in delayed hypersensitivity responses are the result of sequestration of lymphocytes within the lung. There is no evidence to suggest that patients with sarcoidosis suffer from an overall defect in immunity, since the frequency of fungal, viral and bacterial infections is not increased and there is no evidence of any increased risk of developing malignant neoplasms.

**Clinical features**

Sarcoidosis can affect many different organs of the body. The most common presentation is with respiratory symptoms or abnormalities found on chest X-ray (50%). Less common presentations include fatigue or weight loss (5%), peripheral lymphadenopathy (5%) and fever (4%). Neurological presentations are rare but well recognized and can mimic a variety of conditions. Chest X-ray may be normal in up to 20% of non-respiratory cases, though pulmonary lesions may be detected later.

There are four stages of pulmonary involvement based on radiological stage of the disease, which is helpful in prognosis:

- **Stage I**: bilateral hilar lymphadenopathy (BHL) alone
- **Stage II**: BHL with pulmonary infiltrates
- **Stage III**: pulmonary infiltrates without BHL
- **Stage IV**: fibrosis

**Bilateral hilar lymphadenopathy**

This is a characteristic feature of sarcoidosis which is usually symptomless and only detected on chest X-ray. Occasionally, the bilateral hilar lymphadenopathy is associated with a dull ache in the chest, malaise and a mild fever.

Although the lung fields may appear normal on plain chest X-ray, the lung parenchyma is nearly always involved as shown by CT scanning (Fig. 15.38), transbronchial biopsies and bronchoalveolar lavage.

The differential diagnosis of bilateral hilar lymphadenopathy includes:

- **Lymphoma**: though this rarely affects only the hilar lymph nodes
- **Pulmonary tuberculosis**: though it is rare for the hilar lymph nodes to be symmetrically enlarged
- **Carcinoma of the bronchus** with malignant spread to the contralateral hilar lymph nodes: again this is rarely symmetrical.

**Pulmonary infiltration**

Parenchymal sarcoidosis may be asymptomatic. The combination of pulmonary infiltration and normal lung function tests is highly suggestive of sarcoidosis. Other cases are progressive leading to increasing effort dyspnoea and eventually cor pulmonale and death. The chest X-ray shows mottling in the mid-zones evolving over time to generalized fine nodular shadows. Eventually, widespread linear shadows develop, reflecting the underlying fibrosis. A honeycomb appearance can occasionally occur. In progressive disease, lung function tests show a typical restrictive defect with reduced gas transfer (see below).

The principal differential diagnoses are tuberculosis, pneumocooniosis, idiopathic pulmonary fibrosis and alveolar cell carcinoma.

**Extrapulmonary manifestations**

Skin and ocular sarcoidosis are the most common extrapulmonary presentations.

- **Skin lesions** occur in 10% of cases. Sarcoidosis is the most common cause of erythema nodosum (see p. 1216). The association of bilateral symmetrical hilar lymphadenopathy with erythema nodosum occurs only in sarcoidosis. A chilblain-like lesion known as lupus pernio is also seen, as are skin nodules (see p. 1219).

- **Eye lesions**. Anterior uveitis is common and presents with misting of vision, pain and a red eye, but posterior uveitis may present simply as progressive loss of vision. Although ocular sarcoidosis accounts for about 5% of uveitis presenting to ophthalmologists, asymptomatic uveitis may be found in up to 25% of patients with sarcoidosis. Conjunctivitis and retinal lesions have also been reported. **Uveoparotid fever** is a syndrome of bilateral uveitis and parotid gland enlargement together with occasional development of facial nerve palsy and is sometimes seen with sarcoidosis.

- **Keratoconjunctivitis sicca** and lacrimal gland enlargement also occurs.

**Metabolic manifestations**. It is rare for sarcoidosis to present with problems of calcium metabolism, though hypercalcaemia is found in 10% of established cases. Hypercalcaemia and hypercalciuria can lead to the development of renal calculi and nephrocalcinosis. The cause of the hypercalcaemia is an increase in circulating 1,25-dihydroxyvitamin D3, with 1 α-hydroxylation occurring in sarcoid macrophages in the lung in addition to that taking place in the kidney.

**Central nervous system**. CNS involvement is rare (2%) but can lead to severe neurological disease (see p. 1130).

**Bone and joint involvement**. Arthralgia without erythema nodosum is seen in 5% of cases. Bone cysts are found,
particularly in the digits, with associated swelling. In the absence of swelling, routine X-rays of the hands are unnecessary.

Hepatosplenomegaly. Sarcoidosis is a cause of hepatosplenomegaly, though it is rarely of any clinical consequence. Liver biopsy is occasionally performed when the diagnosis is in doubt and will show granulomas.

Cardiac involvement is rare (3%) but can be serious. Ventricular dysrhythmias, conduction defects and cardiomyopathy with congestive cardiac failure are seen.

Investigations

- **Imaging.** Chest X-ray (see above), High-resolution CT is useful for assessment of diffuse lung parenchymal involvement.
- **Full blood count.** There may be a mild normochromic, normocytic anaemia with raised ESR.
- **Serum biochemistry.** Serum calcium is often raised and there is hypergammaglobulinaemia.
- **Transbronchial biopsy** is the most useful investigation, with positive results in 90% of cases of pulmonary sarcoidosis with or without X-ray evidence of lung parenchymal involvement. Pulmonary non-caseating granulomas are found in approximately 50% of patients with extrapulmonary sarcoidosis in whom the chest X-ray is normal.
- **Serum angiotensin-converting enzyme (ACE) level** is raised by two standard deviations above the normal mean value in over 75% of patients with untreated sarcoidosis. Raised (but lower) levels are also seen in patients with lymphoma, pulmonary tuberculosis, asbestosis and silicosis, limiting the diagnostic value of the test. However, the test is useful in assessing disease activity and response to treatment. Reduction of serum ACE during corticosteroid treatment does not, however, imply complete resolution of the disease.
- **Lung function tests** show a restrictive lung defect in patients with pulmonary infiltration or fibrosis. There is a decrease in TLC, FEV1 and FVC, and gas transfer. Lung function is usually normal in patients who present with extrapulmonary disease or who only have hilar adenopathy on chest X-ray.

Treatment

Both the need to treat and the value of corticosteroid therapy are contested in many aspects of this disease. Hilar lymphadenopathy alone does not require treatment. Persisting infiltration visible on the chest X-ray with normal lung function tests should be monitored carefully. Patients with abnormal lung function tests are unlikely to improve without corticosteroid treatment. If the disease is not improving spontaneously 6 months after diagnosis, treatment should be started with prednisolone 30 mg for 6 weeks, reducing to alternate-day treatment with prednisolone 15 mg for 6–12 months. Although there have been no controlled trials of corticosteroids, they are indicated when there is continuing deterioration of lung function. Eye involvement or persistent hypercalcaemia are mandatory indications for systemic steroids.

If the erythema nodosum of sarcoidosis is severe or persistent it will respond rapidly to a 2-week course of prednisolone 5–15 mg daily, as will patients with uveoparotid fever. Myocardial sarcoidosis and neurological manifestations are also treated with prednisolone.

Prognosis

Sarcoidosis is a much more severe disease in certain racial groups, particularly American blacks, where death rates of up to 10% have been recorded. It is probable that the disease is fatal in fewer than 5% of cases in the UK, either as a result of respiratory failure and cor pulmonale or, more rarely, from myocardial sarcoidosis and renal damage. The initial chest X-ray provides a guide to prognosis. The disease remits within 2 years in over two-thirds of patients with hilar lymphadenopathy alone (stage I), in approximately one-half with hilar lymphadenopathy plus chest X-ray evidence of pulmonary infiltration (stage II), but in only one-third of patients with X-ray evidence of infiltration without any demonstrable lymphadenopathy (stage III). Lung volumes and gas transfer are the most useful way to monitor progression.

Granulomatous lung disease with vasculitis

The classification of pulmonary vasculitis and granulomatous disorders is unsatisfactory. In broad terms there are two main groups: the respiratory manifestations of systemic diseases, and disorders associated with the presence of anti-neutrophil cytoplasmic antibodies (ANCA).

Anti-neutrophil cytoplasmic antibodies (ANCAs) (see also p. 587) are found in the acute phase of vasculitides, particularly Wegener’s granulomatosis, Churg–Strauss syndrome and microscopic polyangiitis (polyarteritis) associated with neutrophil infiltration of the vessel wall.

Two major ANCA reactivities are recognized: proteinase-3 (PR3) ANCA and myeloperoxidase (MPO) ANCA.

Some 10–15% cases of progressive glomerulonephritis with anti-glomerular basement membrane (GBM) antibodies Goodpasture’s syndrome (see below) are also MPO-ANCA-positive and these are the most likely to suffer pulmonary haemorrhage.

Wegener’s granulomatosis (granulomatosis with polyangiitis)

This granulomatous disease (see p. 544) of unknown aetiology predominantly affects small arteries. It is characterized by lesions involving the upper respiratory tract, lungs and kidneys. It often starts with severe rhinorrhea, with subsequent nasal mucosal ulceration followed by cough, haemoptysis and pleuritic pain. Occasionally, the skin and nervous system are involved. Single or multiple nodular masses or pneumonic infiltrates with cavitation are seen on chest X-ray. These appear to migrate, with large lesions clearing in one area and new lesions appearing elsewhere. The typical histological changes are usually best seen on renal biopsy, which shows necrotizing microvascular glomerulonephritis. This disease responds well to treatment with cyclophosphamide 150–200 mg daily. Rituximab is also being used. A variant of Wegener’s granulomatosis called ‘midline granuloma’ affects the nose and paranasal sinuses and is particularly mutilating; it has a poor prognosis.

Churg–Strauss syndrome

This condition classically occurs in males in their 4th decade, who present with rhinitis and asthma, eosinophilia and systemic vasculitis. The aetiology is uncertain, with some believing that it is an unusual progression of allergic disease while others regard it as a primary vasculitis which presents like asthma because of the involvement of eosinophils.

There is an eosinophilic infiltration with a characteristic high blood eosinophil count, vasculitis of small arteries and veins, and extravascular granulomas. Typically, it involves the
lungs, peripheral nerves and skin, but renal involvement is uncommon. Transient patchy pneumonia-like shadows may occur, but sometimes these can be massive and bilateral. Skin lesions include tender subcutaneous nodules as well as petechial or purpuric lesions. ANCA is usually positive. The disease responds well to corticosteroids. Occasionally, Churg–Strauss syndrome is revealed when oral steroids are withdrawn in patients being treated for asthma. There is no evidence that anti-asthma drugs precipitate the condition.

Microscopic vasculitis (polyangitis)
This involves the kidneys and the lungs where it results in recurrent haemoptysis. ANCA is usually positive.

### Pulmonary autoimmune rheumatic disease

#### Rheumatoid disease (see also p. 521)
The lungs can be affected by rheumatoid disease and also by some anti-rheumatic drugs used in its treatment (Fig. 15.39).

- **Pleural adhesions, thickening and effusions** are the most common lesions. The effusion is often unilateral and tends to be chronic. It has a low glucose content but this is not specific.

  Several forms of parenchymal disease can occur in patients with rheumatoid arthritis. These include fibrosing alveolitis, rheumatoid nodules, cryptogenic organizing pneumonia, lymphoid interstitial pneumonia and bronchiectasis; other pulmonary problems include pulmonary hypertension and fibrosis (Fig. 15.39). Some patients will have modified presentations because they are already on disease-modifying drugs such as prednisolone or methotrexate for their arthritis.

- **Fibrosing alveolitis** occurring in rheumatoid arthritis can be considered as a variant of the cryptogenic form of the disease (see p. 848). The clinical features and gross appearance are the same but the disease is often more chronic.

- **Rheumatoid nodules** appear on the chest X-ray as single or multiple nodules ranging in size from a few millimetres to a few centimetres. The nodules frequently cavitate. They usually produce no symptoms but can give rise to a pneumothorax or pleural effusion.

- **Obliterative disease of the small bronchioles** is rare. It is characterized by progressive breathlessness and irreversible airflow limitation. Corticosteroids may prevent progression.

- **Cricoarytenoid joint involvement** by rheumatoid arthritis gives rise to dyspnoea, stridor, and hoarseness. Occasionally severe obstruction necessitates tracheostomy.

- **Caplan’s syndrome** is due to a combination of dust inhalation and the disturbed immunity of rheumatoid arthritis. It occurs particularly in coal-worker’s pneumoconiosis but it can occur in individuals exposed to other dusts, such as silica and asbestos. Typically the lesions appear as rounded nodules 0.5–5.0 cm in diameter, though sometimes they become incorporated into large areas of fibrosis that are indistinguishable radiologically from progressive massive fibrosis. There may not be much evidence of simple pneumoconiosis prior to the development of the nodule. These lesions may precede the development of the arthritis. Rheumatoid factor is always present in the serum.

Drugs used in the treatment of rheumatoid arthritis can cause pulmonary problems: e.g. pneumonitis with methotrexate, gold, NSAIDs; fibrosis, with methotrexate; bronchospasm with NSAIDs, aspirin; infections due to corticosteroids, methotrexate; reactivation of tuberculosis with anti-TNF therapy.

#### Systemic lupus erythematosus (see also p. 536)
The most common respiratory manifestation of this disease is pleurisy, occurring in up to two-thirds of cases, with or without an effusion. Effusions are usually small and bilateral. Basal pneumonitis is often present, perhaps as a result of poor movement of the diaphragm, or restriction of chest movements because of pleural pain. Pneumonia also occurs because of either infection or the disease process itself. In contrast to rheumatoid arthritis, diffuse pulmonary fibrosis is rare.

#### Systemic sclerosis (see pp.538 and 1218)
Autopsy studies have indicated that there is almost always some diffuse fibrosis of alveolar walls and obliteration of capillaries and the alveolar space. Severe changes result in nodular then streaky shadowing on the chest X-ray, followed by cystic changes, ending up with a honeycomb lung. Lung function tests reveal a restrictive defect and poor gas transfer. Dilation of the oesophagus increases the risk of aspiration pneumonia (see p. 243). Breathlessness may be worsened by restriction of chest wall movement owing to thickening and contraction of the skin and trunk.

#### Idiopathic interstitial pneumonia (IIP)
A current international classification is shown in Box 15.18. IIP is characterized by diffuse inflammation and fibrosis in the lung parenchyma.

#### Idiopathic pulmonary fibrosis (IPF)
This is also known as usual interstitial pneumonia (UIP) and was previously known as cryptogenic fibrosing alveolitis (CFA).

It is relatively rare with a prevalence of about 20/100 000 population, mean onset is in the late 60s and it is more common in males. The cause is unknown but possible contributory factors include cigarette smoking, chronic aspiration, antidepressants, wood and metal dusts and infections, e.g. Epstein–Barr virus.

---

**Figure 15.39 Respiratory manifestations of rheumatoid disease.** Many drugs affect the lungs, see text, page 1231.
Diffuse diseases of the lung parenchyma

Pathology

The key features are patchy fibrosis of the interstitium (often with intervening normal lung), subpleural and paraseptal changes, minimal or absent inflammation, acute fibroblastic proliferation and collagen deposition (fibroblastic foci) and honeycombing.

Pathogenesis

Several hypotheses have been proposed but it seems likely that injury results from repeated exogenous and endogenous unknown stimuli. It is now understood that inflammation plays little or no part. Multiple micro-injuries to the alveolar cells cause them to secrete growth factors that recruit fibroblasts in a fibrotic environment. These fibroblasts differentiate into myofibroblasts under the influence of TGF-β, synthesize collagen and aggregate to form ‘fibrotic foci’ (Fig. 15.40). In familial pulmonary fibrosis, several mutations have been identified, suggesting a genetic disposition. Genes over-expressed in IPF include matrix metalloproteinases (MMP1, 7), cyclin A2 (CLNA 2), α-defensins, surfactant protein A1 and the gene encoding mucinSB (MUCSB). There is an absence of type 1 pneumocytes with a lack of differentiation of type 2 into type 1 pneumocytes resulting in a dysfunctional alveolar epithelium.

Clinical features

The main features are progressive breathlessness, a non-productive cough and cyanosis, which eventually lead to respiratory failure, pulmonary hypertension and cor pulmonale. Fine bilateral end-inspiratory crackles are heard on auscultation and gross finger clubbing occurs in two-thirds of cases. An acute form known as the Hamman–Rich syndrome occasionally occurs. Various autoimmune diseases are associated with IPF (see also Box 15.17). IPF has also been reported in association with coeliac disease, ulcerative colitis and renal tubular acidosis.

Investigations

- **Chest X-ray** initially shows a ground glass appearance, followed by irregular reticulonodular shadowing (often maximal in the lower zones) and finally a honeycomb lung.

- **High-resolution CT scan (HRCT)** shows characteristic bilateral changes mainly involving the lower lobes (Fig. 15.41). There may be subpleural reticular abnormalities with minimal or no ground glass changes, honeycombing, i.e. thick-walled cysts 0.5–2 cm in diameter in terminal and respiratory bronchioles, and traction bronchiectasis.

- **Respiratory function tests** show a restrictive ventilatory defect – lung volumes are reduced, the FEV₁ to FVC ratio is normal to high (with both values being reduced).
and carbon monoxide gas transfer is reduced. Peak flow rates may be normal.

- **Blood gases** show arterial hypoxaemia, caused by a combination of alveolar-capillary block and ventilation–perfusion mismatch with normal or low $P_{a}CO_2$ owing to hyperventilation.

- **Blood tests.** Anti-nuclear antibodies and rheumatoid factors are present in one-third of patients. The ESR and immunoglobulins are mildly elevated.

- **Bronchoalveolar lavage** shows increased numbers of cells, particularly neutrophils and macrophages.

- **Histological confirmation** is necessary in some patients. Transbronchial lung biopsy is rarely diagnostic, but can exclude other conditions which present similarly, e.g. sarcoidosis or lymphangitis carcinomatosa.

**Video-assisted thoracoscopic lung biopsy is used to obtain a larger specimen, which will allow a clear histological diagnosis to be made.**

**Differential diagnosis**

The diagnosis of IPF is usually made in a patient presenting with the above signs and characteristic HRCT changes. The differential diagnosis of the chest X-ray appearance includes hypersensitivity pneumonitis, bronchiectasis, chronic left heart failure, sarcoidosis, industrial lung disease and lymphangitis carcinomatosa.

**Prognosis and treatment**

The median survival time for patients with IPF is approximately 5 years, although mortality is very high in the more acute forms. Treatment with prednisolone (30 mg daily) is usually prescribed for disabling disease although it produces little benefit. Azathioprine or cyclophosphamide is added if there is no response. A number of other treatments have been tried. Pirfenidone, an anti-fibrotic anti-inflammatory drug, has reduced lung function deterioration in two randomized controlled trials. A tyrosine kinase inhibitor, BIBF1120, has shown the same benefit in a phase II study. Supportive treatment includes domiciliary oxygen therapy. In younger patients with severe disease, lung transplantation is offered.

**Desquamative interstitial pneumonia (DIP)**

This occurs mainly in middle-aged male smokers and is less severe but similar to usual interstitial pneumonia (UIP). Pathologically there are more mononuclear cells than in UIP, due to smoking (pigmented macrophages). The prognosis is good with corticosteroid therapy.

**Respiratory bronchiolitis interstitial lung disease (RBILD)**

Clinically, RBILD is like DIP. Pathologically, pigmented macrophages are seen in the lumen of respiratory bronchioles. It has a better prognosis than UIP.

**Acute interstitial pneumonia (AIP)**

There is a very acute onset of pneumonia, often preceded by an upper respiratory tract infection, and progressive respiratory failure. Diffuse alveolar damage (DAD) is seen on lung biopsy. The prognosis is poor.

**Nonspecific interstitial pneumonia (NSIP)**

The onset is subacute with a fever in 30%. Men and women are equally affected and finger clubbing does not occur. Biopsy reveals a chronic interstitial pneumonia with mononuclear inflammatory cells and some fibrosis. Prognosis is variable (depending on amount of fibrosis).

### Cryptogenic organizing pneumonia (COP)

This condition, previously called bronchiolitis obliterans organizing pneumonia (BOOP), is an organizing pneumonia of unknown aetiology. Typically, patients present with single or recurrent episodes of malaise associated with cough, breathlessness and fever. Pleuritic chest pain is sometimes present but finger clubbing is very rare. Chest X-rays show confluent bilateral parenchymal shadowing. Lung function tests are usually normal but may show a restrictive defect. The white blood count is normal, but the ESR may be raised. The diagnosis is usually made on history and X-ray appearances. Lung biopsy reveals characteristic buds of connective tissue (Masson’s bodies) in respiratory bronchioles and in alveolar ducts. Open biopsy has now been replaced by video-assisted thoracoscopic lung biopsy. COP responds rapidly to corticosteroid treatment but can recur episodically, especially in older women.

**Lymphoid interstitial pneumonia**

This condition is more common in children than in adults and is characterized by infiltration with lymphocytes, plasma cells and immunoblasts. It is thought to be a viral pneumonia and causes diffuse reticulonodular infiltrates on the chest X-ray. Corticosteroid therapy appears to be of benefit, as is zidovudine.

**Drugs**

Drugs causing diffuse parenchymal lung disease are shown on page 854 and in Table 15.22.

### Other types of diffuse lung disease

#### Langerhans’ cell histiocytosis (LCH)

This rare disease (prevalence 1/50,000) is characterized histologically by proliferation of Langerhans’ cells, identified by the presence of Birbeck granules on electron microscopy or the CD1a antigen on the surface of the cells. There is a wide variation in clinical presentation, from unifocal bone lesions in older children (which may regress spontaneously), to more disseminated disease in younger children (with a high mortality). Pulmonary LCH occurs almost exclusively in smokers. Chest X-rays (and HRCT) show multiple small cysts (honeycomb lung), fibrosis or widespread nodular shadows. **Treatment** involves stopping smoking, with regression of disease, corticosteroids and immunosuppressive therapy. For advanced progressive disease, lung transplantation is the only option. Five-year and 10-year survivals are 75% and 65%, respectively.

#### Goodpasture’s syndrome

This disease (see also p. 585) often starts with symptoms of an upper respiratory tract infection followed by cough and intermittent haemoptysis, tiredness and eventually anaemia, although massive bleeding may occur. The chest X-ray shows transient blotchy shadows that are due to intra-pulmonary haemorrhage. These features usually precede the development of an acute glomerulonephritis by several weeks or months. The course of the disease is variable: some patients spontaneously improve while others proceed to renal failure.
The disease usually occurs in individuals over 16 years of age. It is due to a type II cytotoxic reaction driven by antibodies directed against the basement membrane of both kidney and lung. It has been proposed that there is a shared antigen. ANCA may be positive. An association with influenza A2 virus and lung has been proposed. It is due to a type II cytotoxic reaction driven by antibodies directed against the basement membrane of both kidney and lung. ANCA may be positive. An association with influenza A2 virus and lung has been proposed. The general prognosis is poor but treatment with corticosteroids or azathioprine is usually given.

**Diffuse alveolar haemorrhage**

This is clinically similar to Goodpasture’s syndrome, but anti-basement-membrane antibodies are absent and the kidneys are less frequently involved. Most cases occur in children under 7 years of age. The child develops a chronic cough and anaemia. The chest X-ray shows diffuse shadows that are due to intrapulmonary bleeding, and eventually miliary nodulation. Characteristically, haemosiderin-containing macrophages are found in the sputum. There is an association with sensitivity to cow’s milk, and an appropriate diet is usually tried.

**Lymphangioleiomyomatosis**

This is a rare disorder of young women with hamartomatous smooth muscle infiltration of the lungs. Gene mutations in the hamartin–tuberin complex are present; the gene products regulate the activity of rapamycin complex 1. Patients present with dyspnoea, chylos pleural effusions, haemoptysis and pneumothorax. Treatment with hormones/ophorectomy has shown little benefit. Sirolimus (rapamycin) treatment has shown benefit.

**Pulmonary alveolar proteinosis**

This is a rare disease in which there is accumulation of lipoproteinaceous material within the alveoli. It can be congenital, but most cases are acquired and appear to have an autoimmune basis, with antibodies directed against the cytokine GM-CSF. The disease mostly affects men and presents with progressive exertional dyspnoea and cough. Inspiratory crackles are present in only about 50%. Diagnosis is made by bronchial lavage, which reveals a milky appearance and many large, foamy macrophages but few other inflammatory cells.

**Pulmonary infiltration with eosinophilia**

The common types and characteristics of these diseases are shown in Table 15.23. They range from very mild, simple, pulmonary eosinophilias to the often fatal hypereosinophilic syndrome.

</table>
the chest X-ray shows either localized or diffuse opacities. The simple form is probably due to a transient allergic reaction in the alveoli. Many allergens have been implicated, including *Ascaris lumbricoides*, *Ankylostoma*, *Trichuris*, *Trichinella*, *Taenia* and *Strongyloides*. Drugs such as aspirin, penicillin, nitrofurantoin and sulphonamides have been implicated. Often, no allergen is identified. The disease is self-limiting and no treatment is required, apart from treating the cause. In the more chronic form all unnecessary treatment should be withdrawn and, where appropriate, worms are treated. Corticosteroid therapy is indicated, with resolution of the disease over the ensuing weeks.

**Asthmatic bronchopulmonary eosinophilia**

This is characterized by the presence of asthma, transient fleeting shadows on the chest X-ray, and blood or sputum eosinophilia. By far the most common cause worldwide is allergy to *A. fumigatus* (see below), although *Candida albicans* and other mycoses may be the allergen in a small number of patients. In many, no allergen can be identified. Whether these cases are intrinsic or driven by an unidentified extrinsic factor is uncertain.

**Diseases caused by Aspergillus fumigatus**

The various types of lung disease caused by *A. fumigatus* are illustrated in Figure 15.42.

The spores of *A. fumigatus* (diameter 5 mm) are readily inhaled and are present in the atmosphere throughout the year, though they are at their highest concentration in the late autumn. They can be grown from the sputum in up to 15% of patients with chronic lung disease in whom they do not produce disease. They are a cause of extrinsic asthma in atopic individuals.

**Allergic bronchopulmonary aspergillosis (asthmatic pulmonary eosinophilia)**

This rare disease is caused by a hypersensitivity reaction when the bronchi are colonized by *Aspergillus*. It can complicate asthma and cystic fibrosis. Proximal bronchiectasis occurs.

**Clinical features.** There are episodes of eosinophilic pneumonia throughout the year, particularly in late autumn and winter. The episodes present with a wheeze, cough, fever and malaise. They are associated with expectoration of firm sputum plugs containing the fungal mycelium, which results in the clearing of the pulmonary infiltrates on the chest X-ray. Occasionally large mucus plugs obliterate the bronchial lumen, causing collapse of the lung.

Left untreated, repeated episodes of eosinophilic pneumonia can result in progressive pulmonary fibrosis that usually affects the upper zones and can give rise to a chest X-ray appearance similar to that produced by tuberculosis.

**In Investigations.** The peripheral blood eosinophil count is usually raised, and total levels of IgE are usually extremely high, at >1000 ng/mL (both that specific to *Aspergillus* and nonspecific). Skin-prick testing to protein allergens from *A. fumigatus* gives rise to positive immediate skin tests. Sputum may show eosinophils and mycelia. Precipitating antibodies in the serum are usually, but not always, found in the serum.

Lung function tests show a decrease in lung volumes and gas transfer in more chronic cases, but there is evidence of reversible airflow limitation in all cases.

**Treatment** is with prednisolone 30 mg daily, which causes rapid clearing of the pulmonary infiltrates. Frequent episodes of the disease can be prevented by long-term treatment with prednisolone, but doses of 10–15 mg daily are usually required. Antifungal agents (itraconazole, voriconazole) should be used in patients on high doses of steroids; there is evidence that treatment with itraconazole improves pulmonary function. The asthma component responds to inhaled corticosteroids, although these do not influence the occurrence of pulmonary infiltrates. Omalizumab, a humanized monoclonal antibody against IgE, is being trialled.

**Aspergillosis and invasive aspergillosis**

Aspergillosis is the growth of *A. fumigatus* within previously damaged lung tissue where it forms a ball of mycelium within lung cavities. Typically the chest X-ray shows a round lesion with an air ‘halo’ above it. Continuing antigenic stimulation gives rise to large quantities of precipitating antibody in the serum. The aspergillosis itself causes little trouble, though occasionally massive haemoptysis may occur, requiring resection of the area of damaged lung containing the

---

**Further Reading**

Histologically there is an initial infiltration of the small airways.

Pathogenesis

Some examples are illustrated in the most common being microbial spores contaminating the lung. It is due to the inhalation of a number of different antigens, giving the appearance of pneumonia.

The disease is characterized by a very high eosinophil count in peripheral blood. The filarial complement fixation test is positive in almost every case, although the microfilaria are seldom found. The treatment of choice is diethylcarbamazine (see p. 154 for details).

The hypereosinophilic syndrome

This disease is characterized by eosinophilic infiltration in various organs, sometimes associated with an eosinophilic arteritis. The heart muscle is particularly involved, but pulmonary involvement in the form of a pleural effusion or interstitial lung disease occurs in about 40% of cases. Typical features are fever, weight loss, recurrent abdominal pain, persistent non-productive cough and congestive cardiac failure. Corticosteroid treatment may be of value in some cases.

Hypersensitivity pneumonitis

In this disease there is a widespread diffuse inflammatory reaction in both the small airways of the lung and the alveoli. It is due to the inhalation of a number of different antigens, the most common being microbial spores contaminating vegetable matter (e.g. straw, hay, mushroom compost). Some examples are illustrated in Table 15.24. By far the most common of these diseases worldwide is farmer’s lung, which affects up to 1 in 10 of the farming community in disadvantaged, wet communities around the world. Cigarette smokers have a lower risk of developing the disease due to decreased antibody reaction to the antigen.

Pathogenesis

Histologically there is an initial infiltration of the small airways and alveolar walls with neutrophils followed by T lymphocytes and macrophages, leading to the development of small non-caseating granulomas. These comprise multinucleated giant cells, occasionally containing the inhaled antigenic material. The allergic response to the inhaled antigens involves both cellular immunity and the deposition of immune complexes causing foci of inflammation through the activation of complement via the classical pathway. Some of the inhalant materials may also lead to inflammation by directly activating the alternative complement pathway. These mechanisms attract and activate alveolar and interstitial macrophages, so that continued antigenic exposure results in the progressive development of pulmonary fibrosis.

Clinical features

Typically fever, malaise, cough and shortness of breath come on several hours after exposure to the causative antigen. Thus, a farmer forking hay in the morning may notice symptoms during the late afternoon and evening with resolution by the following morning. On examination, the patient may have a fever, tachypnoea, and coarse end-inspiratory crackles and wheezes throughout the chest. Cyanosis caused by ventilation-perfusion mismatch may be severe even at rest. Continued exposure leads to a chronic illness characterized by severe weight loss, effort dyspnoea and cough as well as the features of idiopathic pulmonary fibrosis (see p. 848).

Investigations

- Chest X-ray shows fluffy nodular shadowing with the subsequent development of streaky shadows, particularly in the upper zones. In very advanced cases, honeycomb lung occurs.
- High-resolution CT shows reticular and nodular changes with ground glass opacity, which can be further categorized with multislice CT.
- Lung function tests show a restrictive ventilatory defect with a decrease in carbon monoxide gas transfer.
- Polymorphonuclear leucocyte count is raised in acute cases. Eosinophilia is not a feature.
- Precipitating antibodies are present in the serum. One-quarter of pigeon fanciers have precipitating IgG antibodies against pigeon protein and droppings in their serum, but only a small proportion have lung disease. Precipitating antibodies are evidence of exposure, not disease.
- Bronchoalveolar lavage shows increased T lymphocytes and granulocytes.

Differential diagnosis

Although hypersensitivity pneumonitis due to inhalation of the spores of *Micropolyspora faeni* is common among farmers, it is probably more common for these individuals to suffer from asthma related to inhalation of antigens from a variety of mites that infest stored grain and other vegetable material. These include *Lepidoglyphus domesticus*, *L. destructor* and *Acarus siro*. Symptoms of asthma resulting from inhalation of these allergens are often mistaken for farmer’s lung. Lung function tests will effectively discriminate between the disorders. Pigeon fancier’s lung is quite common, but alveolitis from budgerigars, parrots and parakeets is very rare.

Management

Prevention is the aim. This can be achieved by changes in work practice, with the use of silage for animal fodder and the drier storage of hay and grain. Pigeon fancier’s lung is more difficult to control since affected individuals remain strongly attached to their hobby. Prednisolone, initially in large doses of 30–60 mg daily, may achieve regression during the early stages of the disease. Established fibrosis will not resolve and in some patients the disease may progress inexorably to respiratory failure in spite of intensive therapy. Farmer’s lung is a recognized occupational disease in the UK and sufferers are entitled to compensation, depending upon their degree of disability.

Humidifier fever

Humidifier fever (Table 15.24), one cause of building-related illnesses (p. 936), may present with the typical features of hypersensitivity pneumonitis without any radiographic changes. This disease has occurred in outbreaks in factories in the UK, particularly in printing works. In North America it is more commonly found in office blocks with contaminated air-conditioning systems. Humidifier fever may be effectively prevented by sterilization of the re-circulating water used in large humidifying plants.

Drug and radiation-induced respiratory reactions

Drugs may produce a wide variety of disorders of the respiratory tract (Table 15.22). The mechanisms are varied and include direct toxicity (e.g. bleomycin), immune complex formation with arthritis, hypersensitivity (involving both T cell and IgE mechanisms) and autoimmunity. Tuberculosis activation is seen with immunosuppressive drugs.

Pulmonary infiltrates with fibrosis may result from the use of a number of cytotoxic drugs used in the treatment of cancer. The most common cause of these reactions is bleomycin. The pulmonary damage is dose-related, occurring when the total dosage is >450 mg, but will regress in some cases if the drug is stopped. The most sensitive test is a decrease in carbon monoxide gas transfer, and therefore gas transfer should be measured repeatedly during treatment with the drug. The use of corticosteroids may help resolution. Drugs affecting the respiratory system are shown in Table 15.22, together with the types of reaction they produce. Anaphylaxis with bronchospasm can occur with many drugs. The list is not exhaustive; e.g. over 20 different drugs are known to produce a systemic lupus erythematosus-like syndrome, sometimes complicated by pulmonary infiltrates and fibrosis. Paraquat ingestion causes severe pulmonary oedema and death, and pulmonary fibrosis develops in many of the few who survive.

Irradiation of the lung during radiotherapy can cause a radiation pneumonitis. Patients complain of breathlessness and a dry cough. Radiation pneumonitis results in a restrictive lung defect. Corticosteroids should be given in the acute stage.

OCCUPATIONAL LUNG DISEASE

Exposure to dusts, gases, vapours and fumes at work can cause several different types of lung disease:

- Acute bronchitis and even pulmonary oedema from irritants such as sulphur dioxide, chlorine, ammonia or the oxides of nitrogen
- Pulmonary fibrosis due to mineral dust
- Occupational asthma (see Table 15.13) – this is now the commonest industrial lung disease in the developed world
- Hypersensitivity pneumonitis (see Table 15.24)
- Bronchial carcinoma due to industrial agents (e.g. asbestos, polycyclic hydrocarbons, radon in mines).

The degree of fibrosis that follows inhalation of mineral dust varies. While iron (siderosis), barium (baritosis) and tin (stannosis) lead to dramatic dense nodular shadowing on the chest X-ray, their effect on lung function and symptoms is minimal. In contrast, exposure to silica or asbestos leads to extensive fibrosis and disability. Coal dust has an intermediate fibrogenic effect and used to account for 90% of all compensated industrial lung diseases in the UK. The term ‘pneumoconiosis’ means the accumulation of dust in the lungs and the reaction of the tissue to its presence. The term is not wide enough to encompass all occupational lung disease and is now generally used only in relation to coal dust and its effects on the lung.

Coal-worker’s pneumoconiosis

The disease is caused by dust particles approximately 2–5 μm in diameter that are retained in the small airways and alveoli of the lung. The incidence of the disease is related to total dust exposure, which is highest at the coal face, particularly if ventilation and dust suppression are poor. Improved ventilation and working conditions have reduced the risk of this disease.

Two very different syndromes result from the inhalation of coal.

Simple pneumoconiosis

This simply reflects the deposition of coal dust in the lung. It produces fine micronodular shadowing on the chest X-ray and is by far the most common type of pneumoconiosis. It is graded on the chest X-ray appearance according to standard categories set by the International Labour Office (see below). Considerable dispute remains about the effects of simple pneumoconiosis on respiratory function and symptoms. In many cases, the symptoms are due to COPD related to cigarette smoking, but this is not always the case. Changes to UK workers’ compensation legislation means that coal miners who develop COPD are compensated for their disability regardless of their chest X-ray appearance.

Categories of simple pneumoconiosis are as follows:

1. Small round opacities definitely present but few in number
2. Small round opacities numerous but normal lung markings still visible
3. Small round opacities very numerous and normal lung markings partly or totally obscured.

Simple pneumoconiosis can progress to the development of progressive massive fibrosis (PMF) (see below). PMF virtually never occurs on a background of category 1 simple pneumoconiosis but occurs in about 7% of those with category 2 and in 30% of those with category 3. Miners with category 1 pneumoconiosis are unlikely to receive compensation unless they also have evidence of COPD. Those with more extensive radiographic changes are compensated solely on the basis of their X-ray appearances.

Progressive massive fibrosis
In PMF, patients develop round fibrotic masses several centimetres in diameter, almost invariably in the upper lobes and sometimes having necrotic central cavities. The pathogenesis of PMF is still not understood, though it seems clear that some fibrogenic promoting factor is present in individuals developing the disease, leading to the formation of immune complexes, analogous to the development of large fibrotic nodules in coal miners with rheumatoid arthritis (Caplan’s syndrome). Rheumatoid factor and anti-nuclear antibodies are both often present in the serum of patients with PMF, and also in those suffering from asbestosis or silicosis. Pathologically there is apical destruction and disruption of the lung, resulting in emphysema and airway damage. Lung function tests show a mixed restrictive and obstructive ventilatory defect with loss of lung volume, irreversible airflow limitation and reduced gas transfer.

The patient with PMF suffers considerable effort dyspnoea, usually with a cough. The sputum may be black. The disease can progress (or even develop) after exposure to coal dust has ceased and may lead to respiratory failure.

Silicosis
This disease is uncommon though it may still be encountered in stonemasons, sand-blasters, pottery and ceramic workers and foundry workers involved in fettling (removing sand from metal castings made in sand-filled moulds). Silicosis is caused by the inhalation of silica (silicon dioxide). This dust is highly fibrogenic. For example, a coal miner can remain healthy with 30 g of coal dust in his lungs but 3 g of silica is sufficient to kill. Silica seems particularly toxic to alveolar macrophages and readily initiates fibrogenesis (see Fig. 15.40). The chest X-ray appearances and clinical features of silicosis are similar to those of PMF, but distinctive thin streaks of calcification may be seen around the hilar lymph nodes (‘eggshell’ calcification).

Asbestos
Asbestos is a mixture of silicates of iron, magnesium, nickel, cadmium and aluminium, and has the unique property of occurring naturally as a fibre. It is remarkably resistant to heat, acid and alkali, and has been widely used for roofing, insulation and fireproofing. Asbestos has been mined in southern Africa, Canada, Australia and Eastern Europe.

Several different types of asbestos are recognized: about 90% of asbestos is chrysotile, 6% crocidolite and 4% amosite. Chrysotile or white asbestos is the softest asbestos fibre. Each fibre is often as long as 2 cm but only a few microns thick. It is less fibrogenic than crocidolite.

Crocidolite (blue asbestos) is particularly resistant to chemical destruction and exists in straight fibres up to 50 mm in length and 1–2 μm in width. Crocidolite is the type of asbestos most likely to produce asbestosis and mesothelioma. This may be due to the fact that it is readily trapped in the lung. Its long, thin shape means that it can be inhaled, but subsequent rotation against the long axis of the smaller airways, particularly in turbulent airflow during expiration, causes the fibres to impact. Crocidolite is also particularly resistant to macrophage and neutrophil enzymatic destruction.

Exposure to asbestosis occurred particularly in shipbuilding yards and in power stations, but it was used so widely that low levels of exposure were very common. Up to 50% of city dwellers have asbestos bodies (asbestos fibres covered in protein secretions) in their lungs at post mortem. Regulations in the UK prohibit the use of crocidolite and severely restrict the use of chrysotile. Careful dust control measures are enforced, which should eventually abolish the problem. Workers continue to be exposed to blue asbestos in the course of demolition or in the replacement of insulation, and it should be remembered that there is a considerable time lag between exposure and development of disease, particularly mesothelioma (20–40 years).

The risk of primary lung cancer (usually adenocarcinoma) is increased in people exposed to asbestos, even in non-smokers. This risk is about 5–7-fold greater in those who have parenchymal asbestosis and about 1.5-fold in those with pleural plaques without parenchymal fibrosis. A synergistic relationship exists between asbestosis and cigarette smoking with the risk of bronchial carcinoma multiplied about five-fold above the risk attributable to smoking alone.

Diseases caused by asbestos are summarized in Table 15.25. Bilateral diffuse pleural thickening, asbestosis, mesothelioma and asbestos-related carcinoma of the bronchus are all eligible for industrial injuries benefit in the UK.
Respiratory disease

the mill, particularly in the blowing and carding rooms where raw cotton is cleaned and the fibres are straightened.

The exact nature of the disease and its aetiology remain disputed. Pure cotton does not cause the disease, and cotton dust has some effect on airflow limitation in all those exposed. Individuals with asthma are particularly badly affected by exposure to cotton dust. The most likely aetiology is endotoxins from bacteria present in the raw cotton causing constriction of the airways of the lung. There are no changes on the chest X-ray and there is considerable dispute as to whether the progressive airflow limitation seen in some patients with the disease is due to cotton dust or to other factors such as cigarette smoking or co-existent asthma.

Berylliosis

Beryllium-copper alloy has a high tensile strength and is resistant to metal fatigue, high temperature and corrosion. It is used in the aerospace industry, in atomic reactors and in many electrical devices.

When beryllium is inhaled, it can cause a systemic illness with a clinical picture similar to sarcoidosis. Clinically there is progressive dyspnoea with pulmonary fibrosis. However, strict control of levels in the working atmosphere has made this disease a rarity.

LUNG CYSTS

These can be congenital, bronchogenic or the result of a sequestrated pulmonary segment. Hydatid disease causes fluid-filled cysts. Lung abscesses are thin-walled cysts, which are particularly found in staphylococcal pneumonia, tuberculous cavities, septic pulmonary infarction, primary bronchogenic carcinoma, cavitating metastatic neoplasm, or paragonimiasis caused by the lung fluke Paragonimus westermani.

TUMOURS OF THE RESPIRATORY TRACT

Malignant tumours

Bronchial carcinoma

- Bronchial carcinoma is the most common malignant tumour worldwide, with around 1.4 million deaths annually.
- It is the third most common cause of death in the UK after ischaemic heart disease and cerebrovascular disease and is now the commonest cause of cancer-related death in both men and women.
- Rates are declining in men but still increasing overall reflecting increasing incidence in women.
- The ratio in men-to-women is now 1.2 :1.

Cigarette smoking (including passive smoke exposure) accounts for >90% of lung cancer. There remains a higher incidence of bronchial carcinoma in urban compared with rural areas, even when allowance is made for cigarette smoking. Other aetiological factors include:

- Environmental: radon exposure, asbestos, polycyclic aromatic hydrocarbons and ionizing radiation.
- Occupational exposure to arsenic, chromium, nickel, petroleum products and oils
- Host factors: pre-existing lung disease such as pulmonary fibrosis; HIV infection; genetic factors.

Legislative control over smoking in public places in many parts of the world has been introduced to reduce ill health related to cigarette smoke.
Pathophysiology
Historically, lung cancers are broadly divided into small cell carcinoma and non-small cell carcinoma based upon the histological appearances of the cells seen within the tumour. This distinction is necessary with respect to the behaviour of the tumour, providing prognostic information and determining best treatment. Non-small cell carcinoma is further divided into a number of cell types (adenocarcinoma, squamous cell carcinoma, large cell carcinoma, large cell neuroendocrine (see Table 15.26).

Clinical features
The presentation and clinical course vary between the different cell types (Table 15.26). Symptoms and signs may vary depending on the extent and site of disease. Common presenting features can be divided into those caused by direct/local tumour effects, metastatic spread and non-metastatic extrapulmonary features.

Local effects
- **Cough:** this is the most commonly encountered symptom in lung cancer. Because evidence suggests this symptom is neglected by both patients and healthcare professionals, campaigns in the UK have highlighted the ‘three week cough’ as a symptom that merits a chest X-ray.
- **Breathlessness:** central tumours occlude large airways resulting in lung collapse and breathlessness on exertion. Many patients with lung cancer have co-existent COPD which is also a cause of breathlessness.
- **Haemoptysis:** coughing up fresh or old blood due to tumour bleeding into an airway.
- **Chest pain:** peripheral tumours invade the chest wall or pleura (both well innervated), resulting in sharp pleuritic pain. Large volume mediastinal nodal disease often results in a characteristic dull central chest ache.
- **Wheeze:** monophonic when due to partial obstruction of an airway by tumour.
- **Hoarse voice:** mediastinal nodal or direct tumour invasion of the mediastinum results in compression of the left recurrent laryngeal nerve.

**Nerve compression:** Pancoast tumours in the apex of the lung invade the brachial plexus causing C8/T1 palsy with small muscle wasting in the hand and weakness as well as pain radiating down the arm. An associated Homer’s syndrome due to compression of the sympathetic chain with classic features of miosis, ptosis and anhidrosis also occurs.

**Recurrent infections:** tumour causing partial obstruction of an airway results in post-obstructive pneumonia.

**Bronchial carcinoma** can also directly invade the phrenic nerve, causing paralysis of the ipsilateral hemidiaphragm. It can involve the oesophagus, producing progressive dysphagia, and the pericardium, resulting in pericardial effusion and malignant dysrhythmias.

**Superior vena caval obstruction:** see p. 449.

**Tracheal tumours** present with progressive dysphagia and stridor. Flow volume curves show dramatic reductions in inspiratory flow (see Fig. 15.7c).

Metastatic spread
Bronchial carcinoma commonly spreads to mediastinal, cervical and even axillary or intra-abdominal nodes. In addition, the liver, adrenal glands, bones, brain and skin are frequent sites for metastases:

- **Liver:** common symptoms are anorexia, nausea and weight loss. Right upper quadrant pain radiating across the abdomen is associated with liver capsular pain.
- **Bone:** bony pain and pathological fractures as a result of tumour spread occur. If the spine is involved, there is a risk of spinal cord compression, which requires urgent treatment.
- **Adrenal glands:** metastases to the adrenals do not usually result in renal insufficiency and are usually asymptomatic.
- **Brain:** metastases present as space-occupying lesions with subsequent mass effect and signs of raised intracranial pressure. Less common presentations include carcinomatous meningitis with cranial nerve defects, headache and confusion.

- **Malignant pleural effusion:** this presents with breathlessness and is commonly associated with pleuritic pain.

**Non-metastatic extrapulmonary manifestations of bronchial carcinoma** *(Table 15.27)*

Minor haematological extrapulmonary manifestations of lung cancer such as normocytic anaemia and thrombocytosis are reasonably common. Apart from finger clubbing and HPOA, most other non-metastatic complications are relatively rare. Approximately 10% of small cell tumours produce ectopic hormones giving rise to paraneoplastic syndromes (see Box 9.2).

**Investigations**

Investigations are necessary:

- to stage the extent of disease
- to make a tissue diagnosis (differentiate small cell from non-small cell lung cancer (NSCLC) as well as to detail the cell type in NSCLC – increasingly relevant with newer targeted biological agents) and
- to assess fitness to undergo treatment.

**Staging and diagnosis**

**Chest X-ray**

Plain chest radiographs show obvious evidence of lung cancer or nonspecific appearances *(Box 15.19).* In some cases, the initial radiograph is normal, either because the lesion is small, or the disease is confined to central structures.

**Computed tomography**

CT indicates the extent of disease. Imaging should include the liver and adrenal glands which are common sites for metastases. The International Association for the Study of Lung Cancer (IASLC) has devised the most widely used staging definitions which are based upon CT imaging of tumour size (T), nodal involvement (N) and metastases (M) along with prognostic data. These have been recently updated based upon an extensive review of survival in over 80,000 patients *(Table 15.28).*

Using CT criteria, lymph nodes that are less than 1 cm in diameter are not classed as being enlarged, yet they can still contain malignant cells. With increasing size, the positive predictive value of CT in detecting malignant nodes increases; however, it cannot be assumed that enlarged nodes are definitely malignant and further staging tests should be performed if there are no distant metastases and the primary tumour is thought to be eligible for curative treatment. These tests would include direct sampling of affected nodes and positron emission tomography to assess for distant spread of cancer.

**Positron emission tomography (PET) imaging/CT**

This is the investigation of choice for characterizing extent of mediastinal nodal involvement and highlighting distant metastases either not visualized or indeterminate on CT *(see p. 797).* Most commonly, PET images are combined with CT for best correlation. Negative predictive value is high but a positive node on PET-CT should prompt sampling for confirmation of presence of malignant cells as the positive predictive value is relatively low.

**Other imaging modalities**

MRI is not useful for the diagnosis of primary lung tumours other than in Pancoast tumours with nerve invasion or when assessing for chest wall involvement prior to surgery.

**Fibreoptic bronchoscopy** *(see also this chapter, Fig. 15.43)*

This technique is used to define the bronchial anatomy and to obtain biopsy and cytological specimens. If the carcinoma involves the first 2 cm of either main bronchus, the tumour is inoperable as there would be insufficient resection margins for pneumonectomy. Widening and loss of the sharp angle of the carina indicates the presence of enlarged subcarinal lymph nodes, either malignant or reactive. These can be biopsied ‘blind’ by passage of a needle through the bronchial wall.

**Percutaneous aspiration and biopsy**

Peripheral lung lesions cannot be seen by fibreoptic bronchoscopy. Samples are obtained by aspiration or biopsy through the chest wall under CT guidance. The commonest complication is pneumothorax (around 10% patients), especially if the mass is deep in the lung, as opposed to lesions next to the parietal pleura. Mild haemoptysis occurs in <5%. Implantation metastases do not occur.

**Endobronchial ultrasound**

A fibreoptic scope with ultrasound probe is used in staging of lung cancer, to visualize the majority of mediastinal nodes (not all of which are accessible surgically via mediastinoscopy or mediastinotomy) and then allow fine needle aspiration.

Endoscopic ultrasound via the oesophagus can also be used with the added advantage of enabling sampling of the left adrenal gland, posterior and inferior mediastinal lymph node groups. Figure 15.44 shows the lymph node areas which are commonly involved and sampled in the staging investigations.

**Ultrasound-guided supraclavicular node sampling**

In selected cases, where staging suggests N3 nodes to be involved, even where supraclavicular nodes are not palpable, ultrasound fine needle aspiration can be diagnostic.

**Video-assisted thoracoscopic surgery**

Large effusions with evidence of pleural thickening are amenable to biopsy and drainage via minimally invasive surgery. This technique is particularly useful as pleurodesis to prevent recurrence of effusion can be performed at the same time.

**Other investigations**

These include a full blood count for the detection of anaemia, and biochemistry for liver involvement, hypercalcaemia and hyponatraemia.

**Assessing fitness for treatment**

Before radical treatment, an assessment of fitness for treatment should be carried out. This work-up should include full lung function testing with transfer capacity,

and if cardiovascular disease is present, cardiopulmonary exercise testing, stress echo or occasionally preoperative angiography.

**Treatment**  (see also p. 471)

Treatment of lung cancer involves several different modalities and should be planned by a multidisciplinary team. Unfortunately, the majority of patients have incurable disease at presentation, or have significant comorbidities which preclude radical treatment. Table 15.29 shows the mean survival based on tumour stage for NSCLC and SCC: only 25–30% patients are still alive one year after diagnosis and only 6–8% after 5 years.

**Surgery**

Surgery is performed in early stage non-small cell lung cancer (stage I, II and in selected IIIA) with curative intent. Many patients with stage III disease are treated with chemoradiation with a view to ‘downstaging’ disease and render it amenable to surgical resection. Where surgical staging of resected lung cancer demonstrates nodal involvement, patients require adjuvant chemotherapy.

**Radiation therapy for cure**

In selected patients with adequate lung function and early stage NSCLC, high-dose radiotherapy or continuous
Radiation treatment for symptoms

Radiation therapy has a role in palliation of symptoms from lung cancer. Bone and chest wall pain from metastases or direct invasion, haemoptysis, occluded bronchi and superior vena cava obstruction respond favourably to irradiation in the short term. Radiotherapy is also given at the end of chemotherapy to consolidate treatment in small cell lung cancer.

Chemotherapy

This is discussed on page 471. Adjuvant chemotherapy with radiotherapy improves response rate and extends median survival in non-small cell cancer. Newer targeted agents against epidermal growth factor receptors and tyrosine kinases in NSCLC (in particular adenocarcinoma) offer better outcomes in selected patients and can also be used where

Figure 15.44 Lymph node stations commonly involved in lung cancer and sampled during staging investigations.

hyperfractionated accelerated regimens (CHART) provide a good alternative to surgical resection with almost comparable outcomes. It is the treatment of choice if surgery is not possible due to co-morbidities. Radiation pneumonitis (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10–15% of cases. Radiation fibrosis, a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases. These complications usually cause no problems.

In patients with significant cardiovascular or respiratory co-morbidities and early stage I disease, stereotactic radiotherapy can be used. In the same patient group radiofrequency ablation is used – an image-guided technique using heat to destroy small peripheral tumours.

Further Reading

intravenous chemotherapy offers unacceptable toxicity or as second-line chemotherapy.

**Laser therapy, endobronchial irradiation and tracheobronchial stents**

These techniques are used in the palliation of inoperable lung cancer in selected patients with tracheobronchial narrowing from intraluminal tumour or extrinsic compression causing disabling breathlessness, intractable cough and complications, including infection, haemoptysis and respiratory failure.

A neodymium-Yag (Nd-Yag) laser passed through a fibreoptic bronchoscope can be used to vaporize inoperable fungating intraluminal carcinoma involving short segments of trachea or main bronchi. Benign tumours, strictures and vascular lesions can also be treated effectively with immediate relief of symptoms.

Endobronchial irradiation (brachytherapy) is useful for the treatment of both intraluminal tumour and malignant extrinsic compression. A radioactive source is loaded into a catheter placed adjacent to the carcinoma under fibroptic bronchoscope control. Radiation dose falls rapidly with distance from the source, minimizing damage to adjacent normal tissue. Reduction in endoscopically assessed tumour size occurs in 70–95% of cases.

**Tracheobronchial stents** made of silicone or as expandable metal springs are available for insertion into strictures caused by tumour or from external compression or when there is weakening and collapse of the tracheobronchial wall.

**Palliative care**

Patients dying of cancer of the lung need attention to their overall wellbeing (see Ch. 10, p. 485). Much can be done to make the patient’s remaining life symptom-free and as active as possible. Furthermore, compared with patients with fatal cancers at other sites, patients with lung cancer tend to remain relatively independent and pain-free, but they die more rapidly once they reach the terminal phase. Both the patient and the relatives require psychological and emotional support, a task that should be shared between the respiratory teams, the primary care team and the nurses, social workers, hospital chaplains and doctors, who make up the palliative care team.

**Secondary tumours**

Metastases in the lung are very common and usually present as round shadows (1.5–3.0 cm diameter). They are usually detected on chest X-ray in patients already diagnosed as having carcinoma, but can be the first presentation. Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.

Metastases nearly always develop in the parenchyma and are often relatively asymptomatic even when the chest X-ray shows extensive pulmonary metastases. Rarely metastases develop within the bronchi, when they often present with haemoptysis.

Carcinoma, particularly of the stomach, pancreas and breast, can involve mediastinal glands and spread along the lymphatics of both lungs (lymphangitis carcinomatosis), leading to progressive and severe breathlessness. On the chest X-ray, bilateral lymphadenopathy is seen together with streaky basal shadowing fanning out over both lung fields.

Occasionally, a pulmonary metastasis is detected as a solitary round shadow on chest X-ray in an asymptomatic patient. The most common primary tumour to do this is a renal cell carcinoma.

The differential diagnosis includes:

- Primary bronchial carcinoma
- Tuberculoma

**Benign tumours**

- Benign tumour of the lung
- Hydatid cyst.

Single pulmonary metastases can be removed surgically but, as CT scans usually show the presence of small metastases undetected on chest X-ray, detailed imaging including PET scanning and assessment is essential before undertaking surgery.

**Investigation of solitary pulmonary nodules**

With the increased use of CT scanning for other conditions, there has been increasing incidental detection of asymptomatic small sub-centimetre nodules. The majority of these are benign; however, radiological follow-up should be arranged at intervals, determined by the size of the nodule in millimeters and the size of the risk of developing malignancy (i.e. high risk associated with either current or previous smoking history, occupational exposure to carcinogens or family history of lung cancer; low risk if never smoked and no occupational exposure to potential carcinogens or relevant family history).

**Screening for lung cancer**

A large trial carried out in the USA has demonstrated a 20% mortality benefit from low-dose helical CT screening for lung cancer in high-risk populations of smokers/ex-smokers between the ages of 55–74. A similar trial is underway in Europe. It is likely that CT screening will be employed in the future.

**Benign tumours**

**Pulmonary hamartoma**

This is the most common benign tumour of the lung and is usually seen on the X-ray as a very well-defined round lesion 1–2 cm in diameter in the periphery of the lung. Growth is extremely slow, but the tumour can reach several centimetres in diameter. Rarely it arises from a major bronchus and causes obstruction.

**Bronchial carcinoid**

This rare tumour resembles an intestinal carcinoid tumour and is locally invasive, eventually spreading to mediastinal lymph nodes and finally to distant organs. It is a highly vascular tumour that projects into the lumen of a major bronchus causing recurrent haemoptysis. It grows slowly and eventually blocks the bronchus, leading to lobar collapse. As for the carcinoid, bronchial carcinoids produce ACTH but do not usually produce the 5-hydroxytryptamine that is seen in midgut or hindgut carcinoid tumours. Staging of carcinoid tumours is the same as for NSCLC.

**Cylindroma, chondroma and lipoma**

These are extremely rare tumours that grow in the bronchus or trachea, causing obstruction.

**Tracheal tumours**

Benign tumours include squamous papilloma, leiomyoma, haemangiomas and tumours of neurogenic origin.

**DISORDERS OF THE CHEST WALL AND PLEURA**

**Trauma**

Trauma to the thoracic wall can cause penetrating wounds and lead to pneumothorax or haemothorax.
Rib fractures
Rib fractures are caused by trauma or coughing (particularly in the elderly), and can occur in patients with osteoporosis. Pathological rib fractures are due to metastatic spread (most often from carcinoma of the bronchus, breast, kidney, prostate or thyroid). Ribs can also become involved by a mesothelioma. Fractures may not be readily visible on a PA chest X-ray, so lateral X-rays and oblique views may be necessary.

Pain prevents adequate chest expansion and coughing, and this can lead to pneumonia.

Treatment is with adequate oral analgesia, by local infiltration or an intercostal nerve block.

Two fractures in one rib can lead to a flail segment with paradoxical movement, i.e. part of the chest wall moves inwards during inspiration. This can produce inefficient ventilation and may require intermittent positive-pressure ventilation, especially if several ribs are similarly affected.

Rupture of the trachea or a major bronchus
Rupture of the trachea or a major bronchus can occur during deceleration injuries, leading to pneumothorax, surgical emphysema, pneumomediastinum and haemoptysis. Surgical emphysema is caused by air leaking into the subcutaneous connective tissue; this can also occur after the insertion of an intercostal drainage tube. A pneumomediastinum occurs when air leaks from the lung inside the parietal pleura and extends along the bronchial walls.

Rupture of the oesophagus
Rupture of the oesophagus (p. 244) leads to mediastinitis, usually with mixed bacterial infection. This is a serious complication of external injury, endoscopic procedures, bougienage or necrotic carcinoma, and requires antibacterial chemotherapy.

Lung contusion
This causes widespread fluffy shadows on the chest X-ray owing to intrapulmonary haemorrhage. This may give rise to acute respiratory distress syndrome (see p. 883).

Kyphoscoliosis
Kyphoscoliosis may be congenital, due to disease of the vertebrae such as tuberculosis or osteomalacia, or due to neuromuscular disease such as Friedreich’s ataxia or poliomyelitis. The respiratory effects of severe kyphoscoliosis are often more pronounced than might be expected and respiratory failure and death often occur in the 4th or 5th decade. The abnormality should be corrected at an early stage if possible. Positive airway pressure ventilation delivered through a tightly fitting nasal mask is the treatment of choice for respiratory failure (see p. 895).

Ankylosing spondylitis
Limitation of chest wall movement is often well compensated by diaphragmatic movement, and so the respiratory effects of this disease are relatively mild (see also p. 527). It is occasionally associated with upper lobe fibrosis.

Pectus excavatum and carinatum
Pectus excavatum causes few problems other than embarrassment about the deep vertical furrow in the chest, which can be corrected surgically. The heart is seen to lie well to the left on the chest X-ray. Pectus carinatum (pigeon chest) is often the result of rickets but is rarely seen in the West. No treatment is required.

Pleurisy
Pleurisy is pain arising from any disease of the pleura. The localized inflammation produces sharp localized pain, which is worse on deep inspiration, coughing and occasionally on twisting and bending movements. Common causes are pneumonia, pulmonary infarct and carcinoma. Rarer causes include rheumatoid arthritis and systemic lupus erythematosus.

Epidemic myalgia (Bornholm disease) is due to infection by Coxsackie B virus. This illness is common in young adults in the late summer and autumn and is characterized by an upper respiratory tract illness followed by pleuritic pain in the chest and upper abdomen with tender muscles. The chest X-ray remains normal and the illness clears within a week.

Mesothelioma
This (see also p. 855) is usually associated with asbestos exposure. It is described with other pleural diseases caused by asbestosis in Table 15.25.

Pleural effusion
A pleural effusion is an excessive accumulation of fluid in the pleural space. It can be detected on X-ray when ≥300 mL of fluid is present and clinically, when 500 mL or more is present. The chest X-ray appearances (Fig. 15.45) range from the obliteration of the costophrenic angle to dense homogeneous shadows occupying part or all of the hemithorax. Fluid below the lung (a subpulmonary effusion) can simulate a raised hemidiaphragm. Fluid in the fissures may resemble an intrapulmonary mass. The physical signs are shown in Table 15.2 (p. 857).

Diagnosis
This is by pleural aspiration (see p. 805), usually done with ultrasound guidance. The fluid that accumulates may be a transudate or an exudate (Box 15.20).

Transudates
Effusions that are transudates can be bilateral, but are often larger on the right side. The protein content is <30 g/L, the lactic dehydrogenase is <200 IU/L and the fluid to serum LDH ratio is <0.5. Causes include:

- Heart failure
- Hypoproteinaemia (e.g. nephrotic syndrome)
- Constrictive pericarditis
- Hypothyroidism
- Ovarian tumours producing right-sided pleural effusion – Meigs’ syndrome.

Exudates
The protein content of exudates is >30 g/L and the lactic dehydrogenase is >200 IU/L. Causes include:

Box 15.20 Light’s criteria to diagnose an exudative effusion

- Pleural fluid protein: serum protein >0.5
- Pleural fluid LDH: serum LDH >0.6
- Pleural fluid LDH >½ upper limit of normal for serum (105–333 IU/L)

Respiratory disease

- Bacterial pneumonia (common)
- Carcinoma of the bronchus and pulmonary infarction
  - fluid may be blood-stained (common)
- Tuberculosis
- Autoimmune rheumatic diseases
- Post-myocardial infarction syndrome (rare)
- Acute pancreatitis (high amylase content) (rare)
- Mesothelioma (rare)
- Sarcoidosis (very rare)
- Yellow-nail syndrome (effusion due to lymphoedema) (very rare)
- Familial Mediterranean fever (rare).

Pleural biopsy (see p. 806) may be necessary if the diagnosis has not been established by simple aspiration. **Treatment** is of the underlying condition unless the fluid is purulent (empyema) in which case drainage is mandatory.

**Management of malignant pleural effusions**

Malignant pleural effusions that reaccumulate and are symptomatic can be aspirated to dryness followed by the instillation of a sclerosing agent such as tetracycline or t alc. Effusions should be drained slowly since rapid shift of the mediastinum causes severe pain and occasionally shock. This treatment produces only temporary relief.

**Chylothorax**

This is due to the accumulation of lymph in the pleural space, usually resulting from leakage from the thoracic duct following trauma or infiltration by carcinoma.

**Empyema**

This is the presence of pus in the pleural space and can be a complication of pneumonia (see p. 837).

**Pneumothorax**

‘Pneumothorax’ means air in the pleural space. It may be spontaneous or occur as a result of trauma to the chest. Spontaneous pneumothorax is commonest in young males, the male-to-female ratio being 6:1. It is caused by the rupture of a pleural bleb, usually apical, and is thought to be due to congenital defects in the connective tissue of the alveolar walls. Both lungs are affected with equal frequency. Often these patients are tall and thin. In patients over 40 years of age, the usual cause is underlying COPD. Rarer causes include bronchial asthma, carcinoma, a lung abscess breaking down and leading to bronchopleural fistula, and severe pulmonary fibrosis with cyst formation.

Pneumothorax may be localized if the visceral pleura has previously become adherent to the parietal pleura, or generalized if there are no pleural adhesions. Normally the pressure in the pleural space is negative but this is lost once a communication is made with atmospheric pressure; the elastic recoil pressure of the lung then causes it to partially deflate. If the communication between the airways and the pleural space remains open, a bronchopleural fistula results. Once the communication between the lung and the pleural space is closed, air will be reabsorbed at a rate of 1.25% of the total radiographic volume of the hemithorax per day. Thus, a 50% collapse of the lung will take about 40 days to reabsorb completely once the air leak is closed.

It has been postulated that a valvular mechanism may develop through which air can be sucked into the pleural space during inspiration but not expelled during expiration. The intrapleural pressure remains positive throughout breathing, the lung deflates further, the mediastinum shifts, and venous return to the heart decreases, with increasing respiratory and cardiac embarrassment. This is called tension pneumothorax and is very rare except in patients on positive pressure ventilation.

The usual presenting features are sudden onset of unilateral pleuritic pain or progressively increasing breathlessness. If the pneumothorax enlarges, the patient becomes more breathless and may develop pallor and tachycardia. There may be few physical signs if the pneumothorax is small.

The characteristic features and management are shown in Figure 15.46. The main aim is to get the patient back to active life as soon as possible. The procedure for simple aspiration is shown in Practical Box 15.4.

**Recurrence.** A third of patients will have a recurrence. Chemical pleurodesis with talc is used for patients with...
Disorders of the diaphragm

Practical Box 15.4

Simple aspiration of pneumothorax
1. Explain the nature of the procedure and obtain consent.
2. Infiltrate 2% lidocaine down to the pleura in the second intercostal space in the mid-clavicular line.
3. Push a 3–4 cm 16 French gauge cannula through the pleura.
4. Connect the cannula to a three-way tap and 50 mL syringe.
5. Aspirate up to 2.5 L of air. Stop if resistance to suction is felt or the patient coughs excessively.
6. Repeat chest X-ray (in expiration) in the X-ray department.

Disorders of the diaphragm

Mediastinal lesions

Contraindication for surgery. Bleb resection and pleurodesis are achieved using a video-assisted thoracoscopic (VATS) approach or by open thoracotomy.

Diaphragmatic fatigue
The diaphragm can become fatigued if the force of contraction during inspiration exceeds 40% of the force it can develop in a maximal static effort. When this occurs acutely, in patients with exacerbations of COPD or cystic fibrosis or in quadriplegics, positive-pressure ventilation is required. Further rehabilitation requires exercises to increase the strength and endurance of the diaphragm by breathing against a resistance for 30 minutes a day.

Unilateral diaphragmatic paralysis
This is common and symptomless. The affected diaphragm is usually elevated and moves paradoxically on inspiration. It can be diagnosed when a sniff causes the paralysed diaphragm to rise, and the unaffected diaphragm to descend. Causes include:
- Surgery
- Carcinoma of the bronchus with involvement of the phrenic nerve
- Neurological, including poliomyelitis, herpes zoster
- Trauma to cervical spine, birth injury, subclavian vein puncture
- Infection: tuberculosis, syphilis, pneumonia.

Bilateral diaphragmatic weakness or paralysis
This causes breathlessness in the supine position and is a cause of sleep apnoea leading to daytime headaches and
somnolence. Tidal volume is decreased and respiratory rate increased. Vital capacity is substantially reduced when lying down, and sniffing causes a paradoxical inward movement of the abdominal wall best seen in the supine position. Causes include viral infections, multiple sclerosis, motor neurone disease, poliomyelitis, Guillain–Barré syndrome, quadriplegia after trauma, and rare muscle diseases. Treatment is either diaphragmatic pacing or night-time assisted ventilation.

**Complete eventration of the diaphragm**
This is a congenital condition (invariably left-sided) in which muscle is replaced by fibrous tissue. It presents as marked elevation of the left hemidiaphragm, sometimes associated with gastrointestinal symptoms. Partial eventration, usually on the right, causes a hump (often anteriorly) on the diaphragmatic shadow on X-ray.

**Diaphragmatic hernias**
These are most commonly through the oesophageal hiatus, but occasionally occur anteriorly, through the foramen of Morgagni, posterolaterally through the foramen of Bochdalek, or at any site following traumatic tears.

**Hiccups**
Hiccups are due to involuntary diaphragmatic contractions with closure of the glottis and are extremely common. Occasionally patients present with persistent hiccups. This can be as a result of diaphragmatic irritation (e.g. subphrenic abscess) or a metabolic cause (e.g. uraemia). Treatment for persistent hiccups is with gabapentin 300 mg or pregabalin 50 mg three times daily. The underlying cause should be treated, if known.

**MEDIASTINAL LESIONS**
The mediastinum is defined as the region between the pleural sacs. It is additionally divided as shown in Figure 15.47. Tumours affecting the mediastinum are rare. Masses are detected very accurately on CT, as well as on MR scan (Fig. 15.48).

**Retrosternal or intrathoracic thyroid**
The most common mediastinal tumour is a retrosternal or intrathoracic thyroid, which is nearly always an extension of the thyroid present in the neck. Enlargement of the thyroid by a colloid goitre, malignant disease or rarely, in thyrotoxicosis, can cause displacement of the trachea and oesophagus to the opposite side. Symptoms of compression develop insidiously before producing the cardinal feature of dyspnoea. Flow-volume loops are useful to assess the physiological impact. Very occasionally an intrathoracic thyroid may cause dysphagia or hoarseness and vocal cord paralysis due to stretching of the recurrent laryngeal nerve. The treatment is surgical removal.

**Thymic tumours (thymomas)**
The thymus is large in childhood and occupies the superior and anterior mediastinum. It involutes with age but may be enlarged by cysts, which are rarely symptomatic, or by tumours, which may cause myasthenia gravis or compress the trachea or, rarely, the oesophagus. Surgery is the treatment of choice. Approximately half of the patients presenting with a thymic tumour have myasthenia gravis. Good’s syndrome, a combined defect in humoral and cellular immunity, is seen in 10% of thymomas.

**Pleuropericardial cysts**
These cysts, which may be up to 10 cm in diameter, are filled with clear fluid. 70% of them are situated anteriorly in the cardiophrenic angle on the right side. Infection is rare and malignant change does not occur. The diagnosis is usually made by needle aspiration. No treatment is required, but these patients should be followed up as an increase in cyst size suggests an alternative pathology; surgical excision is then advisable.

Critical care medicine (or ‘intensive care medicine’) is concerned predominantly with the management of patients with acute life-threatening conditions (‘the critically ill’) in specialized units. As well as emergency cases, such units admit high-risk patients electively after major surgery (Table 16.1). Intensive care medicine also encompasses the resuscitation and transport of those who become acutely ill, or are injured in the community. Management of seriously ill patients throughout the hospital (e.g. in coronary care units, acute admissions wards, postoperative recovery areas or emergency units), including critically ill patients who have been discharged to the ward (‘outreach care’), is also undertaken. Teamwork and a multidisciplinary approach are central to the provision of intensive care and are most effective when directed and coordinated by committed specialists.

Intensive care units (ICUs) are usually reserved for patients with established or potential organ failure and provide facilities for the diagnosis, prevention and treatment of multiple organ dysfunction. They are fully equipped with monitoring and technical facilities, including an adjacent laboratory (or ‘near patient testing’ devices) for the rapid determination of blood gases and simple biochemical data such as serum potassium, blood glucose and blood lactate levels. Patients receive continuous expert nursing care and the constant attention of appropriately trained medical staff. High dependency units (HDUs) offer a level of care intermediate between that available on the general ward and that provided in an ICU. They provide monitoring and support for patients with acute (or acute-on-chronic) single organ failure and for those who are at risk of developing organ failure. These units are more comfortable environments for less severely ill patients who are often conscious and alert. They can also provide a ‘step-down’ facility for patients being discharged from intensive care.

The provision of staff and the level of technical support must match the needs of the individual patient and resources are used more efficiently when they are combined in a single critical care facility rather than being divided between physically and managerially separate units.

In the UK, only around 3.4% of hospital beds are designated for intensive care (3.5 ICU beds per 100,000 population), whereas in many other developed economies, the proportion is much higher.

INTRODUCTION

Critical care medicine (or ‘intensive care medicine’) is concerned predominantly with the management of patients with acute life-threatening conditions (‘the critically ill’) in specialized units. As well as emergency cases, such units admit high-risk patients electively after major surgery (Table 16.1). Intensive care medicine also encompasses the resuscitation and transport of those who become acutely ill, or are injured in the community. Management of seriously ill patients throughout the hospital (e.g. in coronary care units, acute admissions wards, postoperative recovery areas or emergency units), including critically ill patients who have been discharged to the ward (‘outreach care’), is also undertaken. Teamwork and a multidisciplinary approach are central to the provision of intensive care and are most effective when directed and coordinated by committed specialists.

Intensive care units (ICUs) are usually reserved for patients with established or potential organ failure and provide facilities for the diagnosis, prevention and treatment of multiple organ dysfunction. They are fully equipped with monitoring and technical facilities, including an adjacent laboratory (or ‘near patient testing’ devices) for the rapid determination of blood gases and simple biochemical data such as serum potassium, blood glucose and blood lactate levels. Patients receive continuous expert nursing care and the constant attention of appropriately trained medical staff. High dependency units (HDUs) offer a level of care intermediate between that available on the general ward and that provided in an ICU. They provide monitoring and support for patients with acute (or acute-on-chronic) single organ failure and for those who are at risk of developing organ failure. These units are more comfortable environments for less severely ill patients who are often conscious and alert. They can also provide a ‘step-down’ facility for patients being discharged from intensive care.

The provision of staff and the level of technical support must match the needs of the individual patient and resources are used more efficiently when they are combined in a single critical care facility rather than being divided between physically and managerially separate units.

In the UK, only around 3.4% of hospital beds are designated for intensive care (3.5 ICU beds per 100,000 population), whereas in many other developed economies, the proportion is much higher.
measures to support cardiovascular and respiratory function in order to restore perfusion of vital organs, improve delivery of oxygen to the tissues and encourage the removal of carbon dioxide and other waste products of metabolism (following the ABC approach: Airway, Breathing, Circulation, see Fig. 16.25, below). The patient’s condition and response to treatment should be closely monitored throughout. The underlying diagnosis may only become clear as the results of investigations become available, a more detailed history is obtained and a more thorough physical examination is performed. In practice resuscitation, assessment and diagnosis usually proceed in parallel.

Critically ill patients require multidisciplinary care with:

- Intensive skilled nursing care (usually 1:1 or 1:2 nurse/patient ratio in the UK).
- Specialized physiotherapy including mobilization and rehabilitation.
- Management of pain and distress with judicious administration of analgesics and sedatives (see p. 893).
- Constant reassurance and support (critically ill patients easily become disorientated and delirium is common).
- H2-receptor antagonists or proton pump inhibitors in selected cases to prevent stress-induced ulceration.
- Compression stockings (full-length and graduated), pneumatic compression devices and subcutaneous low-molecular-weight heparin to prevent venous thrombosis.
- Care of the mouth, prevention of constipation and of pressure sores.
- Nutritional support (see p. 222). Protein energy malnutrition is common in critically ill patients and is associated with muscle wasting, weakness, delayed mobilization, difficulty weaning from ventilation, immune compromise and impaired wound healing. There is also an association between malnutrition and increased mortality. It is therefore recommended that nutritional support should be instituted as soon as is practicable in those unable to meet their nutritional needs orally, ideally within 1–2 days of the acute episode. Enteral

nutrition, which is less expensive, preserves gut mucosal integrity, is more physiological and is associated with fewer complications, is preferred. Recently, the value of early feeding has been questioned, apart from giving small amounts to ensure gut viability. Parenteral nutrition is sometimes indicated at a later stage for those unable to tolerate or absorb enteral nutrition and should be initiated without delay, at least within 3 days. Persistent attempts at enteral nutrition in those with gastrointestinal intolerance leads to underfeeding and malnutrition.

- Critically ill patients commonly require intravenous insulin infusions, often in high doses, to combat hyperglycaemia and insulin resistance (see p. 1006). Although the use of intensive insulin therapy to achieve ‘tight glycaemic control’ (blood glucose level between 4.4 and 6.1 mmol/L) was shown to improve outcome (at least when combined with aggressive nutritional support), more recent studies have failed to confirm this finding and have indicated that this approach is associated with an unacceptably high incidence of hypoglycaemia, and possibly an increase in mortality. Current recommendations suggest that blood glucose levels should be maintained at <8–10 mmol/L.

Discharge of patients from intensive care should normally be planned in advance and should ideally take place during normal working hours. Planned discharge often involves a period in a ‘step-down’ intermediate care area. Premature or unplanned discharge, especially during the night, has been associated with higher hospital mortality rates. A summary including ‘points to review’ should be included in the clinical notes and there should be a detailed handover to the receiving team (medical and nursing). The intensive care team should continue to review the patient, who might deteriorate following discharge, on the ward and should be available at all times for advice on further management (e.g. tracheostomy care, nutritional support). In this way, deterioration and readmission to intensive care (which is associated with a particularly poor outcome) or even cardiorespiratory arrest might be avoided.

This chapter concentrates on cardiovascular and respiratory problems. Many patients also have failure of other organs such as the kidney and liver; treatment of these is dealt with in more detail in the relevant chapters.

**APPLIED CARDIORESPIRATORY PHYSIOLOGY**

**Oxygen delivery and consumption**

Oxygen delivery ($D_O$) (Fig. 16.1) is defined as the total amount of oxygen delivered to the tissues per unit time. It is dependent on the volume of blood flowing through the microcirculation per minute (i.e. the total cardiac output, $Q_t$) and the amount of oxygen contained in that blood (i.e. the arterial oxygen content, $O_2$). Oxygen is transported both in combination with haemoglobin and dissolved in plasma. The amount combined with haemoglobin is determined by the oxygen capacity of haemoglobin (usually taken as 1.34 mL of oxygen per gram of haemoglobin) and its percentage saturation with oxygen ($O_2$), while the volume dissolved in plasma depends on the partial pressure of oxygen ($P_O$). Except when hyperbaric oxygen is administered, the amount of dissolved oxygen in plasma is insignificant.

Clinically, however, the utility of this global concept of oxygen delivery is limited because it fails to account for changes in the relative flow to individual organs and the distribution of flow through the microcirculation (i.e. the efficiency with which oxygen delivery is matched to the metabolic requirements of individual tissues or cells). Furthermore, some organs (such as the heart) have high oxygen requirements relative to their blood flow and will receive insufficient oxygen, even if the overall oxygen delivery is apparently adequate. Lastly, microcirculatory flow is influenced by blood viscosity.

**Oxygenation of the blood**

**Oxyhaemoglobin dissociation curve**

The saturation of haemoglobin with oxygen is determined by the partial pressure of oxygen ($P_O$) in the blood, the relationship between the two being described by the oxyhaemoglobin dissociation curve (Fig. 16.2). The sigmoid shape of this curve is significant for a number of reasons:

- Modest falls in the partial pressure of oxygen in the arterial blood ($P_O$) may be tolerated (since oxygen content is relatively unaffected) provided that the percentage saturation remains above 92%.
- Increasing the $P_O$ to above normal has only a minimal effect on oxygen content unless hyperbaric oxygen is administered (when the amount of oxygen in solution in plasma becomes significant).
- Once on the steep ‘slippery slope’ of the curve (percentage saturation below about 90%), a small decrease in $P_O$ can cause large falls in oxygen content, whereas increasing $P_O$ only slightly, e.g. by administering 28% oxygen to a patient with chronic obstructive pulmonary disease (COPD), can lead to a useful increase in oxygen saturation and content.

The $P_O$ is in turn influenced by the alveolar oxygen tension ($P_O$), the efficiency of pulmonary gas exchange, and the partial pressure of oxygen in mixed venous blood ($P_O$).

**Alveolar oxygen tension ($P_O$)**

The partial pressures of inspired gases are shown in Figure 16.3. By the time the inspired gases reach the alveoli they are fully saturated with water vapour at body temperature (37°C), which has a partial pressure of 6.3 kPa (47 mmHg) and contain CO$_2$ at a partial pressure of approximately...
Pathologically, there are three possible causes of an increased $P_{a\text{-}O_2}$ difference:

- **Diffusion defect.** This is not a major cause of hypoxaemia even in conditions such as lung fibrosis, in which the alveolar-capillary membrane is considerably thickened. Carbon dioxide is also not affected, as it is more soluble than oxygen.

- **Right-to-left shunts.** In certain congenital cardiac lesions or when a segment of lung is completely collapsed, a proportion of venous blood passes to the left side of the heart without taking part in gas exchange, causing arterial hypoxaemia. This hypoxaemia cannot be corrected by administering oxygen to increase the $P_{a\text{-}O_2}$, because blood leaving normal alveoli is already fully saturated; further increases in $P_{O_2}$ will not, therefore, significantly affect its oxygen content. On the other hand, because of the shape of the carbon dioxide dissociation curve (Fig. 16.4), the high $P_{CO_2}$ of the shunted blood can be compensated for by over-ventilating patent alveoli, thus lowering the $CO_2$ content of the effluent blood. Indeed, many patients with acute right-to-left shunts hyperventilate in response to the hypoxia and/or to stimulation of mechanoreceptors in the lung, so that their $P_{a\text{-}CO_2}$ is normal or low.

- **Ventilation/perfusion mismatch** (see p. 796). Diseases of the lung parenchyma (e.g. pulmonary oedema, acute lung injury) result in $V/Q$ mismatch, producing an increase in alveolar deadspace and hypoxaemia. The increased deadspace can be compensated for by increasing overall ventilation. In contrast to the hypoxia resulting from a true right-to-left shunt, that due to areas of low $V/Q$ can be partially corrected by administering oxygen and thereby increasing the $P_{a\text{-}O_2}$ even in poorly ventilated areas of lung.

**Mixed venous oxygen tension $P_{v\text{-}O_2}$ and saturation ($S_{v\text{-}O_2}$)**

The $P_{v\text{-}O_2}$ is the partial pressure of oxygen in pulmonary arterial blood that has been thoroughly mixed during its passage through the right heart. Assuming $P_{v\text{-}O_2}$ remains constant, $R_{Q/O}$ and $S_{v\text{-}O_2}$ will fall if more oxygen has to be extracted from each unit volume of blood arriving at the tissues. A low $R_{Q/O}$ therefore indicates either that oxygen delivery has fallen or that tissue oxygen requirements have increased without a compensatory rise in cardiac output. If $R_{Q/O}$ falls, the effect of a given degree of pulmonary shunting on arterial oxygenation will be exacerbated. Thus, worsening arterial hypoxaemia does not necessarily indicate a deterioration in pulmonary function but might instead reflect a fall in cardiac output and/or a rise in oxygen consumption.
Conversely, a rise in $P_{aO_2}$ and $S_{aO_2}$ may reflect impaired tissue oxygen extraction (due to microcirculatory dysfunction) and/or reduced oxygen utilization (e.g. due to mitochondrial dysfunction) as seen in severe sepsis (see below).

Monitoring the oxygen saturation in central venous ($S_{cVO_2}$), rather than pulmonary artery blood is less invasive and has been shown to be a valuable guide to the resuscitation of critically ill patients (see p. 891).

**Cardiac output**

Cardiac output is the product of heart rate and stroke volume, and is affected by changes in either of these (see Fig. 16.5).

**Heart rate**

When heart rate increases, the duration of systole remains essentially unchanged, whereas diastole, and thus the time available for ventricular filling, becomes progressively shorter, and the stroke volume eventually falls. In the normal heart this occurs at rates greater than about 160 beats per minute, but in those with cardiac pathology, especially when this restricts ventricular filling (e.g. mitral stenosis), stroke volume may fall at much lower heart rates. Furthermore, tachycardias cause a marked increase in myocardial oxygen consumption ($\text{VO}_2$) and this may precipitate ischaemia in areas of the myocardium with restricted coronary perfusion. When the heart rate falls, a point is reached at which the increase in stroke volume is insufficient to compensate for bradycardia and again cardiac output falls.

Alterations in heart rate are often caused by disturbances of rhythm (e.g. atrial fibrillation, complete heart block) in which ventricular filling is not augmented by atrial contraction, exacerbating the fall in stroke volume.

**Stroke volume**

The volume of blood ejected by the ventricle in a single contraction is the difference between the ventricular end-diastolic volume (VEDV) and end-systolic volume (VESV) (i.e. stroke volume = VEDV − VESV). The ejection fraction describes the stroke volume as a percentage of VEDV (i.e. ejection fraction = (VEDV − VESV)/VEDV × 100%) and is an indicator of myocardial performance.

Three interdependent factors determine the stroke volume (see p. 671).

**Preload**

This is defined as the tension of the myocardial fibres at the end of diastole, just before the onset of ventricular contraction, and is therefore related to the degree of stretch of the fibres. As the end-diastolic volume of the ventricle increases, tension in the myocardial fibres is increased and stroke volume rises (Fig. 16.6). Myocardial oxygen consumption ($\text{VO}_2$) increases only slightly with an increase in preload (produced, for example, by a ‘fluid challenge’, see below) and this is therefore the most efficient way of improving cardiac output.

**Myocardial contractility**

This refers to the ability of the heart to perform work, independent of changes in preload and afterload. The state of myocardial contractility determines the response of the ventricles to changes in preload and afterload. Contractility is often reduced in critically ill patients, as a result of either pre-existing myocardial damage (e.g. ischaemic heart disease), or the acute disease process itself (e.g. sepsis). Changes in myocardial contractility alter the slope and position of the Starling curve; worsening ventricular performance is manifested as a depressed, flattened curve (Fig. 16.6 and Fig. 14.5). Inotropic drugs can be used to increase myocardial contractility (see below).

**Afterload**

This is defined as the myocardial wall tension developed during systolic ejection. In the case of the left ventricle, the resistance imposed by the aortic valve, the peripheral vascular resistance and the elasticity of the major blood vessels are the major determinants of afterload. Ventricular wall tension will also be increased by ventricular dilatation, an increase in intraventricular pressure or a reduction in ventricular wall thickness.

Decreasing the afterload (exercise, sepsis, vasodilator agents) can increase the stroke volume achieved at a given preload (Fig. 16.7), while reducing $\text{VO}_2$. The reduction in wall tension also leads to an increase in coronary blood flow, thereby improving the myocardial oxygen supply/demand ratio. Excessive reductions in afterload will cause hypotension.
Increasing the afterload (increased sympathetic activity, vasoconstrictor agents), on the other hand, can cause a fall in stroke volume and is a potent cause of increased \( V_{O_2} \). Right ventricular afterload is normally negligible because the resistance of the pulmonary circulation is very low but is increased in pulmonary hypertension.

Monitoring critically ill patients

As well as allowing immediate recognition of changes in the patient’s condition, monitoring can also be used to establish or confirm a diagnosis, to gauge the severity of the condition, to follow the evolution of the illness, to guide interventions and to assess the response to treatment. Invasive monitoring is generally indicated in the more seriously ill patients and in those who fail to respond to initial treatment. These techniques are, however, associated with a significant risk of complications, as well as additional costs and patient discomfort and should therefore only be used when the potential benefits outweigh the dangers. Likewise, invasive devices should be removed as soon as possible.

Assessment of tissue perfusion

- **Pale, cold skin**, delayed capillary refill and the absence of visible veins in the hands and feet indicate poor perfusion. Although peripheral skin temperature measurements can help clinical evaluation, the earliest compensatory response to hypovolaemia or a low cardiac output, and the last to resolve after resuscitation is vasoconstriction in the splanchnic region.
- **Metabolic acidosis with raised lactate concentration** suggests that tissue perfusion is sufficiently compromised to cause cellular hypoxia and anaerobic glycolysis. Persistent, severe lactic acidosis is associated with a very poor prognosis. In many critically ill patients, especially those with sepsis, however, lactic acidosis can also be caused by metabolic disorders unrelated to tissue hypoxia and can be exacerbated by reduced clearance owing to hepatic or renal dysfunction as well as the administration of adrenaline (epinephrine).
- **Urinary flow** is a sensitive indicator of renal perfusion and haemodynamic performance.

Blood pressure

Alterations in blood pressure are often interpreted as reflecting changes in cardiac output. However, if there is vasoconstriction with a high peripheral resistance, the blood pressure may be normal, even when the cardiac output is reduced. Conversely, the vasodilated patient may be hypotensive, despite a very high cardiac output.

Hypotension jeopardizes perfusion of vital organs. The adequacy of blood pressure in an individual patient must always be assessed in relation to the premorbid value. Blood pressure is traditionally measured using a sphygmomanometer but if rapid alterations are anticipated, continuous monitoring using an intra-arterial cannula is indicated (Practical Box 16.1; Fig. 16.8).

Central venous pressure (CVP)

This provides a fairly simple, but approximate method of gauging the adequacy of a patient’s circulating volume and the contractile state of the myocardium. The absolute value of the CVP is not as useful as its response to a fluid challenge (the infusion of 100–200 mL of fluid over a few minutes)
other cardiovascular values begin to stabilize. At this stage, volume replacement should be slowed, or even stopped, in order to avoid overtransfusion (indicated by an abrupt and sustained rise in CVP, often accompanied by some deterioration in the patient’s condition). In cardiac failure, the venous pressure is usually high; the patient will not improve in response to volume replacement, which will cause a further, sometimes dramatic, rise in CVP.

Central venous catheters are usually inserted via a percutaneous puncture of the subclavian or internal jugular vein using a guidewire technique (Practical Box 16.2; Figs 16.10, 16.11). The guidewire techniques can also be used in conjunction with a vein dilator for inserting multilumen catheters, double lumen cannulae for haemofiltration or pulmonary artery catheter introducers. The routine use of ultrasound to guide central venous cannulation reduces complication rates.

Catheters should be read intermittently using a manometer system or continuously using a transducer and bedside monitor. It is essential that the pressure recorded always be

---

**Figure 16.9** The effects on the central venous pressure (CVP) of a rapid administration of a ‘fluid challenge’ to patients with a CVP within the normal range. (From Sykes MK: Venous pressure as a clinical indication of adequacy of transfusion. Annals of Royal College of Surgeons of England 1963; 33:185–197.)

---

**Practical Box 16.2**

**Internal jugular vein cannulation**

**Technique**

1. The procedure is explained to the patient and, if possible, consent obtained.
2. The patient is placed head-down to distend the central veins (this facilitates cannulation and minimizes the risk of air embolism but may exacerbate respiratory distress and is dangerous in those with raised intracranial pressure).
3. The skin is cleaned with an antiseptic solution such as chlorhexidine. Sterile precautions are taken throughout the procedure.
4. Local anaesthetic (1% plain lidocaine) is injected intradermally to raise a weal at the apex of a triangle formed by the two heads of sternomastoid with the clavicle at its base.
5. A small incision is made through the weal.
6. The cannula or needle is inserted through the incision and directed laterally downwards and backwards in the direction of the nipple until the vein is punctured just beneath the skin and deep to the lateral head of sternomastoid.
7. Check that venous blood is easily aspirated.
8. The cannula is threaded off the needle into the vein or the guidewire is passed through the needle (see Fig. 16.11).
9. The CVP manometer line is connected to a manometer/transducer.
10. A chest X-ray should be taken to verify that the tip of the catheter is in the superior vena cava and to exclude pneumothorax.

**Possible complications**

- Haemorrhage
- Accidental arterial puncture (carotid or subclavian)
- Pneumothorax
- Damage to thoracic duct on left
- Air embolism
- Thrombosis
- Catheter-related sepsis.
related to the level of the right atrium. Various landmarks are advocated (e.g. sternal notch with the patient supine, sternal angle or mid-axilla when the patient is at 45°), but which is chosen is largely immaterial provided it is used consistently in an individual patient. Pressure measurements should be obtained at end-expiration.

The following are common pitfalls in interpreting central venous pressure readings:

- **Blocked catheter.** This results in a sustained high reading, with a damped or absent waveform, which often does not correlate with clinical assessment.
- **Transducer wrongly positioned.** Failure to level the system is a common cause of erroneous readings.
- **Catheter tip in right ventricle.** If the catheter is advanced too far, an unexpectedly high pressure with pronounced oscillations is recorded. This is easily recognized when the waveform is displayed.

### Left atrial pressure

In uncomplicated cases, careful interpretation of the CVP provides a reasonable guide to the filling pressures of both sides of the heart. In many critically ill patients, however, there is a disparity in function between the two ventricles. Most commonly, left ventricular performance is worse, so that the left ventricular function curve is displaced downward and to the right (Fig. 16.12). High right ventricular filling pressures, with normal or low left atrial pressures, are less common but occur with right ventricular dysfunction and in cases where the pulmonary vascular resistance (i.e. right ventricular afterload) is raised, such as in acute respiratory failure and pulmonary embolism.

### Pulmonary artery pressure

A ‘balloon flotation catheter’ enables reliable catheterization of the pulmonary artery. These ‘Swan–Ganz’ catheters can be inserted centrally (Fig. 16.10) or through the femoral vein, or via a vein in the antecubital fossa. Passage of the catheter from the major veins, through the chambers of the heart, into the pulmonary artery and into the wedged position is monitored and guided by the pressure waveforms recorded from the distal lumen (Practical Box 16.3; Fig. 16.13). A chest X-ray should always be obtained to check the final position of the catheter. In difficult cases, screening with an image intensifier may be required.

Once in place, the balloon is deflated and the pulmonary artery mean, systolic and end-diastolic pressures (PAEDP) can be recorded. The pulmonary artery occlusion pressure (PAOP, previously referred to as the pulmonary artery or capillary ‘wedge’ pressure) is measured by reinflating the balloon, thereby propelling the catheter distally until it impacts in a medium-sized pulmonary artery. In this position there is a continuous column of fluid between the distal lumen of the catheter and the left atrium, so that PAOP is usually a reasonable reflection of left atrial pressure.

The technique is generally safe – the majority of complications such as ‘knotting’, valve trauma and pulmonary artery rupture (which can be fatal) are related to user inexperience. Pulmonary artery catheters should preferably be removed within 72 h, since the incidence of complications, especially infection, then increases progressively.

### Cardiac output

Cardiac output can be continuously monitored using a modified pulmonary artery catheter which transmits low heat energy into the surrounding blood and constructs a ‘thermodilution curve’. These catheters also optically measure and continuously display $\text{S}_2\text{O}_2$.

In general, pulmonary artery catheters enable the clinician to optimize cardiac output and oxygen delivery, while minimizing the risk of volume overload. They can also be used to guide the rational use of inotropes and vasoactive agents and are particularly helpful in patients with pulmonary hypertension. There is, however, a considerable body of evidence to suggest that the unselective use of this monitoring device in the absence of evidence-based haemodynamic goals does...
not lead to improved outcomes and less invasive techniques are increasingly preferred.

**Less invasive techniques for assessing cardiac function and guiding volume replacement**

**Arterial pressure variation as a guide to hypovolaemia**

Systolic arterial pressure decreases during the inspiratory phase of intermittent positive pressure ventilation (p. 894). The magnitude of this cyclical variability has been shown to correlate more closely with hypovolaemia than other monitored variables, including CVP. Systolic pressure (or pulse pressure) variation during mechanical ventilation can therefore be used as a simple and reliable guide to the adequacy of the circulatory volume. The response to fluid loading can also easily be predicted by observing the changes in pulse pressure during passive leg raising.

**Oesophageal Doppler**

Stroke volume, cardiac output and myocardial function can be assessed non-invasively using Doppler ultrasonography. A probe is passed into the oesophagus to continuously monitor velocity waveforms from the descending aorta (Fig. 16.14). Although reasonable estimates of stroke volume, and hence cardiac output can be obtained, the technique is best used for trend analysis rather than for making absolute measurements. Oesophageal Doppler probes can be inserted quickly and easily and are particularly valuable for perioperative optimization of the circulating volume and cardiac performance in the unconscious patient. They are contraindicated in patients with oropharyngeal/oesophageal pathology.

**Pulse contour analysis**

Lithium dilution/pulse contour analysis does not require pulmonary artery catheterization or instrumentation of the oesophagus and is suitable for use in conscious patients. A bolus of lithium chloride is administered via a central venous catheter and the change in arterial plasma lithium concentration is detected by a lithium-sensitive electrode. This sensor can be connected to an existing arterial cannula via a three-way tap. A small battery-powered peristaltic pump is used to create a constant blood flow through the sensor and over the electrode tip. The cardiac output determined in this way can be used to calibrate an arterial pressure waveform (‘pulse contour’) analysis programme that will continuously monitor changes in cardiac output. Devices that use uncalibrated pulse contour analysis to estimate cardiac output are also available. As with pulse pressure variation, stroke volume variation using these devices can accurately predict fluid replacements.

**Echocardiography**

Echocardiography is being used increasingly often to provide immediate diagnostic information about cardiac structure and function (myocardial contractility, ventricular filling) in the critically ill patient. Transoesophageal echocardiography (TOE) is preferred because of its superior image clarity (Fig. 16.15).

If there is disagreement between clinical signs and a monitored variable, it should be assumed that the monitor is incorrect until all sources of potential error have been checked.
and eliminated. Changes and trends in monitored variables are more informative than a single reading.

### Disturbances of acid–base balance

The physiology of acid–base control is discussed on page 660. Acid–base disturbances can be described in relation to the diagram illustrated in Figure 13.13, p. 663 (which shows $P_{aCO2}$ plotted against arterial $[H^+]$).

Both acidosis and alkalosis can occur, each of which are either metabolic (primarily affecting the bicarbonate component of the system) or respiratory (primarily affecting $P_{aCO2}$). Compensatory changes may also be apparent. In clinical practice, arterial $[H^+]$ values outside the range 18–126 nmol/L are rarely encountered.

Blood gas and acid–base values (normal ranges) are shown in Table 16.2. (For blood gas analysis, see p. 891.)

**Respiratory acidosis.** This is caused by retention of carbon dioxide. The $P_{aCO2}$ and $[H^+]$ rise. A chronically raised $P_{aCO2}$ is compensated by renal retention of bicarbonate, and the $[H^+]$ returns towards normal. A constant arterial bicarbonate concentration is then usually established within 2–5 days. This represents a primary respiratory acidosis with a compensatory metabolic alkalosis (see p. 666). Common causes of respiratory acidosis include ventilatory failure and COPD (type II respiratory failure where there is a high $P_{aCO2}$ and a low $P_{aO2}$, see p. 814).

**Respiratory alkalosis.** In this case, the reverse occurs and there is a fall in $P_{aCO2}$ and $[H^+]$, often with a small reduction in bicarbonate concentration. If hypocapnia persists, some degree of renal compensation may occur, producing a metabolic acidosis, although in practice this is unusual. A respiratory alkalosis may be produced, intentionally or unintentionally, when patients are mechanically ventilated; it may also be seen with hypoxaemic (type I) respiratory failure (see Ch. 15, p. 817), spontaneous hyperventilation and in those living at high altitudes.

### Metabolic acidosis (p. 664).

This may be due to excessive acid production, most commonly lactate and $H^+$ (lactic acidosis) as a consequence of anaerobic metabolism during an episode of shock or following cardiac arrest. A metabolic acidosis may also develop in chronic renal failure or in diabetic ketoacidosis. It can also follow the loss of bicarbonate from the gut or from the kidney in renal tubular acidosis. Respiratory compensation for a metabolic acidosis is usually slightly delayed because the blood–brain barrier initially prevents the respiratory centre from sensing the increased blood $[H^+]$. Following this short delay, however, the patient hyperventilates and ‘blows off’ carbon dioxide to produce a compensatory respiratory alkalosis. There is a limit to this respiratory compensation, since in practice values for $P_{aCO2}$ less than about 1.4 kPa (11 mmHg) are rarely achieved. Spontaneous respiratory compensation cannot occur if the patient’s ventilation is controlled or if the respiratory centre is depressed, for example by drugs or head injury.

**Metabolic alkalosis.** This can be caused by loss of acid, for example from the stomach with nasogastric suction, or in high intestinal obstruction, or excessive administration of absorbable alkali. Overzealous treatment with intravenous sodium bicarbonate is sometimes implicated. Respiratory compensation for a metabolic alkalosis is often slight, and it is rare to encounter a $P_{aCO2}$ above 6.5 kPa (50 mmHg), even with severe alkalosis.

### SHOCK, SEPSIS AND ACUTE DISTURBANCES OF HAEMODYNAMIC FUNCTION

Shock is the term used to describe acute circulatory failure with inadequate or inappropriately distributed tissue perfusion resulting in generalized cellular hypoxia and/or an inability of the cells to utilize oxygen.

### Causes of shock

Abnormalities of tissue perfusion can result from:

- failure of the heart to act as an effective pump
- mechanical impediments to forward flow
- loss of circulatory volume
- abnormalities of the peripheral circulation.

The causes of shock are shown in Table 16.3. Often shock can result from a combination of these factors (e.g. in sepsis, distributive shock is frequently complicated by hypovolaemia and myocardial depression).

### Pathophysiology

#### The sympatho-adrenal response to shock (Fig. 16.16)

Hypotension stimulates the baroreceptors, and to a lesser extent the chemoreceptors, causing increased sympathetic nervous activity with ‘spill-over’ of noradrenaline (norepinephrine) into the circulation. Later this is augmented by the release of catecholamines (predominantly, adrenaline (epinephrine)) from the adrenal medulla. The resulting vasoconstriction, together with increased myocardial contractility and heart rate, help to restore blood pressure and cardiac output.

Reduction in perfusion of the renal cortex stimulates the juxtaglomerular apparatus to release renin. This converts angiotensinogen to angiotensin I, which in turn is converted in the lungs and by the vascular endothelium to the potent...
with an impaired pressor response to noradrenaline (norepinephrine) and a worse prognosis. The diagnosis, causes and clinical significance of this phenomenon remain unclear.

**Release of pro- and anti-inflammatory mediators**

Severe infection (often with bacteraemia or endotoxaemia), the presence of large areas of damaged tissue (e.g. following trauma or extensive surgery), hypoxia or prolonged/repeated episodes of hypoperfusion can trigger an exaggerated inflammatory response with systemic activation of leucocytes and release of a variety of potentially damaging ‘mediators’ (see also Ch. 3). Although beneficial when targeted against local areas of infection or necrotic tissue, dissemination of this ‘innate immune’ response can produce shock and widespread tissue damage. Characteristically the initial episode of overwhelming inflammation is followed by a period of immune suppression, which in some cases may be profound and during which the patient is at increased risk of developing secondary infections. It also seems that pro- and anti-inflammatory elements of the host response may co-exist.

**Microorganisms and their toxic products**

(Fig. 16.17)

In sepsis/septic shock the innate immune response and inflammatory cascade are triggered by the recognition of pathogen-associated molecular patterns (PAMPs), including cell wall components (e.g. endotoxin) and/or exotoxins (anti-genic proteins produced by bacteria such as staphylococci, streptococci and Pseudomonas).

Endotoxin is a lipopolysaccharide (LPS) derived from the cell wall of Gram-negative bacteria and is a potent trigger of the inflammatory response. The lipid A portion of LPS can be bound by a protein normally present in human serum known as lipopolysaccharide binding protein (LBP). The LBP/LPS complex attaches to the cell surface marker CD14 and,
Combined with a secreted protein (MD2), this complex then binds to a member of the toll-like receptor family (TLR4), which transduces the activation signal into the cell. These receptors act through a critical adaptor molecule, myeloid differentiation factor 88 (MyD88), to regulate the activity of NFκB pathways. Intracellular pattern recognition receptors such as nucleotide-binding oligomerization domain (NOD) 1 may also be involved. Another mechanism in this complex area involves TREM-1 (triggering receptor expressed in myeloid cells, see p. 54), which triggers secretion of pro-inflammatory cytokines.

Specific kinases then phosphorylate inhibitory kappa B (IκB), releasing the nuclear transcription factor NFκB, which passes into the nucleus where it binds to DNA and promotes the synthesis of a wide variety of inflammatory mediators. Gram-positive bacteria have cell wall components which are similar in structure to LPS (e.g., lipoteichoic acid), and can also trigger a systemic inflammatory response, probably through similar (TLR2) but not identical pathways (Fig. 16.17). Following traumatic or surgical tissue injury, inflammatory pathways may be triggered by damage-associated molecular patterns (DAMPS) such as DNA fragments.

**Activation of complement cascade**

Fragments of C3 act as opsonins and co-stimulatory molecules that assist lymphocytes with the adaptive immune response, while small peptides derived from C3, C4 and C5 cause leucocyte chemotaxis, release of cytokines and increased vascular permeability (see p. 51).

**Cytokines**

Pro-inflammatory cytokines (see also p. 49) such as the interleukins (ILs) and tumour necrosis factor (TNF) are also mediators of the systemic inflammatory response. TNF release initiates many of the responses to endotoxin, for example, and acts synergistically with IL-1, in part through induction of cyclo-oxygenase, platelet-activating factor (PAF) and nitric oxide synthase (see below). Subsequently, other cytokines including IL-6 and IL-8 appear in the circulation. IL-6 is the major stimulant for hepatic synthesis of acute phase proteins and is involved in the induction of fever, anaemia and cachexia, while IL-8 is a chemoattractant. The cytokine network is extremely complex, with many endogenous self-regulating mechanisms. For example, naturally occurring soluble TNF receptors are shed from cell surfaces during the
inflammatory response, binding to TNF and thereby reducing its biological activity. An endogenous inhibitory protein that binds competitively to the IL-1 receptor has also been identified.

In addition to pro-inflammatory mediators such as TNF, anti-inflammatory cytokines, e.g. IL-10, are released. When excessive, this anti-inflammatory response is associated with an inappropriate immune hyporesponsiveness.

### Products of arachidonic acid metabolism

Arachidonic acid, derived from the breakdown of membrane phospholipid, is metabolized to form prostaglandins and leukotrienes, which are key inflammatory mediators (see Fig. 15.30 and p. 826).

### Heat shock proteins (HSPs)

HSPs are synthesized after exposure to various harmful stimuli such as heat, cytokines, hypoxia, endotoxin, various chemicals and oxygen free radicals. They appear to be protective in sepsis, probably because they recognize and form complexes with denatured proteins, thus inducing correct protein folding and, where necessary, proteolytic degradation. They also protect normal, functional proteins against degradation and inhibit apoptosis. HSPs are therefore often referred to as ‘molecular chaperones’.

### Adhesion molecules

Adhesion of activated leucocytes to the vessel wall and their subsequent extravascular migration is a key component of the sequence of events leading to endothelial injury, tissue damage and organ dysfunction (see also p. 23). This process is mediated by inducible intercellular adhesion molecules (ICAMs) found on the surface of leucocytes and endothelial cells. Expression of these molecules can be induced by endotoxin and pro-inflammatory cytokines. Several families of molecules are involved in promoting leucocyte-endothelial interaction. The selectins are ‘capture’ molecules and initiate the process of leucocyte rolling on vascular endothelium, while members of the immunoglobulin superfamily (ICAM-1 and vascular cell adhesion molecule-1) are involved in the formation of a more secure bond which leads to leucocyte migration into the tissues (see Fig. 3.13).

### Endothelium-derived vasoactive mediators

Endothelial cells synthesize a number of mediators which contribute to the regulation of blood vessel tone and the fluidity of the blood; these include nitric oxide, prostacyclin and endothelin (a potent vasoconstrictor). Nitric oxide (NO) is synthesized from the terminal guanidino-nitrogen atoms of the amino acid L-arginine under the influence of nitric oxide synthase (NOS). NO inhibits platelet aggregation and adhesion and produces vasodilatation by activating guanylate cyclase in the underlying vascular smooth muscle to form cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP) (Fig. 16.18). There are several distinct NOS enzymes.

- **Constitutive or endothelial NOS** (cNOS or eNOS) present in endothelial cells is responsible for the basal release of NO and is involved in the physiological regulation of vascular tone, blood pressure and tissue perfusion.

- **Neuronal NOS** (nNOS). The role of nerves containing nNOS is uncertain but they probably provide neurogenic vasodilator tone. In the central nervous system nNOS may be a regulator of local cerebral blood flow as well as fulfilling a number of other physiological functions, such as the acute modulation of neuronal firing behaviour.

- **Inducible NOS** (iNOS) is induced in vascular endothelial smooth muscle cells and monocytes within 4-18 h of stimulation with endotoxin and certain cytokines, such as TNF. The resulting prolonged increase in NO formation is believed to be a cause of the sustained vasodilatation, hypotension and reduced reactivity to adrenergic agonists (vasoplegia) that characterizes septic shock. This mechanism is also involved in severe prolonged haemorrhage-traumatic shock. The NO generated by macrophages contributes to their role as highly effective killers of intracellular and extracellular pathogens, in part as a consequence of its ability to bind to cytochrome oxidase and inhibit electron transport, but also via the production of the highly reactive radical peroxynitrite.

### Redox imbalance

In health, the balance between reducing and oxidizing conditions (redox) is controlled by antioxidants which either prevent radical formation (e.g. transferrin and lactoferrin which bind iron, a catalyst for radical formation) or remove/inactivate reactive oxygen and nitrogen species (e.g. enzymes such as superoxide dismutases, vitamins C and E and sulphhydryl group donors such as glutathione). There are also mechanisms to remove and repair oxidatively damaged molecules and in particular to preserve DNA integrity. In severe systemic inflammation the uncontrolled production of oxygen-derived free radicals and reactive nitrogen species, e.g. superoxide (O2•−), hydroxyl radicals (OH•), hydrogen peroxide (H2O2) and peroxynitrite (ONOO−), particularly by activated polymorphonuclear leucocytes, can overwhelm these defensive mechanisms and cause:

- lipid and protein peroxidation
- damage to cell membranes
- increased capillary permeability
- impaired mitochondrial respiration
- DNA strand breakage
- apoptosis (see p. 32) (which may contribute to the organ damage and immune hyporesponsiveness associated with sepsis).

### Influence of genetic variation

Individuals vary considerably in their susceptibility to infection, as well as their ability to recover from apparently similar infections, illnesses or traumatic insults. There is evidence to
suggest that interindividual variations in susceptibility to, and outcome from, sepsis can be partly explained by genetic variation.

**Haemodynamic and microcirculatory changes**

The dominant haemodynamic feature of severe sepsis/septic shock is peripheral vascular failure with:

- vasodilatation
- maldistribution of regional blood flow
- abnormalities in the microcirculation (Fig. 16.19):
  - ‘stop-flow’ capillaries (flow is intermittent)
  - ‘no-flow’ capillaries (capillaries are obstructed)
  - failure of capillary recruitment
  - increased capillary permeability with interstitial oedema.

Although these vascular and microvascular abnormalities may partly account for the reduced oxygen extraction often seen in septic shock, there is also a *primary defect of cellular oxygen utilization* caused by mitochondrial dysfunction (see above). Initially, before hypovolaemia supervenes, or when therapeutic replacement of the circulating volume has been adequate, cardiac output is usually high and peripheral resistance is low. These changes may be associated with impaired oxygen consumption, a reduced arteriovenous oxygen content difference, an increased $S_O_2$ and a lactic acidosis (so-called ‘tissue dysoxia’). Vasodilatation and increased vascular permeability also occur in anaphylactic shock.

In the initial stages of other forms of shock, and sometimes when hypovolaemia and myocardial depression supervene in sepsis and anaphylaxis, cardiac output is low and increased sympathetic activity causes vasoconstriction. This helps to maintain the systemic blood pressure.

**Activation of the coagulation system**

The inflammatory response to shock, tissue injury and infection is frequently associated with systemic activation of the clotting cascade, leading to platelet aggregation, widespread microvascular thrombosis and inadequate tissue perfusion.

Initially the production of PGI2 by the capillary endothelium is impaired. Cell damage (e.g. to the vascular endothelium) leads to exposure to tissue factor (p. 416), which triggers coagulation. In severe cases these changes are compounded by elevated levels of plasminogen activation inhibitor type 1, which impairs fibrinolysis, as well as by deficiencies in physiological inhibitors of coagulation (including antithrombin, proteins C and S and tissue factor-pathway inhibitor). Antithrombin and protein C have a number of anti-inflammatory properties, whereas thrombin is pro-inflammatory.

Plasminogen is converted to plasmin, which breaks down thrombus, liberating fibrin/fibrinogen degradation products (FDPs). In some cases there is increased fibrinolysis. Circulating levels of FDPs are therefore increased, the thrombin time, PTT and PT are prolonged and platelet and fibrinogen levels fall. Activation of the coagulation cascade can be confirmed by demonstrating increased plasma levels of D-dimers. The development of disseminated intravascular coagulation (DIC) often heralds the onset of multiple organ failure. Because clotting factors and platelets are consumed in DIC, they are unavailable for haemostasis elsewhere and a coagulation defect results – hence the alternative name for DIC is ‘consumption coagulopathy’. DIC presents with microvascular bleeding or generalized ‘oozing’ of blood, e.g. from surgical or traumatic wounds and skin puncture sites. In some cases, a microangiopathic haemolytic anaemia develops. DIC is relatively uncommon but is particularly associated with septic shock, especially when due to meningococcal infection (see above). Management of the underlying cause is most urgent. Supportive treatment may include infusions of fresh frozen plasma, platelets, cryoprecipitate when fibrinogen levels are low and occasionally factor VIII concentrates.

**Reperfusion injury**

Restoration of flow to previously hypoxic tissues can exacerbate cell damage through the generation of large quantities of reactive oxygen species and activation of polymorphonuclear leucocytes (see above) (Fig. 16.20). The gut mucosa seems to be especially vulnerable to this ‘ischaemia-reperfusion injury’.
Metabolic response to trauma, major surgery and severe infection

This is initiated and controlled by the neuroendocrine system and various cytokines (e.g. IL-6) acting in concert, and is characterized initially by an increase in energy expenditure (‘hypermetabolism’) (see also p. 201). Gluconeogenesis is stimulated by increased glucagon and catecholamine levels, while hepatic mobilization of glucose from glycogen is increased. Catecholamines inhibit insulin release and reduce peripheral glucose uptake. Combined with elevated circulating levels of other insulin antagonists such as cortisol, and downregulation of insulin receptors, these changes mean that the majority of patients are hyperglycaemic (‘insulin resistance’). Later hypoglycaemia may be precipitated by depletion of hepatic glycogen stores and inhibition of gluconeogenesis. Free fatty acid synthesis is also increased, leading to hypertriglyceridaemia.

Protein breakdown is initiated to provide energy from amino acids, and hepatic protein synthesis is preferentially augmented to produce the ‘acute phase reactants’. The amino acid glutamine (which is indispensable in this situation) is mobilized from muscle for use as a metabolic fuel in rapidly dividing cells such as leucocytes and enterocytes. Glutamine is also required for hepatic production of the free radical scavenger glutathione. When severe and prolonged, this catabolic response can lead to considerable weight loss. Protein breakdown is associated with wasting and weakness of skeletal and respiratory muscle, prolonging the need for mechanical ventilation and delaying mobilization. Tissue repair, wound healing and immune function also are compromised.

Anaphylaxis

- Signs of profound vasodilatation:
  a. Warm peripheries
  b. Low blood pressure
  c. Tachycardia
- Erythema, urticaria, angio-oedema, pallor, cyanosis
- Bronchospasm, rhinitis
- Oedema of the face, pharynx and larynx
- Pulmonary oedema
- Hypovolaemia due to vascular leak
- Nausea, vomiting, abdominal cramps, diarrhoea.

Ideally, 10 mL of clotted blood should be taken within 45–60 minutes after the reaction for confirmation of the diagnosis, e.g. by measurement of mast cell tryptase. Serum should be separated and stored at −20°C. Follow-up of these patients is essential.

Sepsis, severe sepsis and septic shock

- Pyrexia and rigors, or hypothermia (unusual)
- Nausea, vomiting
- Vasodilatation, warm peripheries
- Bounding pulse
- Rapid capillary refill
- Hypotension (septic shock)
- Occasionally signs of cutaneous vasoconstriction
- Other signs:
  a. Jaundice
  b. Coma, stupor
  c. Bleeding due to coagulopathy (e.g. from vascular puncture sites, GI tract and surgical wounds)
  d. Rash and meningism
  e. Hyper- and in more severe cases hypoglycaemia.
Infection
Invasion of normally sterile host tissue by microorganisms

Bacteraemia
Viable bacteria in blood

Systemic inflammatory response syndrome (SIRS)
The systemic inflammatory response to a variety of severe clinical insults. The response is manifested by two or more of the following:
- Temperature >38°C or <36°C
- Heart rate >90 beats/min
- Respiratory rate >20 breaths/min or PaCO₂ <4.3 kPa
- White cell count >12 × 10⁹/L, <4 × 10⁹/L or >10% immature forms.

Sepsis
SIRS resulting from documented infection.

Severe sepsis
Sepsis associated with organ dysfunction, hypoperfusion or hypotension. Hypoperfusion and perfusion abnormalities include, but are not limited to, lactic acidosis, oliguria or an acute alteration in mental state.

Septic shock
Severe sepsis with hypotension (systolic BP <90 mmHg or a reduction of >40 mmHg from baseline) in the absence of other causes for hypotension and despite adequate fluid resuscitation.

(Patients receiving inotropic or vasopressor agents may not be hypotensive when perfusion abnormalities are documented.)

Refractory shock
Shock unresponsive to conventional therapy (intravenous fluids and inotropic/vasoactive agents) within 1 h.

Compensatory anti-inflammatory response syndrome (CARS)
Release of anti-inflammatory mediators which downregulate the inflammatory response. If excessive, may lead to inappropriate immune hyporesponsiveness.

The diagnosis of sepsis is easily missed, particularly in the elderly when the classical signs may not be present. Mild confusion, tachycardia and tachypnoea may be the only clues, sometimes associated with unexplained hypotension, a reduction in urine output, a rising plasma creatinine and glucose intolerance.

The clinical signs of sepsis (triggered by PAMPS) are not always associated with bacteraemia and can occur with non-infectious processes such as pancreatitis, cardiopulmonary bypass or severe trauma (triggered by DAMPS). The term ‘systemic inflammatory response syndrome’ (SIRS) describes the disseminated inflammation that can complicate this diverse range of disorders (Box 16.3). Patterns of systemic inflammatory response are shown in Figure 16.21, which illustrates the pro-inflammatory response (SIRS) and the counter-regulatory anti-inflammatory response syndrome (CARS).

Sepsis and multiple organ failure (MOF) (also known as multiple organ dysfunction syndrome, MODS)
Sepsis is being diagnosed with increasing frequency and is now the commonest cause of death in non-coronary adult intensive care units. The estimated incidence of severe sepsis has varied from 77 to 300 cases per 100 000 of the population. Mortality rates are high (between 20% and 60%) and are closely related to the severity of illness and the number of organs that fail. Those who die are overwhelmed by persistent or recurrent sepsis, with fever, intractable hypotension and failure of several organs (Fig. 16.22).

Sequential failure of vital organs occurs progressively over weeks, although the pattern of organ dysfunction is variable. In most cases the lungs are the first to be affected (acute lung injury, ALI; acute respiratory distress syndrome, ARDS; see below) in association with cardiovascular instability and deteriorating renal function. Damage to the mucosal lining of the gastrointestinal tract, as a result of reduced splanchnic flow followed by reperfusion, allows bacteria within the gut lumen, or their cell wall components, to gain access to the circulation. The liver defences, which are often compromised by poor perfusion, are overwhelmed and the lungs and other organs...
Acute lung injury (ALI) and the more severe acute respiratory distress syndrome (ARDS) are diagnosed in an appropriate clinical setting with one or more recognized risk factors. ALI/ARDS can be defined as follows:

- Respiratory distress
- Stiff lungs (reduced pulmonary compliance resulting in high inflation pressures)
- Chest radiograph: new bilateral, diffuse, patchy or homogeneous pulmonary infiltrates
- Cardiac: no apparent cardiogenic cause of pulmonary oedema (pulmonary artery occlusion pressure <18 mmHg if measured or no clinical evidence of left atrial hypertension)
- Gas exchange abnormalities: ALI – arterial oxygen tension/fractional inspired oxygen (P_{a}O_{2}/F_{O_{2}}) ratio <40 kPa (<300 mmHg); ARDS – P_{a}O_{2}/F_{O_{2}} <26.6 kPa (<200 mmHg) (in both cases, despite normal arterial carbon dioxide tension and regardless of positive end-expiratory pressure). The criterion for arterial oxygen tension/fractional inspired oxygen is arbitrary and the value of differentiating ALI from ARDS has been questioned.

ARDS can occur as a nonspecific reaction of the lungs to a wide variety of direct pulmonary and indirect non-pulmonary insults. By far the commonest predisposing factor is sepsis, and 20–40% of patients with severe sepsis will develop ALI/ARDS (Table 16.4).

### Pathogenesis and pathophysiology of ALI/ARDS

Acute lung injury can be viewed as an early manifestation of a generalized inflammatory response with endothelial dysfunction and is therefore frequently associated with the development of multiple organ dysfunction syndrome (MODS) (see p. 882).

#### Non-cardiogenic pulmonary oedema

This is the cardinal feature of ALI and is the first and clinically most evident sign of a generalized increase in vascular permeability caused by the microcirculatory changes and release of inflammatory mediators described previously (see p. 877), with activated neutrophils playing a particularly key role. The pulmonary epithelium is also damaged in the early stages, reducing surfactant production and lowering the threshold for alveolar flooding.

#### Pulmonary hypertension

Pulmonary hypertension sometimes complicated by right ventricular failure (p. 762) is a common feature of ALI/ARDS. Initially, mechanical obstruction of the pulmonary circulation may occur as a result of vascular compression by interstitial oedema, while local activation of the coagulation cascade leads to thrombosis and obstruction in the pulmonary microvasculature. Later, pulmonary vasoconstriction may develop in response to increased autonomic nervous activity and circulating substances such as catecholamines, serotonin, thromboxane and complement. Those vessels supplying alveoli with low oxygen tensions constrict (the ‘hypoxic vasconstrictor response’), diverting pulmonary blood flow to better oxygenated areas of lung, thus limiting the degree of shunt.

#### Haemorrhagic intra-alveolar exudate

This exudate is rich in platelets, fibrin, fibrinogen and clotting factors and may inactivate surfactant and stimulate inflammation, as well as promoting hyaline membrane formation and the migration of fibroblasts into the air spaces.

#### Resolution, fibrosis and repair

Within days of the onset of lung injury, formation of a new epithelial lining is underway and activated fibroblasts accumulate in the interstitial spaces. Subsequently, interstitial fibrosis progresses, with loss of elastic tissue and obliteration of the lung vasculature, together with lung destruction and emphysema. In those who recover, the lungs are substantially remodelled.

### Physiological changes

Shunt and deadspace increase, compliance falls, and there is evidence of airflow limitation. Although the lungs in ALI and ARDS are diffusely injured, the pulmonary lesions, when identified as densities on a CT scan, are predominantly located in dependent regions (Fig. 16.23). This is partly explained by the effects of gravity on the distribution of extravascular lung water and areas of lung collapse. Pleural effusions are common.
Clinical presentation of ALI/ARDS

The first sign of the development of ALI/ARDS is often an unexplained tachypnoea, followed by increasing hypoxaemia, with central cyanosis, and breathlessness. Fine crackles are heard throughout both lung fields. Later, the chest X-ray shows bilateral diffuse shadowing, interstitial at first, but subsequently with an alveolar pattern and air bronchograms (Fig. 16.24). The differential diagnosis includes cardiac failure and lung fibrosis.

Management of ALI/ARDS

This is based on treatment of the underlying condition (e.g. eradication of sepsis), supportive measures and avoidance of complications such as ventilator-associated pneumonia.

Mechanical ventilation

Strategies designed to minimize ventilator-associated lung injury and encourage lung healing should be used (see p. 895).

Pulmonary oedema limitation. Pulmonary oedema formation should be limited by minimizing left ventricular filling pressure with fluid restriction, the use of diuretics and, if these measures fail, preventing fluid overload by haemofiltration. The aim should be to achieve a consistently negative fluid balance. Cardiovascular support and the reduction of oxygen requirements are also necessary.

Prone position. When the patient is changed from the supine to the prone position, lung densities in the dependent region are redistributed and shunt fraction is reduced. More uniform alveolar ventilation, caudal movement of the diaphragm, redistribution of perfusion and recruitment of collapsed alveoli all contribute to the improvement in gas exchange. Body position changes can be achieved with minimal complications despite the presence of multiple indwelling vascular lines. Repeated position changes between prone and supine allow reductions in airway pressures and the inspired oxygen fraction. The response to prone positioning is, however, variable and it seems that this strategy does not improve overall outcome (and perhaps therefore should be reserved for those with severe refractory hypoxaemia).

Inhaled nitric oxide. This vasodilator, when inhaled, may improve V/Q matching by increasing perfusion of ventilated lung units, as well as reducing pulmonary hypertension. It has been shown to improve oxygenation in so-called ‘responders’ with ALI/ARDS but has not been shown to increase survival. Its administration requires specialized monitoring equipment, as products of its combination with oxygen include toxic nitrogen dioxide.

Aerosolized prostacyclin. This appears to have similar effects to inhaled NO and is easier to monitor and deliver. As with inhaled NO, the response to aerosolized prostacyclin is, however, variable and although it has been shown to improve oxygenation its effect on outcome has yet to be established.

Aerosolized surfactant. Surfactant replacement therapy reduces morbidity and mortality in neonatal respiratory distress syndrome and is beneficial in animal models of ALI/ARDS. In adults with ARDS, however, the value of surfactant administration remains uncertain.

Steroids. Administration of steroids to patients with persistent ALI/ARDS does not appear to improve outcome.

Prognosis

Mortality from ALI/ARDS has fallen over the last decade, from around 60% to between 30% and 40%, perhaps as a consequence of improved general care, the increasing use of management protocols, and attention to infection control and nutrition, as well as the introduction of novel treatments and lung-protective strategies for respiratory support. Prognosis is, however, still very dependent on aetiology. When ARDS occurs in association with intra-abdominal sepsis, mortality rates remain very high, whereas much lower mortality rates are to be expected in those with ‘primary’ ARDS (pneumonia, aspiration, lung contusion). Mortality rises with increasing age and failure of other organs. Most of those dying with ARDS do so as a result of MODS and haemodynamic instability rather than impaired gas exchange.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is a common and serious complication of critical illness which adversely affects the prognosis. A modification of the RIFLE classification has been proposed and covers the spectrum of severity and consequences of acute kidney injury (see Ch. 12; Box 12.5).

The importance of preventing renal injury by rapid and effective resuscitation, as well as the avoidance of nephrotoxic drugs (especially NSAIDs), and control of infection cannot be overemphasized. Shock and sepsis are the most
common causes of AKI in the critically ill, but diagnosis of the cause of renal dysfunction is necessary to exclude reversible pathology, especially obstruction (see Ch. 12).

Oliguria is usually the first indication of renal impairment and immediate attempts should be made to optimize cardiovascular function, particularly by expanding the circulating volume and restoring blood pressure. Restoration of the urine output is a good indicator of successful resuscitation. Evidence now suggests that dopamine is not an effective means of preventing or reversing renal impairment and this agent should not be used for renal protection in sepsis (p. 888). If these measures fail to reverse oliguria, administration of diuretics such as furosemide by bolus or infusion, or less often mannitol (for example in rhabdomyolysis) may be indicated (see Ch. 12). If oliguria persists, it is necessary to reduce fluid intake and review drug doses.

Intermittent haemodialysis has a number of theoretical disadvantages in the critically ill. In particular, it is frequently complicated by hypotension and it may be difficult to remove sufficient volumes of fluid. Nevertheless, provided that strict guidelines are used to improve tolerance and metabolic control, almost all patients with acute kidney injury can be managed successfully with daily haemodialysis. The use of continuous veno-venous haemofiltration, often with dialysis (CVVHD), is however generally preferred in the critically ill (see Ch. 12) and is indicated for fluid overload, electrolyte disturbances (especially hyperkalaemia), severe acidosis and, less often, uraemia. The intensity of renal replacement therapy does not seem to influence outcome. Peritoneal dialysis is unsatisfactory in critically ill patients and is contraindicated in those who have undergone intra-abdominal surgery.

If the underlying problems resolve, renal function almost invariably recovers a few days to several weeks later.

**MANAGEMENT OF SHOCK AND SEPSIS** *(Fig. 16.25)*

Delays in making the diagnosis and in initiating treatment (especially antibiotics), as well as inadequate resuscitation, are associated with increased morbidity and mortality and should be avoided.

A patent airway must be maintained and oxygen must be given. If necessary, an oropharyngeal airway or an endotracheal tube is inserted. The latter has the advantage of preventing aspiration of gastric contents. Very rarely, emergency tracheostomy is indicated (see below). Some patients may require immediate mechanical ventilation.

The underlying cause of shock should be corrected, e.g. haemorrhage should be controlled or infection eradicated. In patients with septic shock, every effort must be made to identify the source of infection and isolate the causative organism. As well as a thorough history and clinical examination, X-rays, ultrasonography or CT scanning may be required to locate the origin of the infection. Appropriate samples (urine, sputum, cerebrospinal fluid, pus drained from abscesses) should be sent to the laboratory for microscopy, culture and sensitivities. Several blood cultures should be performed and empirical, broad-spectrum antibiotic therapy (p. 85) should be commenced within the first hour of recognition of sepsis. If an organism is isolated later, therapy can be adjusted appropriately. The choice of antibiotic depends on the likely source of infection, previous antibiotic therapy and known local resistance patterns, as well as on whether infection was acquired in hospital or in the community. Abscesses must be drained and infected indwelling catheters removed.

Whatever the aetiology of the haemodynamic abnormality, tissue blood flow must be restored by achieving and maintaining an adequate cardiac output, as well as ensuring that arterial blood pressure is sufficient to maintain perfusion of vital organs. Published guidelines for adult patients suffering severe sepsis or septic shock advocate targeting an MAP >65 mmHg, CVP 8–12 mmHg (>12 mmHg if mechanically ventilated), urine output >0.5 ml/kg per hour and an \( S_O_2 \geq 70\% \) (or \( S_O_2 \geq 65\% \)) as the initial goals of resuscitation. Administration of fluids can also be targeted at abolishing arterial pressure variation and/or optimizing stroke volume.

**Preload and volume replacement**

Optimizing preload is the most efficient way of increasing cardiac output. Volume replacement is obviously essential in hypovolaemic shock but is also required in anaphylactic and septic shock because of vasodilatation, sequestration of blood and loss of circulating volume because of vascular leak.

In obstructive shock, high filling pressures may be required to maintain an adequate stroke volume. Even in cardiogenic shock, careful volume expansion may, on occasions, lead to a useful increase in cardiac output. On the other hand, patients with severe cardiac failure, in whom ventricular filling pressures are markedly elevated, often benefit from measures to reduce preload (and afterload) – such as the administration of vasodilators and diuretics (see below). Adequate perioperative volume replacement also reduces morbidity and mortality in high-risk surgical patients.

The circulating volume must be replaced quickly (in minutes not hours) to reduce tissue damage and prevent acute kidney injury. Fluid is administered via wide-bore intra-venous cannulae to allow large volumes to be given quickly, and the effect is continuously monitored.

You must prevent volume overload, which leads to cardiac dilatation, a reduction in stroke volume, and a rise in left atrial pressure with a risk of pulmonary oedema. Pulmonary oedema is more likely in seriously ill patients because of a low colloid osmotic pressure (usually due to a low serum albumin) and disruption of the alveolar-capillary membrane (e.g. in acute lung injury).

**Choice of fluid for volume replacement**

**Blood**

This is conventionally given for haemorrhagic shock as soon as it is available. In extreme emergencies, group-specific crossmatch can be performed in minutes (see p. 408). When available and not contraindicated, blood salvage should be employed for those with severe on-going bleeding.

Although red cell transfusion will augment oxygen-carrying capacity, and hence global oxygen delivery, tissue oxygenation is also dependent on microcirculatory flow. This is influenced by the viscosity of the blood and hence the packed cell volume (PCV). Conventionally, a PCV of 30–35% has been considered to provide the optimal balance between oxygen-carrying capacity and tissue flow, although it is well recognized that previously fit people with haemorrhagic shock can tolerate extremely low Hb concentrations, provided their circulating volume and cardiac output are maintained. Transfusion of old stored red cells, which become spherical rather than biconcave and poorly deformable, with increased adhesiveness, can compromise microvascular flow and worsen tissue hypoxia. Whole blood has now been largely replaced by red cell concentrates (see p. 412).

Massive blood transfusion can be defined as a volume of >8–10 units of red cells transfused within a 24-hour period,
and massive haemorrhage as a loss of 50% of blood volume within 3 hours or a rate of blood loss exceeding 150 mL/min. Complications of blood transfusion are discussed on page 408.

Special problems arise as a result of massive transfusion:
- **Temperature changes.** Bank blood is stored at 4°C; transfusion may result in hypothermia, peripheral vasoconstriction (which slows the rate of the infusion) and arrhythmias. If possible, blood should be warmed during massive transfusion and in those at risk of hypothermia (e.g. during prolonged major surgery with open body cavity).

- **Coagulopathy.** Stored blood has virtually no effective platelets or clotting factors. Massive transfusions that often include large volumes of colloid/crystalloid can therefore be associated with a coagulopathy. This often needs to be treated by replacing clotting factors with fresh frozen plasma and administering platelet concentrates. Occasionally cryoprecipitate is required. There is some evidence that a higher ratio of FFP to blood transfused is associated with improved survival, especially in the military trauma setting. Recombinant factor VIIa may occasionally be indicated in those with uncontrollable bleeding, although the safety of this product has been questioned. Prothrombin complex concentrates have some advantages compared with...
FFP, in that they do not need to be crossmatched or thawed.

- **Hypocalcaemia.** Citrate in stored blood binds calcium ions. During rapid transfusion total body ionized calcium levels may be reduced, causing myocardial depression and exacerbating coagulation defects. This is uncommon in practice but can be corrected by administering 10 mL of 10% calcium chloride intravenously. Routine treatment with calcium is not recommended.

- **Increased oxygen affinity.** In stored blood, the red cell 2,3-disphosphoglycerate (2,3-DPG) content is reduced, so the oxyhaemoglobin dissociation curve is shifted to the left. The oxygen affinity of haemoglobin is therefore increased and oxygen unloading is impaired. Red cell levels of 2,3-DPG are substantially restored within 12 h of transfusion.

- **Hyperkalaemia.** Plasma potassium levels rise progressively as blood is stored. However, hyperkalaemia is rarely a problem as rewarming of the blood increases red cell metabolism – the sodium pump becomes active and potassium levels fall.

- **Microembolism.** Microaggregates in stored blood may be filtered out by the pulmonary capillaries. This process is thought by some to contribute to ALI.

Concern about the supply, cost and safety of blood, including the risk of disease transmission and immune suppression, has encouraged a more conservative approach to transfusion. There is some evidence to suggest that in normovolaemic critically ill patients a restrictive strategy of red cell transfusion (Hb maintained at >70 g/L) is at least as effective, and may be safer than a liberal transfusion strategy (Hb maintained at 100–120 g/L). However, in some groups of patients (e.g. the elderly and those with significant cardiac or respiratory disease and patients who are actively bleeding) it is preferable to maintain Hb closer to the higher level. The use of leucodepleted blood is considered to be safer in terms of disease transmission and immune suppression.

**Crystalloids and colloids**

The choice of intravenous fluid for resuscitation and the relative merits of crystalloids or colloids has long been controversial. Crystalloid solutions such as Hartmann’s solution are cheap, convenient to use and free of side-effects. It has been generally accepted that volumes of crystalloid several times that of colloid are required to achieve an equivalent haemodynamic response and that colloidal solutions produce a greater and more sustained increase in circulating volume, with associated improvements in cardiovascular function and oxygen transport. This traditional view has been challenged, however, and a large, prospective, randomized, controlled trial has demonstrated that in a heterogeneous group of critically ill patients the use of either physiological saline or 4% albumin for fluid resuscitation resulted in similar outcomes.

**Polyygelatin solutions** have an average molecular weight of 35,000, which is iso-osmotic with plasma. They are cheap and do not interfere with crossmatching. Large volumes can be administered, as clinically significant coagulation defects are unusual and renal function is not impaired. However, because they readily cross the glomerular basement membrane, their half-life in the circulation is only approximately 4 h and they can promote an osmotic diuresis. These solutions are useful during the acute phase of resuscitation, especially when volume losses are continuing. Allergic reactions can, however, occur.

**Hydroxyethyl starches (HES).** Numerous preparations are now available, characterized by their concentrations (3%, 6%, 10%) and low, medium or high molecular weight. The half-life of high and medium molecular weight solutions is between 12 and 24 h, while that of the low-molecular-weight solutions is 4–6 h. Elimination of HES occurs primarily via the kidneys following hydrolysis by amylase. HES are stored in the reticuloendothelial system, apparently without causing functional impairment, but skin deposits have been associated with persistent pruritus. HES, especially the higher-molecular-weight fractions, have anticoagulant properties and many therefore recommend limiting the volume administered. HES have been implicated in the development of acute kidney injury.

**Human albumin solution (HAS)** is a natural colloid which has been used for volume replacement in shock and burns, and for the treatment of hypoproteinaemia. HAS is not generally recommended for routine volume replacement, because supplies are limited and other cheaper solutions are equally effective. Some use HAS to expand the circulating volume in patients who are hypoalbuminaemic. There is some suggestion that the administration of HAS may improve outcome from sepsis.

**Myocardial contractility and inotropic agents**

Myocardial contractility can be impaired by many factors such as hypoxaemia and hypocalcaemia, as well as by some drugs (e.g. beta-blockers, antiarrhythmics and sedatives).

Severe lactic acidosis conventionally is said to depress myocardial contractility and limit the response to vasopressor agents. Attempted correction of acidosis with intravenous sodium bicarbonate, however, generates additional carbon dioxide which diffuses across cell membranes, producing or exacerbating intracellular acidosis. Other disadvantages of bicarbonate therapy include sodium overload and a left shift of the oxyhaemoglobin dissociation curve. Ionized calcium levels may be reduced and, combined with the fall in intracellular pH, this may impair myocardial performance. Treatment of lactic acidosis should therefore concentrate on correcting the cause. Bicarbonate should only be administered to correct extreme persistent metabolic acidosis (see Chapter 13).

If the signs of shock persist despite adequate volume replacement, and perfusion of vital organs is jeopardized, pressor agents should be administered to improve cardiac output and blood pressure. Vasopressor therapy may also be required to maintain perfusion in those with life-threatening hypotension, even when volume replacement is incomplete. All inotropes increase myocardial oxygen consumption, particularly if a tachycardia develops, and this can lead to an imbalance between myocardial oxygen supply and demand, with the development or extension of ischaemic areas. Inotropes should therefore be used with especial caution, particularly in cardiogenic shock following myocardial infarction and in those known to have ischaemic heart disease.

Many of the most seriously ill patients become increasingly resistant to the effects of pressor agents, an observation attributed to ‘downregulation’ of adrenergic receptors and NO-induced ‘vasoplegia’ (p. 879).

All inotropic agents should be administered via a large central vein, and their effects continually monitored (Table 16.5).

**Adrenaline (epinephrine)**

Adrenaline stimulates both α- and β-adrenergic receptors, but at low doses, β effects seem to predominate. Heart
rate and cardiac index increase, while peripheral resistance is reduced. If there is an associated increase in perfusion pressure, urine output may improve. Adrenaline at higher doses can cause excessive (α-mediated) vasoconstriction, with reductions in splanchnic flow, and cardiac output may fall. Prolonged high-dose administration can cause peripheral gangrene and lactic acidosis. The minimum effective dose of adrenaline should therefore be used for as short a time as possible.

**Noradrenaline (norepinephrine)**

This is predominantly an α-adrenergic agonist. It is particularly useful in those with hypotension associated with a low systemic vascular resistance, e.g. in septic shock. There is a risk of producing excessive vasoconstriction with impaired organ perfusion and increased afterload. Noradrenaline administration should normally therefore be guided by comprehensive haemodynamic monitoring, including invasive or non-invasive determination of cardiac output (see p. 875) and calculation of systemic vascular resistance.

**Dopamine**

Dopamine is a natural precursor of adrenaline (epinephrine) which acts on β receptors and α receptors, as well as dopaminergic DA_1_ and DA_2_ receptors.

In **low doses** (e.g. 1–3 μg/kg per min), dopaminergic vasodilatory receptors in the renal, mesenteric, cerebral and coronary circulations are activated. DA_1_ receptors are located on postsynaptic membranes and mediate vasodilatation, while DA_2_ receptors are presynaptic and potentiate these vasodilatory effects by preventing the release of adrenaline (epinephrine). Renal and hepatic flow increase and urine output is improved. The significance of the renal vasodilator effect of dopamine has, however, been questioned and it has been suggested that the increased urine output is largely attributable to the rise in cardiac output and blood pressure, combined with a decrease in aldosterone and inhibition of tubular sodium reabsorption mediated via DA_2_ stimulation.

In **moderate doses** (e.g. 3–10 μg/kg per min), dopamine increases heart rate, myocardial contractility and cardiac output. In some patients the dose of dopamine is limited by β-receptor effects such as tachycardia and arrhythmias.

In **higher doses** (e.g. >10 μg/kg per min) the increased noradrenaline (norepinephrine) produced is associated with vasoconstriction. This increases afterload and raises ventricular filling pressures.

**Dopexamine**

Dopexamine is an analogue of dopamine which activates β receptors as well as DA_1_ and DA_2_ receptors. Dopexamine is a weak positive inotrope, but is a powerful splanchnic vasodilator, reducing afterload and improving blood flow to vital organs, including the kidneys. Dopexamine has been used as an adjunct to the perioperative management of high-risk surgical patients (see below).

**Dobutamine**

Dobutamine is closely related to dopamine and has predominantly β_1_ activity. Dobutamine has no specific effect on the renal vasculature but urine output often increases as cardiac output and blood pressure improve. It reduces systemic vascular resistance, as well as improving cardiac performance, thereby decreasing afterload and ventricular filling pressures. Dobutamine is therefore useful in patients with cardiogenic shock.

**Receptor**

- **β_1_** – postsynaptic: Positive inotropism and chronotropism
- **β_2_** – presynaptic: Stimulates noradrenaline (norepinephrine) release
- **α_1_** – postsynaptic: Constriction of peripheral, renal and coronary vascular smooth muscle
- **α_2_** – postsynaptic: Inhibition of noradrenaline (norepinephrine) release, vasodilatation
- **DA_1_** – postsynaptic: Dilates renal, mesenteric and coronary vessels
- **DA_2_** – postsynaptic: Inhibits adrenaline (epinephrine) release

**Action**

- Positive inotropism and chronotropism
- Stimulates noradrenaline (norepinephrine) release
- Constriction of peripheral, renal and coronary vascular smooth muscle
- Inhibition of noradrenaline (norepinephrine) release, vasodilatation
- Dilates renal, mesenteric and coronary vessels
- Inhibits adrenaline (epinephrine) release

**Dose dependence**

- ++++, ++++, +++, ++, +, ±, −, −−, −−−, −−−−
Phosphodiesterase inhibitors (e.g. milrinone, enoximone)
These agents have both inotropic and vasodilator properties. Because the phosphodiesterase type III inhibitors bypass the β-adrenergic receptor they do not cause tachycardia and are less arrhythmogenic than β agonists. They are useful in patients with receptor ‘downregulation’, those receiving beta-blockers, for weaning patients from cardiopulmonary bypass and for patients with cardiac failure. In vasodilated septic patients, however, they can precipitate or worsen hypotension.

Vasopressin
Patients with septic shock have inappropriately low circulating levels of vasopressin. Low-dose vasopressin can increase blood pressure and systemic vascular resistance in patients unresponsive to other vasopressors ('vasoplegia'). A 2008 randomized controlled trial suggests that low-dose vasopressin added to conventional vasopressors may have some value in less severe septic shock.

Levosimendan
Levosimendan is a myofilament calcium sensitizer and novel inotrope. Unlike other inotropes, levosimendan does not exert its action through increases in intracellular Ca²⁺ and as a result does not impair diastolic relaxation of the heart. Levosimendan binds to troponin C with high affinity but only during systole when the intracellular calcium concentration is high. Levosimendan has phosphodiesterase inhibitor actions but these are not thought to be clinically significant. Significantly, a long-acting metabolite of levosimendan has similar calcium sensitizing actions, maintaining the inotropic effect of levosimendan once an infusion is stopped. Adverse cardiovascular effects of levosimendan include tachycardia and hypotension; as a consequence the addition of a vasopressor may be required.

Guidelines for use of inotropic and vasopressor agents
Some still consider dopamine in low to moderate doses to be the first-line agent for restoring blood pressure, although evidence suggests that dopamine is associated with a greater number of adverse events (especially arrhythmias) than norepinephrine. Certainly high-dose dopamine is best avoided. Dobutamine is particularly indicated in patients in whom the vasoconstriction caused by dopamine could be dangerous (i.e. patients with cardiac disease and septic patients with fluid overload or myocardial failure). The combination of dobutamine and norepinephrine (norepinephrine) is popular for the management of patients who are shocked with a low systemic vascular resistance (e.g. septic shock). Dobutamine is given to achieve an optimal cardiac output, while norepinephrine (norepinephrine) is used to restore an adequate blood pressure by reducing vasodilatation. In vasodilated septic patients with a high cardiac output, norepinephrine (norepinephrine) can be used alone. At time of writing, there is evidence to suggest that adrenaline (epinephrine) may be equally safe and effective as a dobutamine/norepinephrine combination. Because of its potency, adrenaline is particularly useful in patients with refractory hypotension. The role of levosimendan in the management of shock has yet to be established.

Targeting haemodynamics and oxygen transport
Although resuscitation has conventionally aimed at achieving normal haemodynamics, survival of many critically ill patients is associated with raised values for cardiac output, DO₂ and VO₂. However, elevation of DO₂ and VO₂ to these ‘supranormal’ levels following admission to intensive care produces no benefit and may be harmful. By contrast, early goal-directed therapy to resuscitate patients in the emergency room, aimed at maintaining a central venous oxygen saturation of more than 70%, significantly improves outcome in patients with severe sepsis or septic shock, as does therapy targeted at lactate clearance.

High-risk surgical patients (Box 16.4)
These patients benefit from intensive perioperative monitoring and circulatory support, in particular maintenance of an adequate circulating volume, and postoperative admission to a critical care area. Volume replacement and administration of inotropes or vasopressors should be guided by monitoring of stroke volume/cardiac output, usually using an oesophageal Doppler or pulse contour analysis. The value of the routine use of inodilators such as dopexamine remains unclear.

Vasodilator therapy
In selected cases, afterload reduction is used to increase stroke volume and decrease myocardial oxygen requirements by reducing the systolic ventricular wall tension. Vasodilatation (see p. 720) also decreases heart size and the diastolic ventricular wall tension so that coronary blood flow is improved. The relative magnitude of the falls in preload and afterload depends on the pre-existing haemodynamic disturbance, concurrent volume replacement and the agent selected (see below). Vasodilators also improve microcirculatory flow.

Vasodilator therapy can be particularly helpful in patients with cardiac failure in whom the ventricular function curve is flat (Fig. 16.6) so that falls in preload have only a limited effect on stroke volume. This form of treatment, combined in selected cases with inotropic support, is therefore useful in cardiogenic shock and in the management of patients with cardiogenic pulmonary oedema or mitral regurgitation.

Nitrate vasodilators are usually used. Nitrates, because of their ability to improve the myocardial oxygen supply/demand ratio, also help to control angina and limit ischaemic myocardial injury.
Sodium nitroprusside (SNP) dilates arterioles and venous capacitance vessels, as well as the pulmonary vasculature by donating nitric oxide. SNP therefore reduces the afterload and preload of both ventricles and can improve cardiac output and the myocardial oxygen supply/demand ratio. The effects of SNP are rapid in onset and spontaneously reversible within a few minutes of discontinuing the infusion. A large overdose of SNP can cause cyanide poisoning, with intracellular hypoxia caused by inhibition of cytochrome oxidase, the terminal enzyme of the respiratory chain. This is manifested as a metabolic acidosis and a fall in the arteriovenous oxygen content difference.

Nitroglycerine (NTG). At low doses, NTG is predominantly a venodilator, but as the dose is increased, it also causes arterial dilatation, thereby decreasing both preload and afterload. Nitrates are particularly useful in the treatment of cardiac failure with pulmonary oedema and are usually used in combination with intravenous furosemide. NTG reduces pulmonary vascular resistance, an effect that can be exploited in patients with a low cardiac output secondary to pulmonary hypertension.

Mechanical support of the myocardium

Intra-aortic balloon counterpulsation (IABCP) is the technique used most widely for mechanical support of the failing myocardium. It is discussed on page 696.

Adjunctive treatment

Initial attempts to combat the high mortality associated with sepsis concentrated on cardiovascular and respiratory support in the hope that survival could be prolonged until surgery, antibiotics and the patient’s own defences had eradicated the infection and injured tissues were repaired. Despite some success, mortality rates remained unacceptably high. So far, attempts to improve outcome by modulating the inflammatory response (including high-dose steroids) or neutralizing endotoxin (Table 16.6) have proved disappointing and in some cases may even have been harmful.

The administration of relatively low, “stress” doses of hydrocortisone to patients with refractory vasopressor-resistant septic shock may assist shock reversal and perhaps improve outcome. Careful control of the blood sugar level to between 8 and 10 mmol/L is also recommended.

The aim of current sepsis guidelines is to combine these, and other evidence-based interventions, with early effective resuscitation (aimed especially at achieving an adequate circulating volume, combined with the rational use of inotropes and/or vasoactive agents to maintain blood pressure, cardiac output and oxygen transport) in order to create “bundles of care” delivered within specific time limits (see http://www.survivingsepsis.org).

### Clinical assessment of respiratory distress

A clinical assessment of respiratory distress should be made on the following criteria (those marked with an asterisk* may be indicative of respiratory muscle fatigue):

- the use of accessory muscles of respiration
- intercostal recession
- tachypnoea*
- tachycardia
- sweating
- pulsus paradoxus (rarely present)
- inability to speak, unwillingness to lie flat
- agitation, restlessness, diminished conscious level
- asynchronous respiration (a discrepancy in the timing of movement of the abdominal and thoracic compartments)*
- paradoxical respiration (abdominal and thoracic compartments move in opposite directions)*
- respiratory alternans (breath-to-breath alteration in the relative contribution of intercostal/accessory muscles and the diaphragm)*

Blood gas analysis should be performed to guide oxygen therapy and to provide an objective assessment of the severity of the respiratory failure. The most sensitive clinical...
Vital capacity is often a better guide to deterioration and is particularly useful in patients with respiratory inadequacy that is due to neuromuscular problems such as the Guillain–Barré syndrome or myasthenia gravis, in which the vital capacity decreases as weakness increases.

**Monitoring of respiratory failure**

**Pulse oximetry**

Lightweight oximeters can be applied to an ear lobe or finger. They measure the changing amount of light transmitted through the pulsating arterial blood and provide a continuous, non-invasive assessment of arterial oxygen saturation (\(S_{\text{aO}_2}\)). These devices are reliable, easy to use and do not require calibration, although remember that pulse oximetry is not a sensitive guide to changes in oxygenation. An \(S_{\text{aO}_2}\) within normal limits in a patient receiving supplemental oxygen does not exclude the possibility of hypoventilation with carbon dioxide retention. Readings are occasionally inaccurate in those with poor peripheral perfusion.

**Blood gas analysis**

Normal values of blood gas analysis are shown in Table 16.2. Errors can result from malfunctioning of the analyser or incorrect sampling of arterial blood. Disposable pre-heparinized syringes are available for blood gas analysis.

- The sample should be analysed immediately.
- Alternatively, the syringe should be immersed in iced water (the end having first been sealed with a cap) to prevent the continuing metabolism of white cells causing a reduction in PO\(_2\) and a rise in PCO\(_2\).
- Air almost inevitably enters the sample. The gas tensions within these air bubbles will equilibrate with those in the blood, thereby lowering the PCO\(_2\) and usually raising the PO\(_2\) of the sample. However, provided the bubbles are ejected immediately by inverting the syringe and expelling the air that rises to the top of the sample, their effect is insignificant.

Interpretation of the results of blood gas analysis can be considered in two separate parts:

- Disturbances of acid–base balance (see pp. 638, 876)
- Alterations in oxygenation.

Correct interpretation requires a knowledge of the clinical history, the age of the patient, the inspired oxygen concentration and any other relevant treatment (e.g. the ventilator settings for those on mechanical ventilation or the administration of sodium bicarbonate). The oxygen content of the arterial blood is determined by the percentage saturation of haemoglobin with oxygen. The relationship between the latter and the \(P_{\text{aO}_2}\) is determined by the oxyhaemoglobin dissociation curve (Fig. 16.2).

**Capnography**

Continuous breath-by-breath analysis of expired carbon dioxide concentration can be used to:

- confirm tracheal intubation
- continuously monitor end-tidal PCO\(_2\), which approximates to \(P_{\text{aCO}_2}\) in normal subjects. Continuous capnography is now recommended for all mechanically ventilated patients to detect acute airway problems, e.g. tracheal tube/tracheostomy blocked/dislodged (also essential when transporting critically ill patients)
- detect apparatus malfunction
- detect acute alterations in cardiorespiratory function.

**Management of respiratory failure**

Standard management of patients with respiratory failure includes:

- administration of supplemental oxygen through a patent airway
- treatment for distal airways obstruction
- measures to limit pulmonary oedema
- control of secretions
- treatment of pulmonary infection.

The load on the respiratory muscles should be reduced by improving lung mechanics. Correction of abnormalities which may lead to respiratory muscle weakness, such as hypophosphataemia and malnutrition, is also necessary.

**Oxygen therapy**

**Methods of oxygen administration**

Oxygen is initially given via a facemask. In the majority of patients (except those with COPD and chronically elevated \(P_{\text{aCO}_2}\) the concentration of oxygen given is not vital and oxygen can therefore be given by a ‘variable performance’ device such as a simple facemask or nasal cannulae (Fig. 16.26).

With these devices, the inspired oxygen concentration varies from about 35% to 55%, with oxygen flow rates of between 6 and 10 L/min. Nasal cannulae are often preferred because they are less claustrophobic and do not interfere with feeding or speaking, but they can cause ulceration of...
the nasal or pharyngeal mucosa. Higher concentrations of oxygen can be administered by using a mask with a reservoir bag attached (Fig. 16.26c). Figure 16.26 should be compared with the fixed-performance mask shown in Figure 15.25, with which the oxygen concentration can be controlled. This latter type of mask is used in patients with COPD and chronic type II failure; the hazards of reducing hypoxic drive can be overemphasized and are less dangerous when the patient is in a critical care unit – remember, severe hypoxaemia is more dangerous than hypercapnia.

**Oxygen toxicity**

Experimentally, mammalian lungs have been shown to be damaged by continuous exposure to high concentrations of oxygen, but oxygen toxicity in humans is less well proven. Nevertheless, it is reasonable to assume that high concentrations of oxygen might damage the lungs, and so the lowest inspired oxygen concentration compatible with adequate arterial oxygenation should be used. Dangerous hypoxia should never be tolerated through a fear of pulmonary oxygen toxicity. There has been concern that in some circumstances (e.g. following myocardial infarction) routine administration of supplemental oxygen may be harmful, perhaps because of associated vasoconstriction.

**Respiratory support**

If, despite the above measures, the patient continues to deteriorate or fails to improve, the institution of some form of respiratory support is necessary (Table 16.7). Non-invasive ventilation via a mask or hood (see p. 895) can be used, particularly in respiratory failure due to COPD, but in critically ill patients invasive ventilation through an endotracheal tube or tracheostomy is more usual.

**Intermittent positive pressure ventilation (IPPV)** is achieved by intermittently inflating the lungs with a positive pressure delivered by a mechanical ventilator. Over the last few decades there have been a number of refinements and modifications to the manner in which positive pressure is applied to the airway and in the interplay between the patient’s respiratory efforts and mechanical assistance (see below) are further indications.

Controlled mechanical ventilation (CMV), with the abolition of spontaneous breathing, rapidly leads to atrophy of respiratory muscles so that assisted modes that are triggered by the patient’s inspiratory efforts (see below) are preferred.

The rational use of mechanical ventilation depends on a clear understanding of its potential beneficial effects, as well as the dangers.

**Beneficial effects of mechanical ventilation**

- **Relief from exhaustion.** Mechanical ventilation reduces the work of breathing, ‘rests’ the respiratory muscles and relieves the extreme exhaustion present in patients with respiratory failure. In some cases, if ventilation is not instituted, this exhaustion may culminate in respiratory arrest.

- **Effects on oxygenation.** Application of positive pressure can prevent or reverse atelectasis. In those with severe pulmonary parenchymal disease, the lungs may be very stiff and the work of breathing is therefore greatly increased. Under these circumstances, the institution of respiratory support significantly reduces total body oxygen consumption; consequently $P_{O_2}$ and thus $P_{O_2}$ may improve.

- **Improved carbon dioxide elimination.** By increasing the volume of ventilation, the $P_{CO_2}$ can be controlled.

**Indications for mechanical ventilation**

- **Acute respiratory failure,** with signs of severe respiratory distress (e.g. respiratory rate $>$40/min, inability to speak, patient exhausted) persisting despite maximal therapy. Confusion, restlessness, agitation, a decreased conscious level, a rising $P_{O_2}$ ($>$8 kPa) and extreme hypoxaemia ($<$8 kPa), despite oxygen therapy, are further indications.

- **Acute ventilatory failure** due, for example, to myasthenia gravis or Guillain–Barré syndrome. Mechanical ventilation should usually be instituted when

The patient is usually hypoxic and hypercarbic, with increased sympathetic activity; the stimulus of laryngoscopy and intubation can precipitate dangerous arrhythmias, bradycardia and even cardiac arrest. Except in an extreme emergency, therefore, the ECG and oxygen saturation should be monitored, and the patient preoxygenated with 100% oxygen before intubation. Resuscitation drugs should be immediately available. If time allows, the circulating volume should be optimized and, if necessary, inotropes commenced before attempting intubation. In some cases, it is appropriate to establish intra-arterial and central venous pressure monitoring before instituting mechanical ventilation, although many patients will not tolerate the supine or head-down position. In some deeply comatose patients, no sedation is required, but in the majority of patients, a short-acting intravenous anaesthetic agent, usually with an opiate followed by muscle relaxation will be necessary. When available, capnography must be used to confirm tracheal intubation.

**Sedation, analgesia and muscle relaxation**

Most critically ill patients will require analgesia and many will receive sedatives. The combination of an opiate with a benzodiazepine or propofol is often used to facilitate mechanical ventilation and to obtund the physiological response to stress. Heavy sedation is indicated in those with severe respiratory failure, especially since ‘lung protective’ ventilatory strategies (see p. 895) are inherently uncomfortable. A few may require neuromuscular blockade, indeed evidence suggests that early administration of atracurium improves outcomes for mechanically ventilated patients with severe ARDS. It is now recognized, however, that minimizing sedation levels using ‘sedation scores’ and ‘daily wakening’, or even the avoidance of sedatives altogether, often in combination with spontaneous breathing modes of respiratory

</table>
support (see p. 895) is associated with reductions in the duration of mechanical ventilation and more rapid discharge from the ICU and hospital. It is also now recognized that benzodiazepines predispose to the development of delirium (which is an independent predictor of increased mortality and length of hospital stay) in critically ill patients. The use of dexamethasone (an α₁ agonist) rather than a benzodiazepine has been shown to be associated with less delirium and reduced time on the ventilator.

**Tracheostomy**

Tracheostomy may be required for the long-term control of excessive bronchial secretions, particularly in those with a reduced conscious level, and/or to maintain an airway and protect the lungs in those with impaired pharyngeal and laryngeal reflexes. Tracheostomy is also performed when ventilation is likely to be prolonged, for patient comfort, to reduce sedation requirements and to facilitate weaning from mechanical ventilation.

Tracheostomy can be performed in the ICU or in an operating theatre. A percutaneous dilatational approach, which is quick and can be performed at the bedside, is a suitable technique for most critically ill patients (and can be used in an emergency). The alternative surgical approach, opening the trachea vertically through the second, third and fourth tracheal rings via a transverse skin incision, involves transferring the patient to an operating theatre.

A life-threatening obstruction of the upper respiratory tract that cannot be bypassed with an endotracheal tube can be relieved by a cricothyroidotomy, which is safer, quicker and easier to perform than a formal tracheostomy. Tracheostomy has a small but significant mortality rate. Complications of tracheostomy are shown in Table 16.9.

**Complications associated with mechanical ventilation**

**Airway complications.** There may be complications associated with tracheal intubation or tracheostomy (see above) (Tables 16.8, 16.9).

**Disconnection, failure of gas or power supply, mechanical faults.** These are unusual but dangerous. A method of manual ventilation, a facemask and oxygen must always be available by the bedside.

**Cardiovascular complications.** The application of positive pressure to the lungs and thoracic wall impedes venous return and distends alveoli, thereby ‘stretching’ the pulmonary capillaries and causing a rise in pulmonary vascular resistance. Both these mechanisms can produce a fall in cardiac output.

**Respiratory complications.** Mechanical ventilation can be complicated by a deterioration in gas exchange because of V/Q mismatch, fluid retention and collapse of peripheral alveoli. Traditionally, the latter was prevented by using high tidal volumes (10–12 mL/kg) but high inflation pressures, with overdistension of compliant alveoli, perhaps exacerbated by the repeated opening and closure of distal airways, can disrupt the alveolar–capillary membrane. There is an increase in microvascular permeability and release of inflammatory mediators leading to ‘ventilator-associated lung injury’. Extreme overdistension of the lungs during mechanical ventilation with high tidal volumes and PEEP can rupture alveoli and cause air to dissect centrally along the perivascular sheaths. This ‘barotrauma’ may be complicated by pneumomediastinum, subcutaneous emphysema, pneumoperitoneum, pneumothorax, and intra-abdominal air. The risk of pneumothorax is increased in those with destructive lung disease (e.g. necrotizing pneumonia, emphysema, asthma or fractured ribs).

A tension pneumothorax can be rapidly fatal in ventilated patients. Suggestive signs include the development of worsening of hypoxia, hypercarbia, respiratory distress, an unexplained increase in airway pressure, as well as hypotension and tachycardia, sometimes accompanied by a rising CVP. Examination may reveal unequal chest expansion, mediastinal shift away from the side of the pneumothorax (deviated trachea, displaced apex beat) and a hyperresonant hemithorax. Although breath sounds are often diminished over the pneumothorax, this sign can be misleading in ventilated patients. If there is time, the diagnosis can be confirmed by chest X-ray prior to definitive treatment with chest tube drainage.

**Ventilator-associated pneumonia.** Hospital-acquired pneumonia occurs in as many as one-third of patients receiving mechanical ventilation and this is associated with a significant increase in mortality. It can be difficult to diagnose. The measurement of serum procalcitonin, a specific marker of severe bacterial infections, can be helpful. Various organisms can be isolated, such as aerobic Gram-negative bacilli, e.g. *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *E. coli*, *Acinetobacter* spp. and *Staphylococcus aureus*, including MRSA. Leakage of infected oropharyngeal secretions past the tracheal tube cuff is thought to be largely responsible. Bacterial colonization of the oropharynx may be promoted by regurgitation of colonized gastric fluid and the risk of ventilator-associated pneumonia can be reduced by nursing patients in the semi-recumbent, rather than the supine, position and by oropharyngeal decontamination.

**Techniques for respiratory support** (Table 16.7)

**Controlled mechanical ventilation (CMV)**

This technique is used in patients in whom respiratory efforts are absent or have been abolished.

Ventilation involves one of two types:

- **Volume controlled ventilation.** The tidal volume and respiratory rate are preset on the ventilator. The airway pressure varies according to both the ventilator setting and the patient’s lung mechanics (airways resistance and compliance).
- **Pressure controlled ventilation.** Both the inspiratory pressure and the respiratory rate are preset but the tidal volume varies according to the patient’s lung mechanics.

**Positive end-expiratory pressure (PEEP)**

A positive airway pressure can be maintained at a chosen level throughout expiration by attaching a threshold resistor valve to the expiratory limb of the circuit. PEEP re-expands underventilated lung units, and redistributes lung water from the alveoli to the perivascular interstitial space, thereby reducing shunt and increasing P\(_{aO_2}\). The inevitable rise in mean intrathoracic pressure associated with the application of PEEP may, however, further impede venous return, increase pulmonary vascular resistance and reduce cardiac output. The fall in cardiac output can be ameliorated by expanding the circulating volume, although in some cases inotropic or vasopressor support is required. Thus, although arterial oxygenation is often improved by the application of PEEP, a simultaneous fall in cardiac output can lead to a reduction in total oxygen delivery.

Traditionally, the application of PEEP was only considered if it proved difficult to achieve adequate oxygenation of arterial blood despite raising the inspired oxygen concentration above 50%. Many now use low levels of PEEP (5–7 cmH\(_2\)O) in the majority of mechanically ventilated patients in order to maintain lung volume, as well as for those with basal atelectasis and in selected cases with airways obstruction.

**Continuous positive airway pressure (CPAP)**

The application of CPAP achieves for the spontaneously breathing patient what PEEP does for the ventilated patient. Oxygen and air are delivered under pressure via an endotracheal tube, a tracheostomy, a tightly fitting facemask or a hood (Fig 16.27). Not only can CPAP improve oxygenation, but the lungs become more compliant, and the work of breathing is reduced.

**Pressure support ventilation (PSV)**

Spontaneous breaths are augmented by a preset level of positive pressure (usually between 5 and 20 cmH\(_2\)O) triggered by the patient’s spontaneous respiratory effort and applied for a given fraction of inspiratory time or until inspiratory flow falls below a certain level. Tidal volume is determined by the set pressure, the patient’s effort and pulmonary mechanics. The level of pressure support can be reduced progressively as the patient improves.

**Intermittent mandatory ventilation (IMV)**

This technique allows the patient to breathe spontaneously between the ‘mandatory’ tidal volumes delivered by the ventilator. These mandatory breaths are timed to coincide with the patient’s own inspiratory effort (synchronized IMV or SIMV). SIMV can be used with or without CPAP, and spontaneous breaths may be assisted with pressure support ventilation.

**‘Lung-protective’ ventilation**

This is designed to avoid exacerbating or perpetuating lung injury by avoiding overdistension of alveoli, minimizing airway pressures and preventing the repeated opening and closure of distal airways. Alveolar volume is maintained with PEEP, and sometimes by prolonging the inspiratory phase, while tidal volumes are limited to 6–8 mL/kg ideal bodyweight. Peak airway pressures should not exceed 35–40 cmH\(_2\)O. An alternative is to deliver a constant preset inspiratory pressure for a prescribed time in order to generate a low tidal volume at reduced airway pressures (‘pressure-limited’ mechanical ventilation). Respiratory rate can be increased to improve CO\(_2\) removal and avoid severe acidosis (pH <7.2), but hypercarbia is frequent and should be accepted (‘permissive hypercapnia’). Both techniques can be used with SIMV. Ventilation with low tidal volumes has been shown to improve outcome in patients with acute lung injury (ALI) or the acute respiratory distress syndrome (ARDS) (see p. 884). Lung protective ventilation should now be used in almost all patients undergoing mechanical ventilation.

**High frequency oscillation (HFO)**

With HFO, there is no bulk flow of gas; rather gas oscillates to and fro at rates of 60–3000 cycles/min with a V\(_{I}\) of 1–3 mL/kg. Both inspiration and expiration are actively controlled with a sine wave pump. The mechanism of gas exchange is not fully understood but lung volume is well maintained and oxygenation may be improved. There is some evidence to suggest that HFO is a safe and effective intervention for patients with severe ARDS.

**Extracorporeal gas exchange (ECGE)**

In patients with severe refractory respiratory failure pumped veno-venous bypass through a membrane lung (extracorporeal membrane oxygenation, ECMO or extracorporeal carbon dioxide removal, ECCO\(_2\)-R) has been used to reduce ventilation requirements, thereby minimizing further ventilation-induced lung damage and encouraging resolution of the lung injury. A recent (2010) randomized controlled trial suggested that ECMO might improve outcome in adult patients with severe respiratory failure. There is also some indication that the technique is particularly valuable in young patients with acute respiratory distress syndrome caused by influenza.

**Non-invasive ventilation (NIV)**

NIV is suitable for patients who are conscious, cooperative and able to protect their airway; they must also be able to cooperate effectively. Positive pressure is applied to the Airways using a tight-fitting full-face/nasal mask or a hood. The most popular ventilators for this purpose are those that deliver bilevel positive airway pressure (BiPAP), which are simple to use, cheap and flexible. With the latter technique,
Neuromuscular weakness complicating critical illness

Polyneuromopathies have most often been described in association with persistent sepsis and multiple organ failure (see below). Critical illness polyneuropathy is characterized by a primary axonal neuropathy involving both motor and, to a lesser extent, sensory nerves. Clinically, the initial manifestation is often difficulty in weaning the patient from respiratory support. There is muscle wasting, the limbs are weak and flaccid, and deep tendon reflexes are reduced or absent.

Cranial nerves are relatively spared. Nerve conduction studies confirm axonal damage. The cerebrospinal fluid (CSF) protein concentration is normal or minimally elevated. These findings differentiate critical illness neuropathy from Guillain–Barré syndrome, in which nerve conduction studies nearly always show evidence of demyelination and CSF protein is usually high.

The cause of critical illness polyneuropathy is not known and there is no specific treatment. Weaning from respiratory support and rehabilitation are likely to be prolonged. With resolution of the underlying critical illness, recovery can be expected after 1–6 months but muscle weakness and fatigue frequently persist.

Myopathies can also occur, often in association with a neuropathy. A severe quadriplegic myopathy has been particularly associated with the administration of steroids and muscle relaxants to mechanically ventilated patients with acute, severe asthma.

Criteria for weaning patients from mechanical ventilation

Clinical assessment is the best way of deciding whether a patient can be weaned from the ventilator. The patient’s conscious level, mood, the effects of drugs and cardiovascular performance must all be taken into account. A subjective evaluation by an experienced clinician of the patient’s response to a short period of spontaneous breathing (spontaneous breathing trial) is the most reliable predictor of weaning success or failure. Objective criteria are based on an assessment of pulmonary gas exchange (blood gas analysis), lung mechanics and muscular strength.

Techniques for weaning

Patients who have received mechanical ventilation for <24–48 hours, e.g. after elective major surgery, can usually resume spontaneous respiration immediately and no weaning process is required. This procedure can also be adopted for those who have been ventilated for longer periods but who tolerate a spontaneous breathing trial and clearly fulfill objective criteria for weaning. Techniques of weaning include the following:

- The traditional method is to allow the patient to breathe entirely spontaneously for a short time, following which respiratory support is re instituted. The periods of spontaneous breathing are gradually increased and the periods of respiratory support are progressively reduced. Initially it is usually advisable to ventilate the patient throughout the night. This method can be stressful and tiring for both patients and staff, although it is sometimes successful when other methods have failed.
- SIMV with progressive reduction in the frequency of mandatory breaths. Spontaneous breaths are usually pressure supported.
- Gradual reduction of the level of pressure support is currently considered by many to be the preferred technique.
- CPAP can prevent the alveolar collapse, hypoxaemia and fall in compliance that might otherwise occur when patients start to breathe spontaneously. It is therefore used during weaning with SIMV or pressure support, during spontaneous breathing trials and in spontaneously breathing patients prior to extubation.
- Tracheostomy is often used to facilitate weaning from mechanical ventilation.

Weaning

Weakness and wasting of respiratory muscles is an inevitable consequence of the catabolic response to critical illness and is often exacerbated by the reduction in respiratory work during mechanical ventilation (‘disuse atrophy’). Often abnormalities of gas exchange and lung mechanics persist. Not surprisingly, therefore, many patients experience difficulty in resuming spontaneous ventilation. In a significant proportion of patients who have undergone a prolonged period of respiratory support the situation is further complicated by the development of a neuropathy, a myopathy or both.

Box 16.5 Some indications for the use of non-invasive ventilation (NIV)

- Inspiratory and expiratory pressure levels and times are set independently and unrestricted spontaneous respiration is possible throughout the respiratory cycle. BiPAP can also be patient triggered. There is a reduced risk of ventilator-associated pneumonia and improved patient comfort, with preservation of airway defence mechanisms, speech and swallowing (which allows better nutrition). Spontaneous coughing and expectoration are not hampered, allowing effective physiotherapy, and sedation is usually unnecessary. Institution of non-invasive respiratory support can rest the respiratory muscles, reduce respiratory acidosis and breathlessness, improve clearance of secretions and re-expand collapsed lung segments. The intubation rate, length of ICU and hospital stay and, in some categories of patient, mortality, may all be reduced. NIV is particularly useful in acute hypercapnic respiratory failure associated with COPD, provided the patient is not profoundly hypoxic. NIV may also be useful as a means of avoiding tracheal intubation in immunocompromised patients with acute respiratory failure. Evidence suggests that early NIV after extubation of hypercapnic patients with respiratory disorders can reduce the risk of subsequent respiratory failure and mortality. Box 16.5 shows some indications for the use of NIV when standard medical treatment has failed. Remember, NIV should not be used as a substitute for invasive ventilation when the latter is clearly more appropriate. |
Non-invasive respiratory support (BiPAP, CPAP) can be used following extubation to prevent respiratory failure and re-intubation.

Extubation and tracheostomy decannulation
This should not be performed until patients can cough, swallow, protect their own airway and are sufficiently alert to be cooperative. Patients who fulfill these criteria can be extubated provided their respiratory function has improved sufficiently to sustain spontaneous ventilation indefinitely. Similar considerations guide the elective removal of tracheostomy tubes.

OUTCOMES: WITHHOLDING AND WITHDRAWING TREATMENT

(See also Ch. 10.)

For many critically ill patients, intensive care is undoubt-edly life-saving and resumption of a normal lifestyle is to be expected. It is also widely accepted that the elective admission of high-risk patients into an ICU or HDU, particularly in the immediate postoperative period, can minimize morbidity and mortality and reduce costs, as well as reducing the demands on medical and nursing personnel on general wards. In the most seriously ill patients, however, immediate mortality rates are high and a significant number die soon after discharge from the intensive care unit. Mortality rates are particularly high in those who require readmission to intensive care. Moreover, the quality of life for some of those who do survive is poor and longer-term mortality rates (up to 5 years post discharge) are also higher than in the general population. Some centres have established specialist follow-up clinics to address long-term sequelae of critical illness.

Inappropriate use of intensive care facilities has other implications. The patient may experience unnecessary suffering and loss of dignity, while relatives may also have to endure considerable emotional pressures. In some cases, treatment may simply prolong the process of dying, or sustain life of dubious quality, and in others the risks of interventions outweigh the potential benefits. Lastly, intensive care is expensive, particularly for those with the worst prognosis, and resources are limited.

Both for a humane approach to the management of critically ill patients and to ensure that limited resources are used appropriately, it is necessary to:

- avoid admitting patients who cannot benefit from intensive care and
- limit further aggressive therapy when the prognosis is clearly hopeless.

Such decisions are extremely difficult; every case must be assessed individually, taking into account previous health and quality of life, primary diagnosis, medium- and long-term prognosis of the underlying condition, and survivability of the acute illness. Age alone should not be a consideration. When in doubt, active measures should continue but with regular review in the light of response to treatment and any other changes.

Decisions to limit therapy, not to resuscitate or to withdraw treatment should be made jointly by the medical staff of the unit, the primary physician or surgeon, the nurses and if possible the patient, normally in consultation with the patient’s family. Limitation of active treatment is not the cessation of medical or nursing care: rather, a caring approach must be adopted to ensure a dignified death, free of pain and distress, with support for family and friends (see Ch. 10).

Scoring systems
A variety of scoring systems have been developed that can be used to evaluate the severity of a patient’s illness. Some have included an assessment of the patient’s previous state of health and the severity of the acute disturbance of physiological function (acute physiology, age, chronic health evaluation, APACHE and simplified acute physiology score, SAPS). Other systems have been designed for particular categories of patient (e.g. the injury severity score for trauma victims).

The APACHE and SAPS scores are widely applicable and have been extensively validated. They can quantify accurately the severity of illness and predict the overall mortality for large groups of critically ill patients, and are therefore useful for defining the ‘casemix’ of patients when auditing a unit’s clinical activity, for comparing results nationally or internationally, and as a means of characterizing groups of patients in clinical studies. Although the APACHE and SAPS methodologies can also be used to estimate risks of mortality, no scoring system has yet been devised that can predict with certainty the outcome in an individual patient. They must not, therefore, be used in isolation as a basis for limiting or discontinuing treatment.

BRAIN DEATH
Brain death means the irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity to breathe. Both of these are essentially functions of the brainstem. Death, if thought of in this way, can arise either from causes outside the brain (i.e. respiratory and cardiac arrest) or from causes within the cranial cavity. With the advent of mechanical ventilation it became possible to support such a dead patient temporarily, although in all cases cardiovascular failure eventually supervenes and progresses to asystole.

Before deciding on a diagnosis of brainstem death, it is essential that certain preconditions and exclusions are fulfilled.

Preconditions
- The patient must be in apnoeic coma (i.e. unresponsive and on a ventilator, with no spontaneous respiratory efforts).
- Irremediable structural brain damage due to a disorder that can cause brainstem death must have been diagnosed with certainty (e.g. head injury, intracranial haemorrhage).

Exclusions
- The possibility that unresponsive apnoea is the result of poisoning, sedative drugs or neuromuscular blocking agents must be excluded.
- Hypothermia must be excluded as a cause of coma. The central body temperature should be more than 35°C.
- There must be no significant metabolic or endocrine disturbance that could produce or contribute to coma or cause it to persist.
- There should be no profound abnormality of the plasma electrolytes, acid-base balance or blood glucose levels.
In the UK, it is not considered necessary to perform confirmatory tests such as EEG and carotid angiography.

The primary purpose of establishing a diagnosis of brainstem death is to demonstrate beyond doubt that it is futile to continue mechanical ventilation and other life-supporting measures.

In suitable cases, and provided the assent of relatives has been obtained (easier if the patient was carrying an organ donor card or is on the organ donor register), the organs of those in whom brainstem death has been established may be used for transplantation. In the UK, each region has a transplant coordinator who can help with the process, as well as providing information, training and advice about organ donation. They should be informed of all potential donors. In all cases in the UK, the coroner’s consent must be obtained.

**Diagnostic tests for the confirmation of brainstem death**

All brainstem reflexes are absent in brainstem death.

**Tests**

*The following tests should not be performed in the presence of seizures or abnormal postures.*

- Oculocephalic reflexes should be absent. In a comatose patient whose brainstem is intact, the eyes will rotate relative to the orbit (i.e. doll’s eye movements will be present). In a brainstem dead patient, when the head is rotated from side to side, the eyes move with the head and therefore remain stationary relative to the orbit.

- The pupils are fixed and unresponsive to bright light.
  - Both direct and consensual light reflexes are absent. The size of the pupils is irrelevant, although most often they will be dilated.

- Corneal reflexes are absent.

- There are no vestibulo-ocular reflexes on caloric testing (see p. 1078).

- There is no motor response within the cranial nerve territory to painful stimuli applied centrally or peripherally. Spinal reflex movements may be present.

- There is no gag or cough reflex in response to pharyngeal, laryngeal or tracheal stimulation.

- Spontaneous respiration is absent. The patient should be ventilated with 100% $\text{O}_2$ (or 5% $\text{CO}_2$ in 95% $\text{O}_2$) for 10 minutes and then temporarily disconnected from the ventilator for up to 10 minutes. Oxygenation is maintained by insufflation with 100% oxygen via a catheter placed in the endotracheal tube. The patient is observed for any signs of spontaneous respiratory efforts. A blood gas sample should be obtained during this period to ensure that the $P_{\text{aCO}_2}$ is sufficiently high to stimulate spontaneous respiration (>6.7 kPa; 50 mmHg).

  The examination should be performed and repeated by two senior doctors.

The patient

The prerequisite of any form of therapeutic intervention is a reliable diagnosis or, at least, an assessment of clinical need. An accurate diagnosis ensures that a patient is not exposed, unnecessarily, to the hazards or costs of a particular intervention. Nevertheless, there are some circumstances when treatment is used in the absence of a clear diagnosis, for example:

- the symptomatic treatment of severe pain
- the initiation of ‘blind’ antimicrobial therapy where delay would expose a patient to hazard or discomfort (e.g. antimicrobial therapy for a patient with a suspected lower urinary tract infection).

In some instances a particular medicine is only effective in subgroups of patients who have a particular disorder. Trastuzumab, for example, is only of value in women with breast cancer whose malignant cells express the HER2 epidermal growth factor receptor. Tailoring treatment, depending on an individual’s specific genetic characteristics or gene expression, is increasingly used. This promising approach approach has become known as ‘personalized medicine’.

Medicines are also given to otherwise healthy individuals. In such circumstances there must be a very clear imperative to ensure that the benefits to the individual outweigh the harm. Examples include:

- Immunization against serious microbial infections (e.g. influenza vaccination)
- The reduction of individual risk factors to prevent later disease (e.g. the use of antihypertensive, or lipid-lowering, agents, to reduce the chances of ischaemic heart disease and stroke)
- Oral contraceptives in sexually active women wishing to avoid pregnancy.

Co-morbidity may also significantly alter the way in which conditions are treated particularly in the elderly. Some examples are shown in Table 17.1.

Prescribing in neonates, infants, children and adolescents

The use of drugs in young people poses special problems. Extrapolating from adult dosage regimens, merely adjusting for weight, leads to excessive (and potentially toxic) doses because:

- The rates of hepatic metabolism and renal excretion of drugs are reduced in neonates and infants.
Premature babies have approximately 1% of their body weight as fat (compared with 20% in adults), leading to a marked increase in plasma drug levels of fat-soluble drugs.

There are other difficulties in prescribing for children:

- Many treatments have never been subject to formal trials in either children or adolescents and their benefits and risks have not, therefore, been appropriately assessed in these age groups. Efforts are being made, internationally, to redress this.
- For many drugs, there are no paediatric preparations or formulations. Instead, adult products are used.
- Precise oral dosing is often impossible in babies who spit out unpleasant-tasting products!
- Adverse effect profiles of medicines may be different in children compared with adults (e.g. Reye’s syndrome in children given aspirin, suicidal ideas in depressed adolescents treated with selective serotonin reuptake inhibitors).

Prescribing for the elderly

The use of drugs in the elderly is often a problem:

- Rates of hepatic drug metabolism and renal excretion decline with age. Extrapolation of drug dosages, from those appropriate in younger adults, may therefore lead to toxic plasma levels.
- Changes in drug distribution due to changes in body composition, and the preferential distribution of the cardiac output to the brain, may also predispose to toxicity.
- Co-morbidity, often associated with polypharmacy, leads to increased opportunities for disease–drug and drug–drug interactions.
- Concordance with treatment regimens diminishes as the number of prescribed drugs increases, and is especially poor in the face of cognitive impairment.

Exaggerated pharmacodynamic effects of drugs acting on the central nervous, cardiovascular and gastrointestinal systems are common.

Examples of common problems encountered in the use of drugs amongst older people are shown in Table 17.2.

Drug use in pregnancy

Clinicians should be extremely cautious about prescribing drugs to pregnant women, and only essential treatments should be given. When a known teratogen is needed during pregnancy (e.g. an anticonvulsant drug or lithium), the potential adverse effects should be discussed with the parents, preferably before conception. If parents wish to go ahead with the pregnancy, they should be offered an appropriate ultrasound scan to assess whether there is any fetal damage. Some known human teratogens are shown in Table 17.3.

Breast-feeding

Although most drugs can be detected in breast milk, the quantity is generally small. This is because, for most drugs, the concentration in milk is in equilibrium with plasma water (i.e. the non-protein-bound fraction). A few drugs (e.g. aspirin, carbimazole) may, however, cause harm to the infant if ingested in breast milk. Relevant drug literature should be consulted when prescribing for nursing mothers.

The drug

Selecting the right drug involves three elements:

- The drug’s clinical efficacy for the proposed use
- The balance between the drug’s efficacy and safety
- Patient preference.
The most common approach to assessing a drug’s efficacy is the randomized controlled trial (RCT), although other approaches (see p. 907) can be informative. The demonstration of absolute efficacy (against placebo) may, itself, be insufficient. Where there is more than one treatment for the same indication these should be compared with one another, taking account of the magnitude of their benefits, their individual adverse reaction profiles, and their costs.

**Pharmacokinetics**

Pharmacokinetics is the study of what the body does to a drug. The intensity of a drug’s action, immediately after parenteral administration, is largely a function of its volume of distribution. This, in turn, is predominantly governed by body composition and regional blood flow. Dosage adjustments, for body weight or surface area, are therefore common (e.g. in cancer chemotherapy) in order to optimize treatment.

The main determinants of a drug’s plasma concentration after oral administration are its bioavailability (the proportion of the unchanged drug that reaches the systemic circulation) and its rate of systemic clearance (by hepatic metabolism or renal excretion). A drug’s oral bioavailability depends on the extent to which it is:

- destroyed in the gastrointestinal tract
- able to cross the gastrointestinal epithelium
- metabolized by the liver before reaching the systemic circulation (so-called presystemic or ‘first pass’ metabolism). First pass metabolism can be avoided by the intravascular (i.v.), intramuscular (i.m.) or sublingual routes.

Liver drug metabolism occurs in two stages:

- **Phase I** is the modification of a drug, by oxidation, reduction or hydrolysis. Of these, oxidation is the most frequent route and is largely undertaken by a family of isoenzymes known as the cytochrome P450 system (see p. 902). Inhibition or induction of cytochrome P450 isoenzymes are major causes of drug interactions (Table 17.5).
- **Phase II** involves conjugation with glucuronate, sulphate, acetate or other substances to render the drug more water soluble and therefore able to be excreted in the urine.

** Genetic causes of altered pharmacokinetics**

Both presystemic hepatic metabolism, and the rate of systemic hepatic clearance, may vary markedly between healthy individuals.
Variability in the genes that encode drug-metabolizing enzymes (Table 17.6) is a major determinant of the interindividual differences in the therapeutic and adverse responses to drug treatment. The most common involve polymorphisms of the cytochrome P450 family of enzymes, CYP. The first to be discovered was the polymorphism in the hydroxylation of the antihypertensive agent debrisoquin (CYP2D6). Defective catalysis was shown to be a monogenetically inherited trait, involving 5–10% of Caucasian populations, and leading to an exaggerated hypotensive response.

A substantial number of other drugs – estimated at 15–25% of all medicines in use – are substrates for CYP2D6. The frequencies of the variant alleles show racial variation and a small proportion of individuals may have two or more copies of the active gene. The phenotypic consequences of the defective CYP2D6 include the increased risk of toxicity with those antidepressants or antipsychotics that undergo metabolism by this pathway. Conversely, in individuals with multiple copies of the active gene, there are extremely rapid rates of metabolism and therapeutic failure at conventional doses.

Warfarin is predominantly metabolized by CYP2C9. In most populations, between 2% and 10% are homozygous for an allele that results in low enzyme activity. Such individuals will therefore metabolize warfarin more slowly leading to higher plasma levels, a greater risk of bleeding, and a requirement for lower doses if the international normalized ratio (INR) is to be maintained within the therapeutic range. Cytochrome P450 is inhibited by the proton pump inhibitors but the consensus view is that co-prescribing with clopidogrel does not cause a significant increase in cardiovascular risk.

Individual differences in the activity of thiopurine methyltransferase (TPMT) determine the doses of mercaptopurine and azathioprine that are used. TMPT activity is therefore undertaken routinely in children undergoing treatment for acute lymphatic leukaemia and people with Crohn’s disease (see p. 233).

CYP, cytochrome; SSRLs, Selective serotonin reuptake inhibitors. *Clopidogrel is a prodrug and impaired metabolizers have a reduced response.

Many drugs undergo metabolism by more than one member of the cytochrome P450 family. Individuals deficient in one enzyme may have normal, or over-expressed, activities of others. Current knowledge (and cost) does not therefore permit predictions of an individual’s dosage requirements for the wide range of drugs for which polymorphisms in metabolism have been identified.

This may, however, become possible in the future, and would contribute – in part – to the prospect of ‘personalized prescribing’ (see p. 899).

**Other causes of altered pharmacokinetics**

Rates of hepatic drug clearance can also be influenced by environmental factors including diet, alcohol consumption and concomitant therapy with drugs capable of inducing or inhibiting (Table 17.5) drug metabolism. Hepatic drug clearance also decreases with age. By contrast, renal drug clearance does not show substantial variation between healthy individuals although it declines with age and in people with intrinsic renal disease.

**Pharmacodynamics**

Pharmacodynamics is the study of what the drug does to the body. Pharmacodynamic sources of variability in the intensity of drug action are at least partly due to drug receptor polymorphisms (Table 17.7). At present, the pharmacodynamic tests used in clinical practice to target therapy are largely confined to the expression of:
Monitoring the effects of treatment

The combination of pharmacokinetic and pharmacodynamic causes of variability makes monitoring of the effects of treatment essential. Three approaches are used.

Pre-treatment dose selection

In patients who have known, or suspected, impaired renal function, it is usually possible to predict dose requirements from their serum creatinine concentrations. If treatment needs to be started before the serum creatinine concentration is available, in patients who have very advanced renal impairment, or if renal function is fluctuating, then treatment can be started with conventional doses but the prescriber needs to be prepared to make adjustments within 24 hours.

Measuring plasma drug concentrations

For a few drugs, dosages can be effectively monitored by reference to their plasma concentrations (Table 17.8). This technique is only useful, however, if both the following criteria are fulfilled:

- There is a reliable and available drug assay.
- Plasma concentrations correlate well with both therapeutic efficacy and toxicity.

Measuring drug effects

For many drugs, dosage adjustments are made in line with patients’ responses. Monitoring can involve dose titration against a therapeutic endpoint or a toxic effect. Objective measures (such as monitoring antihypertensive therapy by measuring blood pressure, or cytotoxic therapy with serial white blood cell counts) are most helpful, but subjective ones are necessary in many instances (as with antipsychotic therapy in people with schizophrenia).

Affordability

The money available for healthcare varies widely across the world and there are marked differences (Fig. 17.1). All healthcare systems try to provide their populations with the highest standards of care within the resources they have at their disposal. The expenditure of large sums on a few people may deprive many of cost-effective remedies – a phenomenon known as the ‘opportunity cost’. The differences in healthcare expenditure shown in Figure 17.1 can be very largely accounted for by their differences in national wealth as reflected by their gross domestic products.

In many countries cost-containment measures are encouraged (or mandated). For example, to reduce costs, all drugs should be prescribed by their generic (approved) names rather than their ‘brand’ ones because, once their patents have expired, generics products are cheaper. Despite

</table>
occasional claims to the contrary, generic products are required to go through the same stringent regulatory processes as their branded counterparts.

Some countries, including Australia, Canada and Britain, assess the cost-effectiveness of new drugs (value for money) before they are available under their publicly funded healthcare systems.

**Adverse drug reactions**

Adverse drug reactions (ADRs), defined as ‘the unwanted effects of drugs occurring under normal conditions of use’, are a significant cause of morbidity and mortality. Around 5% of acute medical emergencies are admitted with ADRs, and around 10–20% of hospital inpatients suffer an ADR during their stay. Unwanted effects of drugs are five to six times more likely in the elderly than in young adults; and the risk of an ADR rises sharply with the number of drugs administered.

**Classification**

Two types of ADR are recognized. **Type A (augmented) reactions** (Table 17.9) are:

- qualitatively normal, but quantitatively abnormal, manifestations of a drug’s pharmacological or toxicological properties
- predictable from its known pharmacological or toxicological actions
- generally dose-dependent
- usually common
- only occasionally serious.

Whilst some such reactions as hypotension with ACE inhibitors may occur after a single dose, others may develop only after months (pulmonary fibrosis with amiodarone) or years (second malignancies with anti-cancer drugs).

**Type B (idiosyncratic) reactions** (Table 17.9) have no resemblance to the recognized pharmacological or toxicological effects of the drug. They are:

- qualitatively abnormal responses to the drug
- unpredictable from its known pharmacological or toxicological actions
- generally dose-independent
- usually rare
- often serious.

**Diagnosis**

All ADRs mimic some naturally occurring disease and the distinction between an iatrogenic aetiology, and an event unrelated to the drug, is often difficult. Although some effects are obviously iatrogenic (e.g. acute anaphylaxis occurring a
few minutes after intravenous penicillin), many are less so. There are six characteristics that can help distinguish an adverse reaction from an event due to some other cause:

- **Appropriate time interval.** The time interval between the administration of a drug and the suspected adverse reaction should be appropriate. Acute anaphylaxis usually occurs within a few minutes of administration, whilst aplastic anaemia will only become apparent after a few weeks (because of the life-span of erythrocytes). Drug-induced malignancy, however, will take years to develop.

- **Nature of the reaction.** Some conditions (maculopapular rashes, angio-oedema, fixed drug eruptions, toxic epidermal necrolysis) are so typically iatrogenic that an adverse drug reaction is very likely.

- **Plausibility.** Where an event is a manifestation of the known pharmacological property of the drug, its recognition as a type A adverse drug reaction can be made (e.g. hypotension with an antihypertensive agent, or hypoglycaemia with an antidiabetic drug). Unless there have been previous reports in the literature, the recognition of type B reactions may be very difficult. The first cases of depression with isorotenin, for example, were difficult to recognize as an ADR even though a causal association is now acknowledged.

- **Exclusion of other causes.** In some instances, particularly suspected hepatotoxicity, an iatrogenic diagnosis can only be made after the exclusion of other causes of disease.

- **Results of laboratory tests.** In a few instances, the diagnosis of an adverse reaction can be inferred from the plasma concentration (Table 17.8). Occasionally, an ADR produces diagnostic histopathological features. Examples include putative reactions involving the skin and liver.

- **Results of dechallenge and rechallenge.** Failure of remission when the drug is withdrawn (i.e. ‘dechallenge’) is unlikely to be an ADR. The diagnostic reliability of dechallenge, however, is not absolute: if the ADR has caused irreversible organ damage (e.g. malignancy) then dechallenge will result in a false-negative response. Rechallenge, involving re-institution of the suspected drug to see if the event recurs, is often regarded as an absolute diagnostic test. This is, in many instances, correct but there are two caveats. First, it is rarely justifiable to subject a patient to further hazard. Second, some adverse drug reactions develop because of particular circumstances which may not necessarily be replicated on rechallenge (e.g. hypoglycaemia with an antidiabetic agent).

### Management

As a general rule, type A reactions can usually be managed by a reduction in dosage whilst type B reactions almost invariably require the drug to be withdrawn (and never re-instituted).

Specific therapy is sometimes required for ADRs such as bleeding with warfarin (vitamin K), acute dystonias (benztropine) or acute anaphylaxis (see Emergency Box 3.1, p. 69).

### Evidence-based medicine

There is general acceptance that clinical practice should, as far as possible, be based on evidence of benefit rather than theoretical speculation, anecdote or pronouncement.

One of the main applications of ‘evidence-based medicine’ is in therapeutics. Treatments should be introduced into, and used in, routine clinical care only if they have been demonstrated to be effective in appropriate studies. Three approaches are used:

1. Randomized controlled trials
2. Controlled observational trials
3. Uncontrolled observational studies.

### Randomized controlled trials

In this type of study, people with a particular condition are allocated to one of two (and sometimes more) treatments randomly. At the end of the study, the outcomes in the groups are compared. The purpose of the randomized controlled trial is to minimize bias and confounding. In order to minimize patient bias, the patients themselves are generally unaware of their treatment allocations (a ‘single-blind’ trial); and in order to reduce doctor bias, treatment allocations are also withheld from the investigators (a ‘double-blind’ trial). To recruit sufficient numbers of patients, and to examine the effects of treatment in different settings, it is often necessary to conduct the trial at several locations (a ‘multicentre’ trial).

Randomized controlled trials are designed to assess whether one treatment is better than another (a ‘superiority’ trial); or whether one treatment is similar to another (an ‘equivalence’ trial).

- In a **superiority trial** the study treatment is usually compared to placebo or to current standard practice.
- In an **equivalence trial** the treatment under study is compared to another treatment for the same condition.

Although RCTs were originally introduced to investigate the efficacy of drugs, the methodology can be used for surgical (and other) procedures and medical devices.

There are a number of variants of the conventional randomized controlled trial including cross-over trials, cluster randomized controlled trials, inferiority trials and futility trials (see Further Reading).

### Assessing randomized controlled trials

In assessing the relevance and reliability of an RCT a number of features need to be taken into account.

#### Randomization

In any RCT the method of randomization should be robust. In particular, the investigator should be unaware of which treatment a patient entering a trial will receive. This avoids selection bias.

#### Maintaining blindness

Although, ideally, in RCTs neither the investigator nor the patient is aware of the treatment allocation until the end of the study, this is not always possible. Adverse drug reactions, for example, may make it obvious which treatment a patient has been given. Nevertheless maintaining ‘blindness’ is necessary where the outcome is subjective (e.g. relief of pain, alleviation of depression) if bias is to be avoided.

### Were the treated and control groups comparable?

Were they similar in their ‘baseline’ characteristics? Were they, for example, of similar age, severity and duration of illness? If not, are the differences likely to influence the results? Has the statistical analysis (using analysis of covariance, or Cox’s proportional hazards model) (see below) tried to adjust for them?

Table 17.10 shows some of the baseline characteristics of a trial comparing prednisolone with placebo in the treatment of Bell’s palsy (idiopathic facial paralysis).

*The House–Brackmann scale scores facial nerve function from 1 (normal) to 6 (complete paralysis). °p < 0.001. (From Sullivan FM, Swan IRC, Donnan PT et al 2007. Early treatment with prednisolone of aciclovir in Bell’s palsy. N Engl J Med 357:1598–1607; with permission)

Outcomes
There are two ways to look at the outcomes of an RCT.

- **Per protocol analysis**: this includes only those who completed the study.
- **Intention-to-treat analysis**: this includes all patients from the time of randomization.

Ideally, there should be no difference but in reality the results of a per protocol analysis are usually more advantageous to a treatment than an intention-to-treat analysis. The reason is that the intention-to-treat analysis will take account of patients who have withdrawn from the trial because of intolerance of the treatment or adverse drug reactions. It is therefore a much more robust approach. The results of the intention-to-treat analysis, in the trial of prednisolone in Bell’s palsy, are shown in Table 17.10. The trial results indicate, with a high probability, that treatment of Bell’s palsy with prednisolone will increase the chances of a full recovery of facial nerve function.

Are the results generalizable?
Were the patients enrolled into the study a reasonable reflection of those likely to be treated in routine clinical practice (a so-called pragmatic trial)? Or were they a selected population that excluded significant patient groups (such as the elderly)? If the latter, view the results with caution.

Analysis of a superiority trial
The analysis of a superiority trial is based on the premise – the ‘null hypothesis’ – that there is no difference between the treatments. The null hypothesis is rejected if the probability of the observed result occurring by chance, the p value, is less than 1 in 20 (i.e. p < 0.05). There are three caveats.

- Any difference may still be due to chance; and it is often better to await the results of at least two independent studies before adopting a new treatment.
- A trial may show no ‘statistically significant’ difference, because too few patients have been included, in other words the trial lacked sufficient ‘power’. The ‘power’ of a study (the number of patients needed in each treatment group to detect a predefined difference) should have been defined at the outset. If the study was underpowered, the results of the study should be interpreted with extreme care.
- A statistically significant difference may not, necessarily, be clinically relevant. Scrutiny of the magnitude of the effect, and its 95% confidence intervals (CI), is a far better guide than the p value.

Effect size. The results of the well-designed trial in Table 17.10 show, very convincingly, that the treatment of Bell’s palsy with prednisolone increases the chances of complete recovery of facial nerve function, at 12 months, from 81.6% to 94.4%. This is a far more convincing description of the benefits of treatment than the p value.

Another expression of the benefit of a treatment such as prednisolone can be derived from the number needed to treat (NNT). This is an estimate of the numbers of patients needed to be treated with a drug to achieve one positive result. In the study shown in Table 17.10, the NNT to enable one patient with Bell’s palsy to regain normal facial nerve function, after prednisolone treatment, is eight.

Analysis of an equivalence trial
The aim of an equivalence trial is to determine whether two (or possibly more) treatments produce similar benefits. During the design of such trials, it is necessary to decide what difference is unimportant and then to calculate the number of patients needed in order to have an 80% or 90% chance of showing this. In equivalence trials such power calculations show that the number of patients required is invariably greater than those needed for superiority trials. In such studies the comparator itself must, of course, already have been shown to be effective.

Meta-analysis
It is possible to summate all the controlled trials that have been performed in the treatment of a particular condition so as to refine the estimate of effectiveness. This technique minimizes random error in the assessment of the effect size.
of a treatment because more patients are included than could be accommodated in any single trial. A meta-analysis should be performed (and interpreted) carefully because of the heterogeneity of the individual studies used in it.

**Controlled observational trials**

Three types of observational study have been used to test the clinical effectiveness of therapeutic interventions:

- Historical controlled trials
- Case–control studies
- Before-and-after studies.

**Historical controlled trials**

Despite the value of the prospective randomized controlled trial there are many treatments that have never been subjected to this technique, yet their efficacy is unquestioned. Examples include insulin in the treatment of diabetic ketoacidosis, thyroxine for hypothyroidism, vitamin B12 in pernicious anaemia and defibrillation for ventricular fibrillation. In a historical controlled trial the outcome in patients treated with the study drug is compared to that of previously untreated people with the same disease. Treatments can be accepted into routine use on the basis of favourable comparisons with historical controls when the following criteria are met:

- There should be a biologically plausible basis for the observed benefits.
- There should be no appropriate treatment that could be reasonably used as a control.
- The condition should have a known and predictable natural history.
- The treatment should not be expected to have adverse effects that would compromise its potential benefits.
- There should be a reasonable expectation that the magnitude of the therapeutic effects of treatment will be large enough to make the interpretation of its benefits unambiguous.

**Case–control studies**

This type of study design compares people with a particular condition (the ‘cases’) with those without (the ‘controls’). The approach has predominantly been used to identify epidemiological ‘risk factors’ for specific conditions such as lung cancer (smoking) or sudden infant death syndrome (lying prone); or in the evaluation of potential adverse drug reactions (such as deep venous thrombosis with oral contraceptives).

A case–control design allows an estimation of the odds ratio (OR), which is the ratio of the probability of an event occurring to the probability of the event not occurring (Box 17.1).

<table>
<thead>
<tr>
<th>Risk factor present</th>
<th>Risk factor absent</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>Controls</td>
</tr>
<tr>
<td>a</td>
<td>c</td>
</tr>
<tr>
<td>b</td>
<td>d</td>
</tr>
</tbody>
</table>

\[
\text{The odds ratio (OR)} = \frac{a \div b}{c \div d}
\]

An OR that is significantly greater than unity indicates a statistical association that may be causal. The OR for deep venous thrombosis and current use of oral contraceptives are associated with a reduced risk of colon cancer. This seems to be a causal effect.

Case–control studies claiming to demonstrate the efficacy of a drug need to be interpreted with great care: the possibility of bias and confounding is substantial as was seen in the studies of hormone-replacement therapy and myocardial infarction. Confirmation from one or more RCTs is usually essential.

**Before-and-after studies**

It has sometimes been inferred that observed improvements seen in patients before, and after, the application of a particular treatment is evidence of efficacy. Such an approach is fraught with difficulties: the combination of a placebo effect, as well as regression to the mean, is likely to negate most studies using this type of design. Nevertheless, there are some circumstances where genuine efficacy can be confidently observed with such designs: the consequences of hip replacement, and cataract surgery, are good examples. Such instances can be regarded as special examples of the use of implicit historical controls.

**Uncontrolled observational studies**

Uncontrolled case series cannot be considered as providing primary evidence of efficacy unless they are undertaken in circumstances that are virtually those of historical controlled trials. When used in this way to demonstrate clinical effectiveness their validity relies on the use of implicit historical controls. Case series can, however, sometimes be of value in demonstrating the generalizability of the results of RCTs.

**Dangers**

Drug trials are carried out in specific groups of selected patients under strict supervision. The results, particularly when dramatic, are often used outside the strict inclusion criteria for clinical trials. The dramatic effect of spironolactone in heart failure (30% reduction in all-cause mortality) has not always been replicated in routine clinical practice because the wrong patients have been treated, often with higher doses, leading to hyperkalaemia and death.

**Evaluation of new drugs**

New drugs are subjected to a vigorous programme of preclinical and clinical testing before they are licensed for general use (Table 17.11) and are also monitored for safety following licensing. Doctors are recommended to fill in yellow cards when they suspect an adverse reaction has taken place.

**Statistical analyses**

The relevance of statistics is not confined to those who undertake research but also to anyone who wants to understand the relevance of research studies to their clinical practice.
The average
Clinical studies may describe, quantitatively, the value of a particular variable (e.g. height, weight, blood pressure, haemoglobin) in a sample of a defined population. The ‘average’ value (or ‘central tendency’ in statistical language) can be expressed as the mean, median or mode depending on the circumstances:

- The mean is the average of a distribution of values that are grouped symmetrically around the central tendency.
- The median is the middle value of a sample. It is used, particularly, where the values in a sample are asymmetrically distributed around the central tendency.
- The mode is the interval, in a frequency distribution of values, that contains more values than any other.

In a symmetrically distributed population, the mean, median and mode are the same.

The average value of a sample, on its own, is of only modest interest. Of equal (and often greater) relevance is the confidence we can place on the sample average as truly reflecting the average value of the population from which it has been drawn. This is most often expressed as a confidence interval, which describes the probability of a sample mean being a certain distance from the population mean. If, for example, the mean systolic blood pressure of 100 undergraduates is 124 mmHg, with a 95% confidence interval of ± 15 mmHg, we can be confident that if we replicated the study 100 times the value of the mean would be within the range 109–139 mmHg on 95 occasions. It is intuitively obvious that the larger the sample the smaller will be the size of the confidence interval.

Correlation
In clinical studies two, or more, independent variables may be measured in the same individuals in a sample population (e.g. weight and blood pressure). The degree of correlation between the two can be investigated by calculating the correlation coefficient (often abbreviated to ‘r’). The correlation coefficient measures the degree of association between the two variables and may range from 1 to –1:
- If $r = 1$, there is complete and direct concordance between the two variables
- If $r = −1$, there is complete but inverse concordance
- If $r = 0$ there is no concordance.

Statistical tables are available to inform investigators as to the probability that $r$ is due to chance. As in other areas of statistics, if the probability is less than 1 in 20 ($p < 0.05$) then by custom and practice it is regarded as statistically significant. There are, however, two caveats:

- The 1 in 20 rule is a convention and does not exclude the possibility that a presumed association is due to chance
- The fact that there is an association between two variables does not necessarily mean that it is causal.

Correlation analyses can become complicated. The simplest (least squares regression analysis) presumes a straight-line relationship between the two variables. More complicated techniques can be used to estimate $\hat{r}$ where a non-linear relationship is presumed (or assumed); where the distributions deviate from normal; where the scales of one or both variables are intervals or ranks; or where a correlation between three or more variables is sought.

Expressions of benefit and harm
There are three ways in which the outcomes, in clinical studies, are expressed:

1. Binary (dichotomous) outcomes
2. Survival analyses
3. Continuous outcomes

**Binary outcomes** are often used in the design and analysis of RCTs. Such outcomes are dichotomous (such as alive or dead). The results are usually expressed as the relative risk (or risk ratio – RR). In a trial where the outcome is (say) mortality, the relative risk is the ratio of the proportion of treated patients dying to the proportion of control patients dying. Usually, RR of $<1$ is suggestive of benefit; an RR of $>1$ is suggestive of harm. RRs are almost invariably reported with their 95% confidence intervals. If the boundaries of the 95% confidence intervals do not cross unity the results are generally statistically significant (at least at the 5% level).

**Survival analyses.** In studies in which individuals are observed over a long(ish) period of time, and in which it is unreasonable (or erroneous) to assume that event rates are constant, the technique of survival analysis is used. This is most commonly reported as the hazard ratio (HR) and its 95% confidence interval. The HR is the probability that, if an event in question has not already occurred, it will happen in the next (short) time interval. It has, broadly, a comparable interpretation to the RR.

**Continuous outcomes.** Studies such as that in Table 17.10 may report outcomes using one or more continuous scales. In this study of the effects of prednisolone in the treatment of Bell’s palsy, the House–Brackmann measure of facial nerve function was used as the outcome measure.

---

**Symmetrical data (normal)**

- Mean (average)
- Median (middle value)
- Mode (most common value)

Normal or Gaussian distribution curve

**Skewed data**

- Median
- Mode

Averages. In symmetrical data the mean, mode and median are the same.
Conventional tests of statistical significance using Student’s t-test, for example, can be calculated to assess whether the null hypothesis should be rejected.

**Number needed to treat (NNT).** As discussed earlier, the NNT is an estimate of the number of patients that need to be treated for one to benefit compared to no treatment. If the probabilities of the end-points with the active drug and no treatment (i.e. placebo) are respectively \( p_{\text{active}} \) and \( p_{\text{no treatment}} \) then the NNT can be calculated thus:

\[
\text{NNT} = \frac{1}{p_{\text{active}} - p_{\text{no treatment}}}
\]

An analogous measure – the number needed to harm (NNH) – is the number of patients that need to be treated with a drug to cause one patient to be subject to a specific harm.

**Other statistical techniques**

Statisticians have developed a range of sophisticated methods to handle a wide variety of biomedical problems. Unless an investigator is supremely (and usually unwisely) confident it is wise to seek professional advice in analysing numerical data that look complicated. In doing so, it is invariably wiser to do so at the time the study is being designed rather than after the results have been generated.

**POISONING**

**The nature of the problem**

Exposure to a substance is often equated with poisoning. However, absorption is necessary for there to be a toxic effect and, even if this occurs, poisoning does not necessarily result, because the amount absorbed may be too small. In developed countries, poisoning causes approximately 10% of acute hospital medical presentations. In such cases poisoning is usually by self-administration of prescribed and over-the-counter medicines, or illicit drugs. Poisoning in children aged less than 6 months is most commonly iatrogenic and involves overtreatment with, e.g. paracetamol. Children between 8 months and 5 years of age also ingest poisons accidentally, or they may be administered deliberately to cause harm, or for financial or sexual gain. Occupational poisoning as a result of dermal or inhalational exposure to chemicals is a common occurrence in the developing world and still occurs in the developed world. Sometimes inappropriate treatment of a patient by a doctor is responsible for the development of poisoning, e.g. in the case of digoxin toxicity.

In adults, self-poisoning is commonly a ‘cry for help’. Those involved are most often females under the age of 35 who are in good physical health. They take an overdose either deliberately to cause harm, or for financial or sexual gain. Occupational poisoning as a result of dermal or inhalational exposure to chemicals is a common occurrence in the developing world and still occurs in the developed world. Sometimes inappropriate treatment of a patient by a doctor is responsible for the development of poisoning, e.g. in the case of digoxin toxicity.

**Self-poisoning can kill**

All must be aware of the dangers of drugs and chemicals. Education on safe storage and careful handling of household and workplace chemicals is necessary on a continuing basis.

A third of patients admitted with an overdose in the UK state that they are unaware of the toxic effects of the substance involved; the majority take whatever drug is easily available at home (Box 17.2). Studies reveal that:

- Acute overdoses often involve more than one agent;
- Alcohol is the most commonly implicated second agent.
- There is often a poor correlation between the drug history and the toxicological analytical findings.
- Therefore, a patient’s statement about the type and amount of drug ingested cannot always be relied upon.

The majority of cases of self-poisoning do not require intensive medical management, but all patients require a sympathetic and caring approach, a psychiatric and social assessment and, sometimes, psychiatric treatment. However,

**Current information sources**

Pharmacotherapy moves at a very rapid pace and it is impossible for anyone to keep up with contemporary advances. Details of current prescribing advice can be found in:

- The Summary of Product Characteristics (SmPCs) produced by manufacturers but vetted by drug regulatory authorities (for the UK, these are the Medicines and Healthcare Products Regulatory Agency and the European Medicines Agency).
- The relevant national formulary. Many countries have their own formularies, for example the UK has the British National Formulary (BNF), produced jointly by the British Medical Association and the Royal Pharmaceutical Society.
- Guidance produced by the Technology Appraisals Guidance series from the UK’s National Institute for Health and Clinical Excellence (NICE).

Advice on the management of individual conditions is available in the form of clinical guidelines (systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances).

**Box 17.2 Prevention of self-poisoning**

Patients usually take what is readily available at home.

- Only small amounts of drugs should be bought
- Foil-wrapped drugs are less likely to be taken in overdose
- Keep drugs in a safe place
- Keep drugs and liquids in their original containers
- Child-resistant drug containers should be used
- Doctors should be careful in prescribing all drugs
- Prescriptions for any susceptible patient (e.g. the depressed) must be monitored carefully
- Household products should be labelled and kept safely away from children

**FURTHER READING**

**SIGNIFICANT WEBSITES**

Sources of clinical guidelines:
- Scottish Intercollegiate Guidelines Network (SIGN): http://www.sign.ac.uk/.
as the majority of patients ingest relatively non-toxic agents, receive good supportive care and, when appropriate, the administration of specific antidotes, the in-hospital mortality in most developed countries is now less than 1%. Fatalities in the UK are due predominantly to carbon monoxide, antidepressants, paracetamol, analgesic combinations containing paracetamol and an opioid, heroin, methadone or cocaine. Deaths from poisoning in children are usually accidental and due to inappropriate storage of drugs such as digoxin and quinine and from drugs of abuse purchased or prescribed for a parent or carer.

### THE APPROACH TO THE PATIENT

#### History

More than 80% of adults are conscious on arrival at hospital and the diagnosis of self-poisoning can usually be made from the history (Table 17.12). In the unconscious patient a history from friends or relatives is helpful, and the diagnosis can often be inferred from the medicine containers or a 'suicide note' brought by the paramedics. In any patient with an altered level of consciousness, acute poisoning must always be considered in the differential diagnosis.

#### Examination

On arrival at hospital, the patient must be assessed urgently (Airways, Breathing and Circulation). The following should be evaluated:

- **Level of consciousness**: the Glasgow Coma Scale should be used (see p. 1092)
- **Ventilation**: pulse oximetry can be used to measure oxygen saturation. The displayed reading may be inaccurate when the saturation is below 70%, there is poor peripheral perfusion and in the presence of carboxyhaemoglobin and methaemoglobin. Only measurement of arterial blood gases will indicate the presence both of hypercapnia and hypoxia
- **Blood pressure and pulse rate**
- **Pupil size and reaction to light**
- **Evidence of intravenous drug use**
- **A head injury** complicating poisoning.

If the patient is unconscious, the following should also be checked:

- **Cough and gag reflex**: present or absent.
- **Temperature**: measured with a low-reading rectal thermometer if the ear temperature suggests it is low.

Some of the physical signs that may aid identification of the agents responsible for poisoning are shown in Table 17.13. The cluster of features on presentation may be distinctive and diagnostic. For example, sinus tachycardia, fixed dilated pupils, exaggerated tendon reflexes, extensor plantar responses and coma suggest tricyclic antidepressant poisoning (Table 17.13 and Table 17.14).

#### PRINCIPLES OF MANAGEMENT OF POISONING (Table 17.15)

Most people with self-poisoning require only general care and support of the vital systems. However, for a few drugs additional therapy is required.

#### Care of the unconscious patient (see also p. 1135)

In all cases the patient should be nursed in the lateral position with the lower leg straight and the upper leg flexed; in this position the risk of aspiration is reduced. A clear passage for air should be ensured by the removal of any obstructing object, vomit or dentures, and by backward pressure on the mandible. Nursing care of the mouth and pressure areas should be instituted. Immediate catheterization of the bladder in unconscious patients is usually unnecessary as it can be emptied by gentle suprapubic pressure. Insertion of a venous cannula is usual, but administration of intravenous fluids is unnecessary unless the patient has been unconscious for more than 12 hours or is hypotensive.

#### Ventilatory support

If respiratory depression is present, as determined by pulse oximetry or preferably by arterial blood gas analysis, an oropharyngeal airway should be inserted, and supplemental-oxygen should be administered. Pulse oximetry alone will...
not detect hypercapnia. Loss of the cough or gag reflex is the prime indication for intubation. The gag reflex can be assessed by positioning the patient on one side and making him or her gag using a suction tube. In many severely poisoned patients, the reflexes are depressed sufficiently to allow intubation without the use of sedatives or relaxants. The complications of endotracheal tubes are discussed on page 885 in Chapter 16. If ventilation remains inadequate to allow intubation without the use of sedatives or relaxants, intermittent positive-pressure ventilation (IPPV) should be instituted.

### Cardiovascular support

Although hypotension (systolic blood pressure below 80 mmHg) is a recognized feature of acute poisoning, the classic features of shock: tachycardia and pale cold skin, are observed only rarely.

Hypotension and shock may be caused by:

- A direct cardio-depressant action of the poison (e.g. beta-blockers, calcium channel blockers, tricyclic antidepressants)
- Vasodilation and venous pooling in the lower limbs (e.g. ACE inhibitors, phenothiazines)
- A decrease in circulating blood volume because of gastrointestinal losses (e.g. profuse vomiting in theophylline poisoning), increased insensible losses (e.g. salicylate poisoning), increased renal losses (e.g. poisoning due to diuretics) and increased capillary permeability.

Hypotension may be exacerbated by co-existing hypoxia, acidosis and dysrhythmias. In people with marked hypotension, volume expansion with crystalloids should be used, guided by monitoring of central venous pressure (CVP). Urine output (aiming for 35–50 mL/h) is also a useful guide to the adequacy of the circulation. If a patient fails to respond to the above measures, more intensive therapy is required. In such patients, it is helpful to undertake invasive haemodynamic monitoring to confirm that adequate volume replacement has been administered. Volume replacement and the use of inotropes are discussed on page 874. All patients with cardiogenic shock should have ECG monitoring.

Systemic hypertension can be caused by a few drugs when taken in overdose. If this is mild and associated with agitation, a benzodiazepine may suffice. In more severe cases, for example those due to a monoamine oxidase inhibitor, there may be a risk of arterial rupture, particularly intracranially. To prevent this, an α-adrenergic blocking agent such as phentolamine, 2–5 mg i.v. every 10–15 min, or intravenous isosorbide dinitrate 2–10 mg/h up to 20 mg/h if necessary, or sodium nitroprusside 0.5–1.5 μg/kg per min by intravenous infusion, should be administered until the blood pressure is controlled.

Arrhythmias can occur, e.g. tachyarrhythmias following ingestion of a tricyclic antidepressant or theophylline; bradyarrhythmias with digoxin poisoning. Known arrhythmogenic factors such as hypoxia, acidosis and hypokalaemia should be corrected.

### Other problems

#### Hypothermia and hyperthermia

A rectal temperature below 35°C is a recognized complication of poisoning, especially in older patients or those who are comatose. The patient should be covered with a ‘space blanket’ and, if necessary, given intravenous and intraocular fluids at normal body temperature. The administration of heated (37°C), humidified oxygen delivered by face mask is also useful.

Rarely, body temperature may increase to potentially fatal levels after poisoning with central nervous system stimulants such as cocaine, amphetamines including ecstasy (MDMA), monoamine oxidase inhibitors or theophylline. Muscle tone is often increased and convulsions and rhabdomyolysis are common. Cooling measures, sedation with diazepam and, in severe cases, i.v. dantrolene 1 mg/kg body weight should be given.

#### Skin blisters

Skin blisters may be found in poisoned patients who are, or have been, unconscious. Such lesions are not diagnostic of specific poisons, but are sufficiently common in poisoned patients (and sufficiently uncommon in patients unconscious from other causes) to be of diagnostic value.

#### Rhabdomyolysis

Rhabdomyolysis can occur from pressure necrosis in drug-induced coma, or it may complicate, e.g. ecstasy (MDMA) abuse in the absence of coma. People with rhabdomyolysis are at risk of developing, firstly, acute kidney injury from myoglobinemia, particularly if they are hypovolaemic and have an acidosis and, secondly, wrist or ankle drop from the development of a compartment syndrome (see p. 509).

#### Convulsions

These may occur, e.g. in poisoning due to tricyclic antidepressants, mfenamic acid or opioids. Usually the seizures are short-lived but, if they are prolonged, diazepam 10–20 mg
i.v. or lorazepam 4 mg i.v. should be administered. Persistent fits must be controlled rapidly to prevent severe hypoxia, brain damage and laryngeal trauma. If diazepam or lorazepam in repeated dose is ineffective, the patient should also receive a loading dose of phenytoin (20 mg/kg) administered intravenously at not more than 50 mg/min, with ECG monitoring.

**Stress ulceration and bleeding**

Measures to prevent stress ulceration of the stomach should be started on admission in all patients who are unconscious and require intensive care. A proton pump inhibitor should be administered intravenously.

**Body ‘packers’ and body ‘stuffers’**

**Body ‘packers’** (sometimes called ‘mules’ or ‘swallowers’) are those who swallow a substantial number of packages containing illicit drugs for the purpose of smuggling. Heroin used to be the drug of choice but this has been superseded by cocaine. Although each package contains a potentially lethal amount of drug, packets are now usually machine manufactured using a material which usually does not leak. Body packers may ingest up to 100–200 packages.

**Body ‘stuffers’** are those who swallow a small number of packages containing an illicit drug, usually heroin, cocaine, cannabis or an amphetamine, in an unplanned attempt to conceal evidence when on the verge of being arrested. These drugs are usually either unpackaged or poorly packaged and as a consequence leakage may occur over the ensuing 3–6 hours and cause significant symptoms. Some also hide illicit drug packages in their rectum or vagina with the same intent (these are sometimes known as body ‘pushers’).

The role of imaging is confined to body packers; imaging has little role in the care of body stuffers or pushers. Ultrasonound is of similar accuracy to abdominal X-ray in locating packages and less accurate than CT. A urine screen for drugs of misuse should be performed. A screen that is positive for one or more drugs of misuse suggests that either the patient has used the drug in the previous few days, or at least one packet is leaking. A negative screen strongly suggests that no packet is leaking. Screens should be repeated daily, or immediately if the patient develops features of intoxication, to confirm the diagnosis.

Packages can be removed most expeditiously in body stuffers by employing whole bowel irrigation (see p. 913). In the past early surgery was advocated in body packers. However, with the development of improved packaging, a more conservative approach (the use of lactulose or whole bowel irrigation) can now be adopted with which there is a complication rate of 5%. Immediate surgery is indicated if acute intestinal obstruction develops, or when packets can be seen radiologically and there is clinical or analytical evidence to suggest leakage, particularly if the drug involved is cocaine.

Packets in the vagina can usually be removed manually.

### Specific management

**Antidotes**

Specific antidotes are available for only a small number of poisons (Table 17.16).

Antidotes may exert a beneficial effect by:

- **Forming an inert complex** with the poison (e.g. desferrioxamine (defereroxamine), D-penicillamine, dimercaptosuccinic acid (DMSA), dimercaprol, HI-6, hydroxocobalamin, obidoxime, pralidoxime, protamine, Prussian (Berlin) blue, sodium calcium edetate, succimer (DMSA), unithiol (DMPS))

- **Accelerating detoxification** of the poison (e.g. acetylcysteine, sodium thiosulphate)

- **Reducing the rate of conversion** of the poison to a more toxic compound (e.g. ethanol, fomepizole)

- **Competing with the poison** for essential receptor sites (e.g. oxygen, naloxone, phytomenadione)

- **Blocking essential receptors** through which the toxic effects are mediated (e.g. atropine)

- **By-passing the effect** of the poison (e.g. oxygen, glucagon).

### Reducing poison absorption

To reduce poison absorption through the lungs, remove the casualty from the toxic atmosphere, making sure that rescuers themselves are not put at risk. Contaminated clothing should be removed to reduce dermal absorption and contaminated skin washed thoroughly with soap and water.

</table>
Gut decontamination. While it appears logical to assume that removal of unabsorbed drug from the gastrointestinal tract will be beneficial (gut decontamination), the efficacy of gastric lavage and syrup of ipecacuanha remains unproven and efforts to remove small amounts of non-toxic drugs are clinically not worthwhile or appropriate.

Gastric lavage should only be performed if a patient has ingested a potentially life-threatening amount of a poison, e.g. iron, and the procedure can be undertaken within 60 minutes of ingestion. Intubation is required if airway protective reflexes are lost. Lavage is also contraindicated if a hydrocarbon with high aspiration potential or a corrosive substance has been ingested.

Syrop of ipecacuanha should not be used as the amount of drug recovered is highly variable, diminishes with time and there is no evidence that it improves the outcome of poisoned patients.

Single-dose activated charcoal. Activated charcoal is able to adsorb a wide variety of compounds. Exceptions are strong acids and alkalis, ethanol, ethylene glycol, iron, lithium, mercury and methanol.

In studies in volunteers given 50 g activated charcoal, the mean reduction in absorption was 40%, 16% and 21%, at 60 min, 120 min and 180 min, respectively after ingestion. Based on these studies, activated charcoal should be given in those who have ingested a potentially toxic amount of a poison (known to be adsorbed by charcoal). There are insufficient data to support or exclude its use after 1 hour. There is no evidence that administration of activated charcoal improves the clinical outcome.

Cathartics have no role in the management of the poisoned patient.

Whole bowel irrigation requires the insertion of a nasogastric tube into the stomach and the introduction of polyethylene glycol electrolyte solution 1500–2000 mL/h in an adult, which is continued until the rectal effluent is clear. Whole bowel irrigation may be used for potentially toxic ingestions of sustained-release or enteric-coated drugs or to remove illicit drug packets.

Increasing poison elimination

Multiple-dose activated charcoal (MDAC) involves the repeated administration of oral activated charcoal to increase the elimination of a drug that has already been absorbed into the body. Drugs are secreted in the bile and re-enter the gut by passive diffusion if the concentration in the gut is lower than that in the blood. The rate of passive diffusion depends on the concentration gradient and the intestinal surface area, permeability and blood flow. Activated charcoal will bind any drug that is in the gut lumen.

Elimination of drugs with a small volume of distribution (<1 L/kg), low pKa (which maximizes transport across membranes), low binding affinity and prolonged elimination half-life following overdose is particularly likely to be enhanced by MDAC. MDAC also improves total body clearance of the drug when endogenous processes are compromised by liver and/or renal failure.

Although MDAC has been shown to significantly increase drug elimination, it has not reduced morbidity and mortality in controlled studies. At present, MDAC should only be used in patients who have ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine or theophylline.

Dosage. In adults, charcoal should be administered in an initial dose of 50–100 g and then at a rate of not less than 12.5 g/h, preferably via a nasogastric tube. If the patient has ingested a drug that induces protracted vomiting (e.g. theophylline), intravenous ondansetron 4–8 mg is effective as an antiemetic and thus enables administration of MDAC.

Urine alkalization. Increasing the urine pH enhances elimination of salicylate, phenobarbital, chloropropamide and chlorophenoxy herbicides (e.g. 2,4-dichlorophenoxyacetic acid) by mechanisms which are not clearly understood. Urine alkalization is not recommended as first-line therapy for poisoning with phenobarbital as MDAC is superior, and supportive care is invariably adequate for chloropropamide. A substantial diuresis is required in addition to urine alkalization to achieve clinically relevant elimination of chlorophenoxy herbicides.

Urine alkalization is a metabolically invasive procedure requiring frequent biochemical monitoring and medical and nursing expertise. Before commencing urine alkalization, correct plasma volume depletion, electrolytes (administration of sodium bicarbonate exacerbates pre-existing hypokalaemia) and metabolic abnormalities. Sufficient bicarbonate is administered to ensure that the pH of the urine, which is measured by narrow range indicator paper or a pH meter, is more than 7.5 and preferably close to 8.5. In one study, sodium bicarbonate 225 mmol was the mean amount required initially. This is most conveniently administered as 225 mL of an 8.4% solution (1 mmol bicarbonate/mL) i.v. over 1 hour.

Haemodialysis and haemodialfiltration. Haemodialysis and haemodialfiltration are of little value in patients poisoned with drugs with large volumes of distribution (e.g. tricyclic antidepressants), because the plasma contains only a small proportion of the total amount of drug in the body. These methods are indicated in people with severe clinical features and high plasma concentrations of ethanol, ethylene glycol, isopropanol, lithium, methanol and salicylate.

Toxicological investigations

On admission, or at an appropriate time post overdose, a timed blood sample should be taken if it is suspected that aspirin, digoxin, ethylene glycol, iron, lithium, methanol, paracetamol, paraquat, quinine or theophylline has been ingested. The determination of the concentrations of these drugs will be valuable in management. Drug screens on blood and urine are occasionally indicated in severely poisoned patients in whom the cause of coma is unknown. A poison information service will advise.

Non-toxicological investigations (Table 17.17)

Some routine investigations are of value in the differential diagnosis of coma or the detection of poison-induced hypokalaemia, hyperkalaemia, hypoglycaemia, hyperglycaemia, hepatic or renal failure or acid–base disturbances (Table 17.18). Measurement of carboxyhaemoglobin, methaemoglobin and cholinesterase activities are of assistance in the diagnosis and management of cases of poisoning due to carbon monoxide, methaemoglobin-inducing agents such as nitrates and organophosphorus insecticides, respectively.

ECG

Routine ECG is of limited diagnostic value, but continuous ECG monitoring should be undertaken in those ingesting potentially cardiotoxic drugs; for example, sinus tachycardia with prolongation of the PR and QRS intervals in an unconscious patient suggests tricyclic antidepressant overdose. Q–T interval prolongation is an adverse effect of several drugs (e.g. quetiapine and quinine).
Clinical features

Amphetamines cause euphoria, extrovert behaviour, a lack of desire to eat or sleep, tremor, dilated pupils, tachycardia and hypertension. More severe intoxication is associated with agitation, paranoid delusions, hallucinations and violent behaviour. Convulsions, rhabdomyolysis, hyperthermia and cardiac arrhythmias may develop in severe poisoning. Rarely, intracerebral and subarachnoid haemorrhage occur and can be fatal.

MDMA poisoning is characterized by agitation, tachycardia, hypertension, widely dilated pupils, trismus and sweating. In more severe cases, hyperthermia, disseminated intravascular coagulation, rhabdomyolysis, acute kidney injury and hyponatraemia (secondary to inappropriate antidiuretic hormone secretion) predominate.

Treatment

Agitation is controlled by diazepam 10–20 mg i.v. or chlorpromazine 50–100 mg i.m. The peripheral sympathomimetic actions of amphetamines are antagonized by β-adrenoceptor blocking drugs. If hyperthermia is present, dantrolene 1 mg/kg body weight i.v. is used.

Anticonvulsants

Clinical features

The clinical features of poisoning with anticonvulsant drugs are summarized in Table 17.19.

Treatment

Multiple-dose activated charcoal has been shown to significantly increase elimination of carbamazepine. Early intravenous supplementation with L-carnitine should be used in severe valproate poisoning if hepatotoxicity and encephalopathy are present. Haemodialysis should also be instituted if severe hyperammonaemia and electrolyte and acid–base disturbances occur.

Antidepressants: MAOIs

Monoamine oxidase inhibitors are now used less frequently in the treatment of depression because of the dangers of dietary and drug interactions.

Clinical features

Features after overdose may be delayed for 12–24 hours and include excitement, restlessness, hyperpyrexia, hyperreflexia, convulsions, opisthotonos, rhabdomyolysis and coma. Sinus tachycardia and either hypo- or hypertension have also been observed.

Treatment

Treatment is supportive with control of convulsions and marked excitement; diazepam 10–20 mg i.v. should be given as necessary and repeated. Dantrolene 1 mg/kg i.v. should be administered if hyperpyrexia develops. Hypotension should be treated with plasma expansion and hypertension by the administration of an α-adrenoceptor blocker such as chlorpromazine.

Antidepressants: tricyclics and SSRIs

Tricyclic antidepressants block the reuptake of noradrenaline (norepinephrine) into peripheral and intracerebral neurones, thereby increasing the concentration of monoamines in these

Radiology

Routine radiology is of little diagnostic value. It can confirm ingestion of metallic objects (e.g. coins, button batteries) or injection of globules of metallic mercury. Rarely, hydrocarbon solvents (e.g. carbon tetrachloride) may be seen as a slightly opaque layer floating on the top of the gastric contents with the patient upright, or outlining the small bowel. Some enteric-coated or sustained-release drug formulations may be seen on plain abdominal radiographs, but, with the exception of iron salts, ordinary formulations are seldom seen. Ingested packets of illicit substances can sometimes be seen on CT (see p. 912). Radiology can confirm complications of poisoning, e.g. aspiration pneumonia, non-cardiogenic pulmonary oedema (salicylates), acute respiratory distress syndrome (ARDS).

The medicinal product is usually the dextro-isomer, dexamphetamine. The N-methylated derivative, metametamine (the crystalline form of this salt is known as ‘crystal meth’ or ‘ice’), and 3,4-methylendioxymetametamine (MDMA), commonly known as ecstasy, are used worldwide.

- Amphetamines are CNS and cardiovascular stimulants. These effects are mediated by increasing synaptic concentrations of adrenaline (epinephrine) and dopamine.

| Topiramate         | Lethargy, ataxia, nystagmus, myoclonus, coma, seizures, non-anion gap metabolic acidosis  
Metabolic acidosis can appear within hours of ingestion and persist for days |

Clinical features

Even large overdoses of SSRIs appear to be relatively safe unless potentiated by ethanol. Most patients will show no signs of toxicity but drowsiness, nausea, diarrhoea and sinus tachycardia have been reported. Rarely, junctional bradycardia, seizures and hypertension have been encountered and influenza-like symptoms may develop. In contrast, drowsiness, sinus tachycardia, dry mouth, dilated pupils, urinary retention, increased reflexes and extensor plantar responses are the most common features of mild tricyclic antidepressant poisoning. Severe intoxication leads to coma, often with divergent strabismus and convulsions. Plantar, oculocephalic and oculovestibular reflexes may be abolished temporarily. An ECG will often show a wide QRS interval and there is a reasonable correlation between the width of the QRS complex and the severity of poisoning. Metabolic acidosis and cardiorespiratory depression are observed in severe cases.

Treatment

The majority of patients recover with supportive therapy alone (adequate oxygenation, control of convulsions and correction of acidosis), although a small percentage of patients who ingest a tricyclic will require assisted ventilation for 24–48 hours. The onset of supraventricular tachycardia and ventricular tachycardia should be treated with sodium bicarbonate (8.4%) 50 mmol intravenously over 20 min, even if there is no acidosis present. If ventricular tachycardia is compromising cardiac output, amiodarone 300 mg i.v. over 20–60 min should be administered.

Antidiabetic drugs

Insulin (if injected but not if ingested) and sulfonylureas cause hypoglycaemia, not seen with metformin, since its mode of action is to increase glucose utilization, but lactic acidosis is a potentially serious complication of metformin poisoning.

Clinical features

Features of severe hypoglycaemia include drowsiness, coma, convulsions, depressed limb reflexes, extensor plantar responses and cerebral oedema. Hypokalaemia may be associated. Neurogenic diabetes insipidus and persistent vegetative states are possible long-term complications if hypoglycaemia is prolonged. Cholestatic jaundice has been described as a late complication of chlorpropamide poisoning.

Treatment

The blood or plasma glucose concentration should be measured urgently and intravenous glucose given, if necessary. Glucagon produces only a slight rise in blood glucose, although it can reduce the amount of glucose required (see p. 1001).

Severe insulin poisoning. A continuous infusion of 10–20% glucose (with K+ 10–20 mmol/L) together with carbohydrate-rich meals are required, though there may be difficulty in maintaining normoglycaemia.

Sulfonylurea poisoning. The administration of glucose increases already high circulating insulin concentrations. Octreotide (50 μg i.v.), which inhibits insulin release, should be given as well as glucose.

Antimarialls

Clinical features

Chloroquine. Hypotension is often the first clinical manifestation of chloroquine poisoning. It may progress to acute heart failure, pulmonary oedema and cardiac arrest. Agitation and acute psychosis, convulsions and coma may ensue. Hypokalaemia is common and is due to chloroquine-induced potassium channel blockade. Bradycarrhythmias and tachyarrhythmias are common and ECG conduction abnormalities are similar to those seen in quinine poisoning.

Quinine. Cinchonism (tinnitus, deafness, vertigo, nausea, headache and diarrhoea) is common. In more severe poisoning, convulsions, hypotension, pulmonary oedema and cardiorespiratory arrest is seen (due to ventricular arrhythmias which are often preceded by ECG conduction abnormalities, particularly QT prolongation). Quinine cardiotoxicity is due to sodium channel blockade. Patients may also
develop ocular features, including blindness, which can be permanent.

**Primaquine.** The main concern regarding primaquine is its propensity to cause methaemoglobinemia and haemolytic anaemia.

**Treatment**

Multiple-dose oral activated charcoal increases quinine and probably chloroquine clearance. Hypokalaemia should be corrected. Sodium bicarbonate 50–100 mmol i.v. is given if the ECG shows intraventricular block but will exacerbate hypokalaemia, which should be corrected first. Mechanical ventilation, the administration of an inotrope and high doses of diazepam (1 mg/kg as a loading dose and 0.25–0.4 mg/kg per hour maintenance) may reduce the mortality in severe chloroquine poisoning. Overdrive pacing may be required if torsades de pointes (p. 710) occurs in quinine poisoning and does not respond to magnesium sulphate infusion. If clinically significant methaemoglobinemia (generally above 30%) develops in primaquine poisoning, methylthioninium (methylene blue) 1–2 mg/kg body weight should be administered.

**β-Adrenoceptor blocking drugs**

**Clinical features**

In mild poisoning, sinus bradycardia is the only feature, but if a substantial amount has been ingested, coma, convulsions and hypotension develop. Less commonly, delirium, hallucinations and cardiac arrest supervene.

**Treatment**

Glucagon 50–150 μg/kg (typically 5–10 mg in an adult) followed by an infusion of 1–5 mg/h is the most effective agent. It acts by by-passing the blocked beta-receptor thus activating adenyl cyclase and promoting formation of cyclic AMP from ATP; cyclic AMP in turn exerts a direct beta-stimulant effect on the heart. Atropine 0.6–1.2 mg i.v. can be used to treat bradycardia but is usually less effective.

**Benzodiazepines**

Benzodiazepines are commonly taken in overdose but rarely produce severe poisoning except in the elderly or those with chronic respiratory disease.

**Clinical features**

Benzodiazepines produce drowsiness, ataxia, dysarthria and nystagmus. Coma and respiratory depression develop in severe intoxication.

**Treatment**

If respiratory depression is present in patients who have severe benzodiazepine poisoning, flumazenil 0.5–1.0 mg i.v. is given in an adult and this dose often needs repeating. Flumazenil use often avoids ventilation. It is contraindicated in mixed tricyclic antidepressant (TCA)/benzodiazepine poisoning and in those with a history of epilepsy because it may cause convulsions.

**Calcium channel blockers**

Calcium channel blockers all act by blocking voltage-gated calcium channels. Dihydropyridines (e.g. amlodipine, felodipine, nifedipine) are predominantly peripheral vasodilators while verapamil and, to a lesser extent, diltiazem also have significant cardiac effects. Poisoning, particularly with verapamil and diltiazem, causes heart block and hypotension and there is a substantial fatality rate.

**Clinical features**

Hypotension occurs due to peripheral vasodilatation, myocardial depression and conduction block. The electrocardiogram may progress from sinus bradycardia through first, then higher, degrees of block, to asystole. Cardiac and non-cardiac pulmonary oedema may ensue in severely poisoned patients. Other features include nausea, vomiting, seizures and a lactic acidosis. When a sustained-release preparation has been ingested the onset of severe features is delayed, sometimes for more than 12 hours. Overdose with even small amounts can have profound effects.

**Treatment**

Intravenous atropine 0.6–1.2 mg, repeated as required, should be given for bradycardia and heart block. The initial dose can be repeated every 3–5 min but if there is no response in pulse rate or blood pressure after three such doses it is unlikely that further boluses will be helpful. The response to atropine is sometimes improved following intravenous 10% calcium chloride, 5–10 mL (at 1–2 mL/min). If there is an initial response to calcium, a continuous infusion is warranted; this is given as 10% calcium chloride, 1–10 mL/h.

Cardiac pacing has a role if there is evidence of AV conduction delay but failure to capture occurs.

Treat hypotension initially with intravenous crystalloid. If significant hypotension persists despite volume replacement, administer glucagon (see p. 409) as it activates myosin kinase independent of calcium. Give i.v. glucagon 10 mg (150 μg/kg) as a slow bolus and repeat. If there is a favourable response in blood pressure, an infusion of 5–10 mg/h can be commenced; if there is no response after the initial boluses, discontinue.

Insulin–glucose euglycaemia has been shown to improve myocardial contractility and systemic perfusion. If hypotension persists despite the above measures, insulin is given as a bolus dose of 1 U/kg, followed by an infusion of 1–10 U/kg per hour with 10% glucose and frequent monitoring of blood glucose and potassium.

Acidosis impairs L-type channel function (see p. 708) and is corrected by the administration of sodium bicarbonate, which has been shown experimentally to improve myocardial contractility and cardiac output.

**Cannabis (marijuana)**

Cannabis is usually smoked but may be ingested as a ‘cake’, made into a tea or injected intravenously. Apart from alcohol, it is the drug most widely used in developed countries. The major psychoactive constituent is delta-11-tetrahydrocannabinol (THC). THC possesses activity at the benzodiazepine, opioid and cannabinoid receptors. Street names include pot, grass, ganja, reefs and spliff. It is prepared as marijuana (gangja) from the female flowers; hashish or charas – a concentrated resin of glandular trichomes; kief – chopped female flowers (ganga) from the female flowers; and bhang – a drink prepared from cannabis leaves boiled in milk with spices.

**Clinical features**

Initially there is euphoria, followed by distorted and heightened images, colours and sounds, altered tactile sensations and sinus tachycardia. Visual and auditory hallucinations and acute psychosis are particularly likely to occur after substantial ingestion in naïve cannabis users. Intravenous injection leads to watery diarrhoea, tachycardia, hypotension and arthralgia.
Heavy users suffer impairment of memory and attention and poor academic performance. There is an increased risk of anxiety and depression. Regular users are at risk of dependence. Cannabis use results in an overall increase in the relative risk for later schizophrenia and psychotic episodes (see p. 1185). Cannabis smoke is probably carcinogenic.

**Treatment**

Reassurance is usually the only treatment required, although sedation with intravenous diazepam 10–20 mg i.v. in an adult or chlorpromazine 50–100 mg i.m. in an adult is sometimes required. Hypotension requires i.v. fluids.

**Cocaine**

Cocaine hydrochloride (‘street’ cocaine, ‘coke’) is a water-soluble powder or granule that can be taken orally, intravenously or intranasally. ‘Freebase’ or ‘crack’ cocaine comprises crystals of relatively pure cocaine without the hydrochloride moiety and is obtained in rocks (150 mg of cocaine). It is more suitable for smoking in a pipe or mixed with tobacco and can also be heated on foil and the vapour inhaled (approximately 35 mg of drug per ‘line’ or a ‘rail’). The ‘effects’ of cocaine are experienced almost immediately with i.v. or smoking routes, about 10 min in the intranasal route and 45–90 min when taken orally. The effects start resolving in about 20 min and last up to 90 min. In severe poisoning, death occurs in minutes but survival beyond 3 hours is not usually fatal.

Cocaine blocks the reuptake of biogenic amines. Inhibition of dopamine reuptake is responsible for the psychomotor agitation which commonly accompanies cocaine use. Blockade of noradrenaline (norepinephrine), reuptake produces tachycardia, and inhibition of serotonin reuptake induces hallucinations. Cocaine also enhances CNS arousal by potentiating the effects of excitatory amino acids. Cocaine is also a powerful local anaesthetic and vasoconstrictor.

**Clinical features**

After initial euphoria, cocaine produces agitation, tachycardia, hypertension, sweating, hallucinations, convulsions, metabolic acidosis, hyperthermia, rhabdomyolysis and ventricular arrhythmias. Dissection of the aorta, myocarditis, myocardial infarction, dilated cardiomyopathy, subarachnoid haemorrhage, and cerebral haemorrhage and infarction also occur. If a young person presents with a stroke or myocardial infarction, cocaine poisoning, because of its vasoconstrictor effect, is a possible diagnosis.

**Treatment**

Diazepam 10–20 mg i.v. is used to control agitation and convulsions. Active external cooling should be used for hyperthermia. Hypertension and tachycardia usually respond to sedation and cooling. If hypertension persists, give i.v. nitrates such as glyceryl trinitrate starting at 1–2 mg/h and gradually increase the dose (maximum 12 mg/h) until BP is controlled. Calcium channel blockers such as nifedipine, verapamil or diltiazem are an alternative as second-line therapy. The use of beta-blockers is controversial. Early use of a benzodiazepine is often effective in relieving cocaine-associated non-cardiac chest pain. Aspirin and nitrates should be given to all people with chest pain suspected of being cardiac in origin. Treat myocardial ischaemia/infarction conventionally.

**Digoxin**

Toxicity occurring during chronic administration is common, though acute poisoning is infrequent.

**Clinical features**

These include nausea, vomiting, dizziness, anorexia and drowsiness. Rarely, confusion, visual disturbances and hallucinations occur. Sinus bradycardia is often marked and may be followed by supraventricular arrhythmias with or without heart block, ventricular premature beats and ventricular tachycardia. Hyperkalaemia occurs due to the inhibition of the sodium-potassium activated ATPase pump.

**Treatment**

Sinus bradycardia, atrioventricular block and sinoatrial standstill are often reduced or even abolished by atropine 1.2–2.4 mg i.v. If cardiac output is compromised, however, digoxin-specific antibody fragments (digoxin-Fab) should be administered. In both acute and chronic poisoning, only half the estimated dose (calculated from amount of drug taken or serum digoxin concentration) required for full neutralization need be given initially; a further dose is given if clinically indicated.

**Gamma-hydroxybutyric acid (GHB)**

Gamma-hydroxybutyric acid occurs naturally in mammalian brain where it is derived metabolically from gamma-aminobutyric acid (GABA). GHB has emerged as a major recreational drug for body building, weight loss and for producing a ‘high’. Street names include cherry meth and liquid X. It is taken as a colourless liquid dissolved in water.

**Clinical features**

Poisoning with GHB is characterized by aggressive behaviour, ataxia, amnesia, vomiting, drowsiness, bradycardia, respiratory depression and apnoea, seizures and characteristically coma, which is short-lived.

**Management**

In a patient who is breathing spontaneously, the management of GHB poisoning is primarily supportive with oxygen supplementation and the administration of atropine for persistent bradycardia, as necessary. Those who are severely poisoned will require mechanical ventilation, although recovery is usually complete within 6–8 hours.

**Iron**

Unless more than 60 mg of elemental iron per kg of body weight is ingested (a ferrous sulphate tablet contains 60 mg of iron), features are unlikely to develop. As a result poisoning is seldom severe but deaths still occur. Iron salts have a direct corrosive effect on the upper gastrointestinal tract.

**Clinical features**

The initial features are characterized by nausea, vomiting (the vomit may be grey or black in colour), abdominal pain and diarrhoea. Severely poisoned patients develop haematemesis, hypotension, coma and shock at an early stage. Usually, however, most patients only suffer mild gastrointestinal symptoms. A small minority deteriorate 12–48 hours after ingestion and develop shock, metabolic acidosis, acute tubular necrosis and hepatocellular necrosis. Rarely, up to 6 weeks after ingestion, intestinal strictures due to corrosive damage occur. The serum iron concentration should be measured some 4 hours after ingestion and if the concentration exceeds the predicted normal iron binding capacity (usually >5 mg/L: 90 μmol/L), free iron is circulating and treatment with desferrioxamine is required.
Treatment
The majority of patients ingesting iron do not require desferreroxamine therapy. If a patient develops coma or shock, desferreroxamine should be given without delay in a dose of 15 mg/kg per hour i.v. (total amount of infusion usually not to exceed 80 mg/kg in 24 hours). If the recommended rate of administration is continued for several days, adverse effects including pulmonary oedema and ARDS have been reported.

Lithium
Lithium toxicity is usually the result of therapeutic overdosage (chronic toxicity) rather than deliberate self-poisoning (acute toxicity). However, single large doses are occasionally ingested by individuals on long-term treatment with the drug (acute on therapeutic toxicity).

Clinical features
Features of intoxication include thirst, polyuria, diarrhoea and vomiting and in more serious cases impairment of consciousness, hypertonia and convulsions; irreversible neurological damage occurs. Measurement of the serum lithium concentration confirms the diagnosis. Acute massive overdose may produce concentrations of 5 mmol/L (34.7 mg/L) without causing toxic features, whereas chronic toxicity is associated with neurological features at concentrations >1.5 mmol/L (6.94 mg/L).

Treatment
Forced diuresis with sodium chloride 0.9% is effective in increasing elimination of lithium, though haemodialysis is far superior and should be undertaken particularly if neurological features are present, if renal function is impaired and if chronic toxicity or acute on chronic toxicity are the modes of presentation.

Neuroleptics and atypical neuroleptics
Neuroleptic (antipsychotic) drugs are thought to act predominantly by blockade of the dopamine D2 receptors. Older neuroleptics include the phenothiazines, the butyrophenones (benperidol, haloperidol) and the substituted benzamides (sulpiride). More selective ‘atypical’ antipsychotics include amisulpride, aripiprazole, clozapine, olanzapine, quetiapine and risperidone.

Clinical features
These include impaired consciousness, hypotension, respiratory depression, hypothermia or hyperthermia, antimuscarinic effects such as tachycardia, dry mouth and blurred vision, occasionally seizures, rhabdomyolysis, cardiac arrhythmias (both atrial and ventricular) and acute respiratory distress syndrome. Extrapyramidal effects, including acute dystonic reactions, occur but are not dose related. Most ‘atypical’ antipsychotics have less profound sedative actions than the older neuroleptics. Q–T interval prolongation and subsequent ventricular arrhythmias (including torsades de pointes) have occurred following overdose with the atypical neuroleptics. Unpredictable fluctuations in conscious level, with variations between agitation and marked somnolence, have been particularly associated with olanzapine overdose.

Treatment
Prochlorperazine 5–10 mg i.v. in an adult is occasionally required for the treatment of dyskinesia and oculogyric crisis. If hypotension is severe and does not respond to intravenous fluids, a sympathomimetic amine such as noradrenaline (norepinephrine) is used. After correcting acidosis with sodium bicarbonate, the preferred treatment for arrhythmias caused by antipsychotic drugs (usually torsades de pointes) is intravenous magnesium or cardiac pacing. Amiodarone is used if multifocal ventricular arrhythmias occur.

Non-steroidal anti-inflammatory agents (NSAIDs)
Self-poisoning with NSAIDs has increased, particularly now that ibuprofen is available without prescription in many countries.

Clinical features and treatment
In most cases minor gastrointestinal disturbance is the only feature but, in more severe cases, coma, convulsions and acute kidney injury have occurred. Transient renal impairment is common after ibuprofen overdose. Poisoning with mefenamic acid commonly results in convulsions though these are usually short-lived.

Treatment is symptomatic and supportive.

Opiates and opioids
Clinical features
Cardinal signs of opiate poisoning are pinpoint pupils, reduced respiratory rate and coma. Hypothermia, hypoglycaemia and convulsions are occasionally observed in severe cases. In severe heroin overdose, non-cardiogenic pulmonary oedema has been reported.

Treatment
Naloxone 1.2–2.0 mg i.v. will reverse at least partially severe respiratory depression and coma. In severe poisoning larger initial doses or repeat doses will be required. The duration of action of naloxone is often less than the drug taken in overdose, e.g. methadone, which has a very long half-life. For this reason an infusion of naloxone is often required. Non-cardiogenic pulmonary oedema should be treated with mechanical ventilation.

Paracetamol (acetaminophen)
Paracetamol is the most common form of poisoning encountered in the UK. In therapeutic dose, paracetamol is conjugated with glucuronide and sulphate. A small amount of paracetamol is metabolized by mixed function oxidase enzymes to form a highly reactive compound (N-acetyl-p-benzoquinoneimine, NAPQI), which is then immediately conjugated with glutathione and subsequently excreted as cysteine and mercapturic conjugates. In overdose, large amounts of paracetamol are metabolized by oxidation because of saturation of the sulphate conjugation pathway. Liver glutathione stores become depleted so that the liver is unable to deactivate the toxic metabolite. Paracetamol-induced renal damage probably results from a mechanism similar to that which is responsible for hepatotoxicity.

The severity of paracetamol poisoning is dose related. There is, however, some variation in individual susceptibility to paracetamol-induced hepatotoxicity. People with pre-existing liver disease, those suffering from acute or chronic starvation (patients not eating for a few days for example due to a recent febrile illness or dental pain), those suffering from anorexia nervosa and other eating disorders, those receiving enzyme-inducing drugs, and those with HIV infection should be considered to be at greater risk and given treatment at
plasma paracetamol concentrations lower than those normally used for interpretation (Fig. 17.2).

**Clinical features**

Following the ingestion of an overdose of paracetamol, patients usually remain asymptomatic for the first 24 hours. Following the ingestion of an overdose of paracetamol, patients usually remain asymptomatic for the first 24 hours. Clinical features

**Treatment**

The treatment protocol is dependent on the time of presentation and is summarized in Table 17.20. Acetylcysteine has emerged as an effective protective agent provided that it is administered within 8–10 hours of ingestion of the overdose. It acts by replenishing cellular glutathione stores, though it may also repair oxidation damage caused by NAPQI. The treatment regimen is shown in Table 17.21. If a staggered overdose has been taken (multiple ingestions over several hours), acetylcysteine should be given when the paracetamol dose exceeds 150 mg/kg body weight in any one 24-hour period or 75 mg/kg body weight in those at high risk (see above).
Up to 15% of patients treated with intravenous acetylcysteine (20.25-h regimen) develop rash, angio-oedema, hypotension and bronchospasm. These reactions, which are related to the initial bolus, are seldom serious and discontinuing the infusion is usually all that is required. In more severe cases, chlorphenamine 10–20 mg i.v. in an adult should be given.

If liver or renal failure ensues, this should be treated conventionally though there is evidence that a continuing infusion of acetylcysteine (continue 16-h infusion until recovery) will improve the morbidity and mortality. Liver transplantation has been performed successfully in patients who have paracetamol-induced fulminant hepatic failure (see p. 316).

Salicylates
Aspirin is metabolized to salicylic acid (salicylate) by esterases present in many tissues, especially the liver, and subsequently to salicyluric acid and salicyl phenolic glucuronide (Fig. 17.3); these two pathways become saturated with the consequence that the renal excretion of salicylic acid increases after overdose; this excretion pathway is extremely sensitive to changes in urinary pH.

Clinical features
Salicylates stimulate the respiratory centre, increase the depth and rate of respiration, and induce a respiratory alkalosis. Compensatory mechanisms, including renal excretion of bicarbonate and potassium, result in a metabolic acidosis. Salicylates also interfere with carbohydrate, fat and protein metabolism, and disrupt oxidative phosphorylation, producing increased concentrations of lactate, pyruvate and ketone bodies, all of which contribute to the acidosis.

Thus, tachypnoea, sweating, vomiting, epigastric pain, tinnitus and deafness develop. Respiratory alkalosis and metabolic acidosis supervene and a mixed acid–base disturbance is observed commonly. Rarely, in severe poisoning, non-cardiogenic pulmonary oedema, coma and convulsions ensue.

The severity of salicylate toxicity is dose-related.

Treatment
Fluid and electrolyte replacement is required and special attention should be paid to potassium supplementation. Severe metabolic acidosis requires at least partial correction with the administration of sodium bicarbonate intravenously. Mild cases of salicylate poisoning are managed with parenteral fluid and electrolyte replacement only. Patients whose plasma salicylate concentrations are in excess of 500 mg/L (3.62 mmol/L) should receive urine alkalinization (see p. 913). Haemodialysis is the treatment of choice for severely poisoned patients (plasma salicylate concentration >700 mg/L; >5.07 mmol/L), particularly those with coma and metabolic acidosis.

Theophylline
Poisoning may complicate therapeutic use as well as being the result of deliberate self-poisoning. If a slow-release preparation is involved, peak plasma concentrations are not attained until 6–12 hours after overdosage and the onset of toxic features is correspondingly delayed.

Clinical features
Nausea, vomiting, hyperventilation, haematemesis, abdominal pain, diarrhoea, sinus tachycardia, supraventricular and ventricular arrhythmias, hypotension, restlessness, irritability, headache, hyperreflexia, tremors and convulsions have been observed. Hypokalaemia probably results from activation of Na’/K’ ATPase. A mixed acid–base disturbance is common. Most symptomatic patients have plasma theophylline concentrations in excess of 25 mg/L (430 µmol/L). Convulsions are seen more commonly when concentrations are >50 mg/L (>860 µmol/L). Plasma potassium concentrations of <2.6 mmol/L, metabolic acidosis, hypotension, seizures and arrhythmias are indications of severe poisoning.

Treatment
There is good evidence that multiple-dose (12.5 g/h) activated charcoal enhances the elimination of theophylline. However, protracted theophylline-induced vomiting may mitigate the benefit of this therapy, unless vomiting is suppressed by a 5HT₃ antagonist such as ondansetron 4–8 mg i.v. Correction of hypokalaemia to prevent or treat tachyarrhythmias is of great importance. A non-selective β-adrenoceptor blocking drug, such as propranolol, is also useful in the treatment of tachyarrhythmias secondary to hypokalaemia, but should not be given if the patient has severe airways disease. Convulsions should be treated with diazepam 10–20 mg i.v. in an adult.

Specific poisons: chemicals

Carbamate insecticides
Carbamate insecticides inhibit acetylcholinesterase, as do organophosphorus insecticides, but the duration of this inhibition is comparatively short-lived in comparison since the carbamate–enzyme complex tends to dissociate spontaneously. The clinical features and treatment are similar except that an oxime such as pralidoxime is not usually required because the enzyme complex dissociates spontaneously; recovery invariably occurs within 24 hours (see p. 923).

Carbon monoxide
The commonest source of carbon monoxide is an improperly maintained and poor, ventilated heating system. In addition, inhalation of methylene chloride (found in paint strippers) may also lead to carbon monoxide poisoning as methylene chloride is metabolized in vivo to carbon monoxide. The affinity of haemoglobin for carbon monoxide is some 240 times greater than that for oxygen. Carbon monoxide combines with haemoglobin to form carboxyhaemoglobin, thereby reducing the total oxygen carrying capacity of the blood and increasing the affinity of the remaining haem groups for oxygen. This...
results in tissue hypoxia. In addition, carbon monoxide also inhibits cytochrome oxidase $a_3$.

**Clinical features**
Symptoms of mild to moderate exposure to carbon monoxide may be mistaken for a viral illness. A peak carboxyhaemoglobin (COHb) concentration of less than 10% is not normally associated with symptoms and peak COHb concentrations of 10–30% usually result only in headache and mild exertional dyspnoea. Higher concentrations of COHb are associated with coma, convulsions and cardiorespiratory arrest. Metabolic acidosis, myocardial ischaemia, hypertension, extensor plantar responses, retinal haemorrhages and papilloedema also occur. Neuropsychiatric features may develop after apparent recovery from carbon monoxide exposure.

**Treatment**
In addition to removing the patient from carbon monoxide exposure, high flow oxygen should be administered using a tightly fitting face mask. Endotracheal intubation and mechanical ventilation is required in those who are unconscious. Several controlled studies of hyperbaric oxygen have been published but none have shown long-term clinical benefit.

**Cyanide**
Cyanide and its derivatives are used widely in industry. Hydrogen cyanide is also released during the thermal decomposition of polyurethane foams. Cyanide reversibly inhibits cytochrome oxidase $a_3$ so that cellular respiration ceases.

**Clinical features**
Inhalation of hydrogen cyanide produces symptoms within seconds and death within minutes. By contrast, the ingestion of a cyanide salt may not produce features for 1 hour. After exposure initial symptoms are non-specific and include a feeling of constriction in the chest and dyspnoea. Coma, convulsions and metabolic acidosis may then supervene.

**Treatment**
Oxygen should be administered and, if available, dicyclon edetate 300 mg should be administered intravenously; the dose is repeated in severe cases. Dicyclon edetate (and the free cobalt contained in the preparation) complexes free cyanide. An alternative but expensive antidote is hydroxocobalamin, which enhances endogenous cyanide detoxification mechanisms: 5 g i.v. is administered, and a second dose may be required in severe cases. If these two antidotes are not available sodium thiosulphate 12.5 g i.v., which acts by enhancing endogenous detoxification, and sodium nitrite 300 mg i.v. should be administered. Sodium nitrite produces methaemoglobin; methaemoglobin combines with cyanide to form cyanmethaemoglobin.

**Ethanol**
Ethanol is commonly ingested in beverages and deliberately with other substances in overdose. It is also present in many cosmetic and antiseptic preparations. Following absorption, ethanol is oxidized to acetaldehyde and then to acetic acid. Ethanol is a CNS depressant and the features of ethanol intoxication are generally related to blood concentrations (Table 17.22).

**Clinical features**
In children in particular severe hypoglycaemia may accompany alcohol intoxication due to inhibition of gluconeogenesis. Hypoglycaemia is also observed in those who are malnourished or who have fasted in the previous 24 hours. In severe cases of intoxication, coma and hypothermia are often present and lactic acidosis, ketoacidosis and acute kidney injury have been reported.

**Ethylene and diethylene glycol**
Ethylene and diethylene glycol are found in a variety of common household products including antifreeze, windshield washer fluid, brake fluid and lubricants. The features observed are due to metabolites predominantly, not the parent chemical. Ethylene glycol (Fig. 17.4) is metabolized to glycolate, the cause of the acidosis. A small proportion of glyoxylic acid is metabolized to oxalate. Calcium ions chelate oxalate to form insoluble calcium oxalate, which is responsible for renal toxicity. Diethylene glycol is metabolized to 2-hydroxyethoxyacetate (Fig. 17.5), which is the cause of metabolic acidosis, and diglycolic acid (the cause of renal failure).

**Clinical features**
Initially, the features of ethylene glycol poisoning are similar to ethanol intoxication (though there is no ethanol on the breath). Coma and convulsions follow and a variety of neuropsychiatric abnormalities, including nystagmus and ophthalmoplegias, are seen. Severe metabolic acidosis, hypocalcaemia and acute kidney disease are well-recognized complications. In diethylene glycol poisoning nausea and vomiting, headache, abdominal pain, coma, seizures, metabolic acidosis and acute kidney injury commonly occur. Pancreatitis and hepatitis, together with cranial neuropathies and demyelinating peripheral neuropathy, are also seen.

**Treatment**
If the patient presents early after ingestion, the first priority is to inhibit metabolism using either intravenous fomepizole...

FURTHER READING

Household products
The agents most commonly involved are bleach, cosmetics, toiletries, detergents, disinfectants and petroleum distillates such as paraffin and white spirit. Ingestion of household products is usually accidental and is most common among children less than 5 years of age.

Clinical features
If the ingestion is accidental, features very rarely occur except in the case of petroleum distillates where aspiration is a recognized complication because of their low surface tension. Powder detergents, sterilizing tablets, denture cleaning tablets and industrial bleaches (which contain high concentrations of sodium hypochlorite) are corrosive to the mouth and pharynx if ingested. Nail polish and nail polish remover contain acetone that may produce coma if ingested in substantial quantities. Inhalation by small children of substantial quantities of talcum powder has occasionally given rise to severe pulmonary oedema and death.

Lead
Exposure to lead occurs occupationally, children may eat lead-painted items in their homes (pica) and the use of lead-containing cosmetics or ‘drugs’ has also resulted in lead poisoning.

Clinical features
Mild intoxication may result in no more than lethargy and occasional abdominal discomfort, though abdominal pain, vomiting, constipation and encephalopathy (seizures, delirium, coma) may develop in more severe cases. Encephalopathy is more common in children than in adults but is now rare in the developed world. Typically, though very rarely, lead poisoning results in foot drop attributable to peripheral motor neuropathy. A bluish discoloration of the gum margins due to the deposition of lead sulphide is observed occasionally.

The characteristic haematological features include:
- Normochromic normocytic anaemia, due to inhibition by lead of several enzymes involved in haem synthesis, including ALA synthetase
- Haemolysis, which is usually mild, resulting from damage to the red cell membrane
- Punctate basophilia (or basophilic stippling: the blood film shows red cells with small, round, blue particles), due to aggregates of RNA in immature red cells owing to inhibition by lead of pyrimidine-5-nucleotidase, which normally disperses residual RNA to produce a diffuse blue staining seen in reticulocytes on blood films (polychromasia).

Treatment
The social and occupational dimensions of lead poisoning must be recognized. Simply giving the patient chelation therapy and then returning them to a contaminated environment is of no value.

The decision to use chelation therapy is based not only on the blood lead concentration but on the presence of symptoms. Parenteral sodium calcium edetate 75 mg/kg per day has been the chelating agent of choice for over 50 years, but there is now evidence to suggest that oral DMSA 30 mg/kg per day is of similar efficacy. At least 5 days’ treatment is usually required.

Mercury
Mercury is the only metal that is liquid at room temperature. It exists in three oxidation states (elemental/metallic Hg0, mercurous Hg2+, and mercuric Hg2+) and can form inorganic (e.g. mercuric chloride) and organic (e.g. methylmercury) compounds. Metallic mercury is very volatile and when spilled, has a large surface area so that high atmospheric concentrations may be produced in enclosed spaces, particularly when environmental temperatures are high. Thus, great care should be taken in clearing up a spillage. If ingested, metallic mercury will usually be eliminated per rectum, though small amounts may be found in the appendix. Mercury salts are well absorbed following ingestion as are organometallic compounds where mercury is covalently bound to carbon.

Clinical features
Inhalation of acute mercury vapour causes headache, nausea, cough, chest pain, bronchitis and occasionally pneumonia. Proteinuria and nephrotic syndrome are
observed rarely. In addition a fine tremor and neurobehavioural impairment occurs and peripheral nerve involvement has also been observed. Ingestion of inorganic and organic mercury compounds causes an irritant gastroenteritis with corrosive ulceration, bloody diarrhoea and abdominal cramps and may lead to circulatory collapse and shock. Mercurous compounds are less corrosive and toxic than mercuric salts.

**Treatment**

Dimercaptopropanesulphonate (DMPS) is the antidote of choice and is given intravenously in a dose of 30 mg/kg per day. At least 5 days’ treatment is usually required.

**Methanol**

Methanol is used widely as a solvent and is found in anti-freeze solutions. Methanol is metabolized to formaldehyde and formate (Fig. 17.6). The concentration of formate increases greatly and is accompanied by accumulation of hydrogen ions causing metabolic acidosis.

**Clinical features**

Methanol causes inebriation and drowsiness. After a latent period coma supervenes. Blurred vision and diminished visual acuity occur due to formate accumulation. The presence of dilated pupils that are unreactive to light suggests that permanent blindness is likely to ensue. A severe metabolic acidosis may develop and be accompanied by hyperglycaemia and a raised serum amylase activity. A blood methanol concentration of 500 mg/L (15.63 mmol/L) confirms severe poisoning. The mortality correlates well with the severity and duration of metabolic acidosis. Survivors may show permanent neurological sequelae including parkinsonian-like signs as well as blindness.

**Treatment**

Treatment is similar to that of ethylene glycol poisoning (see p. 921) with the addition of folic acid 30 mg i.v. 6-hourly, which accelerates formate metabolism thereby reducing ocular toxicity.

**Nerve agents**

Nerve agents are related chemically to organophosphorus insecticides (see below) and have a similar mechanism of toxicity, but a much higher mammalian acute toxicity, particularly via the dermal route. In addition to inhibition of acetylcholinesterase, a chemical reaction known as ‘ageing’ also occurs rapidly and more completely than in the case of insecticides. This makes the enzyme resistant to spontaneous reactivation or by treatment with oximes (pralidoxime, obidoxime or HI-6).

Two classes of nerve agent are recognized: G agents (named for Gerhardt Schrader who synthesized the first agents) and V agents (V allegedly stands for venoms).

**Clinical features**

G agents include tabun, sarin, soman and cyclosarin. The V agents were introduced later, e.g. VX. The G agents are both dermal and respiratory hazards, whereas the V agents, unless aerosolized, are contact poisons.

Agents used in bioterrorism are described on page 935.

**Organophosphorus insecticides**

Organophosphorus (OP) insecticides are used widely throughout the world and are a common cause of poisoning, causing thousands of deaths annually, in the developing world. Intoxication may follow ingestion, inhalation or dermal absorption. Organophosphorus insecticides inhibit acetylcholinesterase causing accumulation of acetylcholine at central and peripheral cholinergic nerve endings, including neuromuscular junctions. Many OP insecticides require biotransformation before becoming active and so the features of intoxication may be delayed.

**Clinical features**

Poisoning is characterized by anxiety, restlessness, tiredness, headache, and muscarinic (cholinergic) features such as nausea, vomiting, abdominal colic, diarrhoea, tenesmus, sweating, hypersalivation and chest tightness. Miosis may be present. Nicotinic effects include muscle fasciculation and flaccid paresis of limb muscles, respiratory muscles, and, occasionally, of extraocular muscles. Respiratory failure will ensue in severe cases and is exacerbated by the development of bronchorrhoea and pulmonary oedema. Coma and convulsions occur in severe poisoning. Diagnosis is confirmed by measuring the erythrocyte cholinesterase activity; plasma cholinesterase activity is less specific but may also be depressed. Delayed polyneuropathy is a rare complication of acute exposure to some OP insecticides not marketed in most countries. It is initiated by phosphorylation and subsequent ageing of at least 70% of neuropathy target esterase (NTE) in peripheral nerves.

The intermediate syndrome usually becomes established 2–4 days after exposure when the symptoms and signs of the acute cholinergic syndrome are no longer obvious. The characteristic features of the syndrome are weakness of the muscles of respiration (diaphragm, intercostal muscles and
accessory muscles including neck muscles) and of proximal limb muscles. Accompanying features often include weakness of muscles innervated by some cranial nerves.

**Treatment**

Mild cases require no specific treatment other than the removal of soiled clothing. Atropine 2 mg i.v. should be given every 3–5 min if necessary to reduce increased secretions, rhinorrhoea and bronchorrhoea. Symptomatic patients should also be given an oxime (pralidoxime, obidoxime or HI-6) to reactivate inhibited acetylcholinesterase: for example, pralidoxime chloride 30 mg/kg by slow i.v. injection followed by an infusion of pralidoxime mesylate 8–10 mg/kg per hour.

**Phosphides**

Aluminium and zinc phosphides are used as rodenticides and insecticides. They react with moisture in the air (and the gastrointestinal tract) to produce phosphine, the active pesticide. Acute poisoning with these compounds may be direct, due to ingestion of the salts, or indirect from accidental inhalation of phosphine generated during their approved use.

**Clinical features**

Ingestion causes vomiting, epigastric pain, peripheral circulatory failure, severe metabolic acidosis, acute kidney injury and disseminated intravascular coagulation, in addition to the features induced by phosphine. Exposure to phosphine causes lacrimation, rhinorrhoea, productive cough, breathlessness, chest tightness, dizziness, headache, nausea and drowsiness. Acute pulmonary oedema, hypertension, cardiac arrhythmias, convulsions and jaundice have been described in severe cases. Ataxia, intention tremor and diplopia are found on examination.

**Treatment**

Treatment is symptomatic and supportive. Gastric lavage should not be used as it can increase the rate of disintegration of the product ingested and increase toxicity. Activated charcoal may bind metal phosphides. The mortality is high despite supportive care.

### Specific poisons: marine animals

#### Amnesic shellfish (domoic acid) poisoning

The syndrome should be known more accurately as domoic acid poisoning because amnesia is not always present. In one outbreak, the first symptoms were experienced between 15 minutes and 38 hours after mussel consumption.

**Clinical features and treatment**

The most common symptoms are nausea, vomiting, abdominal cramps, headache, diarrhoea and short-term memory loss. Axonal sensory motor neuropathy, seizures, coma and death have also been reported. Treatment is symptomatic and supportive.

#### Diarrhoeic shellfish (okadaic) poisoning

Okadaic acid is produced by dinoflagellates belonging to the genera *Dinophysis* spp. Okadaic acid inhibits the activity of the protein phosphatases 1 and 2a.

**Clinical features and treatment**

The predominant symptoms are diarrhoea, nausea, vomiting and abdominal pain. Symptoms tend to occur between 30 minutes and a few hours after shellfish consumption, with patients recovering within 2–3 days. Treatment is symptomatic and supportive.

### Neurotoxic shellfish (brevetoxin) poisoning

Neurotoxic shellfish poisoning is caused by brevetoxins produced by the dinoflagellate *Gymnodinium breve*. Brevetoxins open voltage-gated sodium ion channels in cell walls and enhance the inward flow of sodium ions into the cell.

**Clinical features and treatment**

The symptoms of neurotoxic shellfish poisoning occur within 30 minutes to 3 hours, last a few days and include nausea, vomiting, diarrhoea, chills, sweats, reversal of temperature, hypotension, arrhythmias, numbness, tingling, paraesthesias of the lips, face and extremities, cramps, bronchoconstriction, paralysis, seizures and coma. Treatment is symptomatic and supportive.

#### Paralytic shellfish (saxitoxin) poisoning

This is caused by bivalve molluscs being contaminated with neurotoxins, including saxitoxin, produced by toxic dinoflagellates on which the molluscs graze. Saxitoxin blocks voltage-gated sodium channels in nerve and muscle cell membranes, thereby blocking nerve signal transmission.

**Clinical features and treatment**

Symptoms develop within 30 minutes. The illness is characterized by paraesthesias of the mouth, lips, face and extremities and is often accompanied by nausea, vomiting and diarrhoea. In more severe cases, dystonia, dysphagia, muscle weakness, paralysis, ataxia and respiratory depression occur. In one outbreak involving 187 cases, there were 26 deaths. Treatment is symptomatic and supportive.

#### Ciguatera fish poisoning

Over 400 fish species have been reported as ciguatoxic (*Cigua* is Spanish for poisonous snail), though barracuda, red snapper, amberjack and grouper are most commonly implicated. Ciguatera fish contain ciguatoxin, maitotoxin and scaritoxin, which are lipid soluble, heat stable compounds that are derived from dinoflagellates such as *Gambierdiscus toxicus*. Ciguatoxin opens voltage-sensitive sodium channels at the neuromuscular junction and maitotoxin opens calcium channels of the cell plasma membrane.

**Clinical features and treatment**

The onset of symptoms occurs from a few minutes to 30 hours after ingestion of toxic fish. Typically features appear between one and six hours and include abdominal cramps, nausea, vomiting and watery diarrhoea. In some cases, numbness and paraesthesias of the lips, tongue and throat occur. Other features described include malaise, dry mouth, metallic taste, myalgia, arthralgia, blurred vision, photophobia and transient blindness. In more severe cases, hypotension, cranial nerve palsies and respiratory paralysis have been reported. Treatment is symptomatic and supportive. Recovery takes from 48 hours to 1 week in the mild form and from 1 to several weeks in the severe form. The mortality in severe cases may be as high as 12%.

#### Scombroid fish poisoning

This is due to the action of bacteria such as *Proteus morgani* and *Klebsiella pneumoniae* in decomposing flesh of fish such as tuna, mackerel and other fish.
as tuna, mackerel, mahi-mahi, bonito and skipjack if the fish are stored at insufficiently low temperatures. The spoiled fish can contain excessively high concentrations of histamine (muscle histidine is broken down by the bacteria to histamine), though the precise role of histamine in the pathogenesis of the clinical syndrome is uncertain.

**Clinical features and treatment**

Clinically, the mean incubation period is 30 min. The illness is characterized by flushing, headache, sweating, dizziness, burning of the mouth and throat, abdominal cramps, nausea, vomiting and diarrhoea and is usually short-lived; the mean duration is 4 hours. Treatment is symptomatic and supportive. Antihistamines may alleviate the symptoms.

**Stings from marine animals**

Several species of fish have venomous spines in their fins. These include the weaver fish, short-spine cottus, spiny dogfish and the stingray. Bathers and fishermen may be stung if they tread on or handle these species. The immediate result of a sting is intense local pain, swelling, bruising, blistering, necrosis and, if the poisoned spine is not removed, chronic sepsis (although this is uncommon). Occasionally systemic symptoms including, vomiting, diarrhoea, hypotension and tachycardia occur. Treatment by immersing the affected part in hot water may relieve local symptoms as this denatures the thermolabile toxin.

**Jellyfish**

Most of the jellyfish found in North European coastal waters are non-toxic as their stings cannot penetrate human skin. A notable exception is the ‘Portuguese man-o’-war’ (Physalia physalis) whose sting contains a toxic peptide, phospholipase A, and a histamine-liberating factor. Toxic jellyfish are found more frequently in Australia and some cause the Irukandji syndrome.

**Clinical features and treatment**

Local pain occurs followed by myalgia, nausea, griping abdominal pain, dyspnoea and even death. The cluster of severe systemic symptoms that constitute the Irukandji syndrome occur some 30 min after the jellyfish sting. The symptoms include severe low back pain, excruciating muscle cramps in all four limbs, the abdomen and chest, sweating, anxiety, restlessness, nausea, vomiting, headache, palpitations, life-threatening hypertension, pulmonary oedema and toxic global heart dilatation.

Adhesive tape may be used to remove any tentacles still adherent to the bather. Local application of 5% acetic acid to the affected part in hot water may relieve local symptoms as this denatures the thermolabile toxin.

**Scorpions**

Scorpion stings are a serious problem in North Africa, the Middle East and the Americas. Scorpion venoms stimulate the release of acetylcholine and catecholamines causing both cholinergic and adrenergic symptoms.

**Clinical features and treatment**

Severe pain occurs immediately at the site of puncture, followed by swelling. Signs of systemic involvement, which may be delayed for 24 hours, include vomiting, sweating, piloerection, abdominal colic, diarrhoea. In some cases, depending on the species, shock, respiratory depression and pulmonary oedema may develop.

Local infiltration with anaesthetic or a ring block will usually alleviate local pain, though systemic analgesia may be required. Specific antivenom, if available, should be administered as soon as possible.

**Spiders**

The black widow spider (Latrodectus mactans) is found in North America and the tropics and occasionally in Mediterranean countries.

**Clinical features and treatment**

The bite quickly becomes painful and generalized muscle pain, sweating, headache and shock may occur. No systemic treatment is required except in cases of severe systemic toxicity, when specific antivenom should be given, if this is available.

**Venomous snakes**

Approximately 15% of the 3000 species of snake found worldwide are considered to be dangerous to humans. Snake bite is common in some tropical countries (Table 17.23).

There are three main groups of venomous snakes, representing some 200 species, which have in their upper jaws a pair of enlarged teeth (fangs) that inject venom into the tissues of their victim. These are:

- **Viperidae** (with two subgroups: Viperinae: European adders and Russell’s vipers; and Crotalinae: American rattlesnakes, moccasins, lance-headed vipers and Asian pit vipers)
- **Elapidae** (cobras, kraits, mambas, coral snakes, Australian venomous snakes)
- **Hydrophidae** (sea snakes).

In addition, some members of the family Colubridae are mildly venomous (mongoose snake).

**Specific poisons: venomous animals**

**Insect stings and bites**

Insect stings from wasps and bees, and bites from ants, produce pain and swelling at the puncture site. Following the sting or bite, patients should be observed for 2 hours for any signs of evolving urticaria, pruritus, bronchospasm or oropharyngeal oedema. The onset of anaphylaxis requires urgent treatment (see p. 69).

**Further reading**

Clinical features

Viperidae (Viperinae and Crotalinae)

Russell’s viper causes most of the snake-bite mortality in India, Pakistan and Myanmar. There is local swelling at the site of the bite (Fig. 17.7) which may become massive. Local tissue necrosis may occur. Evidence of systemic involvement (envenomation) occurs within 30 minutes, including vomiting, evidence of shock and hypotension. Haemorrhage due to incoagulable blood can be fatal.

Elapidae

There is not usually any swelling at the site of the bite, except with Asian cobras and African spitting cobras – here the bite is painful and is followed by local tissue necrosis. Vomiting occurs first followed by shock and then neurological symptoms and muscle weakness, with paralysis of the respiratory muscles in severe cases. Cardiac muscle can be involved.

Hydrophiidae

Envenomation produces muscle involvement, myalgia and myoglobinuria, which can lead to acute kidney injury. Cardiac and respiratory paralysis may occur.

Treatment

As a first aid measure, a firm pressure bandage should be placed over the bite and the limb immobilized. This may delay the spread of the venom. Arterial tourniquets should not be used, and incision or excision of the bite area should not be performed. Local wounds often require little treatment. If necrosis is present, antibiotics should be given. Skin grafting may be required later. Antitetanus prophylaxis must be given. The type of snake should be identified if possible.

In about 50% of cases, no venom has been injected by the bite. Nevertheless, careful observation for 12–24 hours is necessary in case envenomation develops. General supportive measures should be given, as necessary. These include intravenous fluids with volume expanders for hypotension and diazepam for anxiety. Treatment of acute respiratory, cardiac and kidney injury is instituted as necessary.

Antivenoms are not generally indicated unless envenomation is present, as they can cause severe allergic reactions. Antivenoms can rapidly neutralize venom, but only if an amount in excess of the amount of venom is given. Large quantities of antivenom may be required. As antivenoms cannot reverse the effects of the venom, they must be given early to minimize some of the local effects and may prevent necrosis at the site of the bite. Antivenoms should be administered intravenously by slow infusion, the same dose being given to children and adults.

Allergic reactions are frequent, and adrenaline (epinephrine) 1 in 1000 solution should be available. In severe cases, the antivenom infusion should be continued even if an allergic reaction occurs, with subcutaneous injections of adrenaline being given as necessary. Some forms of neurotoxicity, such as those induced by the death adder, respond to anticholinesterase therapy with neostigmine and atropine.

Specific poisons: plants

Life-threatening poisoning from plant ingestion is rare though many plants contain potentially toxic substances. These include antimuscarinic agents, calcium oxalate crystals, cardiogenic glycosides, pro-convulsants, cyanogenic compounds, mitotic inhibitors, nicotine-like alkaloids, alkylating agent precursors, sodium channel activators and toxic proteins (toxalbumins). While many plants contain gastrointestinal toxins, these rarely give rise to life-threatening sequelae. In contrast, other botanical poisons may cause specific organ damage and death may occur from only small ingestions of yew (genus: Taxus), oleander (Thevetia peruviana and Nerium oleander) and cowbane (genus: Cicuta).

Atropa belladonna

Atropa belladonna (deadly nightshade) contains hyoscyamine and atropine and causes antimuscarinic effects – a dry mouth, nausea and vomiting – leading to blurred vision, hallucinations, confusion and hyperpyrexia.

Cicuta species

Cicuta spp. (water hemlock) and the related genus Oenanthe contain cicutoxin, a potent central nervous system (CNS) stimulant that produces violent seizure activity. The CNS effects of cicutoxin are similar to those of picrotoxin, a known inhibitor of GABA. Severe gastrointestinal symptoms, diarrhoea, salivation and skeletal muscle stimulation may precede the seizure activity.

Conium maculatum

Conium maculatum (poison hemlock) contains a variety of volatile pyridine alkaloids, including conine, N-methylconine and gammaconiceine. Coniceine is significantly more toxic than conine and is thought to be the precursor to conine. The toxic activity of the alkaloids is similar to that of nicotine. Large doses produce non-polarizing neuromuscular blockade which may result in respiratory depression and death.

Datura stramonium

Datura stramonium (jimsonweed) and other Datura species contain L-hyoscyamine and atropine. These alkaloids are potent antagonists of acetylcholine at muscarinic receptors and produce the anticholinergic syndrome. While morbidity is significant, fatalities are rare and are the consequence of hyperthermia, seizures and/or arrhythmias.

Digitalis purpurea, Nerium oleander, Thevetia peruviana

Ingestion of Digitalis purpurea, or the common (Nerium oleander) or yellow (Thevetia peruviana) oleander can produce a syndrome similar to digoxin poisoning (see p. 917). A randomized controlled trial has shown that digoxin-specific antibody fragments rapidly and safely reverse yellow oleander-induced arrhythmias, restore sinus rhythm, and rapidly reverse bradycardia and hyperkalaemia. The administration
Principles of management of poisoning

...of multiple doses of activated charcoal is used, but the effect on survival is debated.

**Specific poisons: mushrooms**

Poisoning due to mushrooms is usually accidental, though ingestion of hallucinogenic (‘magic’) mushrooms is invariably intentional.

**Cytotoxic mushrooms**

Cytotoxic mushroom poisoning is caused by amatoxins and orellanin. Amatoxins are found in *Amanita phalloides*, *A. virosa* and *A. verna*, and in some *Galerina* and *Lepiota* spp. Amatoxins inhibit transcription from DNA to mRNA by the blockade of nuclear RNA polymerase II; this results in impaired protein synthesis and cell death.

**Clinical features and treatment**

Intense watery diarrhoea starts 8–24 hours after ingestion and persists for 24 hours or longer. Patients often become severely dehydrated. Signs of liver damage appear during the 2nd day and hepatic failure may ensue. Impaired kidney function is often seen both because of fluid loss and as a result of direct kidney injury. In all patients, fluid, electrolyte and acid–base disturbances should be corrected and renal and hepatic function supported. The value of silybin and benzylpenicillin is not proven. Occasionally, liver transplantation is necessary.

**Gyromitrin poisoning**

Gyromitrin is found in *Gyromitra* spp., including in particular the false morel (*Gyromitra esculenta*) and *Cudonia circinans*. Gyromitrin decomposes in the stomach, to form hydrazines that reduce pyridoxine in the CNS and, hence, GABA synthesis, causing glutathione depletion in red blood cells and may form free oxygen radicals that bind to hepatic macromolecules.

**Clinical features and treatment**

Vapours from the mushrooms are irritating to the eyes and respiratory tract. Gastrointestinal symptoms appear 5–8 hours after exposure. Vertigo, sweating, diplopia, headache, dysarthria, incoordination and ataxia may follow. Symptomatic and supportive care are required. Pyridoxine 25 mg/kg as an infusion over 30 min, should be given if severe CNS toxicity develops; repeat doses may be required.

**Hallucinogenic mushroom poisoning**

Psilocybin produces pharmacological effects similar to those of LSD and is found in *Psilocybe* and *Panaeolus* spp.

**Clinical features and treatment**

Symptoms occur within 20–60 min. Effects include altered time and space sense, depersonalization, hallucinations, derealization and euphoria. Symptoms are usually maximal within 2 hours and disappear within 4–6 hours, though ‘flashbacks’ may recur after weeks or months. Anxiety and agitation should be treated with diazepam, 10–20 mg i.v., repeated if necessary.

**Isoxazole poisoning**

Isoxazoles (e.g. ibotenic acid, muscimol, muscrazine) occur in *Amanita muscaria* and *A. pantherina* and act as γ-aminobutyric acid agonists.

**Clinical features and treatment**

Nausea, vomiting, inebriation, euphoria, confusion, anxiety, visual disturbances and hallucinations occur within 30 minutes. Severe agitation and violent behaviour are occasionally seen. Other features include myoclonic jerks, muscle fasciculation, seizures and coma. Symptomatic and supportive care should be given as necessary. Diazepam, 10–20 mg, repeated as required, should be administered for anxiety, agitation and seizures.

**Neurotoxic mushroom poisoning**

Muscarine is found in, for example, *Inocybe* spp., *Clitocybe* spp. and *Mycena pura*. Muscarine stimulates cholinergic receptors in the autonomic nervous system.

**Clinical features and treatment**

Diarrhoea, abdominal pain, diaphoresis, salivation, lacrimation, miosis, bronchorrhoea, bronchospasm, bradycardia and hypotension occur. Atropine, 0.6–2 mg i.v. should be given to manage the cholinergic syndrome.

**Orellanin poisoning**

Orellanin is a potent nephrotoxin found in, for example, *Cortinarius orellanus* and *C. speciosissimus*. A metabolite of orellanin inhibits protein synthesis in the kidneys.

**Clinical features and treatment**

Symptoms are typically delayed for 2–4 days. Some patients suffer a mild gastrointestinal disturbance before developing signs of renal impairment, headache, fatigue, intense thirst, chills, muscular discomfort, and abdominal, lumbar and flank pain. Transient polyuria with proteinuria, haematuria and, characteristically, leucocyturia is followed by oliguria and then anuria. Renal function may recover only partially; chronic kidney disease is reported in about 10–40% of cases. Management involves careful monitoring and haemodialysis/haemofiltration if renal failure supervenes. Renal transplantation may be required.

DISEASE AND THE ENVIRONMENT

The incidence and prevalence of disease and causes of death within a community are a reflection of interrelated factors:

- Genetic predisposition
- Nutrition, poverty and affluence
- Purity of water sources, sanitation and atmospheric pollution
- Environmental disasters and accidents
- Background ionizing radiation and man-made radiation exposure, deliberate or accidental
- Environmental temperature
- Patterns of infective disease
- Political forces determining levels of healthcare, preventative strategies and effects of war on civilian populations.

Some of these environmental effects have been clearly documented within the last decade, e.g. the massive civilian mortality and morbidity during the current Afghan and previous Iraq wars, and loss of life and disease prevalence following the 2006 tsunami, the earthquakes in Sechuan (2008) and Haiti (2010) and cyclone Nargris in the Irawaddy delta. Flooding caused by *El Niño* in East Africa not only resulted in an increase in breeding sites for mosquito vectors but a major outbreak of Rift Valley fever due to the enforced close proximity of cattle with humans.

Smoking (active and passive), obesity and excess alcohol consumption also play a significant role in disease. Worldwide health programmes have been established in most countries to reduce their effects.

Environmental temperature

The effect of environmental temperature (*T*<sub>env</sub>) is paramount in infective diseases; changes as small as 1°C cause major changes in disease vectors. Climate change is an unquestionable phenomenon. Patterns of infective disease are likely to change radically within the next 20 years. There are suggestions that climate effects are already becoming apparent, e.g.:

- Patterns of malaria in South-east Asia
- The occurrence of dengue fever in southern Italy
- Outbreaks of cholera, and seasonal variation in diarrhoea and vomiting.

Research into the effect of climate change on the changing patterns of infective diseases will point to potential ways in which national and international efforts can be targeted.

HEAT

Body core temperature (*T*<sub>core</sub>) is maintained at 37°C by the thermoregulator centre in the hypothalamus.

Heat is produced by cellular metabolism and is dissipated through the skin by both vasodilatation and sweating and in expired air via the alveoli. When the environmental temperature (*T*<sub>env</sub>) is >32.5°C, profuse sweating occurs. Sweat evaporation is the principal mechanism for controlling *T*<sub>core</sub> following exercise or in response to an increase in *T*<sub>env</sub>.

**Heat acclimatization.** Acclimatization to heat takes place over several weeks. The sweat volume increases and the sweat salt content falls. Increased evaporation of sweat reduces *T*<sub>core</sub>.

**Heat cramps.** Painful muscle cramps, usually in the legs, often occur in fit people when they exercise excessively,
Hypothermia is a prominent cause of death. Hypothermia can occur when $T_{\text{Core}}$ falls below 32°C. It is frequently lethal when $T_{\text{Core}}$ falls below 30°C. Survival, with full recovery has however been recorded with $T_{\text{Core}}$ of <16°C. Cold injury includes:

- **Frostbite**: the local cold injury that follows freezing of tissue
- **Non-freezing cold injury**: the damage – usually to feet – following prolonged exposure to $T_{\text{Env}}$ between 0 and 5°C, usually in damp conditions.

**Hypothermia**

Hypothermia occurs in many settings. At home, hypothermia can occur when $T_{\text{Env}}$ is below 8°C, when there is poor heating, inadequate clothing and poor nutrition. Depressant drugs, e.g. hypnotics, as well as alcohol, hypothyroidism or intercurrent illness also contribute. Hypothermia is commonly seen in the poor, frail and elderly. The elderly have diminished ability to sense cold and also have little insulating fat. Neonates and infants become hypothermic rapidly because of a relatively large surface area in proportion to subcutaneous fat.

**Outdoors on land.** Hypothermia is a prominent cause of death in climbers, skiers, polar travellers and in wartime. Wet, cold conditions with wind chill, physical exhaustion, injuries and inadequate clothing are contributory. Babies and children are at risk because they cannot take action to warm themselves.

**Cold water immersion.** Dangerous hypothermia can develop following immersion for more than 30 min to 1 hour in water temperatures of 15–20°C. In $T_{\text{Water}}$ below 12°C limbs rapidly become numb and weak. Recovery takes place gradually, over several hours following rescue.

**Clinical features**

Mild hypothermia ($T_{\text{Core}} <32^\circ\text{C}$) causes shivering and initially intense discomfort. However, the hypothermic subject, though alert, may not act appropriately to rewarming, e.g. by huddling, wearing extra clothing or exercising. As the $T_{\text{Core}}$ falls below 32°C, severe hypothermia causes impaired judgement – including lack of awareness of cold – drowsiness and coma. Death follows, usually from ventricular fibrillation.

**Diagnosis**

Diagnosis is straightforward, if a low-reading thermometer is available. If not, rapid clinical assessment is reliable. Someone who feels icy to touch – abdomen, groin, axillae – is probably substantially hypothermic. If they are clammy, uncooperative or sleepy, $T_{\text{Core}}$ is almost certainly <32°C.

**Sequelae**

Pulse rate and systemic BP fall. Cardiac output and cerebral blood flow are low in hypothermia and can fall further if the upright position is maintained, the thorax restrained by a harness or by hauling during evacuation. This is why helicopter and lifeboat winch rescues are often carried out with a stretcher, rather than a chest harness.

Respiration becomes shallow and slow. Muscle stiffness develops; tendon reflexes become sluggish, then absent. As coma ensues, pupillary and other brainstem reflexes are lost; pupils are fixed and may be dilated in severe hypothermia. Metabolic changes are variable, with either metabolic acidosis or alkalosis. Arterial $\text{PO}_2$ may appear normal, i.e. falsely high.

There is shift of the oxygen dissociation curve to the left because of the reduction in temperature of haemoglobin. Thus, if an arterial blood sample from a hypothermic patient...
is analysed at 37°C, the $P_{O_2}$ will be falsely high. Within the range 37–33°C this factor is around 7% per °C. Many blood gas machines also calculate the arterial saturation; this too will be falsely high. When a patient is monitored using a pulse oximeter, the level of arterial oxygen saturation ($S_aO_2$) will however be correct – but if $S_aO_2$ is then converted by calculation to $P_{O_2}$, a downwards correction must be applied – simply due to hypothermia.

Bradyardia with ‘J’ waves (rounded waves above the isoelectric line at the junction of the QRS complex and ST segment) are pathognomonic of hypothermia. Prolongation of PR and QT intervals and QRS complex also occur. Ventricular dysrhythmias (tachycardia/fibrillation) or asystole are usually associated.

**Principles of hypothermia management**

- Maintain the patient horizontal, or slightly head down.
- Rewarm gradually.
- Correct metabolic abnormalities.
- Anticipate and treat dysrhythmias.
- Check for hypothyroidism (see p. 962).

If the patient is awake, with a core temperature of $>$32°C, place them in a warm room, use a foil wrap and give warm fluids orally. Outdoors, add extra dry clothing, huddle together and use a warmed sleeping bag. Rewarming may take several hours. Avoid alcohol: this adds to confusion, boosts confidence factitiously, causes peripheral vasodilatation and further heat loss, and can precipitate hypoglycaemia.

**Severe hypothermia**

In severe hypothermia, people look dead. Always exclude hypothermia before diagnosing brainstem death (see p. 897). Warm gradually, aiming at a 1°C/hour increase in $T_{Core}$. Direct mild surface heat from an electric blanket can be helpful. Treat any underlying condition promptly, e.g. sepsis. Monitor all vital functions. Correct dysrhythmias. Check for sedative drugs.

Give warm i.v. fluids slowly. Correct metabolic abnormalities. Hypothyroidism, if present, should be treated with liothyronine. Various methods of artificial rewarming exist – inhaled oxygen, various methods of heat and warm humidified air, gastric or peritoneal lavage, and haemodialysis. These are rarely used.

**Prevention**

Hypothermia in the field can often be prevented by forethought and action. For the elderly, improved home heating and insulation, central heating in bedrooms and electric blankets are helpful in cold spells. This can be expensive and unaffordable for some people, so supplemental finance is required.

**Cold injury**

**Frostbite**

Ice crystals form within skin and superficial tissues when the temperature of the tissue ($T_{Tissue}$) falls to $-3$°C. $T_{Env}$ generally must be below $-6$°C. Wind chill is frequently a factor. Typically, fingers, toes, nose and ears become frostbitten.

Frostbitten tissue is pale, greyish and initially doughy to touch. Later, tissue freezes hard, looking like meat from a freezer. Frostbite can easily occur when working or exercising in low temperatures and typically develops without the patient’s knowledge. Below $T_{Env}$ 5°C, hands or feet that have lost their feeling are at risk of cold injury.

**Management**

Transport the patient – or if this is impossible, make them walk, even on frostbitten feet – to a place of safety before commencing warming. Warm the frozen part by immersion in hand hot water at 39–42°C, if feasible. Assess hypothermia. Continue warming until obvious thawing occurs; this can be painful. Vasodilator drugs have no part in management. Blisters form within several days and, depending on the depth of frostbite, a blackened shell – the carapace – develops as blisters regress or burst. Dry, non-adherent dressings and aseptic precautions are essential, though hard to achieve. Frostbitten tissues are anaesthetic and at risk from further trauma and infection. Recovery takes place over many weeks, and may be incomplete. Surgery may be needed, but should be avoided in the early stages.

**Chilblains**

These are small, purplish itchy inflammatory lesions, occurring on toes and fingers. They occur in cold, wet conditions. They are more common in women and heal in 7–14 days. Prevention is by keeping warm and wearing gloves and warm footwear.

**Non-freezing cold injury (NFCI)**

NFCI (trench foot) describes tissue damage following prolonged exposure, usually for several hours or more, at $T_{Env}$ around or slightly above freezing, but without frostbite. Wet socks and boots are the usual cause. There is severe vasoconstriction, blotchiness of the lower limbs, with pain and oedema on rewarming. Recovery usually follows over several weeks. There may be prolonged late susceptibility to cold. NFCI is a prominent cause of morbidity in troops operating in low temperatures, and a subsequent cause of litigation.

Prevention of frostbite and NFCI is largely by education and common sense: avoid damp feet and wet boots. Always carry spare dry socks, gloves and headgear.

**HIGH ALTITUDES**

The partial pressure of atmospheric oxygen – and hence alveolar and arterial oxygen – falls in a near-linear relationship as barometric pressure falls with increasing altitude (Fig. 18.1).

![Figure 18.1 The decrease in oxygen and barometric pressure with increasing altitude.](image-url)
Commercial aircraft are pressurized to 2750 m (lowering the oxygen saturation by 3–4%). The incidence of deep venous thrombosis and pulmonary embolism is slightly greater in sedentary passengers on long-haul flights than in a similar population at sea level. Dehydration and alcohol probably contribute. Prophylactic aspirin is not recommended.

On land, below 3000 m there are few clinical effects. The resulting hypoxaemia causes breathlessness only in those with severe cardiorespiratory disease. Above 3000–3500 m hypoxia causes a spectrum of related syndromes that affect high-altitude visitors, principally climbers, trekkers, skiers and troops (Table 18.1), especially when they exercise. These conditions occur largely during acclimatization, a process that takes several weeks and once completed can enable man to live – permanently if necessary – up to about 5600 m. At greater heights, although people can survive for days or weeks, deterioration due to chronic hypoxia is inevitable.

The world’s highest railway is to Lhasa, reaching altitudes over 5000 m. Emergency oxygen is provided in the carriages. Roads at similar altitudes in central Asia are used extensively but since road passengers do not exercise, serious altitude-related illnesses are unusual. Climbing the world’s highest summits is just possible without supplementary oxygen, though it is often used on peaks above 7500 m. At the summit of Everest (8848 m) the barometric pressure is 34 kPa (253 mmHg). An acclimatized mountaineer has an alveolar PO\textsubscript{2} of 4.0–4.7 kPa (30–35 mmHg) – near man’s absolute physiological limit.

Acute mountain sickness (AMS)

AMS describes malaise, nausea, headache and lassitude and affects the majority of people for a few days, above 3500 metres. Following arrival at this altitude there is usually a latent interval of 6–36 hours before symptoms begin. Treatment is rest, with analgesics if necessary. Recovery is usually spontaneous over several days.

Prophylactic treatment with acetazolamide, a carbonic anhydrase inhibitor and a respiratory stimulant, is of some value in preventing AMS. Acclimatizing, i.e. ascending gradually, provides better and more natural prophylaxis.

In the minority, more serious sequelae – high-altitude pulmonary oedema and high-altitude cerebral oedema develop.

High-altitude pulmonary oedema

Predisposing factors include youth, rapidity of ascent, heavy exertion and severe AMS. Breathlessness, occasionally with frothy blood-stained sputum, indicates established oedema. Unless treated rapidly this leads to cardiorespiratory failure and death. Milder forms are common. Breathlessness at rest should raise the suspicion of pulmonary oedema.

### High-altitude cerebral oedema

Cerebral oedema is the result of abrupt increase in cerebral blood flow that occurs even at modest altitudes of 3500–4000 metres. It is unusual below 4500 metres, and occurs typically in the first 2 weeks, during acclimatization. Cerebral oedema can also develop suddenly in well-acclimatized climbers above 7000 metres. Headache is followed by drowsiness, ataxia and papilloedema, with coma and death if brain oedema progresses.

### Treatment

Any but the milder forms of AMS require urgent treatment. Oxygen should be given by mask if available, and descent should take place as quickly as possible. Nifedipine reduces pulmonary hypertension and is used in pulmonary oedema. Dexamethasone is effective in reducing brain oedema. Portable pressure bags inflated by a foot pump are widely used; the patient is enclosed in the bag.

### Retinal haemorrhages

Small flame haemorrhages within the retinal nerve fibre layer are common above 5000 metres, and usually symptomless. Rarely a haemorrhage will cover the macula, causing painless loss of central vision. Recovery is usual.

### Deterioration

Prolonged residence between 6000 and 7000 metres leads to weight loss, anorexia and listlessness after several weeks. Above 7500 metres, the effects of deterioration become apparent over several days, although it is possible to survive for a week or more at altitudes near 8000 metres without supplementary oxygen.

### Chronic mountain sickness

Chronic mountain sickness occurs in long-term residents at high altitudes, usually after several decades and is seen in the Andes and in central Asia.

Headache, polycythaemia, lassitude, cyanosis, finger clubbing, congested cheeks and ear lobes, and right ventricular enlargement develop. Chronic mountain sickness is gradually progressive. Coronary artery disease and hypertension are rare in high-altitude native populations.

### DIVING

Free diving by breath-holding is possible to around 5 metres, or with practice to greater depths. Air can be supplied to divers by various methods. With a snorkel, providing air to a depth of c. 0.5 metres, inspiratory effort is the limiting factor. At depths >0.5 metres, i.e. with a longer snorkel tube, forced negative-pressure ventilation can cause pulmonary capillary damage with haemorrhagic alveolar oedema. Scuba divers, i.e. recreational sports divers descending to 30 metres, carry bottled compressed air, or a nitrogen–oxygen mixture. Divers who work at great depths commercially breathe helium–oxygen or nitrogen–oxygen mixtures, delivered by hose from the surface. Ambient pressures at various depths are shown in Table 18.2.
Decompression problems do not only occur immediately on the chokes, but also in the form of other symptoms such as retrosternal discomfort, breathlessness and cough, which are known as neurological bends. At depths around 10 metres, around 10% of divers experience these symptoms. At around 700 metres, the CNS becomes affected, leading to symptoms such as apprehension, nausea, vomiting, vertigo, and in some cases, cortical blindness, with skin irritation and mottling and/or joint pain. Type 2, surface accidents occur when divers ascend too rapidly to the surface. Decompression tables indicate that at 1.5 atmospheres, at depths around 5 metres, the bends can begin. At around 10 atmospheres, at depths around 150 metres, severe neurological damage may persist, but complaints of fatigue and poor concentration are issues compounded by litigation that commonly follows diving accidents. Objective, evidence-based assessments are essential.

### Lung rupture, pneumothorax and surgical emphysema

These emergencies occur when divers breathe-hold during emergency ascents after gas supplies become exhausted. There is dyspnoea, cough and haemoptysis. Pneumothorax and surgical emphysema resolve with 100% oxygen. Air embolism can also occur and is treated with recompression.

### Problems during descent

**Middle ear barotrauma (squeeze)** is common and caused by inability to equalize pressure in the middle ear – Eustachian tube blockage is the usual cause. Pain and hearing loss occur, sometimes with tympanic membrane rupture and acute vertigo.

**Sinus squeeze** is intense local pain due to blockage of the nasal and paranasal sinus ostia.

**Treatment** is by holding the nostrils closed and swallowing, or similar manoeuvres – and decongestants. Diving with a respiratory or sinus infection should be avoided.

### Oxygen narcosis

Pure oxygen is not used for diving because of oxygen toxicity. Lung atelectasis, endothelial cell damage and pulmonary oedema occur when alveolar oxygen pressure exceeds 1.5 atmospheres, at depths around 5 metres. At around 10 atmospheres the CNS becomes affected: apprehension, nausea and sweating are followed by muscle twitching and generalized convulsions.

### Nitrogen narcosis

When compressed air is breathed below 30 metres, narcotic effects of nitrogen begin to impair brain function. Poor judgement is hazardous; this also occurs with nitrogen–oxygen mixtures in recreational diving. Nitrogen narcosis is avoided by replacing air with helium–oxygen mixtures, enabling descent to 700 metres. At these extreme depths, direct effect of pressure on neurones can cause tremor, hemiparesis and cognitive impairment.

### Problems during and following ascent

Free divers who breathe-hold often hyperventilate deliberately prior to plunging in. This drives off CO₂ – reducing the stimulus to inspire. During the subsequent breath-hold PICO₂ rises; PICO₂ falls. On surfacing, decompression lowers PICO₂ further. This can lead to syncope, known as a shallow water blackout. Since loss of consciousness can take place in the water, this can lead to fatalities.

### Decompression sickness

Decompression sickness (the bends) are caused by release of bubbles of nitrogen or helium and follow returning too rapidly to the surface. Decompression tables indicate the duration for safe return from a given depth to the surface. The bends can be mild (type 1, non-neurological bends), with skin irritation and motting and/or joint pain. Type 2, neurological bends, are more serious – cortical blindness, hemiparesis, sensory disturbances or cord lesions develop. If bubbles form in pulmonary vessels, divers experience retrosternal discomfort, breathlessness and cough, known as the chokes. These develop within minutes or hours of a dive. Decompression problems do not only occur immediately on reaching the surface, they may take some hours to become apparent. Over the subsequent 24 h, further ascent, e.g. air travel, can occasionally provoke the bends.

Other problems during ascent include paranasal sinus pain and nosebleeds – medically minor but dramatic, with exsanguinating pain and a mask full of bloody fluid. Toothache can be caused by gas bubbles within rotten fillings.

**Management.** All but the mildest forms of decompression sickness, e.g. skin motting alone, require recompression in a pressure chamber, following strict guidelines. Recovery is usually a long-term problem is aseptic necrosis of the hip due to nitrogen bubbles causing infarction. Focal neurological damage may persist, but complaints of fatigue and poor concentration are issues compounded by litigation that commonly follows diving accidents. Objective, evidence-based assessments are essential.

### Lung rupture, pneumothorax and surgical emphysema

These emergencies occur when divers breathe-hold during emergency ascents after gas supplies become exhausted. There is dyspnoea, cough and haemoptysis. Pneumothorax and surgical emphysema resolve with 100% oxygen. Air embolism can also occur and is treated with recompression.

### DROWNING AND NEAR-DROWNING

Drowning is a common cause of accidental death worldwide. In the UK, some 40% of drownings occur in children under 5 years of age. Drowning can also follow a seizure or a myocardial infarct. Exhaustion, alcohol, drugs and hypothermia all contribute to deaths following immersion.

#### Dry drowning

Between 10% and 15% of drownings occur without water aspiration into the lungs. Laryngeal spasm develops acutely, followed by apnoea and cardiac arrest.

#### Wet drowning

Fresh or seawater aspiration destroys pulmonary surfactant, leading to alveolar collapse, ventilation/perfusion mismatch and hypoxaemia. Aspiration of hypertonic seawater (5% NaCl) pulls additional fluid into the alveoli with further ventilation/perfusion mismatch. In practice, there is little difference between saltwater and freshwater aspiration. In both, severe hypoxaemia develops rapidly. Severe metabolic acidosis develops in the majority of survivors.

**Treatment and prognosis**

Cardiopulmonary resuscitation should be started immediately (see p. 691). Patients have survived for up to 30 minutes underwater without suffering brain damage – and sometimes for longer periods if Twater is near 10°C. Survival is probably related to the protective role of the diving reflex; submersion causes bradycardia and vasocostriction. Oxygen consumption is also decreased by hypothermia.

Resuscitation should always be attempted, even with absent pulse and fixed dilated pupils. Patients frequently make a dramatic recovery. All survivors should be admitted to hospital for intensive monitoring – lung injury can develop during the subsequent 48 hours. Recovery is frequently complete if consciousness is regained within several minutes of commencing resuscitation but poor if a patient remains stuporous or in coma at 30 minutes.

IONIZING RADIATION

Ionizing radiation is either penetrating (X-rays, γ-rays or neutrons) or non-penetrating (α- or β-particles). Penetrating radiation affects the skin and deeper tissues, while non-penetrating radiation affects the skin alone. All radiation effects depend on the type of radiation, the distribution of dose and the dose rate.

**Dosage** is measured in joules per kilogram (J/kg); 1 J/kg = 1 gray (1 Gy) = 100 rads.

**Radioactivity** is measured in becquerels (Bq). 1 Bq is defined as the activity of a quantity of radioactive material in which one nucleus decays per second; 3.7 × 10^10 Bq = one curie (Ci), the older, non-SI unit.

Radiation differs in the density of ionization it causes. Therefore a dose-equivalent called a sievert (Sv) is used. This is the absorbed dose weighted for the damaging effect of the radiation. The annual background radiation is approximately 2.5 mSv. A chest X-ray delivers 0.02 mSv, and CT of the abdomen/pelvis about 10 mSv (see Table 9.5). A cumulative risk of cancer following repeated imaging procedures has been established and reduction of X-ray exposures should be made if possible.

Excessive exposure to ionizing radiation follows accidents in industry, nuclear power plants and hospitals and deliberate nuclear explosions designed to eliminate populations – and in industry, nuclear power plants and hospitals and deliberate nuclear explosions designed to eliminate populations – and exceptionally, by poisoning, e.g. with polonium.

**Mild acute radiation sickness**

Nausea, vomiting and malaise follow doses of approximately 1 Gy. Lymphopenia occurs within several days, followed 2–3 weeks later by a fall in all white cells and platelets.

**Acute radiation sickness**

Many systems are affected; the extent depends on the dose of radiation (Table 18.3).

**Haemopoietic syndrome**

Absorption of 2–10 Gy is followed by transient vomiting in some individuals, followed by a period of improvement. Lymphocytes are particularly sensitive to radiation damage; severe lymphopenia develops over several days. A decrease in granulocytes and platelets follows 2–3 weeks later, since no new cells are formed in the marrow. Thrombocytopenia with bleeding develops and frequent overwhelming infections, with a high mortality.

**Gastrointestinal syndrome**

Doses >6 Gy cause vomiting several hours after exposure. This then stops, only to recur some 4 days later accompanied by diarrhoea. The villous lining of the intestine becomes denuded. Intractable bloody diarrhoea follows, with dehydration, secondary infection and sometimes death.

**CNS syndrome**

Exposures of >30 Gy are followed rapidly by nausea, vomiting, disorientation and coma. Death due to cerebral oedema can follow, usually within 36 hours.

**Radiation dermatitis**

Skin erythema, purpura, blistering and secondary infection occur. Total loss of body hair is a bad prognostic sign and usually follows an exposure >5 Gy.

**Late effects of radiation exposure**

Survivors of the nuclear bombing of Hiroshima and Nagasaki in 1945 provided data on long-term radiation effects. Risks of acute myeloid leukaemia and cancer, particularly of skin, thyroid and salivary glands, increase. Infertility, teratogenesis and cataract are also late sequelae, developing years after exposure.

The sequelae of therapeutic radiation – early, early-delayed and late-delayed radiation effects are discussed on page 448. Focussing techniques are used to target radiation towards the field being treated; radiosensitive structures such as the ovaries are protected by shielding.

**Treatment**

Acute radiation sickness is an emergency. Absorption of the initial radiation dose can be reduced by removing contaminated clothing.

Treatment is largely supportive – prevention and treatment of infection, haemorrhage and fluid loss. Harvesting of blood products is sometimes carried out.

Accidental ingestion of, or exposure to, bone-seeking radioisotopes (e.g. strontium-90 and caesium-137) are treated with chelating agents, e.g. EDTA and massive doses of oral calcium. Radioiodine contamination should be treated immediately with potassium iodide to block radioiodine absorption by the thyroid.

### ELECTRIC SHOCK

Electric shock can produce:

- **Pain and psychological sequelae.** The common domestic electric shock is typically painful, rarely fatal or followed by serious sequelae. Nevertheless, it is an unpleasant and intensely frightening experience. A brief immediate jerking episode can occur, that is not an epileptic seizure. There is usually no lasting neurological, cardiac or skin damage. More serious effects are distinctly rare following accidents in the home or in industry, but claims by survivors following industrial accidents are frequently made.

- **Cardiac, neurological and muscle damage.** Ventricular fibrillation, muscular contraction and spinal cord damage can follow a major shock. These are seen typically following lightning strikes with exceedingly high voltage and ampereage.

- **Electrical burns.** These are commonly restricted to the skin – non-fatal lightning strikes cause fern-shaped burns. Muscle necrosis and spinal cord damage can also occur.

- **Electrocution.** This means death following ventricular fibrillation, either accidentally, or deliberately as a
method of execution. In the USA, at executions an initial voltage of >2000 volts was applied for some 15 seconds in the electric chair, causing loss of consciousness and ventricular fibrillation before the voltage was lowered. The T_{Con} during the execution process would sometimes reach >50°C, leading to severe damage to internal organs.

**SMOKE**

Smoke is air containing toxic and/or irritant gases and carbon particles, coated with organic acids, aldehydes and synthetic materials. Carbon monoxide, sulphur dioxide, sulphuric and hydrochloric acids and other toxins may also be present. The highly toxic polyvinyl chloride is no longer used in household goods. Air pollution is discussed on page 807.

On smoke inhalation, patients become breathless and tachypnoeic immediately. Choking and stridor may require intubation. Pulmonary oedema and hypoxia can be fatal.

Breathing through a wet towel or clothing is the best emergency treatment. Remove the victim from the scene as rapidly as possible. Give oxygen, and arrange ITU support. **Prevention.** Smoke alarms should be in every household.

**NOISE**

Sound intensity is expressed as the square of sound pressure. The bel is the ratio equivalent to a 10-fold increase in sound intensity; a decibel (dB) is one-tenth of a bel. Sound is made up of a number of frequencies ranging from 30 Hz to 20 kHz, with most being between 1 and 4 kHz. In practice, a scale known as A-weighted sound is used; sound levels are reported as dB(A). A hazardous sound source is defined as one with an overall sound pressure of >90 dB(A).

Repeated prolonged exposure to loud noise, particularly between 2 and 6 kHz, causes first temporary and later permanent hearing loss, by physically destroying hair cells in the organ of Corti and, eventually, auditory neurones. Noise-induced hearing loss is a common occupational problem, not only in industry and the armed forces, but also in the home (drills and sanders), in sport (motor racing) and in entertainment (musicians, DJs and their audiences).

Serious noise-induced hearing loss is almost wholly preventable by personal protection (ear muffs, ear plugs). Little can be offered once hearing loss has become established.

**Other effects of noise**

Noise is intensely irritating, increasing or producing anxiety and anger. Excessive, repetitive noise is used in torture. Excess noise possibly affects child development and reading skills.

**BIOTERRORISM/BIOWARFARE**

Interest in biological warfare and bioterrorism intensified during the 1991 Iraq war and later following the destruction of the Twin Towers in New York in 2001. The potential of bacteria as weapons is illustrated by a suggestion that several kilograms of anthrax spores might kill as many people as a Hiroshima-sized nuclear weapon.

<table>

</tbody>
</table>

A simulated anthrax attack postulated release of anthrax powder from a truck passing a sports stadium with 74,000 spectators; 16,000 were estimated to have become infected, with a death rate of 25%. In Russia, following accidental release of anthrax from a bioweapons factory, the death rate was substantial in those nearby, especially downwind.

**Botulism**

The toxin produced by *Clostridium botulinum* is one of the most potent poisons known (see p. 86).

As a bioweapon, botulinum toxin could be transmitted in food or by air, e.g. from a crop-spraying light aircraft. The toxin is inactivated by chlorine in domestic water supplies. There is no vaccine available.

**Plague**

Plague (see p. 136) could be transmitted as a bioweapon either by air-borne dissemination or by infected rats. Immunization is of limited value.

Other potential infective agents are listed in Table 18.4.

**Emergency planning**

Many countries have plans to deal with bioterrorist attacks. These include training of healthcare staff and police. Such plans indicate the awareness of governments of the possibility of these threats. Stockpiling of vaccines, antibiotics and protective clothing is essential.

**TRAVEL**

**Motion sickness**

This common problem is caused by repetitive stimulation of the labyrinth. Motion sickness occurs frequently at sea and in cars (especially in children), but also with less usual forms of transport such as camels or elephants. Nowadays, motion sickness is rare during commercial flights, but it is a problem during space travel, and on airships – one reason why the airship industry has not flourished.

Nausea, sweating, dizziness, vertigo and profuse vomiting occur, accompanied by an irresistible desire to stop moving. Prostration and intense incapacitating malaise can develop, e.g. in seasickness.

Prophylactic antihistamines, vestibular sedatives (hyoscine or cinnarizine) and stem ginger are of some value.

**Jet-lag**

Jet-lag (circadian dyschronism) is the well-known phenomenon that follows travelling through time-zones, particularly from West to East. Intense insomnia, fatigue, poor concentration, irritability and loss of appetite are common. Headaches may occur. Symptoms last several days.

Mechanisms relate to the hypothalamic body clock within the suprachiasmatic nuclei. The clock is regulated by various zeitgebers (time-givers), e.g. light and melatonin.

Management of jet-lag includes its acceptance as a phenomenon causing poor performance – and thus waiting for 3–5 days to recover. Drink plenty of fluid, avoiding alcohol. Various hypnotics can help insomnia, but their value is disputed. Oral melatonin is widely used to reduce jet-lag but is not available on prescription in the UK. Melatonin probably hastens resetting the body clock.

**BUILDING-RELATED ILLNESSES**

**Nonspecific building-related illness**

Multi-storey buildings typically have a controlled environment, often with automated heating and air-conditioning, and without ready access to external ventilation. More than half the adult workforce in developed countries work in such offices.

Headache, fatigue and difficulty concentrating, sometimes in epidemics, are the main complaints – but have become less frequent. Psychological factors are thought to have a substantial role. Temperature, humidity, dust, volatile organic compounds, e.g. paints and solvents, and even low level carbon monoxide toxicity have all been blamed, none with any scientific foundation.

**Specific building-related illnesses**

**Legionnaires’ disease** (see p. 836) can follow contamination of air-conditioning systems.

**Humidifier fever** (see p. 854) is also due to contaminated systems, probably by fungi, bacteria and protozoa. Many common viruses are potentially transmissible in an enclosed environment, e.g. the common cold, influenza and rarely pulmonary TB. Allergic disorders, e.g. rhinitis, asthma and dermatitis, also occur following exposure to indoor allergens such as dust mites and plants. Office equipment, e.g. fumes from photocopiers, has also been implicated. Passive smoking (see p. 807) is no longer an issue in Europe and North America, following legislation against smoking.
INTRODUCTION

The endocrine system consists of glands that exert their actions at distant parts of the body via the production of biologically active hormones secreted into the bloodstream. Unlike the neurological system, which produces an immediate response, the endocrine system typically has a slower and longer lasting effect on the body. The main endocrine glands are the pituitary, thyroid, adrenals, gonads, parathyroids and pancreas and the common endocrine problems seen in clinical practice are shown in Figure 19.1. The pituitary gland, a pea-sized structure situated at the base of the brain, plays a key role in the control and feedback mechanisms of the endocrine system and has been termed the ‘conductor of the endocrine orchestra’.

Clinical presentation of endocrine disease

History

Hormones produce widespread effects in the body, and states of hormonal deficiency or excess typically present with symptoms that are generalized, diffuse and nonspecific. Symptoms of tiredness, weakness or lack of energy or drive and changes in appetite or thirst are common presentations. Other typical ‘hormonal’ symptoms include changes in body size and shape, problems with libido and potency, periods or sexual development, and changes in the skin (dry, greasy, acne, bruising, thinning or thickening) and hair (loss or excess). The differential diagnosis is often wide but endocrine disorders should be always considered when assessing a patient with any of these common complaints.

The past, family and social history is essential for making the diagnosis, planning appropriate management and interpreting results of borderline hormonal blood tests.

- The past history should include previous surgery or radiation involving endocrine glands, menstrual history, pregnancy and growth and development in childhood.
- A full drug history will exclude common iatrogenic endocrine problems (Table 19.1).
- A family history of autoimmune disease, endocrine disease including tumours, diabetes and cardiovascular disease is frequently relevant, and knowledge of family members’ height, weight, body habitus, hair growth and age of sexual development may aid interpretation of the patient’s own symptoms.

Examination

A full general examination is essential to endocrine assessment because endocrine disorders affect all organ systems. Weight, height, body mass index (BMI), blood pressure and general habitus should all be documented, together with presence or absence of specific signs of deficiency or excess of individual hormone axes (signs of hyper- or hypothyroidism, acromegaly, Cushing’s).

In people with suspected pituitary disease, visual fields and adjacent cranial nerves should be assessed clinically. In thyroid disease, presence of goitre or thyroid eye disease

should be documented. Skin changes may give clinical clues, including pigmentation (Addison’s and Nelson’s), vitiligo (autoimmune endocrinopathies), acanthosis nigricans (polycystic ovary syndrome (PCOS) and diabetes), skin thinning (Cushing’s, hypogonadism) or thickening (acromegaly, PCOS) and bruising and striae (Cushing’s). Hirsutism is a key sign in women and signs of hair loss from the head (following a change in thyroid function, androgen excess in women or normal virilization in men) or from the body, axillary and pubic areas (hypogonadism) may occur in both sexes.

In children, height and pubertal status are an essential part of the clinical examination.

Specific clinical signs associated with particular endocrine diseases are discussed in detail in the appropriate sections.

Common endocrine conditions

The most common endocrine disorders, excluding obesity (Ch. 5) and diabetes mellitus (Ch. 20), are:

- Thyroid disorders: hypothyroidism, hyperthyroidism, goitre
- Menstrual disorders
- Hirsutism, usually due to polycystic ovary syndrome
- Subfertility
- Osteoporosis and metabolic bone disease
- Disorders of growth or puberty.

While most other endocrine conditions are uncommon, they often affect young people and are usually curable or completely controllable with appropriate therapy.

Aetiology of endocrine disease

Aetiological mechanisms common to many endocrine disorders include:

Autoimmune disease

Organ-specific autoimmune diseases can affect every major endocrine organ (Table 19.2). They are characterized by the presence of specific antibodies in the serum, often present years before clinical symptoms are evident, are usually more common in women and have a strong genetic component, often with an identical-twin concordance rate of 50% and with HLA associations (see individual diseases). Several of the autoantigens have been identified.

Endocrine tumours

Most endocrine tumours are benign, although a cytological or histological diagnosis may be needed if there is clinical or radiological suspicion of malignancy. Clinical presentation depends on whether the tumour is functional or non-functional, the latter presenting only as a mass clinically or on imaging. Palpable thyroid nodules are common, and mass effects are a frequent presentation of pituitary adenomas, but the increased use of high-resolution ultrasound and detailed cross-sectional imaging has revealed a very high prevalence of asymptomatic, incidentally-discovered thyroid, adrenal and pituitary lesions, commonly termed ‘incidentalomas’ (see p. 989).

Functional tumours cause their effects via excess secretion of the relevant hormone. While often considered to be ‘autonomous’, i.e. independent of the physiological control mechanisms, many functional tumours do show evidence of feedback occurring at a higher ‘set-point’ than normal (e.g. ACTH secretion from a pituitary basophil adenoma). This is relevant in the dynamic assessment of endocrine diseases such as in the differential diagnosis of Cushing’s syndrome.

Endocrine adenomas typically present in a single gland, although rarer multiple endocrine neoplasia (MEN) syndromes exist due to very specific mutations of a single gene, such as the mutations of the RET proto-oncogene in MEN 2 or the MEN1 gene mutation in MEN 1 (see p. 997).

Enzyme defects

The biosynthesis of most hormones involves many stages. Deficient or abnormal enzymes can lead to absent or reduced production of the secreted hormone. In general, severe deficiencies present early in life with obvious signs; partial

deficiencies usually present later with mild signs or are only evident under stress. An example of an enzyme deficiency is congenital adrenal hyperplasia (CAH), where the molecular basis has also been identified as mutations or deletions of the gene encoding the relevant enzymes (see p. 987).

Receptor abnormalities

There are rare conditions in which hormone secretion and control are normal but the receptors are defective; thus, if androgen receptors are defective, normal levels of androgen will not produce masculinization (e.g. testicular feminization). There are also a number of rare syndromes of diabetes and insulin resistance from receptor abnormalities (see p. 1006); other examples include nephrogenic diabetes insipidus, pseudohypoparathyroidism and thyroid hormone resistance which can cause an unusual pattern of thyroid blood results.

HORMONAL ACTIVITY

Synthesis, storage and release of hormones

Hormones may be of several chemical structures: polypeptide, glycoprotein, steroid or amine. Hormone release is the end-product of a long cascade of intracellular events. In the case of polypeptide hormones, neural or endocrine stimulation of the cell leads to increased transcription from DNA to a specific mRNA, which is in turn translated to the peptide product. This is often in the form of a precursor molecule that may itself be biologically inactive. This ‘prohormone’ is then further processed before being packaged into granules, in the Golgi apparatus. These granules are then transported to the plasma membrane before release, which is itself regulated by a complex combination of intracellular regulators. Hormone release may be in a brief spurt caused by the sudden stimulation of granules, often induced by an intracellular Ca2+-dependent process, or it is ‘constitutive’ (immediate and continuous secretion).

Plasma transport

Most classical hormones are secreted into the systemic circulation. In contrast, hypothalamic releasing hormones are released into the pituitary portal system so that much higher concentrations of the releasing hormones reach the pituitary than occur in the systemic circulation.

Many hormones are bound to proteins within the circulation. In most cases, only the free (unbound) hormone is available to the tissues and thus biologically active. This binding serves to buffer against very rapid changes in plasma levels of the hormone, and some binding protein interactions are also involved in the active regulation of hormone action. Many tests of endocrine function measure total rather than free hormone, which can give rise to difficulties in interpretation when binding proteins are altered in disease states or by drugs.

Binding proteins comprise both specific, high-affinity proteins of limited capacity, such as thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), sex-hormone-binding globulin (SHBG) and IGF-binding proteins (e.g. IGF-BP3) and other less specific, low-affinity ones, such as prealbumin and albumin.

Hormone action and receptors

Hormones act by binding to specific receptors in the target cell. Most hormone receptors are proteins with complex tertiary structures. The structure of the hormone-binding domain of the receptor complements the tertiary structure of the hormone, while changes in other parts of the receptor in response to hormone binding are responsible for the effects of the activated receptor within the cell. The structure of common hormones and their receptors is described under individual hormone axes.

Hormone receptors are broadly divided into:

- **Cell surface or membrane receptors**: typically transmembrane receptors which contain hydrophobic sections spanning the lipid-rich plasma membrane and which trigger internal cellular messengers (see also p. 18)
- **Nuclear receptors** which typically bind hormones and translocate them to the nucleus where they bind hormone response elements of nuclear DNA via characteristic amino-acid sequences (e.g. so-called ‘zinc fingers’, see p. 27).

Abnormal receptors are an occasional cause of endocrine disease (see p. 43).

Mechanisms of hormone-receptor action

Common structural mechanisms of hormone-receptor action are illustrated in Figure 2.9 (p. 25) and include:

- **G-protein coupled receptors** (7-transmembrane or serpentine receptors). These bind hormones on their extracellular domain and activate the membrane G-protein complex with their intracellular domain. The activated complex may then:
  - stimulate cyclic AMP (cAMP) generation by adenylate cyclase – activating further intracellular kinases and leading to phosphorylation
  - activate phospholipase C (PLC) leading to generation of inositol 1,4,5-triphosphate (IP₃) and release of intracellular calcium – in turn leading to calmodulin-dependent kinase activity and phosphorylation
  - lead to diacylglycerol (DAG) activation of C-kinase and subsequent protein phosphorylation.

Most peptide hormones act via G-protein coupled receptors.

- **Dimeric transmembrane receptors**, from several receptor superfamilies, bind hormone in their extracellular components (sometimes causing the dimerization of the receptor monomer) and directly phosphorylate intracellular messengers via their intracellular components, leading to a variety of intracellular activation cascades. Growth hormone, prolactin and insulin-like growth factor-1 (IGF-1) act via this type of receptor.

**Lipid-soluble molecules** pass through the cell membrane and typically bind with their **nuclear receptors** in the cell cytoplasm before translocation of the activated hormone-receptor complex to the nucleus where it binds to nuclear DNA, often in combination with a multi-component complex of promoters, inhibitors and transcription factors. This interaction usually leads to increased transcription of the relevant gene product. Steroid and thyroid hormones act via this type of receptor.

**Hormone release and binding to receptors.** The activation of intracellular kinases, phosphorylation, release of intracellular calcium and other ‘second messenger’ pathways and the direct stimulation of DNA transcription results in some or all of the following:

- **Stimulation or release of pre-formed hormone from storage granules**
- **Stimulation or synthesis of hormone and other cellular components**
Opening or closing of ion or water channels in the cell membrane (e.g. calcium channels or aquaporin water channels)

Activation or deactivation of other DNA binding proteins leading to stimulation or inhibition of DNA transcription.

In each case, binding of the hormone to its receptor is the first step in a complex cascade of interrelated intracellular events which eventually lead to the overall effects of that hormone on cellular function.

**The sensitivity and/or number of receptors** for a hormone are often decreased after prolonged exposure to a high hormone concentration, the receptors thus becoming less sensitive (‘downregulation’, e.g. angiotensin II receptors, β-adrenoceptors). The reverse is true when stimulation is absent or minimal, the receptors showing increased numbers or sensitivity (‘upregulation’).

**Control and feedback**

Most hormone systems are under tight regulatory control (typically by the hypothalamo-pituitary (HP) axis) by a system known as negative feedback. An example of the negative feedback system in the hypothalamo-pituitary-thyroid axis is demonstrated in Figure 19.2 and described here:

- TRH (thyrotrophin-releasing hormone) is secreted in the hypothalamus and travels via the portal system to the pituitary where it stimulates the thyrotrophs to produce thyroid-stimulating hormone (TSH).
- TSH is secreted into the systemic circulation where it stimulates increased thyroidal iodine uptake by the thyroid and the synthesis and release of thyroxine (T4) and triiodothyronine (T3).
- Serum levels of T3 and T4 are increased by TSH; in addition, the conversion of T4 to T3 (the more active hormone) in peripheral tissues is stimulated by TSH.
- T3 and T4 then enter cells where they bind to nuclear hormone receptors and promote increased metabolic and cellular activity.
- Levels of T3, from the blood and from local conversion of T4, are sensed by receptors in the pituitary and the hypothalamus. If they rise above normal, TRH and TSH production is suppressed, leading to reduced T3 and T4 secretion.
- Peripheral T3 and T4 levels fall to normal.
- If, however, T3 and T4 levels are low, for example after thyroidectomy, increased amounts of TRH and TSH are secreted, stimulating the remaining thyroid to produce more T3 and T4; blood levels of T3 and T4 may be restored to normal, at the expense of increased TSH drive, reflected by a high TSH level, ‘compensated euthyroidism’.
- Conversely, in thyrotoxicosis when factors other than TSH itself are maintaining high T3 and T4 levels, the same mechanisms lead to suppression of TSH secretion.

**Primary and secondary gland failure**

It is useful in clinical endocrinology to distinguish between ‘primary’ disease of the end-organ gland (e.g. due to autoimmune destruction, atrophic change, infiltration or surgical removal of the gland), and ‘secondary’ disorders of the same axis caused by disease of the pituitary gland. An understanding of the negative feedback system is key to interpreting endocrine blood results and diagnosing the site of the disease process in clinical practice. In general terms:

- **‘Primary’ hormone deficiency** due to a disease process in the endocrine end-organ (thyroid, adrenal or gonad) will lead to a loss of negative feedback and subsequent elevation in the corresponding anterior pituitary hormone. Conversely, an abnormal hormone excess due to a disease process in the primary endocrine gland, or excess amount of exogenous hormone, will lead to increased negative feedback and suppression of the corresponding pituitary hormones.
- In **‘secondary gland failure’** there are low or ‘inappropriately normal’ levels of the pituitary trophic hormone in the face of a low end-organ hormone level. For example, if a patient has low circulating free T3 (fT3) and T4 levels in the context of a low TSH, pituitary disease should be suspected. Equally, the presence of a non-suppressed plasma ACTH in the context of Cushing’s syndrome implies that the pituitary rather than the adrenal itself is the cause.

**Hormone resistance**

In certain situations, receptor abnormalities can give rise to abnormal negative feedback due to hormone resistance, which can lead to an unusual pattern of blood results. For example, thyroid hormone resistance, due to mutations in the thyroid hormone receptor, is characterized by an elevation in thyroid hormones with a non-suppressed TSH. With this pattern of thyroid results, the clinician should also consider the rare diagnosis of a TSH secreting pituitary tumour.
Measurement of hormones

Hormones are measured in routine clinical practice by biochemical assays in the laboratory. It is possible to measure pituitary trophic hormones and the hormones produced by the end-organ glands, but hypothalamic hormones are not routinely measured in practice because of their low concentration and local action within the hypothalamo-pituitary axis. Circulating levels of most hormones are very low (10⁻¹⁰–10⁻¹⁵ mol/L) and cannot be measured by simple chemical techniques. Hormones are therefore usually measured by immunoassays, which rely on highly specific polyclonal or monoclonal antibodies, which bind to the hormone being measured during the assay incubation. This hormone-antibody interaction is measured by use of labelled hormone after separation of bound and free fractions (Fig. 19.3).

Immunooassays are sensitive but have limitations. In particular, the immunological activity of a hormone, as used in developing the antibody, may not necessarily correspond to biological activity and there may be false positive and negative results. The patient’s blood may also contain heterophile antibodies which interact with the animal antibodies used in the assay, and result in falsely low or high values. When there is a discrepancy between endocrine blood results and the clinical presentation, the clinician must question the validity of an endocrine result, and a close relationship with the relevant laboratory is essential. It may be necessary for the sample to be measured in a different laboratory using an alternative antibody, or to measure hormones in ways other than by immunooassay. Examples of alternative techniques to accurately quantify and characterize hormone levels include equilibrium dialysis, high-pressure liquid chromatography (HPLC) and, increasingly, mass spectroscopy.

Hormone binding proteins

Many hormones are transported in the bloodstream from the primary gland to their distant target organ attached to a specific binding protein (p. 940). It is more helpful to measure the free hormone rather than total bound hormone level, as this is the part that is biologically active. Some modern assays attempt to measure the free hormone level directly (e.g. free T₄) and are therefore a more accurate reflection of biological activity, although there are often technical problems with this approach and many assays still measure total hormone level.

Cortisol, which is bound to cortisol binding globulin (CBG), and testosterone, which is bound to sex hormone binding globulin (SHBG), are still usually measured in their total form and can be affected by alterations in binding protein levels. In women who are pregnant or on the combined oral contraceptive pill, high oestrogen levels may lead to an elevation in CBG which can overestimate cortisol and give the false impression of hypercortisolaemia. In people with diabetes mellitus or other insulin-resistant states which may lower SHBG levels, low total testosterone levels may give the false impression of androgen deficiency. Conversely, hyperthyroidism or oestrogen excess can cause an elevation in SHBG, leading to apparently high total testosterone levels. As with all endocrine results, the data need to be interpreted in the clinical context.

Patterns of hormonal secretion

Hormone secretion can be continuous or intermittent, for example:

- **Continuous secretion** is shown by the thyroid hormones, with a half-life of 7–10 days for T₄ and 6–10 hours for T₃, and with little variation in levels over the day, month and year.
- **Pulsatile secretion** is the normal pattern for the gonadotrophins, LH and FSH, with major pulses released every 1–2 hours depending on the phase of the menstrual cycle. Growth hormone is also secreted in a pulsatile fashion, with undetectable levels in between pulses. A single measurement is therefore not helpful to diagnose GH deficiency or excess.

Biological rhythms

*Circadian* means changes over the 24 hours of the day–night cycle and is best shown for the pituitary–adrenal axis. Figure 19.4 shows plasma cortisol levels measured over 24 hours – levels are highest in the early morning and lowest overnight. Additionally, cortisol release is pulsatile, following the pulsatility of pituitary ACTH. Thus ‘normal’ cortisol levels vary during the day and great variations can be seen in samples taken only 30 minutes apart.

The menstrual cycle is an example of a longer and more complex (28-day) biological rhythm (see p. 972).

Other regulatory factors

- **Stress.** Physiological ‘stress’ and acute illness produce rapid increases in ACTH and cortisol, growth hormone (GH), prolactin, adrenaline (epinephrine) and noradrenaline (norepinephrine). These can occur within seconds or minutes.
- **Sleep.** Secretion of GH and prolactin is increased during sleep, especially the rapid eye movement (REM) phase.
- **Feeding and fasting.** Many hormones regulate the body’s control of energy intake and expenditure and are
The healthy results may prove uninterpretable. For these hormones, all relevant details must be recorded or renin/aldosterone vary with sodium intake, posture and age. and progesterone vary with time of menstrual cycle and normal low levels of cortisol at this time). LH/FSH, oestrogen (typically at 08:00 to 10:00 but, e.g. at 24:00 to demonstrate dian rhythm (testosterone in men, cortisol, ACTH, 17

diet or posture concerned. Hormones with a marked circa-

with respect to normal ranges for the time of day/month, therefore profoundly influenced by feeding and fasting. Secretion of insulin is increased and growth hormone decreased after ingestion of food, and secretion of a number of hormones is altered during prolonged food deprivation.

**TESTING ENDOCRINE FUNCTION**

Endocrine function is assessed by measurement of hormone levels in blood (or more precisely in plasma or serum) and sometimes in other body fluids on samples obtained basally and in response to stimulation and suppression tests.

**Basal blood levels**

Assays for all clinically relevant pituitary and end-organ hormones are available.

The time, day and condition of measurement make great differences to hormone levels, and the method and timing of samples therefore depends upon the characteristics of the endocrine system involved. There are also sex, developmental and age differences.

Basal levels are especially useful for systems with long half-lives (e.g. T₄ and T₃, IGF-1, androstenedione, SHBG). These vary little over the short term and random samples are therefore satisfactory.

Basal samples for many hormones need to be interpreted with respect to normal ranges for the time of day/month, diet or posture concerned. Hormones with a marked circadian rhythm (testosterone in men, cortisol, ACTH, 17αOH-progesterone) must be measured at appropriate time of day (typically at 08:00 to 10:00 but, e.g. at 24:00 to demonstrate normal low levels of cortisol at this time). LH/FSH, oestrogen and progesterone vary with time of menstrual cycle and renin/aldosterone vary with sodium intake, posture and age. For these hormones, all relevant details must be recorded or the results may prove uninterpretable.

**Stress-related hormones**

Measurement of stress-related hormones may be problematic either because the patient is stressed by hospital attendance or venepuncture, leading to falsely high levels (e.g. catecholamines, prolactin where sampling via an indwelling needle some time after initial venepuncture may be required) or because low levels in a non-stressed individual are unable to confirm an adequate reserve required for normal physiological stress (cortisol and GH).

**Urine collections**

Collections over 24 hours have the advantage of providing an ‘integrated mean’ of a day’s secretion but in practice are often incomplete or wrongly timed. They also vary with sex and body size or age. Written instructions should be provided for the patient to ensure accurate collection. Examples of hormones measured in this way are catecholamines and urinary free cortisol levels.

**Saliva**

Saliva is sometimes used for steroid estimations, especially in children or for samples taken at home. Midnight salivary cortisol levels are increasingly used for the diagnosis of Cushing’s syndrome due to the practical difficulties in obtaining a midnight blood sample.

**Stimulation and suppression tests**

These tests are used when basal levels give equivocal information. In general, stimulation tests are used to confirm suspected deficiency, and suppression tests to confirm suspected excess of hormone secretion. These tests are valuable in many instances.

For example, where the secretory capacity of a gland is damaged, maximal stimulation by the trophic hormone will give a diminished output. Thus, in the short ACTH stimulation test for adrenal reserve (Box 19.1, Fig. 19.5a), the healthy subject shows a normal response while the subject with primary hypoadrenalism (Addison’s disease) demonstrates an impaired cortisol response to tetracosactide (an ACTH analogue).

A patient with a hormone-producing tumour usually fails to show normal negative feedback. A patient with Cushing’s disease (excess pituitary ACTH) will thus fail to suppress ACTH and cortisol production when given a dose of synthetic steroid, in contrast to normal subjects. Figure 19.5b shows the response of a normal subject given dexamethasone 1 mg at midnight; cortisol is suppressed the following morning. The subject with Cushing’s disease shows inadequate suppression.

The detailed protocol for each test must be followed exactly, since differences in technique will produce variations in results.
THE PITUITARY GLAND AND HYPOTHALAMUS

Anatomy
Most peripheral hormone systems are controlled by the hypothalamus and pituitary. The hypothalamus is sited at the base of the brain around the third ventricle and above the pituitary stalk, which leads down to the pituitary itself, carrying the hypophyseal-pituitary portal blood supply.

The anatomical relations of the hypothalamus and pituitary (Fig. 19.6) include the optic chiasm just above the pituitary fossa; any expanding lesion from the pituitary or hypothalamus can thus produce visual field defects by pressure on the chiasm. Such upward expansion of the gland through the diaphragma sellae is termed ‘suprasellar extension’. Lateral extension of pituitary lesions may involve the vascular and nervous structures in the cavernous sinus and may rarely reach the temporal lobe of the brain. The pituitary is itself encased in a bony box, therefore any lateral, anterior or posterior expansion must cause bone erosion.

Embryologically, the anterior pituitary is formed from an upgrowth of Rathke’s pouch (ectodermal) which meets an outpouching of the third ventricular floor which becomes the posterior pituitary. This unique combination of primitive gut and neural tissue provides an essential link between the rapidly responsive central nervous system and the longer-acting endocrine system. Several transcription factors – LHX3, HESX1, PROP1, POU1F1 – are responsible for the differentiation and development of the pituitary cells. Mutation of these produces pituitary disease.

Physiology
Hypothalamus
This contains many vital centres for such functions as appetite, thirst, thermal regulation and sleeping/waking. It acts as an integrator of many neural and endocrine inputs to control the release of pituitary hormone-releasing factors. It plays a role in the circadian rhythm, menstrual cyclicity, and responses to stress, exercise and mood.

Hypothalamic neurones secrete pituitary hormone-releasing and -inhibiting factors and hormones (Table 19.3) into the portal system which run down the stalk to the pituitary. As well as the classical hormones illustrated in Figure 19.7, the hypothalamus also contains large amounts of other neuropeptides and neurotransmitters such as neuropeptide Y, vasoactive intestinal peptide (VIP) and nitric oxide that can also alter pituitary hormone secretion.

Synthetic hypothalamic hormones and their antagonists are available for the testing of many aspects of endocrine function and for treatment.

Anterior pituitary
The majority of anterior pituitary hormones are under predominantly positive control by the hypothalamic releasing hormones apart from prolactin, which is under tonic inhibition by dopamine. Pathological conditions interrupt the flow of hormones between the hypothalamus and pituitary gland and therefore cause deficiency of most hormones but oversecretion of prolactin. There are five major anterior pituitary axes: the gonadotrophin axis, the growth axis, prolactin, the thyroid axis and the adrenal axis.

Posterior pituitary
The posterior pituitary is neuro-anatomically connected to specific hypothalamic nuclei, and acts merely as a storage organ. Antidiuretic hormone (ADH, also called vasopressin) and oxytocin, both nonapeptides, are synthesized in the supraoptic and paraventricular nuclei in the anterior hypothalamus. They are then transported along the axon and stored in the posterior pituitary (Fig. 19.7). This means that damage

to the stalk or pituitary alone does not prevent synthesis and release of ADH and oxytocin. ADH is discussed on page 991; oxytocin produces milk ejection and uterine myometrial contraction.

**PRESENTATIONS OF PITUITARY AND HYPOTHALAMIC DISEASE**

Diseases of the pituitary can cause under- or overactivity of each of the hypothalamo-pituitary-end-organ axes which are under the control of this gland. The clinical features of the syndromes associated with such altered pituitary function, e.g. Cushing’s syndrome, can be the presenting symptom of pituitary disease or of end-organ disease and are discussed later. First, however, we look at clinical features of pituitary disease which are common to all hormonal axes.

**Pituitary space-occupying lesions and tumours**

Pituitary tumours (Table 19.4) are the most common cause of pituitary disease, and the great majority of these are benign pituitary adenomas, usually monoclonal in origin. Problems are caused by:

- local effects of a tumour
- excess hormone secretion
- the result of inadequate production of hormone by the remaining normal pituitary, i.e. hypopituitarism.

**Investigations (of a possible or proven mass)**

- Is there a tumour?

If there is, how big is it and what local anatomical effects is it exerting? Pituitary and hypothalamic space-occupying lesions, hormonally active or not, can cause symptoms by pressure on, or infiltration of:

- the visual pathways, with field defects and visual loss (most common)
- the cavernous sinus, with III, IV and VI cranial nerve lesions
- bony structures and the meninges surrounding the fossa, causing headache
- hypothalamic centres: altered appetite, obesity, thirst, somnolence/wakefulness or precocious puberty
- the ventricles, causing interruption of cerebrospinal fluid (CSF) flow leading to hydrocephalus
- the sphenoid sinus with invasion causing CSF rhinorrhoea.

**Investigations**

- **MRI of the pituitary.** MRI is superior to CT scanning (Fig. 19.8) and will readily show any significant pituitary mass. Small lesions within the pituitary fossa on MRI consistent with small pituitary microadenomas are very common (10% of normal individuals in some studies). Such small lesions are sometimes detected during MRI scanning of the head for other reasons – so-called ‘pituitary incidentalomas’.

- **Visual fields.** These should be plotted formally by automated computer perimetry or Goldmann perimetry, but clinical assessment by confrontation using a small red pin as target is also sensitive and valuable. Common defects are upper temporal quadrantanopia and bitemporal hemianopia (see p. 1073).

- **Is there a hormonal excess?**

There are three major conditions usually caused by secretion from pituitary adenomas which will show positive immuno-staining for the relevant hormone:

- Prolactin excess (prolactinoma or hyperprolactinaemia): histologically, prolactinomas are ‘chromophobe’ adenomas (a description of their appearance on classical histological staining)

- **GH excess (acromegaly or gigantism):** somatotroph adenomas, usually ‘acidophil’, and sometimes due to specific G-protein mutations (see p. 945)
Treatment depends on the type and size of tumour (Table 19.5). In general, therapy has three aims:

**Removal/control of tumour**
- **Surgery** via the trans-sphenoidal route is usually the treatment of choice. Very large tumours are occasionally removed via the open transcranial (usually transfrontal) route.
- **Radiotherapy** – by conventional linear accelerator or newer stereotactic techniques – is usually employed when surgery is impracticable or incomplete, as it controls but rarely abolishes tumour mass. The conventional regimen involves a dose of 45 Gy, given as 20–25 fractions via three fields. Stereotactic techniques use either a linear accelerator or multiple cobalt sources (“gamma-knife”).
- **Medical therapy** with somatostatin analogues and/or dopamine agonists sometimes causes shrinkage of specific types of tumour (see p. 954) and if successful can be used as primary therapy.

**Reduction of excess hormone secretion**
Reduction is usually obtained by surgical removal but sometimes by medical treatment. Useful control can be achieved

**Figure 19.8** (a) Coronal MRI of pituitary, showing a left-sided lucent intrasellar microadenoma (arrowed). The pituitary stalk is deviated slightly to the right. (b) Coronal MRI of pituitary, showing macroadenoma with moderate suprasellar extension, and lateral extension compressing left cavernous sinus. The top of the adenoma is compressing the optic chiasm (arrowed). (c) Sagittal MRI of head, showing a pituitary macroadenoma with massive suprasellar extension (arrows).
with dopamine agonists for prolactinomas or somatostatin analogues for acromegaly, but ACTH secretion usually cannot be controlled by medical means. Growth hormone antagonists are also available for acromegaly (p. 955).

**Replacement of hormone deficiencies**
Replacement of hormone deficiencies, i.e. hypopituitarism, is discussed below (see Table 19.8).
Small tumours producing no significant symptoms, pressure or endocrine effects may be observed with appropriate clinical, visual field, imaging and endocrine assessments.

**Differential diagnosis of pituitary or hypothalamic masses**
Although pituitary adenomas are the most common mass lesion of the pituitary (90%), a variety of other conditions may also present as a pituitary or hypothalamic mass and form part of the differential diagnosis.

**Other tumours**
- **Craniopharyngioma** (1–2%), a usually cystic hypothalamic tumour, often calcified, arising from Rathke’s pouch, often mimics an intrinsic pituitary lesion. It is the most common pituitary tumour in children but may present at any age.
- **Uncommon tumours** include meninomias, gliomas, chondromas, germinomas and pinealomas. Primary pituitary carcinomas are very rare, but occasionally prolactin and ACTH secreting tumours can present in an aggressive manner which may require chemotherapy in addition to conventional treatment. Secondary deposits occasionally present as apparent pituitary tumours, typically presenting with headache and diabetes insipidus.

**Hypophysitis and other inflammatory masses**
A variety of inflammatory masses occur in the pituitary or hypothalamus. These include rare pituitary-specific conditions (e.g. autoimmune [lymphocytic] hypophysitis, giant cell hypophysitis, postpartum hypophysitis) or pituitary manifestations of more generalized disease processes (sarcoidosis, Langerhans’ cell histiocytosis, Wegener’s granulomatosis). These lesions may be associated with diabetes insipidus and/or an unusual pattern of hypopituitarism.

**Other lesions**
Carotid artery aneurysms may masquerade as pituitary tumours and must be diagnosed before surgery. Cystic lesions may also present as a pituitary mass, including arachnoid and Rathke cleft cysts.

**Hypopituitarism**

**Pathophysiology**
Deficiency of hypothalamic releasing hormones or of pituitary tropic hormones can be selective or multiple. Thus isolated deficiencies of GH, LH/FSH, ACTH, TSH and vasopressin (ADH) are all seen, some cases of which are genetic and congenital and others sporadic and autoimmune or idiopathic in nature.

Multiple deficiencies usually result from tumour growth or other destructive lesions. There is generally a progressive loss of anterior pituitary function. GH and gonadotrophins are usually first affected. Hyperprolactinaemia, rather than prolactin deficiency, occurs relatively early because of loss of tonic inhibitory control by dopamine. TSH and ACTH are usually last to be affected.

**Panhypopituitarism** refers to deficiency of all anterior pituitary hormones; it is most commonly caused by pituitary tumours, surgery or radiotherapy. Vasopressin (ADH) and oxytocin secretion will be significantly affected only if the hypothalamus is involved by a hypothalamic tumour or major suprasellar extension of a pituitary lesion, or if there is an infiltrative/inflammatory process. Posterior pituitary deficiency is rare in an uncomplicated pituitary adenoma.

**Genetics of hypopituitarism**
Specific genes are responsible for the development of the anterior pituitary involving interaction between signalling
molecules and transcription factors. For example, mutations in PROP1 and POU1F1 (previously PIT-1) prevent the differentiation of anterior pituitary cells (precursors to somatotroph, lactotroph, thyrotroph and gonadotroph cells), leading to deficiencies of GH, prolactin, TSH and GnRH. In addition, novel mutations within GH and GHRH receptor genes have been identified which may explain the pathogenesis of isolated GH deficiency in children. Despite these advances, most cases of hypopituitarism do not have specific identifiable genetic causes.

**Causes**

Disorders causing hypopituitarism are listed in Table 19.6. Pituitary and hypothalamic tumours, and surgical or radiotherapy treatment, are the most common.

**Clinical features**

Symptoms and signs depend upon the extent of hypothalamic and/or pituitary deficiencies, and mild deficiencies may not lead to any complaint by the patient. In general, symptoms of deficiency of a pituitary-stimulating hormone are the same as primary deficiency of the peripheral endocrine gland (e.g. TSH deficiency and primary hypothyroidism cause similar symptoms due to lack of thyroid hormone secretion).

- **Secondary hypothyroidism and adrenal failure** both lead to tiredness and general malaise.
- **Hypothyroidism** causes weight gain, slowness of thought and action, dry skin and cold intolerance.
- **Hypoadrenalism** causes mild hypotension, hyponatraemia and ultimately cardiovascular collapse during severe intercurrent stressful illness.

- **Gonadotrophin** and thus **gonadal deficiencies** lead to loss of libido, loss of secondary sexual hair, amenorrhoea and erectile dysfunction.
- **Hyperprolactinaemia** may cause galactorrhoea and hypogonadism.
- **GH deficiency** causes growth failure in children and impaired wellbeing in some adults.
- **Weight may increase** (due to hypothyroidism, see above) or decrease in severe combined deficiency (pituitary cachexia).

- Longstanding **panhypopituitarism** gives the classic picture of pallor with hairlessness (‘alabaster skin’).

**Particular syndromes related to hypopituitarism** are:

- **Kallmann’s syndrome.** This is isolated gonadotrophin (GnRH) deficiency (p. 976). This syndrome arises due to mutations in the KAL1 gene which is located on the short (p) arm of the X chromosome. Kallmann’s is classically characterized by anosmia because the KAL1 gene provides instructions to make anosmin, which has a role in development of both the olfactory system as well as migration of GnRH secreting neurones.

- **Septo-optic dysplasia.** This is a rare congenital syndrome (associated with mutations in the HESX1 gene) presenting in childhood with a clinical triad of midline forebrain abnormalities, optic nerve hypoplasia and hypopituitarism.

**Sheehan’s syndrome** is due to pituitary infarction following postpartum haemorrhage and is rare in developed countries.

- **Pituitary apoplexy.** A pituitary tumour occasionally enlarges rapidly owing to infarction or haemorrhage. This may produce severe headache, double vision and sudden severe visual loss, sometimes followed by acute life-threatening hypopituitarism. Often pituitary apoplexy can be managed conservatively with replacement of hormones and close monitoring of vision, although if there is a rapid deterioration in visual acuity and fields, surgical decompression of the optic chiasm may be necessary.

**The ‘empty sella’ syndrome.** An ‘empty sella’ is sometimes reported on pituitary imaging. This is sometimes due to a defect in the diaphragma and extension of the subarachnoid space (cisternal herniation) or may follow spontaneous infarction or regression of a pituitary tumour. All or most of the sella turcica is devoid of apparent pituitary tissue, but, despite this, pituitary function is usually normal, the pituitary being eccentrically placed and flattened against the floor or roof of the fossa.

**Investigations**

Each axis of the hypothalamic-pituitary system requires separate investigation. However, the presence of normal gonadal function (ovulation/menstruation or normal libido/erections) suggests that multiple defects of anterior pituitary function are unlikely.

Tests range from the simple basal levels (e.g. free T4 for the thyroid axis), to stimulatory tests for the pituitary, and tests of feedback for the hypothalamus (Table 19.7). Assessment of the hypothalamic-pituitary-adrenal axis is complex: basal 09:00 hours cortisol levels above 400 nmol/L usually indicate an adequate reserve, while levels below 100 nmol/L predict an inadequate stress response. In many cases basal levels are equivocal and a dynamic test is essential: the insulin tolerance test (Box 19.2) is widely regarded as the ‘gold standard’ but the short ACTH stimulation test (Box 19.1), though an indirect measure, is used by many as a routine test of hypothalamic-pituitary-adrenal status. Occasionally, the difference between ACTH deficiency and normal
Precise cortisol normal ranges are variable between laboratories and assays – appropriate local reference ranges must be used.

Indication
- Diagnosis or exclusion of ACTH and growth hormone deficiency

Procedure
- Test explained to patient and consent obtained
- Should only be performed in experienced, specialist units
- Exclude cardiovascular disease (ECG), epilepsy or unexplained blackouts; exclude severe untreated hypopituitarism (basal cortisol must be >100 nmol/L; normal free T₄)
- Intravenous hydrocortisone and glucose available for emergency
- Overnight fast, begin at 08:00–09:00 hours
- Soluble insulin, 0.15 U/kg, i.v. at time 0
- Glucose, cortisol and GH levels at 0, 30, 45, 60, 90, 120 min

Normal response
- Cortisol rises above 550 nmol/L⁺
- GH rises above 7 ng/L (severe deficiency = <3 ng/L (<9 mU/L))
- Glucose must be <2.2 mmol/L to achieve adequate stress response

*Releasing hormone tests were a traditional part of pituitary function testing, but have been largely replaced by the advent of more reliable assays for basal hormones. They test only the “readily releasable pool” of pituitary hormones and normal responses may be seen in hypopituitarism.

</tbody>
</table>

HPA axis can be subtle, and the assessment of adrenal reserve is best left to an experienced endocrinologist.

**Treatment**
- Steroid and thyroid hormones are essential for life.
- Both are given as oral replacement drugs, as in primary thyroid and adrenal deficiency, aiming to restore the patient to clinical and biochemical normality (Table 19.8) and levels are monitored by routine hormone assays.

**Note:** Thyroid replacement should not commence until normal glucocorticoid function has been demonstrated or replacement steroid therapy initiated, as an adrenal ‘crisis’ may otherwise be precipitated.

- Sex hormones are replaced with androgens and oestrogens, both for symptomatic control and to prevent long-term problems related to deficiency (e.g. osteoporosis).
Growth and abnormal stature

When fertility is desired, gonadal function is stimulated directly by human chorionic gonadotrophin (HCG, mainly acting as LH), purified or biosynthetic gonadotrophins, or indirectly by pulsatile gonadotrophin-releasing hormone (GnRH – also known as luteinizing hormone-releasing hormone, LHRH); all are expensive and time-consuming and should be restricted to specialist units.

GH therapy is given in the growing child, under the care of a paediatric endocrinologist. In adult GH deficiency, GH therapy also produces improvements in body composition, work capacity and psychological wellbeing, together with reversal of lipid abnormalities associated with a high cardiovascular risk, and often results in significant symptomatic benefit in some cases. NICE recommends GH replacement for people with severe GH deficiency and significant quality of life impairment. It is expensive and in the UK costs £2500–6000 per annum.

Glucocorticoid deficiency may mask impaired urine concentrating ability, diabetes insipidus only becoming apparent after steroid replacement because steroids are required for excretion of free water.

**GROWTH AND ABNORMAL STATURE**

**Physiology and control of growth hormone (GH)** (Fig. 19.9)

GH is the pituitary factor responsible for stimulation of body growth in humans. Its secretion is stimulated by GHRH, released into the portal system from the hypothalamus; it is also under inhibitory control by somatostatin. A separate GH stimulating system involves a distinct receptor (GH secretogogue receptor), which interacts with ghrelin (see p. 259). It is not known how these two systems interact but because ghrelin is synthesized in the stomach, it suggests a nutritional role for GH.

**GH** acts by binding to a specific (single transmembrane) receptor located mainly in the liver (Table 19.3). This induces an intracellular phosphorylation cascade involving the JAK/STAT (Janus kinase/signal transducing activators of transcription) pathway (p. 32). STAT proteins are translocated from the cytoplasm into the cell nucleus and cause GH-specific effects by binding to nuclear DNA.

**IGF-1 (insulin-like growth factor-1)**, a somatomedin stimulates growth and its hepatic secretion is stimulated by a tissue-specific effect of GH on the liver. There are multiple IGF-binding proteins (IGF-BP) in plasma – IGF-BP3 can be measured clinically to improve assessment of GH status, particularly in children. The metabolic actions of the system are:

- Increasing collagen and protein synthesis
- Promoting retention of calcium, phosphorus and nitrogen, necessary substrates for anabolism
- Opposing the action of insulin (a ‘counter-regulatory’ hormone effect).

GH release is intermittent and mainly nocturnal, especially during REM sleep. The frequency and size of GH pulses increase during the growth spurt of adolescence and decline thereafter. Acute stress and exercise both stimulate GH release while, in the normal subject, hyperglycaemia suppresses it. IGF-1 may, in addition, play a major role in maintaining neoplastic growth. A relationship has been shown between circulating IGF-1 concentrations and breast cancer in premenopausal women and prostate cancer in men.

**Normal growth**

There are factors other than GH involved in linear growth in the human.

- **Genetic factors.** Children of two short parents will probably be short and vice-versa.
- **Nutritional factors.** Adequate nutrients must be available. Impaired growth can result from inadequate dietary intake or small bowel disease (e.g. coeliac disease).
- **General health.** Any serious systemic disease in childhood is likely to reduce growth (e.g. chronic kidney disease or chronic infection).
- **Intrauterine growth retardation.** These infants often grow poorly in the long term, while infants with simple prematurity usually catch up. There is some evidence that low birthweight may predispose to hypertension, diabetes and other health problems in later adult life (p. 195).
- **Emotional deprivation and psychological factors.** These can impair growth by complex, poorly understood mechanisms, probably involving temporarily decreased GH secretion.

In general, there are three overlapping phases of growth: infantile (0–2 years), which appears largely substrate (food) dependent; childhood (age 2 years to puberty), which is largely GH dependent; and the adolescent ‘growth spurt’, dependent on GH and sex hormones.
The relevant aspects of history and examination in the assessment of problems are shown in Box 19.3.

### Assessment of growth

Charts showing normal centiles of height and weight are essential to monitor growth; they are available for normal British children (Fig. 19.10) and many other national and ethnic groups. Height must be measured, ideally at the same time of day on the same instrument by the same observer.

Height velocity is more helpful than current height. It requires at least two measurements some months apart and, ideally, multiple serial measurements. Height velocity is the rate of current growth (cm per year), while the current attained height is largely dependent upon previous growth. Standard deviation scores (SDS) based on the degree of deviation from age-sex norms are widely used. Computer programs also allow calculation of many of these indices.

The approximate future height of a child (‘mid-parental height’) can be simply predicted from the parental heights. For a boy, this is:

\[(\text{Maternal height} + 14 \text{ cm} (5.5 \text{ inches}) + \text{Paternal height})/2\]

and for a girl:

\[(\text{Paternal height} – 14 \text{ cm} (5.5 \text{ inches}) + \text{Maternal height})/2\]

Thus, with a father of 180 cm and mother of 154 cm, the predicted heights are 174 cm for a son and 160 cm for a daughter.

### Growth failure: short stature

When children or their parents complain of short stature, particular attention should focus on:

- Intrauterine growth retardation, weight and gestation at birth
- Possible systemic disorders – any system, but especially small bowel disease
- Evidence of skeletal, chromosomal or other congenital abnormalities
- Endocrine status – particularly thyroid
- Dietary intake and use of drugs, especially steroids for asthma
- Emotional, psychological, family and school problems

School, general practitioner, clinic and home records of height and weight should be obtained if possible to allow growth-velocity calculation. If unavailable, such data must be obtained prospectively.

A child with normal growth velocity is unlikely to have significant endocrine disease and the commonest cause of short stature in this situation is pubertal or ‘constitutional’ delay. However, low growth velocity without apparent systemic cause requires further investigation. Sudden cessation of growth suggests major physical disease; if no gastrointestinal, respiratory, renal or skeletal abnormality is apparent, then a cerebral tumour or hypothyroidism is likely.

Consistently slow-growing children require full endocrine assessment. Features of the more common causes of growth failure are given in Table 19.9.

Around the time of puberty, where constitutional delay is clearly shown and symptoms require intervention, then very low-dose sex steroids in 3- to 6-month courses will usually induce acceleration of growth.

### Investigations

Systemic disease having been excluded, perform:

- **Thyroid function tests**: serum TSH and free $T_4$ to exclude hypothyroidism
- **GH status**. Basal levels are of little value. Dynamic tests include the GH response to insulin (the ‘gold standard’; Box 19.2), glucagon, arginine, exercise and clonidine. Tests should only be performed in centres experienced in their use and interpretation. Normal responses depend on test and GH assay used.
Blood levels of IGF-1 (insulin-like growth factor-1) and IGF-BP3 (binding protein 3) may provide evidence of GH undersecretion.

Assessment of bone age. Non-dominant hand and wrist X-rays allow assessment of bone age by comparison with standard charts.

Karyotyping in females. Turner’s syndrome (p. 978) is associated with short stature. It is thought that this is due to a defect in the short stature homeobox (SHOX) gene which has a role in non-GH mediated growth.

Constitutional delay
- Often present
- Slow from birth, immature but appropriate with late but spontaneous puberty
- Moderate delay
- Often difficult to differentiate from GH deficiency
- Growth velocity measurement vital

Familial short stature
- Positive
- Slow from birth, clinically normal with normal puberty
- Normal
- Need heights of family members
- Growth velocity normal

GH insufficiency
- Rare
- Slow growth, immature, often overweight, delayed puberty
- Moderate delay, increasing with time
- Early investigation and treatment vital
- Increased suspicion if child is plump

Primary hypothyroidism
- Rare
- Slow growth, immature and delayed puberty
- Marked delay
- Measure TSH, T4 in all cases of short stature
- Clear clinical signs not obvious

Small bowel disease
- Sometimes
- Slow, immature, usually thin for height, delayed puberty
- Delayed
- Diarrhoea and/or macrocytosis/anaemia
- Occasionally no GI symptoms

Acromegaly and gigantism

Growth hormone stimulates skeletal and soft tissue growth. GH excess therefore produces gigantism in children if acquired before epiphyseal fusion and acromegaly in adults. Both are due to a GH secreting pituitary tumour (somatotroph adenoma) in almost all cases. Hyperplasia due to ectopic GHRH excess is very rare. Overall incidence is approximately 3–4/million per year and the prevalence is 50–80/million worldwide. Acromegaly usually occurs sporadically, although gene mutations can rarely give rise to familial acromegaly, typically the AIP gene in familial isolated pituitary adenoma.

Clinical features

Symptoms and signs of acromegaly are shown in Figure 19.11. One-third of patients present with changes in appearance, one-quarter with visual field defects or headaches; in the remainder the diagnosis is made by an alert observer in another clinic, e.g. GP, diabetic, hypertension, dental dermatology. Sleep apnoea is common and requires investigation and treatment if there are suggestive symptoms (see p. 818). Sweating, headaches and soft tissue swelling are particularly useful symptoms of persistent growth hormone secretion. Headache is very common in acromegaly and may be severe even with small tumours; it is often improved after surgical cure or with somatostatin analogues.

Investigations

- GH levels may exclude acromegaly if undetectable but a detectable value is non-diagnostic taken alone. Normal adult levels are <0.5 μg/L for most of the day except during stress or a ‘GH pulse’.
- A glucose tolerance test is diagnostic if there is no suppression of GH. Acromegalics fail to suppress GH below 0.3 μg/L and some show a paradoxical rise; about 25% of acromegalics have a positive diabetic glucose tolerance test.
- IGF-1 levels are almost always raised in acromegaly – a single plasma level of IGF-1 reflects mean 24-hour GH levels and is useful in diagnosis. A normal IGF-1 together with random growth hormone <1 μg/L may be taken to exclude acromegaly if the diagnosis is clinically unlikely.
- Visual field examination: defects are common, e.g. bitemporal hemianopia.
- MRI scan of pituitary if above tests abnormal. This will almost always reveal the pituitary adenoma.
- Pituitary function: partial or complete anterior hypopituitarism is common.

**Symptoms of hypopituitarism may also be present:**
- Goitre
- Breathlessness
- Polyuria/polydipsia
- Muscular weakness
- Joint pains

**Old photographs are frequently useful:

- Signs of greater discriminant value:
  - Prolactin: mild to moderate hyperprolactinaemia occurs in 30% of patients (see Fig. 19.13). In some, the adenoma secretes both GH and prolactin.

### Management and treatment

Untreated acromegaly results in markedly reduced survival. Most deaths occur from heart failure, coronary artery disease and hypertension-related causes. In addition, there is an increase in deaths due to neoplasia, particularly large bowel tumours (some specialist centres advocate regular colonoscopy to detect and remove colonic polyps to reduce the risk of colonic cancer). Treatment is therefore indicated in all except the elderly or those with minimal abnormalities. The aim of therapy is to achieve a mean growth hormone level below 2.5 μg/L; this is not always ‘normal’ but has been shown to reduce mortality to normal levels and is therefore considered a ‘safe’ GH level. A normal IGF-1 is also a goal shown to reduce mortality to normal levels and is therefore considered a ‘safe’ IGF-1 level. Occasionally there can be discordance between GH and IGF-1 levels, which can create management dilemmas.

When present, hypopituitarism should be corrected (see p. 950) and concurrent diabetes and/or hypertension should be treated conventionally; both usually improve with treatment of the acromegaly.

The general advantages and disadvantages of surgery, radiotherapy and medical treatment are discussed on page 947. Progress can be assessed by monitoring GH and IGF-1 levels.

**Surgery.** Trans-sphenoidal surgery is the appropriate first-line therapy. It will result in clinical remission in a majority of cases (60–90%) with pituitary microadenoma, but in only 50% of those with macroadenoma. Very high preoperative GH and IGF-1 levels are also poor prognostic markers of surgical cure. Surgical success rates are variable and highly dependent upon experience, and a specialist pituitary surgeon is essential. Transfrontal surgery is rarely required except for massive macroadenomas. There is approximately a 10% recurrence rate.

**Pituitary radiotherapy.** External radiotherapy is normally used after pituitary surgery fails to normalize GH levels rather than as primary therapy. It is often combined with medium-term treatment with a somatostatin analogue, dopamine agonist or GH antagonist because of the slow biochemical response to radiotherapy, which may take 10 years or more and is often associated with hypopituitarism which makes it unattractive in patients of reproductive age. Stereotactic radiotherapy is used in some centres.

**Medical therapy.** There are three receptor targets for the treatment of acromegaly: pituitary somatostatin receptors and dopamine (D2) receptors and growth hormone receptors in the periphery.

- **Somatostatin receptor agonists.** Octreotide and lanreotide are synthetic analogues of somatostatin (p. 951) that selectively act on somatostatin receptor subtypes (SST2 and SST5), which are highly expressed in growth-hormone-secreting tumours. These drugs were used as a short-term treatment whilst other modalities become effective, but now are sometimes used as primary therapy. They reduce GH and IGF levels in most patients but not all achieve treatment targets. Both drugs are typically administered as monthly depot injections and are generally well tolerated but are associated with an increased incidence of gallstones and are expensive.

- **Dopamine agonists.** Dopamine agonists act on D2 receptors (p. 878) and can be given to shrink tumours prior to definitive therapy or to control symptoms and persisting GH secretion; they are probably most effective in mixed growth-hormone-producing (somatotroph) and prolactin-producing (mammotroph) tumours. Typical doses are bromocriptine 10–60 mg daily or cabergoline 0.5 mg daily (higher than for prolactinomas). Given alone they reduce GH to ‘safe’ levels in only a minority of cases – but they are useful for mild residual disease or in combination with somatostatin analogues. Drugs with combined...
somatostatin and dopamine receptor activity are under development.

- Growth hormone antagonists. Pegvisomant (a genetically modified analogue of GH) is a GH receptor antagonist which has its effect by binding to and preventing dimerization of the GH receptor. It does not lower growth hormone levels or reduce tumour size but has been shown to normalize IGF-1 levels in 90% of patients. It is given by a daily injection and its main role at the present time is treatment of patients in whom GH and IGF levels cannot be reduced to safe levels with somatostatin analogues alone, surgery or radiotherapy.

**Hyperprolactinaemia**

The hypothalamic-pituitary control of prolactin secretion is illustrated in Figure 19.12. Prolactin is a large peptide secreted in the pituitary and acts via a transmembrane receptor stimulating JAK2 and other pathways (Table 19.3).

Prolactin is under tonic dopamine inhibition: factors known to increase prolactin secretion (e.g. TRH) are probably of less relevance. Prolactin stimulates milk secretion (but not breast tissue development) but also inhibits gonadal activity. It decreases GnRH pulsatility at the hypothalamic level and, to a lesser extent, blocks the action of LH on the ovary or testis, producing hypogonadism even when the pituitary gonadal axis itself is intact.

The role of prolactin outside pregnancy and lactation is not well defined, although there is some epidemiological evidence of a link between high prolactin levels and breast cancer which has led to an interest in the development of prolactin receptor antagonists.

Physiological hyperprolactinaemia occurs in pregnancy, lactation and severe stress, as well as during sleep and coitus. The range of serum prolactin seen in common causes of hyperprolactinaemia is illustrated in Figure 19.13. Mildly increased prolactin levels (400–600 mU/L) may be physiological and asymptomatic but higher levels require a diagnosis. Levels above 5000 mU/L always imply a prolactin-secreting pituitary tumour.

**Causes**

Hyperprolactinaemia has many causes. Common pathological causes include prolactinoma, co-secretion of prolactin in tumours causing acromegaly, stalk compression due to pituitary adenomas and other pituitary masses, polycystic ovary syndrome, primary hypothyroidism and ‘idiopathic’ hyperprolactinaemia. Rarer causes are oestrogen therapy (e.g. the ‘pill’), renal failure, liver failure, post-ictal state and chest wall injury. Dopamine antagonist drugs (metoclopramide, domperidone, most antipsychotics) are a common iatrogenic cause, as well as most other antiemetics (except cyclizine) and opiates.

**Clinical features**

Hyperprolactinaemia stimulates milk production in the breast and inhibits GnRH and gonadotrophin secretion per se. It usually presents with:

- Galactorrhoea, spontaneous or expressible (60% of cases)
- Oligomenorrhea or amenorrhea
- Decreased libido in both sexes
- Decreased potency in men
- Subfertility
- Symptoms or signs of oestrogen or androgen deficiency – in the long term osteoporosis may result, especially in women
- Delayed or arrested puberty in the peripubertal patient
- Mild gynaecomastia is often seen in men due to the associated hypogonadism rather than a direct effect of prolactin.

Additionally, headaches and/or visual field defects occur if there is a pituitary tumour (more common in men). Note that many people with galactorrhoea do not have FURTHER READING

---

**Figure 19.12** The control and actions of prolactin. Prolactin is mainly controlled by tonic inhibition by hypothalamic dopamine. Prolactin stimulates lactation but also inhibits both hypothalamic GnRH secretion and the gonadal actions of LH.

**Figure 19.13** Range of serum prolactin seen in common causes of hyperprolactinaemia.
hyperprolactinaemia – ‘normoprolactinaemic galactorrhoea’ – and the causes are poorly understood.

Investigations

Hyperprolactinaemia should be confirmed by repeat measurement. If there are no clinical features of hyperprolactinaemia, the possibility of macroprolactinaemia should be considered. This is a higher molecular weight complex of prolactin bound to IgG, which is physiologically inactive but occurs in a small proportion of normal people and can therefore lead to unnecessary treatment. Macroprolactinaemia can be diagnosed in the laboratory by precipitation of IgG with polyethylene glycol, after which prolactin levels will be normal on testing; most laboratories will do this routinely.

Further tests are appropriate after physiological and drug causes have been excluded:

- **Visual fields** should be checked.
- **Primary hypothyroidism** must be excluded since this is a cause of hyperprolactinaemia.
- **Anterior pituitary function** should be assessed if there is any clinical evidence of hypopituitarism or radiological evidence of a pituitary tumour (Table 19.7; Box 19.1, Box 19.2).
- **MRI of the pituitary** is necessary if there are any clinical features suggestive of a pituitary tumour, and desirable in all cases when prolactin is significantly elevated (above 1000 mU/L).

In the presence of a pituitary mass on MRI, the level of prolactin helps determine whether the mass is a prolactinoma or a non-functioning pituitary tumour causing stalk-disconnection hyperprolactinaemia: levels of above 5000 mU/L in the presence of a macroadenoma, or above 2000 mU/L in the presence of a microadenoma (or with no radiological abnormality), strongly suggest a prolactinoma (see p. 946). Macroprolactinaemia refers to tumours above 10 mm diameter, microprolactinoma to smaller ones.

Occasionally, very large prolactinomas can be associated with such high serum prolactin levels that some assays give an artefactual falsely low result (known as the ‘hook effect’). If suspected, this can be excluded by serial dilutions of the serum sample.

Treatment

Hyperprolactinaemia is usually treated to avoid the long-term effects of oestrogen deficiency (even if the patient would otherwise welcome the lack of periods!) or testosterone deficiency in the male. Exceptions include minor elevations (400–1000 mU/L) with preservation of normal regular menstruation (or normal male testosterone levels) and postmenopausal people with microprolactinomas who are not taking oestrogen replacement. 

**Medical treatment.** Hyperprolactinaemia is controlled with a dopamine agonist.

- **Cabergoline** (500 μg once or twice a week judged on clinical response and prolactin levels) is the best tolerated and longest-acting drug and is the first drug of choice.
- **Bromocriptine** is the longest-established therapy and therefore preferred if pregnancy is planned: initial doses should be small (e.g. 1 mg), taken with food and gradually increased to 2.5 mg two or three times daily. Side-effects, which prevent effective therapy in a minority of cases, include nausea and vomiting, dizziness and syncope, constipation and cold peripheries.
- **Quinagolide** (75–150 μg once daily) is an alternative.

Complications seen, when cabergoline is used in higher doses in Parkinson’s disease, include pulmonary, retroperitoneal and pericardial fibrotic reactions and cardiac valve lesions. Patients need monitoring, although such adverse effects appear to be very rare in patients on lower, ‘endocrine’ doses.

In most cases a dopamine agonist will be the first and only therapy and can be used in the long term. Prolactinomas usually shrink in size on a dopamine agonist, and in macroadenomas any pituitary mass effects commonly resolve (Fig. 19.14). Microprolactinomas may not recur after several years of dopamine agonist therapy in a minority of cases, but in the majority hyperprolactinaemia will recur if treatment is stopped.

**Trans-sphenoidal surgery** may restore normoprolactinaemia in people with microadenoma, but is rarely completely successful with macroadenomas and risks damage to normal pituitary function. Therefore most patients and physicians elect to continue medical therapy rather than proceed to surgery. Prolactinoma should therefore always be measured before surgery on any mass in the pituitary region. Some surgeons believe that long-term bromocriptine increases the hardness of the adenoma and makes resection more difficult, but others dissent from this view.

**Radiotherapy** usually controls adenoma growth and is slowly effective in lowering prolactin but causes progressive hypopituitarism. It may be advocated after medical tumour shrinkage or after surgery in larger tumours, especially where

---

**Figure 19.14** Macroprolactinoma before (a) and after (b) 2 years treatment with the dopamine agonist cabergoline showing marked adenoma shrinkage.
families are complete or if the drug treatment is poorly tolerated, but most workers simply advocate continuation of dopamine agonist therapy in responsive cases.

In patients planning pregnancy, it is useful to know the size of the pituitary lesion before starting dopamine agonist therapy. Rarely, tumours enlarge during pregnancy to produce headaches and visual field defects. Dopamine agonists, which are traditionally stopped after conception, can be restarted if there are any signs of tumour growth during pregnancy.

**Cushing’s syndrome**

Cushing’s syndrome is the term used to describe the clinical state of increased free circulating glucocorticoid. It occurs most often following the therapeutic administration of synthetic steroids or ACTH (see below).

**Pathophysiology and causes**

Spontaneous Cushing’s syndrome is rare, with an incidence of <5/million per year. Causes of Cushing’s syndrome are usually subdivided into two groups (Table 19.10):

1. Increased circulating ACTH from the pituitary (65% of cases), known as Cushing’s disease, or from an ‘ectopic’, non-pituitary, ACTH-producing tumour elsewhere in the body (10%) with consequent glucocorticoid excess (‘ACTH dependent’ Cushing’s)

2. A primary excess of endogenous cortisol secretion (25%) by an adrenal tumour or nodular hyperplasia, with subsequent (physiological) suppression of ACTH (‘non-ACTH-dependent’ Cushing’s). Rare cases are due to aberrant expression of receptors for other hormones (e.g. glucose-dependent insulinotrophic peptide (GIP), LH or catecholamines) in adrenal cortical cells.

**Clinical features**

The clinical features of Cushing’s syndrome are those of glucocorticoid excess and are illustrated in Figure 19.15.

- **Pigmentation** occurs only with ACTH-dependent causes.
- **A cushingoid appearance** can be caused by excess alcohol consumption (pseudo-Cushing’s syndrome) – the pathophysiology is poorly understood.
- **Impaired glucose tolerance** or frank diabetes is common, especially in the ectopic ACTH syndrome.
- **Hypokalaemia** due to the mineralocorticoid activity of cortisol is common with ectopic ACTH secretion.
- **Hypertension** is common in all causes of Cushing’s syndrome.

**Diagnosis**

There are two phases to the investigation.

1. **Confirmation**

Most obese, hirsute, hypertensive patients do not have Cushing’s syndrome, and some cases of genuine Cushing’s have relatively subtle clinical signs. Confirmation rests on demonstrating inappropriate cortisol secretion, not suppressed by exogenous glucocorticoids; difficulties occur with obesity and depression where cortisol dynamics are often abnormal. Random cortisol measurements are of no value.

**Figure 19.15 Cushing’s syndrome: symptoms and signs.** Bold type indicates signs of most value in discriminating Cushing’s syndrome from simple obesity and hirsutism.
Occasional patients are seen with so-called ‘cyclical Cushing’s’ where the abnormalities come and go. Investigations to confirm the diagnosis include:

- **48-hour low-dose dexamethasone test** (see Table 19.11). Normal individuals suppress plasma cortisol to <50 nmol/L. People with Cushing’s syndrome fail to show complete suppression of plasma cortisol levels (although levels may fall substantially in a few cases). This test is highly sensitive (>97%). The overnight dexamethasone test is slightly simpler, but has a higher false-positive rate.

- **24-hour urinary free cortisol measurements.** This is simple, but less reliable – repeatedly normal values render the diagnosis most unlikely, but some people with Cushing’s syndrome have normal values on some collections (approximately 10%).

- **Circadian rhythm.** After 48 hours in hospital, cortisol samples are taken at 09:00 hours and 24:00 hours (without warning the patient). Normal subjects show a pronounced circadian variation (see Fig. 19.4, p. 942); those with Cushing’s syndrome have high midnight cortisol levels (>100 nmol/L), though the 09:00 hours value may be normal. Midnight salivary cortisol collected at home gives the same information more simply where the assay is available.

- **Other tests.** There are frequent exceptions to the classic responses to diagnostic tests in Cushing’s syndrome. If any clinical suspicion of Cushing’s remains after preliminary tests then specialist investigations are still indicated. These may include insulin stress test, desmopressin suppression test (p. 993) and CRH tests.

2. **Differential diagnosis of the cause**

This can be extremely difficult since all causes can result in clinically identical Cushing’s syndrome. The classical ectopic ACTH syndrome is distinguished by a short history, pigmentation and weight loss, unprovoked hypokalaemia, clinical or chemical diabetes and plasma ACTH levels above 200 ng/L, but many ectopic tumours are benign and mimic pituitary disease closely, both clinically and biochemically. Severe hirsutism/virilization suggests an adrenal tumour.

Biochemical and radiological procedures for diagnosis include:

- **Plasma ACTH levels.** Low or undetectable ACTH levels (<10 ng/L) on two or more occasions are a reliable indicator of non-ACTH-dependent disease.

- **Adrenal CT or MRI scan.** Adrenal adenomas and carcinomas causing Cushing’s syndrome are relatively large and always detectable by CT scan. Carcinomas are distinguished by large size, irregular outline and signs of infiltration or metastases. Bilateral adrenal hyperplasia may be seen in ACTH-dependent causes or in ACTH-independent nodular hyperplasia.

- **Pituitary MRI.** A pituitary adenoma may be seen but the adenoma is often small and not visible in a significant proportion of cases.

- **Plasma potassium levels.** Hypokalaemia is common with ectopic ACTH secretion. (All diuretics must be stopped.)

- **High-dose dexamethasone test** (Table 19.11). Failure of significant plasma cortisol suppression suggests an ectopic source of ACTH or an adrenal tumour.

- **CRH test.** An exaggerated ACTH and cortisol response to exogenous CRH suggests pituitary-dependent Cushing’s disease, as ectopic sources rarely respond.

- **Chest X-ray** to look for a carcinoma of the bronchus or a bronchial carcinoid. Carcinoid lesions may be very small; if ectopic ACTH is suspected, whole-lung, mediastinal and abdominal CT scanning should be performed.

Further investigations may involve selective catheterization of the inferior petrosal sinus to measure ACTH for pituitary lesions, or blood samples taken throughout the body in a search for ectopic sources. Radiolabelled octreotide (111In octreotide) is occasionally helpful in locating ectopic ACTH sites.

**Treatment**

Successful treatment of Cushing’s syndrome with a normal biochemical profile should lead to reversal of the presenting clinical features. However, untreated Cushing’s syndrome has a very bad prognosis, with death from hypertension, myocardial infarction, infection and heart failure. Whatever the underlying cause, cortisol hypersecretion should be controlled prior to surgery or radiotherapy. Considerable morbidity and mortality is otherwise associated with operating on unprepared patients, especially when abdominal surgery is required.
The thyroid axis

The usual drug is metyrapone, an 11β-hydroxylase blocker, which is given in doses of 750 mg to 4 g daily in 3–4 divided doses. Ketoconazole (200 mg three times daily) is also used and is synergistic with metyrapone. Plasma cortisol should be monitored, aiming to reduce the mean level during the day to 150–300 nmol/L, equivalent to normal production rates. Aminoglutethimide and trilostane (which reversibly inhibits 3-hydroxysteroid dehydrogenase/5–5,4 isomers) are occasionally used.

Choice of further treatment depends upon the cause.

**Cushing’s disease (pituitary-dependent hyperadrenalinism)**

- **Trans-sphenoidal removal of the tumour** is the treatment of choice. Selective adenomectomy nearly always leaves the patient ACTH deficient immediately postoperatively, and this is a good prognostic sign. Overall, pituitary surgery results in remission in 75–80% of cases, but results vary considerably and an experienced surgeon is essential.

- **External pituitary irradiation** alone is slow acting, only effective in 50–60% even after prolonged follow-up and mainly used after failed pituitary surgery. Children, however, respond much better to radiotherapy, 80% being cured. Stereotactic radiotherapy can be useful in selected cases.

- **Medical therapy** to reduce ACTH (e.g. bromocriptine, cabergoline, cyproheptadine, somatostatin analogues such as pasireotide) is rarely effective. There is some evidence that aggressive corticotroph adenomas may respond to temozolomide chemotherapy.

- **Bilateral adrenalectomy** is an effective last resort if other measures fail to control the disease (see Nelson’s syndrome). This can be performed laparoscopically.

**Cushing’s syndrome due to other causes**

Adrenal adenomas should be resected after achievement of clinical remission with metyrapone or ketoconazole. Contra-lateral adrenal suppression may last for a year or more. Adrenal carcinomas are highly aggressive and the prognosis is poor. In general, if there are no widespread metastases, tumour bulk should be reduced surgically. The adrenolytic drug mitotane may inhibit growth of the tumour and prolong survival, though it can cause nausea and ataxia. Some would also give radiotherapy to the tumour bed after surgery.

Tumours secreting ACTH ectopically should be removed if possible. Otherwise chemotherapy/radiotherapy may be used, depending on the tumour. Control of the Cushing’s syndrome with metyrapone or ketoconazole is beneficial for symptoms, and bilateral adrenalectomy may be appropriate to give complete control of Cushing’s syndrome if prognosis from the tumour itself is reasonable.

If the source of ACTH is not clear, cortisol hypersecretion should be controlled with medical therapy until a diagnosis can be made.

**Nelson’s syndrome**

Nelson’s syndrome is increased pigmentation (because of high levels of ACTH) associated with an enlarging pituitary tumour, which occurs in about 20% of cases after bilateral adrenalectomy for Cushing’s disease. The syndrome is rare now that adrenalectomy is an uncommon primary treatment, and its incidence may be reduced by pituitary radiotherapy soon after adrenalectomy. The Nelson’s adenoma may be treated by pituitary surgery and/or radiotherapy (unless given previously).

**Hypersecretion of other pituitary hormones**

Pituitary tumours may rarely secrete TSH (and cause thyrotoxicosis). Such ‘TSHomas’ lead to the unusual biochemical pattern of elevated $fT_3$ levels with normal or high circulating TSH levels. FSH and LH secreting pituitary tumours may cause elevated sex steroids but are extremely uncommon.

**THE THYROID AXIS**

The metabolism of virtually all nucleated cells of many tissues is controlled by the thyroid hormones. Overactivity or underactivity of the gland are the most common of all endocrine problems.

**Anatomy**

The thyroid gland consists of two lateral lobes connected by an isthmus. It is closely attached to the thyroid cartilage and to the upper end of the trachea, and thus moves on swallowing. It is often palpable in normal women.

Embryologically it originates from the base of the tongue and descends to the middle of the neck. Remnants of thyroid tissue can sometimes be found at the base of the tongue (lingual thyroid) and along the line of descent. The gland has a rich blood supply from superior and inferior thyroid arteries.

The thyroid gland consists of follicles lined by cuboidal epithelioid cells. Inside is the colloid (the iodinated glycoprotein thyroglobulin) which is synthesized by the follicular cells. Each follicle is surrounded by basement membrane, between which are parafollicular cells containing calcitonin-secreting C cells.

**Physiology**

**Synthesis.** The thyroid synthesizes two hormones:

- **Triiodothyronine ($T_3$), which acts at the cellular level**
- **L-thyroxine ($T_4$), which is the prohormone**

Inorganic iodide is trapped by the gland by an enzyme-dependent system, oxidized and incorporated into the glycoprotein thyroglobulin to form mono- and diiodotyrosine and then $T_3$ and $T_4$ (Fig. 19.16).

More $T_3$ than $T_4$ is produced, but $T_4$ is converted in some peripheral tissues (liver, kidney and muscle) to the more active $T_3$ by 5′-monodeiodination; an alternative 3′-monodeiodination yields the inactive reverse $T_3$ (r$T_3$). The latter step occurs particularly in severe non-thyroidal illness (see below).

In plasma, more than 99% of all $T_4$ and $T_3$ is bound to hormone-binding proteins (thyroxine-binding globulin, TBG; thyroid-binding prealbumin, TBPA; and albumin). Only free hormone is available for action in the target tissues, where $T_3$ binds to specific nuclear receptors within target cells. Many drugs and other factors affect TBG; all may result in confusing total $T_4$ levels in blood, and most laboratories therefore now measure free $T_4$ levels.

**Control of the hypothalamic-pituitary-thyroid axis.** Thyrotrophin-releasing hormone (TRH), a peptide produced in the hypothalamus, stimulates the pituitary to secrete thyroid-stimulating hormone (TSH) (see Fig. 19.2). TSH in turn stimulates growth and activity of the thyroid follicular cells via the G-protein coupled TSH membrane receptor (see Table 19.3). The $T_3$ and $T_4$ subsequently secreted into the circulation by follicular cells exert negative feedback on the hypothalamus, as described on page 941.
Endocrine disease

Circulating T4 is peripherally deiodinated to T3 which binds to the thyroid hormone nuclear receptor (TR) on target organ cells to cause modified gene transcription. There are two TR receptors (TR-α and TR-β) and the tissue-specific effects of T3 are dependent upon the local expression of these TR receptors. TR-α knockout mice show poor growth, bradycardia and hypothermia, whilst TR-β knockout mice show thyroid hyperplasia and high T4 levels in the presence of inappropriately normal circulating TSH, suggesting a role for the latter receptors in thyroid hormone resistance (see p. 967).

Physiological effects of thyroid hormones. The physiological effects of thyroid hormones are summarized in Table 19.12.

Dietary iodine requirement. Globally, dietary iodine deficiency is a major cause of thyroid disease, as iodine is an essential requirement for thyroid hormone synthesis. The recommended daily intake of iodine should be at least 140 μg, and dietary supplementation of salt and bread has reduced the number of areas where ‘endemic goitre’ still occurs (see below).

Thyroid function tests

Immunnoassays for free T4, free T3 and TSH are widely available. There are only minor circadian rhythms, and measurements may be made at any time. Particular uses of the tests are summarized in Table 19.13, with typical findings in common disorders.

TSH measurement

In most circumstances, TSH levels can discriminate between hyperthyroidism, hypothyroidism and euthyroidism (normal thyroid gland function). Exceptions are hypopituitarism, and the ‘sick euthyroid’ syndrome where low levels (which normally imply hyperthyroidism) occur in the presence of low or normal T4 and T3 levels. As a single test of thyroid function TSH is the most sensitive in most circumstances, but

*2,3-BPG, 2,3-bisphosphoglyceric acid.*
accurate diagnosis requires at least two tests, e.g. TSH plus free T4 or free T3, where hyperthyroidism is suspected, TSH plus serum free T4 where hypothyroidism is likely.

**TRH test**

This has been rendered almost obsolete by modern sensitive TSH assays except for investigation of hypothalamic-pituitary dysfunction. TRH (proterelin) is occasionally used to differentiate between thyroid hormone resistance and TSHoma in the context of raised rT3 and TSH levels. Typically, after TRH administration there is a rise in TSH in thyroid hormone resistance, whilst in TSHoma there is a flat response due to continued autonomous TSH secretion which does not respond to TRH.

**Problems in interpretation of thyroid function tests**

There are three major areas of difficulty.

1. **Serious acute or chronic illness**

   Thyroid function is affected in several ways:
   - Reduced concentration and affinity of binding proteins
   - Decreased peripheral conversion of T4 to T3 with more rT3
   - Reduced hypothalamic-pituitary TSH production.

   Systemically ill patients can therefore have an apparently low total and free T4 and T3 with a normal or low basal TSH (the ‘sick euthyroid’ syndrome). Levels are usually only mildly below normal and are thought to be mediated by interleukins IL-1 and IL-6; the tests should be repeated after resolution of the underlying illness.

2. **Pregnancy and oral contraceptives**

   These lead to greatly increased TBG levels and thus to high or high-normal total T4. Free T4 is usually normal. Normal ranges for free T4 and TSH alter with the normal physiological changes during pregnancy and TSH is often slightly suppressed in the first trimester, but this rarely causes clinical problems.

3. **Drugs**

   Amiodarone decreases T4 to T3 conversion and free T4 levels may therefore be above normal in a euthyroid patient; conversely amiodarone may induce both hyper- and hypothyroidism – the TSH level is usually reliable.

   Many drugs affect thyroid function tests by interfering with protein binding but this now rarely causes a problem with free T4 assays.

**Antithyroid antibodies**

Serum antibodies to the thyroid are common and may be either destructive or stimulating; both occasionally co-exist in the same patient.

**Destructive antibodies** are directed against the microsomes or against thyroglobulin; the antigen for thyroid microsomal antibodies is the thyroid peroxidase (TPO) enzyme. TPO antibodies are found in up to 20% of the normal population, especially older women, but only 10–20% of these develop overt hypothyroidism.

**TSH receptor IgG antibodies (TRAb)** typically stimulate, but occasionally block, the receptor; they can be measured in two ways:

- By the inhibition of binding of TSH to its receptors (TSH-binding inhibitory immunoglobulin, TBII)
- By demonstrating that they stimulate the release of cyclic AMP (thyroid-stimulating immunoglobulin/antibody TSI, TSAb).

**Hypothyroidism**

**Pathophysiology**

Underactivity of the thyroid is usually primary, from disease of the thyroid, but may be secondary to hypothalamic-pituitary disease (reduced TSH drive) (Table 19.14). Primary hypothyroidism is one of the most common endocrine conditions with an overall UK prevalence of over 2% in women, but under 0.1% in men; lifetime prevalence for an individual is higher – perhaps as high as 9% for women and 1% for men with mean age at diagnosis around 60 years. The worldwide prevalence of subclinical hypothyroidism varies from 1% to 10%.

**Causes of primary hypothyroidism** (Table 19.14)

**Autoimmune**

**Atrophic (autoimmune) hypothyroidism.** This is the most common cause of hypothyroidism and is associated with
antithyroid autoantibodies leading to lymphoid infiltration of the gland and eventual atrophy and fibrosis. It is six times more common in females and the incidence increases with age. The condition is associated with other autoimmune disease such as pernicious anaemia, vitiligo and other endocrine deficiencies (p. 939). Occasionally intermittent hypothyroidism occurs with subsequent recovery; antibodies which block the TSH receptor may sometimes be involved in the aetiology.

**Hashimoto’s thyroiditis.** This form of autoimmune thyroiditis, again more common in women and most common in late middle age, produces atrophic changes with regeneration, leading to goitre formation. The gland is usually firm and rubbery but may range from soft to hard. TPO antibodies are present, often in very high titres (>1000 IU/L). Patients may be hypothyroid or euthyroid, though they may go through an initial toxic phase, ‘Hashi-toxicity’. Lefthyroxine therapy may shrink the goitre even when the patient is not hypothyroid.

**Postpartum thyroiditis.** This is usually a transient phenomenon observed following pregnancy. It may cause hyperthyroidism, hypothyroidism or the two sequentially. It is believed to result from the modifications to the immune system necessary in pregnancy, and histologically is a lymphocytic thyroiditis. The process is normally self-limiting, but when conventional antibodies are found there is a high chance of this proceeding to permanent hypothyroidism. Postpartum thyroiditis may be misdiagnosed as postnatal depression, emphasizing the need for thyroid function tests in this situation.

**Defects of hormone synthesis**

**Iodine deficiency.** Dietary iodine deficiency still exists (p. 213) in some areas as ‘endemic goitre’ where goitre, occasionally massive, is common. The patients may be euthyroid or hypothyroid depending on the severity of iodine deficiency. The mechanism is thought to be borderline hypothyroidism leading to TSH stimulation and thyroid enlargement in the face of continuing iodine deficiency. Iodine deficiency is still a problem in the Netherlands, Western Pacific, India, South East Asia, Russia and parts of Africa. Efforts to prevent deficiency by providing iodine in salt continue worldwide but often with incomplete success. Even in the late 20th century of the 500 million with iodine deficiency in India, about 2 million had cretinism (see below).

**Dyshormonogenesis.** This rare condition is due to genetic defects in the synthesis of thyroid hormones; patients develop hypothyroidism with a goitre. One particular familial form is associated with sensorineural deafness due to a deletion mutation in chromosome 7, causing a defect of the transporter pendrin (Pendred’s syndrome) (see Fig. 19.16).

**Clinical features** (Fig. 19.17)

Hypothyroidism produces many symptoms. The alternative term ‘myxoedema’ refers to the accumulation of mucopolysaccharide in subcutaneous tissues. The classic picture of the slow, dry-haired, thick-skinned, deep-voiced patient with weight gain, cold intolerance, bradycardia and constipation makes the diagnosis easy. Milder symptoms are, however, more common and hard to distinguish from other causes of nonspecific tiredness. Many cases are detected on biochemical screening.

Special difficulties in diagnosis may arise in certain circumstances:

- **Children with hypothyroidism** may not show classic features but often have a slow growth velocity, poor school performance and sometimes arrest of pubertal development.

- **Young women with hypothyroidism** may not show obvious signs. Hypothyroidism should be excluded in all people with oligomenorrhoea/amenorrhoea, menorrhagia, infertility or hyperprolactinaemia.

- **The elderly** show many clinical features that are difficult to differentiate from normal ageing.

**Investigation of primary hypothyroidism**

**Serum TSH** is the investigation of choice; a high TSH level confirms primary hypothyroidism. A low free $T_4$ level confirms the hypothyroid state (and is also essential to exclude TSH deficiency if clinical hypothyroidism is strongly suspected and TSH is normal or low).

Thyroid and other organ-specific antibodies may be present. Other abnormalities include the following:

---

**Table:**

**Table 19.17** Hypothyroidism: symptoms and signs. Bold type indicates symptoms or signs of greater discriminant value. A history from a relative is often revealing. Symptoms of other autoimmune disease may be present.

- **Anaemia**, which is usually normochromic and normocytic in type but may be macrocytic (sometimes this is due to associated pernicious anaemia) or microcytic (in women, due to menorrhagia)
- **Increased serum aspartate transferase levels**, from muscle and/or liver
- **Increased serum creatine kinase levels**, with associated myopathy
- **Hypercholesterolaemia** and hypertriglyceridaemia
- **Hyponatraemia** due to an increase in ADH and impaired free water clearance.

**Treatment**

**Replacement therapy** with levothyroxine (thyroxine, i.e. T₄) is given for life. The starting dose will depend upon the severity of the deficiency and on the age and fitness of the patient, especially their cardiac performance: 100 μg daily for the young and fit, 50 μg (increasing to 100 μg after 2–4 weeks) for the small, old or frail. People with ischaemic heart disease require even lower initial doses, especially if the hypothyroidism is severe and longstanding. Most physicians would then begin with 25 μg daily and perform serial ECGs, increasing the dose at 3- to 4-week intervals if angina does not occur or worsen and the ECG does not deteriorate. Occasional patients develop ‘thyrotoxic’ (hyperthyroid) symptoms despite normal fT₄ levels if dose if increased too rapidly.

**Monitoring.** The aim is to restore T₄ and TSH to well within the normal range. Adequacy of replacement is assessed clinically and by thyroid function tests after at least 6 weeks on a steady dose. If serum TSH remains high, the dose of T₄ should be increased in increments of 25–50 μg with the tests repeated at 6–8 weeks intervals until TSH becomes normal. Complete suppression of TSH should be avoided because of the risk of atrial fibrillation and osteoporosis. The usual maintenance dose is 100–150 μg given as a single daily dose. An annual thyroid function test is recommended – this is usually performed in the primary care setting, often assisted and prompted by district ‘thyroid registers’.

Clinical improvement on T₄ may not begin for 2 weeks or more, and full resolution of symptoms may take 6 months. The necessity of lifelong therapy must be emphasized and the possibility of other autoimmune endocrine disease developing, especially Addison’s disease or pernicious anaemia, should be considered. During pregnancy, an increase in T₄ dosage of about 25–50 μg is often needed to maintain normal TSH levels, and the necessity of optimal replacement during pregnancy is emphasized by the finding of reductions in cognitive function in children of mothers with elevated TSH during pregnancy.

A few people with primary hypothyroidism complain of incomplete symptomatic response to T₄ replacement. Combination T₃ and T₄ replacement has been advocated in this context, but randomized clinical trials show no consistent benefit in quality of life symptoms.

**Borderline hypothyroidism or ‘compensated euthyroidism’**

Patients are frequently seen with low-normal serum T₄ levels and slightly raised TSH levels. Sometimes this follows surgery or radioactive iodine therapy when it can reasonably be seen as ‘compensatory’. Treatment with levothyroxine is normally recommended where the TSH is consistently above 10 mU/L, or when possible symptoms, high-titre thyroid antibodies, or lipid abnormalities are present. Where the TSH is only marginally raised, the tests should be repeated 3–6 months later.

Conversion to overt hypothyroidism is more common in men or when TPO antibodies are present. In practice, vague symptoms in people with marginally elevated TSH (below 10 mU/L) rarely respond to treatment, but a ‘therapeutic trial’ of replacement may be needed to confirm that symptoms are unrelated to the thyroid. It is also considered best to normalize TSH during (and ideally before) pregnancy to avoid fetal adverse effects.

**Myxoedema coma**

Severe hypothyroidism, especially in the elderly, may present with confusion or even coma. Myxoedema coma is very rare: hypothermia is often present and the patient may have severe cardiac failure, pericardial effusions, hypoventilation, hypoglycaemia and hyponatraemia. The mortality was previously at least 50% and patients require full intensive care. Optimal treatment is controversial and data lacking; most physicians would advise T₄ orally or intravenously in doses of 2.5–5 μg every 8 hours, then increasing as above. Large intravenous doses should not be used. Additional measures, though unproven, should include:

- Oxygen (by ventilation if necessary)
- Monitoring of cardiac output and pressures
- Gradual rewarming
- Hydrocortisone 100 mg i.v. 8-hourly
- Glucose infusion to prevent hypoglycaemia

**Myxoedema madness.** Depression is common in hypothyroidism. Rarely, with severe hypothyroidism in the elderly, the patient may become frankly demented or psychotic, sometimes with striking delusions. This may occur shortly after starting T₄ replacement.

**Screening for hypothyroidism**

- The incidence of congenital hypothyroidism is approximately 1 in 3500 births. Untreated, severe hypothyroidism produces permanent neurological and intellectual damage (‘cretinism’). Routine screening of the newborn using a blood spot, as in the Guthrie test, to detect a high TSH level as an indicator of primary hypothyroidism is efficient and cost-effective; cretinism is prevented if T₄ is started within the first few months of life.

- **Screening of elderly** patients for thyroid dysfunction has a low pick-up rate and is controversial and not currently recommended. However, patients who have undergone thyroid surgery or received radioactive iodine should have regular thyroid function tests, as should those receiving lithium or amiodarone therapy.

**Hyperthyroidism**

Hyperthyroidism (thyroid overactivity, thyrotoxicosis) is common, affecting perhaps 2–5% of all females at some time and with a sex ratio of 5:1, most often between the ages of 20 and 40 years. Nearly all cases (>99%) are caused by intrinsic thyroid disease; a pituitary cause is extremely rare (Table 19.15).

**Graves’ disease**

This is the most common cause of hyperthyroidism and is due to an autoimmune process. Serum IgG antibodies bind to TSH receptors in the thyroid, stimulating thyroid hormone production, i.e. they behave like TSH. These TSH receptor antibodies (TSHR-Ab) are specific for Graves’ disease.
Persistent high levels predict a relapse when drug treatment is stopped. There is an association with HLA-B8, DR3 and DR2 and a 40% concordance rate amongst monozygotic twins with a 5% concordance rate in dizygotic twins. There is a weak association with cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), HLA-DRB*08 and DRB3*0202 on chromosome 6.

Yersinia enterocolitica, Escherichia coli and other Gram-negative organisms contain TSH binding sites. This raises the possibility that the initiating event in the pathogenesis may be an infection with possible ‘molecular mimicry’ in a genetically susceptible individual, but the precise initiating mechanisms remain unknown in most cases.

Thyroid eye disease accompanies the hyperthyroidism in many cases (see below) but other components of Graves’ disease, e.g. Graves’ dermopathy, are very rare. Rarely lymphadenopathy and splenomegaly may occur. Graves’ disease is also associated with other autoimmune disorders such as pernicious anaemia, vitiligo and myasthenia gravis.

The natural history is one of fluctuation, many patients showing a pattern of alternating relapse and remission; perhaps only 40% of subjects have a single episode. Many patients eventually become hypothyroid.

Other causes of hyperthyroidism/thyrotoxicosis

Solitary toxic adenoma/nodule
This is the cause of about 5% of cases of hyperthyroidism. It does not usually remit after a course of antithyroid drugs.

Toxic multinodular goitre
This commonly occurs in older women. Again, antithyroid drugs are rarely successful in inducing a remission, although they can control the hyperthyroidism.

de Quervain’s thyrotoxicosis
This is transient hyperthyroidism from an acute inflammatory process, probably viral in origin. Apart from the toxicosis, there is usually fever, malaise and pain in the neck with tachycardia and local thyroid tenderness. Thyroid function tests show initial hyperthyroidism, the erythrocyte sedimentation rate (ESR) and plasma viscosity are raised, and thyroid uptake scans show suppression of uptake in the acute phase.

Hypothyroidism, usually transient, may then follow after a few weeks. Treatment of the acute phase is with aspirin, using short-term prednisolone in severely symptomatic cases.

Postpartum thyroiditis
This is described on page 967.

Amiodarone-induced thyrotoxicosis
Amiodarone, a class III antiarrhythmic drug (see p. 699), causes two types of hyperthyroidism.

Type I amiodarone-induced thyrotoxicosis (AIT) is associated with pre-existing Graves’ disease or multinodular goitre. In this situation hyperthyroidism is probably triggered by the high iodine content of amiodarone. Type II AIT is not associated with previous thyroid disease and is thought to be due to a direct effect of the drug on thyroid follicular cells leading to a destructive thyroiditis with release of T4 and T3. Type II AIT may be associated with a hypothyroid phase several months after presentation. Because amiodarone inhibits the deiodination of T4 to T3, biochemical presentation of both types of AIT may be associated with higher T4:T3 ratios than usual.

Clinical features of hyperthyroidism

The symptoms and signs of hyperthyroidism affect many systems (Fig. 19.18). Symptomatology and signs vary with age and with the underlying aetiology.

- The eye signs, of lid lag and ‘stare’ may occur with hyperthyroidism of any cause but other features of thyroid eye disease (see below) occur only in Graves’ disease.
- Graves’ dermopathy is rare: pretibial myxoedema is an infiltration of the skin on the shin. Thyroid acropachy is very rare and consists of clubbing, swollen fingers and periosteal new bone formation.
- In the elderly, a frequent presentation is with atrial fibrillation, other tachycardias and/or heart failure, often with few other signs. Thyroid function tests are mandatory in any patient with atrial fibrillation.
- Children frequently present with excessive height or excessive growth rate, or with behavioural problems such as hyperactivity. They may also show weight gain rather than loss.
- So-called ‘apathetic thyrotoxicosis’ in some elderly patients presents with a clinical picture more like hypothyroidism. There may be very few signs and a high degree of clinical suspicion is essential.

Differential diagnosis

Hyperthyroidism is often clinically obvious but treatment should never be instituted without biochemical confirmation. Differentiation of the mild case from anxiety states may be difficult; useful positive clinical markers are eye signs, a diffuse goitre, proximal myopathy and wasting. Weight loss, despite a normal or increased appetite, is a very useful clinical symptom of hyperthyroidism. The hyperdynamic circulation with warm peripheries seen with hyperthyroidism can be contrasted with the clammy hands of anxiety.

Investigations

- Serum TSH is suppressed in hyperthyroidism (<0.05 mU/L), except for the very rare instances of TSH hypersecretion.
The thyroid axis

A raised free T4 or T3 confirms the diagnosis; T4 is almost always raised but T3 is more sensitive as there are occasional cases of isolated ‘T3 toxicity’.

Thyroid peroxidase (TPO) and thyroglobulin antibodies are present in most cases of Graves’ disease.

TSHR-Ab are not measured routinely, but are commonly present: thyroid-stimulating immunoglobulin (TSI) 80% positive, TSH-binding inhibitory immunoglobulin (TBII) 60–90% in Graves’ disease (see p. 961).

Treatment

Three possibilities are available: antithyroid drugs, radioiodine and surgery. Practices and beliefs differ widely within and between countries.

Antithyroid drugs

Carbamazepine is most often used in the UK, and propylthiouracil (PTU) is also used. Thiouracil (methimazole), the active metabolite of carbimazole, is used in the USA. These drugs inhibit the formation of thyroid hormones and also have other minor actions; carbimazole/thiouracil is also an immunosuppressive agent. Initial doses and side-effects are detailed in Table 19.16.

Although thyroid hormone synthesis is reduced very quickly, the long half-life of T4 (7 days) means that clinical benefit is not apparent for 10–20 days. As many of the manifestations of hyperthyroidism are mediated via the sympathetic system, beta-blockers are used to provide rapid partial symptomatic control; they also decrease peripheral conversion of T4 to T3.

Drugs preferred are those without intrinsic sympathomimetic activity, e.g. propranolol (Table 19.16). They should not be used alone for hyperthyroidism except when the condition is self-limiting, as in subacute thyroiditis.

Subsequent management is either by gradual dose titration or a ‘block and replace’ regimen. Neither regimen has been shown to be unequivocally superior. TSH often remains suppressed for many months after clinical improvement and normalization of T4 and T3.

Symptoms

Weight loss
Increased appetite
Irritability/behaviour change
Restlessness
Malaise
Stiffness
Muscle weakness
Tremor
Chorea
Breathlessness

|                    |                     |                                                  | without intrinsic                           |
|                    |                     |                                                  | sympathomimetic                             |
|                    |                     |                                                  | activity as receptors                       |
|                    |                     |                                                  | highly sensitive                             |

- A raised free T4 or T3 confirms the diagnosis; T4 is almost always raised but T3 is more sensitive as there are occasional cases of isolated ‘T3 toxicity’.
- Thyroid peroxidase (TPO) and thyroglobulin antibodies are present in most cases of Graves’ disease.

TSHR-Ab are not measured routinely, but are commonly present: thyroid-stimulating immunoglobulin (TSI) 80% positive, TSH-binding inhibitory immunoglobulin (TBII) 60–90% in Graves’ disease (see p. 961).

Treatment

Three possibilities are available: antithyroid drugs, radioiodine and surgery. Practices and beliefs differ widely within and between countries.

Antithyroid drugs

Carbamazepine is most often used in the UK, and propylthiouracil (PTU) is also used. Thiouracil (methimazole), the active metabolite of carbimazole, is used in the USA. These drugs inhibit the formation of thyroid hormones and also have other minor actions; carbimazole/thiouracil is also an immunosuppressive agent. Initial doses and side-effects are detailed in Table 19.16.

Although thyroid hormone synthesis is reduced very quickly, the long half-life of T4 (7 days) means that clinical benefit is not apparent for 10–20 days. As many of the manifestations of hyperthyroidism are mediated via the sympathetic system, beta-blockers are used to provide rapid partial symptomatic control; they also decrease peripheral conversion of T4 to T3.

Drugs preferred are those without intrinsic sympathomimetic activity, e.g. propranolol (Table 19.16). They should not be used alone for hyperthyroidism except when the condition is self-limiting, as in subacute thyroiditis.

Subsequent management is either by gradual dose titration or a ‘block and replace’ regimen. Neither regimen has been shown to be unequivocally superior. TSH often remains suppressed for many months after clinical improvement and normalization of T4 and T3.
Dosage regimen

Gradual dose titration.

1. Start carbimazole 20–40 mg daily.
2. Review after 4–6 weeks and reduce the dose of carbimazole, depending on clinical state and fT4/fT3 levels. TSH levels may remain suppressed for several months and are unhelpful at this stage.
3. When clinically and biochemically euthyroid, stop beta-blockers.
4. Review thyroid function regularly during the planned course of treatment (typically 18 months – but some use courses between 6 and 24 months).
5. Reduce carbimazole if fT4 falls below or TSH rises above normal – and when approaching the end of the planned course.
6. Increase carbimazole if fT4 or fT3 are above normal (and consider if TSH remains suppressed after several months with a normal fT4).
7. Stop treatment at end of course if the patient is euthyroid on 5 mg daily carbimazole.

PTU is used in similar fashion (Table 19.16).

‘Block and replace’ regimen. With this policy, full doses of antithyroid drugs, usually carbimazole 40 mg daily, are given to suppress the thyroid completely while replacing thyroid activity with 100 μg of levothyroxine daily once euthyroidism has been achieved. This is continued usually for 18 months, the claimed advantages being the avoidance of over- or undertreatment and the better use of the immunosuppressive action of carbimazole. This regimen is contraindicated in pregnancy as T4 crosses the placenta less well than carbimazole.

Relapse

About 50% of patients will relapse after a course of carbimazole or PTU, mostly within the following 2 years but occasionally much later. Long-term antithyroid therapy is then used or surgery or radiotherapy is considered (see below). Most patients (90%) with hyperthyroidism have a diffuse goitre but those with large single or multinodular goitres are unlikely to remit after a course of antithyroid drugs and will usually require definitive treatment. Severe biochemical hyperthyroidism is also less likely to remain in remission.

Toxicity

The major side-effect of drug therapy is agranulocytosis that occurs in approximately 1 in 1000 patients, usually within 3 months of treatment. All patients must be warned to seek immediate medical attention for a white blood cell count if they develop unexplained fever or sore throat – written information is essential. Rashes are more frequent and usually require a change of drug. If toxicity occurs on carbimazole, PTU may be used and vice-versa; side-effects are only occasionally repeated on the other drug.

Radioactive iodine

Radioactive iodine (RAI) is given to patients of all ages, although it is contraindicated in pregnancy and while breastfeeding. RAI is the most common treatment modality in the USA whereas antithyroid drugs tend to be favoured in Europe. ¹³¹Iodine is given in an empirical dose (usually 200–550 MBq) because of variable uptake and radiosensitivity of the gland. It accumulates in the thyroid and destroys the gland by local radiation although it takes several months to be fully effective.

Patients must be rendered euthyroid before treatment. They should stop antithyroid drugs at least 4 days before radioactive iodine, and not recommence until 3 days after radioiodine. Patients on PTU should stop antithyroid medication earlier than those on carbimazole before RAI because it has a radioprotective action. Many patients do not need to restart antithyroid medication after treatment.

Early discomfort in the neck and immediate worsening of hyperthyroidism are sometimes seen; if worsening occurs, the patient should receive propranolol (Table 19.16); if necessary carbimazole can be restarted. Euthyroidism normally returns in 2–3 months. People with dysthyroid eye disease are more likely to show worsening of eye problems after radioiodine than after antithyroid drugs; this represents a partial contraindication to RAI, although worsening can usually be prevented by steroid administration.

Long-term surveillance. Hypothyroidism affects the majority of subjects over the following 20 years. Some 75% of patients are rendered euthyroid in the short term but a small proportion remain hyperthyroid and may require a second dose of radioiodine. Long-term surveillance of thyroid function is necessary with frequent tests in the first year after therapy, and at least annually thereafter.

Risk of carcinogenesis has been long debated, but the overwhelming evidence suggests that overall cancer incidence and mortality are not increased after radioactive iodine (and indeed are significantly reduced in some studies).

Surgery

Thyroidectomy should be performed only in patients who have previously been rendered euthyroid. Conventional practice is to stop the antithyroid drug 10–14 days before operation and to give potassium iodide (60 mg three times daily), which reduces the vascularity of the gland.

The operation should be performed only by experienced surgeons to reduce the chance of complications:

- Early postoperative bleeding causing tracheal compression and asphyxia is a rare emergency requiring immediate removal of all clips/sutures to allow escape of the blood/haematoma.
- Laryngeal nerve palsy occurs in 1%. Vocal cord movement should be checked preoperatively. Mild hoarseness is more common and thyroidectomy is best avoided in professional singers!
- Transient hypocalcaemia occurs in up to 10% but with permanent hypoparathyroidism in fewer than 1%.
- Ongoing thyroid function depends on the operation performed. With a single toxic nodule excision of the lesion is curative. With Graves’ disease or multinodular goitre the traditional ‘subtotal’ thyroidectomy, aiming for euthyroidism on no treatment, results in recurrent hyperthyroidism in 1–3% within 1 year, then 1% per year and hypothyroidism in about 10% of patients within 1 year, and then increasing with time. ‘Near-total’ thyroidectomy is therefore now preferred with inevitable hypothyroidism but a much reduced risk of recurrence.

Indications for either surgery or radioiodine are given in Box 19.4.

Special situations in hyperthyroidism

Thyroid crisis or ‘thyroid storm’

This rare condition, with a mortality of 10%, is a rapid deterioration of hyperthyroidism with hyperpyrexia, severe tachycardia, extreme restlessness, cardiac failure and liver dysfunction. It is usually precipitated by stress, infection or surgery in an unprepared patient, or radioiodine therapy. With careful management it should no longer occur and most
Propranolol in full doses is started immediately together with potassium iodide, antithyroid iodine is absolutely contraindicated.

Occasionally, hyperthyroidism can lead to a thyrotoxic cardiomyopathy which causes ischaemic changes on a 12-lead ECG which reverse after reversion to euthyroidism.

Hyperthyroidism in pregnancy and neonatal life
Since hyperthyroidism typically affects young women, pregnancies, both planned and unplanned, inevitably occur during antithyroid treatment. PTU is usually the preferred antithyroid drug during pregnancy or in any woman planning pregnancy, due to rare reports of congenital abnormalities with carbimazole which have not been described with PTU.

The high level of HCG found in normal pregnancy is a weak stimulator of the TSH receptor, commonly causing suppressed TSH with slightly elevated T4T3 in the first trimester which may be associated with hyperemesis gravidarum. True maternal hyperthyroidism occurring de novo during pregnancy is however uncommon and usually mild. Diagnosis can be difficult because of the overlap with symptoms of normal pregnancy and misleading thyroid function tests, although TSH is largely reliable. The pathogenesis is almost always Graves’ disease.

Thyroid-stimulating immunoglobulin (TSI) crosses the placenta to stimulate the fetal thyroid. Carbimazole and PTU (see below) also cross the placenta, but T4 does so poorly, so a ‘block-and-replace’ regimen is contraindicated. The smallest dose necessary of PTU (see above) is used and the fetus must be monitored. If necessary (high doses needed, poor patient compliance or drug side-effects), surgery can be performed, preferably in the second trimester. Radioactive iodine is absolutely contraindicated.

The fetus and maternal Graves’ disease
Any mother with a history of Graves’ disease may have circulating TSI. Even if she is euthyroid after surgery or RAI, the immunoglobulin may still be present to stimulate the fetal thyroid, and the fetus can thus become hyperthyroid.

Any such patient should therefore be monitored during pregnancy. Fetal heart rate provides a direct biological assay of fetal thyroid status, and monitoring should be performed at least monthly. Rates above 160/minute are strongly suggestive of fetal hyperthyroidism, and maternal treatment with PTU and/or propranolol is used. Direct measurement of TSHR-Ab may be helpful to predict neonatal thyrotoxicosis in this situation. To prevent a euthyroid mother becoming hypothyroid, T4 may be given as this does not easily cross the placenta. Sympathomimetics, used to prevent premature labour, are contraindicated as they may provoke fatal tachycardia in the fetus. The paediatrician should be informed and the infant checked immediately after birth – overtreatment with PTU or carbimazole can cause fetal goitre. Breastfeeding while on usual doses of carbimazole or PTU appears to be safe.

Hyperthyroidism may also develop in the neonatal period as TSI has a half-life of approximately 3 weeks. Manifestations in the newborn include irritability, failure to thrive and persisting weight loss, diarrhoea and eye signs. Thyroid function tests are difficult to interpret as neonatal normal ranges vary with age.

Untreated neonatal hyperthyroidism is probably associated with hyperactivity in later childhood.

Thyroid hormone resistance
Thyroid hormone resistance is an inherited condition caused by an abnormality of the thyroid hormone receptor. Mutations to the receptor (TR β) result in the need for higher levels of thyroid hormones to achieve the same intracellular effect. As a result, the normal feedback control mechanisms (see Fig. 19.2, p. 941) result in high blood levels of T4 with a normal TSH in order to maintain a euthyroid state. This has two consequences:

1. Thyroid function tests appear abnormal even when the patient is euthyroid and requires no treatment. Specialist review is required to differentiate from hyperthyroidism due to inappropriate TSH secretion.

2. Different tissues contain different thyroid hormone receptors and, in some families, receptors in certain tissues may have normal activity. In this case the level of thyroid hormones to maintain euthyroidism at pituitary and hypothalamic levels (which controls secretion of TSH) may be higher than that required in other tissues such as heart and bone, so that these tissues may exhibit ‘thyrotoxic’ effects in spite of a normal serum TSH. This ‘partial thyroid hormone resistance’ can be very difficult to manage effectively.

Long-term consequences of hyperthyroidism
Long-term follow-up studies of hyperthyroidism show a slight increase in overall mortality, which affects all age groups, is not fully explained and tends to occur in the first year after diagnosis. Thereafter, the only long-term risk of adequately treated hyperthyroidism appears to be an increased risk of osteoporosis. People with persistently suppressed TSH levels have an increased likelihood of developing atrial fibrillation which may predispose to thromboembolic disease.

Thyroid eye disease
This is also known as dysthyroid eye disease or ophthalmic Graves’ disease.

Pathophysiology
The ophthalmopathy of Graves’ disease is due to a specific immune response that causes retro-orbital inflammation (Fig. 19.19). Swelling and oedema of the extraocular muscles lead to limitation of movement and to proptosis which is usually bilateral but can sometimes be unilateral. Ultimately increased pressure on the optic nerve may cause optic atrophy. Histology of the extraocular muscles shows focal oedema and glycosaminoglycan deposition followed by fibrosis. The precise autoantigen which leads to the immune response remains to be identified, but it appears to be an antigen in
Thyroid Graves’ orbitopathy.

Graves’ Orbitopathy: management of (EUGOGO) on European Group on Consensus Bartalena L et al.

*The clinical appearances are characteristic (Fig. 19.18) but thyroid eye disease demonstrates a wide range of severity. A high proportion of people with Graves’ disease notice some soreness, painful watering or prominence of the eyes, and the ‘stare’ of lid retraction is relatively common. More severe proptosis occurs in a minority of cases, and limitation and discomfort of eye movement and visual impairment due to optic nerve compression are relatively uncommon. Proposis and lid retraction may limit the ability to close the eyes completely so that corneal damage may occur. There is peri-orbital oedema and conjunctival oedema and inflammation. Eye manifestations do not parallel the degree of biochemical thyrotoxicosis, or the need for antithyroid therapy, but exacerbation of eye disease is more common after radioiodine treatment (15% versus 3% on antithyroid drugs). Sight is threatened in only 5–10% of cases, but the discomfort and cosmetic problems cause great patient anxiety. Few investigations are necessary if the appearances are characteristic and bilateral. TSH, T3 and T4 are measured. There are a variety of grading systems but none is universally accepted. It is essential to clearly document eye movements and the degree of oedema and inflammation. The exophthalmos should be measured to allow progress to be monitored. MRI or CT of the orbits will exclude retro-orbital space-occupying lesions, show enlarged muscles and oedema, and may show a taut optic nerve due to raised intra-orbital pressure.*

**Clinical features**

Eye disease is a manifestation of Graves’ disease and can occur in patients who may be hyperthyroid, euthyroid or hypothyroid. Thyroid dysfunction and ophthalmopathy usually occur within two years of each other although sometimes a gap of many years is seen. TSH receptor antibodies are almost invariably found in the serum but their role in the pathogenesis is becoming clearer (Fig. 19.19). Ophthalmopathy is more common and more severe in smokers.

**Treatment**

If the patient is thyrotoxic this should be treated, but this will not directly result in an improvement of the ophthalmopathy, and hypothyroidism must be avoided as it may exacerbate the eye problem. Smoking should be stopped. Treatment of the eyes may be either local or systemic, and always requires close liaison between specialist endocrinologist and opthalmologist:

- **Methylcellulose or hypromellose eyedrops** are given to aid lubrication and improve comfort.
- **Some patients gain relief by sleeping upright.**
- **The eyelids can be taped to ensure closure at night.**
- **Systemic steroids** (prednisolone 30–120 mg daily) usually reduce inflammation if more severe symptoms are present. Pulse intravenous methylprednisolone may be used initially and is more rapidly effective in severe cases.
- **Surgical decompression of the orbit(s)** may be required, particularly if pressure of orbital contents on the optic nerve threatens vision, and at a later, stable stage for cosmetic reasons.
- **Lid surgery** will protect the cornea if lids cannot be closed, and can be useful later for cosmetic reasons.
- **Corrective eye muscle surgery** may improve diplopia due to muscle changes, but should be deferred until the situation has been stable for 6 months and should follow any orbital decompression.
- **Irradiation of the orbits** (20 Gy in divided doses) is used in some centres. This improves inflammation and ocular motility but has little effect on proptosis and its precise role is debated.
- **Immunomodulatory agents** may produce a response in some patients when conventional treatments fail, although clinical trial evidence is inconsistent.

**Goitre (thyroid enlargement)**

Goitre is more common in women than in men and may be either physiological or pathological.
Clinical features
Goitres are present on examination in up to 9% of the population. Most commonly a goitre is noticed as a cosmetic defect by the patient or by friends or relatives. The majority are painless, but pain or discomfort can occur in acute varieties. Large goitres can produce dysphagia and difficulty in breathing, implying oesophageal or tracheal compression.

A small goitre may be more easily visible (on swallowing) than palpable. Clinical examination should record the size, shape, consistency and mobility of the gland as well as whether its lower margin can be demarcated (thus implying the absence of retrosternal extension). A bruit may be present. Associated lymph nodes should be sought and the tracheal position determined if possible. Examination should never omit an assessment of the patient’s clinical thyroid status.

Specific enquiry should be made about any medication, especially iodine-containing preparations, and possible exposure to radiation.

Particular points of note are:
- Puberty and pregnancy may produce a diffuse increase in size of the thyroid.
- Pain in a goitre may be caused by thyroiditis, bleeding into a cyst or (rarely) a thyroid tumour.
- Excessive doses of carbimazole or PTU will induce goitre.
- Iodine deficiency and dyshormonogenesis (see above) can also cause goitre.

Assessment
There are two major aspects of any goitre: its pathological nature and the patient’s thyroid status.

The nature can often be judged clinically. Goitres (Table 19.17) are usually separable into diffuse and nodular types, the causes of which differ.

Diffuse goitre
Simple goitre
In this instance, no clear cause is found for enlargement of the thyroid, which is usually smooth and soft. It may be associated with thyroid growth-stimulating antibodies.

Autoimmune thyroid disease
Hashimoto’s thyroiditis and thyrotoxicosis are both associated with firm diffuse goitre of variable size. A bruit is often present in thyrotoxicosis.

Thyroiditis
Acute tenderness in a diffuse swelling, sometimes with severe pain, is suggestive of an acute viral thyroiditis (de Quervain’s). It may produce transient clinical hyperthyroidism with an increase in serum T3 (see p. 964).

Nodular goitres
Multinodular goitre
Most common is the multinodular goitre, especially in older patients. The patient is usually euthyroid but may be hyperthyroid or borderline with suppressed TSH levels but normal free T4 and T3. Multinodular goitre is the most common cause of tracheal and/or oesophageal compression and can cause laryngeal nerve palsy. It may also extend retrosternally.

The classical ‘multinodular goitre’ is usually readily apparent clinically, but it should be noted that modern, high-resolution ultrasound frequently reports multiple small nodules in glands which are clinically diffusely enlarged and associated with autoimmune thyroid disease. These nodules are also found in up to 40% of the normal population.

Solitary nodular goitre
Such a goitre presents a difficult problem of diagnosis. Malignancy should be of concern in any solitary nodule – however, the majority of such nodules are cystic or benign and, indeed, may simply be the largest nodule of a multinodular goitre. The diagnostic challenge is to identify the small minority of malignant nodules, which require surgery, from the majority of benign nodules, which do not. Sometimes a history of rapid enlargement, associated lymph nodes or pain may suggest an aggressive malignancy, but most thyroid cancers are painless and slow-growing so that investigations are paramount. Risk factors for malignancy include previous irradiation, longstanding iodine deficiency and occasional familial cases.

Solitary toxic nodules are quite uncommon and may be associated with T3 toxicosis.

Fibrotic goitre (Riedel’s thyroiditis)
Fibrotic goitre is a rare condition, usually producing a ‘woody’ gland. It is associated with other midline fibrosis and is often difficult to distinguish from carcinoma, being irregular and hard. Clinical clues include systemic symptoms of inflammation and elevation in inflammatory markers; it has been shown to be an IgG4-related disease.

Malignancy
In addition to thyroid carcinomas (see below), the thyroid is rarely the site of a metastatic deposit or the site of origin of a lymphoma.

Investigations
Clinical findings will dictate appropriate initial tests:
- Thyroid function tests: TSH plus free T4 or T3 (see Table 19.7).
- Thyroid antibodies: to exclude autoimmune aetiology.
- Ultrasound. Ultrasound with high resolution is a sensitive method for delineating nodules and can demonstrate whether they are cystic or solid. In addition, a multinodular goitre may be demonstrated when only a single nodule is palpable. Unfortunately, even cystic lesions can be malignant and thyroid tumours may arise within a multinodular goitre; therefore fine-needle aspiration (see below) is often required and performed under ultrasound control at the same time as the scan.
- Chest and thoracic inlet X-rays or CT scan to detect tracheal compression and large retrosternal extensions in people with very large goitre or clinical symptoms.

Retrosternal goitre showing deviation and compression of trachea on a CT scan.
- **Fine-needle aspiration (FNA).** In people with a solitary nodule or a dominant nodule in a multinodular goitre, there is a 5% chance of malignancy; in view of this, FNA should be performed in the outpatient clinic or during ultrasound. Cytology in expert hands can usually differentiate the suspicious or definitely malignant nodule.

  FNA reduces the necessity for surgery, but there is a 5% false-negative rate, which must be borne in mind (and the patient appropriately counselled). Continued observation is required when an isolated thyroid nodule is assumed to be benign without excision.

- **Thyroid scan** ($^{99m}$Tc, $^{125}$I or $^{131}$I) can be useful to distinguish between functioning (hot) or non-functioning (cold) nodules. A hot nodule is only rarely malignant; however, a cold nodule is malignant in only 10% of cases and FNA has largely replaced isotope scans in the diagnosis of thyroid nodules.

**Treatment**

**Euthyroid goitre**

Many goitres are small, cause no symptoms and can be observed (including self-monitoring by the patient in the long term). In particular, during puberty and pregnancy a goitre associated with euthyroidism rarely requires intervention and the patient can be reassured that spontaneous resolution is likely. Indications for surgical intervention are:

- **The possibility of malignancy.** A positive or suspicious FNA makes surgery mandatory and surgery may be necessary if doubt persists even in the presence of a negative FNA (especially if the patient is concerned by the false-negative rate).

- **Pressure symptoms on the trachea or, more rarely, oesophagus.** The possibility of retrosternal extension should be excluded.

- **Cosmetic reasons.** A large goitre is often a considerable anxiety to the patient even though functionally and anatomically benign.

  Radioactive iodine has also been advocated for the treatment of euthyroid goitre, particularly when surgery is an unattractive option.

**Toxic nodule**

This is initially with antithyroid drugs but surgery or radioactive iodine is often required.

**Thyroid carcinoma**

Types of thyroid carcinoma, their characteristics and treatment are listed in Table 19.18. While not common, these tumours are responsible for 400 deaths annually in the UK and an annual incidence of 30,000 cases in the USA. Over 75% occur in women. In 90% of cases they present as thyroid nodules (see above), but occasionally with cervical lymphadenopathy (about 5%), or with lung, cerebral, hepatic or bone metastases.

Carcinomas derived from thyroid epithelium may be papillary or follicular (differentiated) or anaplastic (undifferentiated). Medullary carcinomas (about 5% of all thyroid cancers) arise from the calcitonin-producing C cells. The pathogenesis of thyroid epithelial carcinomas is not understood except for occasional familial papillary carcinoma and those cases related to previous head and neck irradiation or ingestion of radioactive iodine (e.g. post-Chernobyl). These tumours are minimally active hormonally and are extremely rarely associated with hyperthyroidism; over 90%, however, secrete thyroglobulin, which can therefore act as a tumour marker after thyroid ablation.

**Papillary and follicular carcinomas**

The primary treatment is surgical, normally total or near-total thyroidectomy for local disease. Regional or more extensive neck dissection is needed where there is local nodal spread or involvement of local structures.

Most tumours will take up iodine, and UK and other guidelines currently recommend radioactive iodine (RAI) ablation of residual thyroid tissue postoperatively for most people with differentiated thyroid cancer. After ablation of normal thyroid in this way, RAI may be used to localize residual disease (scanning using low doses) or to treat it (using high doses: 5.5–7.5 GBq). When recurrence does occur, local invasion and lymph node involvement is most common, and lungs and bone are the most common sites of distant metastases.

To minimize risk of recurrence patients are treated with suppressive doses of levothyroxine (sufficient to suppress TSH levels below the normal range). Patient progress is monitored both clinically and biochemically using serum thyroglobulin levels as a tumour marker. The measurement of thyroglobulin is most sensitive when TSH is high but this requires the withdrawal of levothyroxine therapy. Recombinant TSH (thyrotropin alfa, rhTSH) 900 μg (2 doses over 48 hours) is used to stimulate thyroglobulin without stopping thyroxine therapy. Detectable thyroglobulin suggests recurrence, in which case whole body $^{131}$I scanning is required. Unfortunately the presence of anti-thyroglobulin antibodies can make the assay unreliable.

The prognosis is extremely good when differentiated thyroid cancer is excised while confined to the thyroid gland, and the specific therapies available lead to a relatively good prognosis even in the presence of metastases at diagnosis. Accepted markers of high risk include greater age (>40 years), larger primary tumour size (>4 cm) and macroscopic invasion of capsule and surrounding tissues.

**Anaplastic carcinomas and lymphoma**

These do not respond to radioactive iodine, and external radiotherapy produces only a brief respite.

Medullary carcinoma

Medullary carcinoma (MTC) is a neuroendocrine tumour of the calcitonin-producing C cells of the thyroid. This condition is often associated with multiple endocrine neoplasia type 2 (MEN 2, see p. 998) – approximately 25% of patients diagnosed with MTC have a mutation of the RET proto-oncogene, although the other manifestations of MEN 2 may be absent, hence the importance of genetic counselling and family screening. People with MEN2 mutations are advised to have a prophylactic thyroidectomy as early as 5 years of age to prevent the development of MTC.

Total thyroidectomy and wide lymph node clearance is frequent, and the tumour responds poorly to treatment, although progression is often slow.

**REPRODUCTION AND SEX**

Terminology in reproductive medicine is shown in Box 19.5.

**Embryology**

Up to 8 weeks of gestation the sexes share a common development, with a primitive genital tract including the Wolffian and Müllerian ducts. There are additionally a primitive perineum and primitive gonads.

- In the presence of a Y chromosome, the potential testis develops while the ovary regresses.
- In the absence of a Y chromosome, the potential ovary develops and related ducts form a uterus and the upper vagina.

Production of Müllerian inhibitory factor from the early ‘testis’ produces atrophy of the Müllerian duct, while, under the influence of testosterone and dihydrotestosterone, the Wolffian duct differentiates into an epididymis, vas deferens, seminal vesicles and prostate. Androgens induce transformation of the perineum to include a penis, penile urethra and scrotum containing the testes, which descend in response to androgenic stimulation. At birth, testicular volume is 0.5–1 mL.

**Physiology**

**The male**

An outline of the hypothalamic-pituitary-gonadal axis is shown in Figure 19.20.

1. Pulses of gonadotrophin-releasing hormone (GnRH) are released from the hypothalamus and stimulate LH.

**Figure 19.20** Male and female hypothalamic-pituitary-gonadal axes. LH and FSH are secreted in pulses in response to hypothalamic GnRH and have differential effects on the gonads (see text). Testosterone and oestrogens have multiple peripheral effects and exert negative feedback on LH secretion. Inhibin exerts negative feedback on FSH secretion.
and FSH release from the pituitary. LH and FSH are composed of two glycoprotein chains (α and β subunits). The α subunits are identical and are shared with TSH, whilst the β subunit confers specific biological activity.

2. LH stimulates testosterone production from Leydig cells of the testis.

3. Testosterone acts via nuclear androgen receptors which interact with coregulatory proteins to produce the appropriate tissue responses: male secondary sexual characteristics, anabolism and the maintenance of libido. It also acts locally within the testis to aid spermatogenesis. Testosterone circulates largely bound to sex hormone-binding globulin (SHBG) (see p. 942). Testosterone feeds back on the hypothalamus/pituitary to inhibit GnRH secretion.

4. FSH stimulates the Sertoli cells in the seminiferous tubules to produce mature sperm and the inhibins A and B.

5. Inhibin feeds back to the pituitary to decrease FSH secretion. Activin, a related peptide, counteracts inhibin.

**The secondary sexual characteristics of the male.** For which testosterone is necessary are the growth of pubic, axillary and facial hair, enlargement of the external genitalia, deepening of the voice, sebum secretion, muscle growth and frontal balding.

**The female**

Female physiology is more complex (Figs 19.20, 19.21).

1. In the adult female, higher brain centres impose a menstrual cycle of 28 days upon the activity of hypothalamic GnRH.

2. Pulses of GnRH, at about 2-hour intervals, stimulate release of pituitary LH and FSH.

3. LH stimulates ovarian androgen production by the ovarian theca cells.

4. FSH stimulates follicular development and aromatase activity (an enzyme required to convert ovarian androgens to oestrogens) in the ovarian granulosa cells. FSH also stimulates release of inhibin from ovarian stromal cells, which inhibits FSH release. Activin counteracts inhibin (Fig. 19.20).

5. Although many follicles are ‘recruited’ for development in early folliculogenesis, by day 8–10 a ‘leading’ (or ‘dominant’) follicle is selected for development into a mature Graafian follicle.

6. Oestrogens have a double feedback action on the pituitary (Fig. 19.20). Initially they inhibit gonadotrophin secretion (negative feedback), but later high-level exposure results in increased GnRH secretion and increased LH sensitivity to GnRH (positive feedback), which leads to the mid-cycle LH surge inducing ovulation from the leading follicle (Fig. 19.21).

7. The follicle then differentiates into a corpus luteum, which secretes both progesterone and oestradiol during the second half of the cycle (luteal phase).

8. Oestrogen initially and then progesterone cause uterine endometrial proliferation in preparation for possible implantation; if implantation does not occur, the corpus luteum regresses and progesterone secretion and inhibin levels fall so that the endometrium is shed (menstruation) allowing increased GnRH and FSH secretion.

9. If implantation and pregnancy follow, human chorionic gonadotrophin (HCG) production from the trophoblast maintains corpus luteum function until 10–12 weeks of gestation, by which time the placenta will be making sufficient oestrogen and progesterone to support itself.

**Secondary sexual characteristics of the female.** These are induced by oestrogens, especially development of the breast and nipples, vaginal and vulval growth and pubic hair development. Oestrogens also induce growth and maturation of the uterus and fallopian tubes. They circulate largely bound to SHBG.

**Puberty**

The mechanisms initiating puberty are poorly understood but are thought to result from withdrawal of central inhibition of GnRH release. Environmental and physical factors are involved in the timing of puberty (including body fat changes, physical exercise) as well as genetic factors (e.g. a G protein-coupled receptor gene, GPR54) required for pubertal maturation. Kisspeptin is the endogenous ligand for kisspeptin receptor KISS1R formerly known as GPR54 and this peptide is believed to play a crucial role in the regulation of GnRH production and the timing of puberty.

LH and FSH are both low in the prepubertal child. In early puberty, FSH begins to rise first, initially in nocturnal pulses; this is followed by a rise in LH with a subsequent increase in testosterone/oestrogen levels. The milestones of puberty in the two sexes are shown in Figure 19.22.

**In boys,** pubertal changes begin at between 10 and 14 years and are complete at between 15 and 17 years. The genitalia develop, testes enlarge and the area of pubic hair increases. Peak height velocity is reached between ages 12 and 17 years during stage 4 of testicular development. Full spermatogenesis occurs comparatively late.

**In girls,** events start a year earlier. Breast bud enlargement begins at age 9–13 years and continues to 12–18 years. Pubic hair growth commences at ages 9–14 years and is completed at 12–16 years. Menarche occurs relatively late (age 11–15 years) but peak height velocity is reached earlier (at age 10–13 years), and growth is completed much earlier than in boys.

---

**FURTHER READING**

Delayed puberty

Over 95% of children show signs of pubertal development by the age of 14 years. In its absence, investigation should begin by the age of 15 years. Causes of hypogonadism (see below) are clearly relevant but most cases represent constitutional delay.

In constitutional delay, pubertal development, bone age and stature are in parallel. A family history may confirm that other family members experienced the same delayed development, which is common in boys but very rare in girls.

In boys, a testicular volume >5 mL indicates the onset of puberty. A rising serum testosterone is an earlier clue.

In girls, the breast bud is the first sign. Ultrasound allows accurate assessment of ovarian and uterine development.

Elevated LH/FSH levels will identify a primary gonadal defect, and in other cases, GnRH (LHRH) tests can indicate the stage of early puberty.

If any progression into puberty is evident clinically, investigations are not required. When delay is great and problems are serious (e.g. severe teasing at school), low-dose short-term sex hormone therapy is used to induce puberty.

The menopause

The menopause, or cessation of periods, naturally occurs at about the age of 45–55 years. During the late 40s, FSH initially, and then LH concentrations begin to rise, probably as follicle supply diminishes. Oestrogen levels fall and the cycle becomes disrupted. Most women notice irregular scanty periods coming on over a variable period, though in some sudden amenorrhoea or menorrhagia occurs. Eventually the menopausal pattern of low oestradiol levels with grossly elevated LH and FSH levels (usually >50 and >25 U/L, respectively) is established. Premature menopause may also occur surgically, with radiotherapy to the ovaries and with ovarian disease.

Clinical features and treatment

Features of oestrogen deficiency are hot flushes (which occur in most women and can be disabling), vaginal dryness and atrophy of the breasts. There may also be symptoms of loss of libido, loss of self-esteem, nonspecific aches and pains, sleep disturbance, irritability, depression, loss of concentration and weight gain.

Women show a rapid loss of bone density in the 10 years following the menopause (osteoarthritis, see p. 552) and the premenopausal protection from ischaemic heart disease disappears.

Hormone replacement therapy (HRT). Symptomatic patients should usually be treated but the previous widespread use of HRT has been thrown into doubt by a number of large prospective studies which have reported in recent years. Although scientific debate continues, the overall benefits and risks are summarized as in Box 19.6.

Absolute risks and benefits for individual women clearly depend on their background risk of that disease, and there is as yet no evidence on the relative risks of different hormone preparations or routes of administration (oral, transdermal or implant). Overall, the WHI study estimated that, over 5 years of treatment, an extra one woman in every 100 would develop an illness that would not have occurred had she not been taking HRT. However, the decision about whether or not a woman takes HRT is now very much an individual decision based on:

- the severity of the woman’s menopausal symptoms
- her personal risk of conditions which may be prevented or made more likely by HRT
- individual patient choice.

Precocious puberty

Development of secondary sexual characteristics, or menarche in girls, at or before the age of 9 years is premature. All cases require assessment by a paediatric endocrinologist.

Idiopathic (true) precocity is most common in girls and very rare in boys. This is a diagnosis of exclusion. With no apparent cause for premature breast or pubic hair development, and an early growth spurt, it may be normal and may run in families. Treatment with long-acting GnRH analogues (given by nasal spray, by subcutaneous injection or by implant) causes suppression of gonadotrophin release via downregulation of the receptor – and therefore reduced sex hormone production – and is moderately effective; cyproterone acetate, an antiandrogen with progestational activity, is also used.

Other forms of precocity include:

- **Cerebral precocity**. Many causes of hypothalamic disease, especially tumours, present in this way. In boys this must be rigorously excluded. MRI scan is almost always indicated to exclude this diagnosis.

- **McCune–Albright syndrome**. This usually occurs in girls, with precocity, polyostotic fibrous dysplasia and skin pigmentation (café-au-lait). See also page 998.

- **Premature thelarche**. This is early breast development alone, usually transient, at age 2–4 years. It may regress or persist until puberty. There is no evidence of follicular development.

- **Premature adrenarche**. This is early development of pubic hair without significant other changes, usually after the age of 5 years and more commonly in girls. It is also more common in obese children due to reduced SHBG levels leading to higher free circulating androgens. In boys with precocious adrenarche, the rare possibility of an androgen-secreting testicular tumour should be looked for if serum androgens are high and LH is suppressed.
HRT is not recommended purely for prevention of postmenopausal osteoporosis in the absence of menopausal symptoms. Symptomatic treatment is the main indication with the lowest effective dose given for short-term rather than long-term treatment.

Selective oestrogen receptor modulators, SERMs (e.g. raloxifene), offer a potentially attractive combination of positive oestrogen effects on bone and cardiovascular system with no effects on oestrogen receptors of uterus and breast and possible reduction in breast cancer incidence; long-term outcome studies, however, are still awaited.

Premature menopause and ovarian failure

The most common cause of premature menopause in women (before age 40) is ovarian failure. This may be autoimmune, and is rarely caused by identifiable genetic causes such as the fragile X pre-mutation but is most commonly of unknown aetiology, although often familial. Repeat LH/FSH levels are necessary before giving a diagnosis of premature menopause because of the psychological impact of this diagnosis and the possibility that a single elevation of LH/FSH might simply be the mid-cycle ovulatory surge. Bilateral oophorectomy and some chemotherapy regimens cause the same oestrogen deficiency state.

Treatment. HRT should almost always be given, as the risk of osteoporosis and other conditions related to oestrogen deficiency almost always outweighs the risks of HRT at this younger age. HRT may still also be actively recommended when normal menopause occurs relatively early (e.g. before the age of 50).

The ageing male

In the male, there is no sudden ‘change of life’. However, there is a progressive loss in sexual function with reduction in morning erections and frequency of intercourse. The age of onset varies widely. Typically, overall testicular volume diminishes and sex hormone-binding globulin (SHBG) and gonadotrophin levels gradually rise, but other men present with low or borderline testosterone without elevation of LH/FSH. Low testosterone certainly increases the risk of osteoporosis and in some studies is associated with increased cardiovascular risk, but it remains unclear to what extent general symptoms of lack of energy, drive, muscle strength and general wellbeing may relate to these hormonal changes. Loss of libido and erectile dysfunction are common symptoms even when hormones are normal, and long-term outcome studies of testosterone replacement are still awaited. Therefore, the decision to offer testosterone replacement to an ageing male is currently based on full clinical and biochemical assessment and full discussion of potential risks (including prostate disease) as well as benefits. If testosterone is unequivocally low (<7 pmol/L) most authorities would recommend replacement. However, few would treat if testosterone is >12 pmol/L with normal LH/FSH. Clinically, a large proportion of cases are in the borderline range (7–12 pmol/L), which can lead to difficulties in reaching a firm diagnosis.

Clinical features of disorders of sex and reproduction

A detailed history and examination of all systems is required (Box 19.7). A man having regular satisfactory intercourse or a woman with regular ovulatory periods is most unlikely to have significant endocrine disease, assuming the history is accurate.

Tests of gonadal function

Much can be deduced from basal measurements of the gonadotrophins, oestrogens/testosterone and prolactin:

- Low testosterone or oestradiol with high gonadotrophins indicates primary gonadal disease.
- Low levels of testosterone/oestradiol with low or normal LH/FSH imply hypothalamic-pituitary disease.
- Demonstration of ovulation (by measurement of luteal phase serum progesterone and/or by serial ovarian ultrasound in the follicular phase) or a healthy sperm count (20–200 million/mL, >60% grade I motility and

<20% abnormal forms), provide absolute confirmation of normal female or male reproductive endocrinology, but these tests are not always essential.

- Pregnancy provides complete demonstration of normal male and female function.
- Hyperprolactinaemia can be confirmed or excluded by direct measurement. Levels may increase with stress; if this is suspected, a cannula should be inserted and samples taken through it 30 min later.

More detailed tests are indicated in Table 19.19.

Disorders in the male

Hypogonadism

Clinical features

Male hypogonadism may be a presenting complaint or an incidental finding, such as during investigation for subfertility. The tests may be small and soft and there may be gynaecomastia. Except with subfertility, the symptoms are usually of androgen deficiency, primarily poor libido, erectile dysfunction and loss of secondary sexual hair (Table 19.20) rather than deficiency of semen production. Sperm makes up only a very small proportion of seminal fluid volume; most is prostatic fluid.

Causes of male hypogonadism are shown in Table 19.21.

Investigations

Testicular disease may be immediately apparent but basal levels of testosterone, LH and FSH should be measured. These will allow the distinction between primary gonadal (testicular) failure and hypothalamic-pituitary disease to be made. Depending on the causes, semen analysis, chromosomal analysis (e.g. to exclude Klinefelter’s syndrome) and bone age estimation are required.

In clear-cut gonadotrophin deficiency, pituitary MRI scan, prolactin levels and other pituitary function tests are needed. However, equivocal lowering of serum testosterone (7–10 nmol/L) without elevation of gonadotrophins is a relatively common biochemical finding, and is a frequent cause of referral in men with poor libido or erectile dysfunction. Such tests are compatible with mild gonadotrophin deficiency, but may also be seen in acute illness of any cause and often
Klinefelter’s syndrome

Klinefelter’s syndrome is a common congenital abnormality, affecting 1 in 1000 males. It is a chromosomal disorder (47XXY and variants, e.g. 46XY/47XXY mosaicism), i.e. a male with an extra X chromosome. There is both a loss of Leydig cells and seminiferous tubular dysgenesis. Patients usually present in adolescence with poor sexual development, small or undescended testes, gynaecomastia or infertility. In 47XXY there is long leg length with tall stature – the androgen deficiency leads to lack of epiphyseal closure in puberty. Patients occasionally have behavioural problems and learning difficulties. There is also a predisposition to diabetes mellitus, breast cancer, emphysema and bronchiectasis; these are all unrelated to the testosterone deficiency.

Clinical examination shows a wide spectrum of features with small pea-sized but firm testes, usually gynaecomastia and other signs of androgen deficiency. Some patients have a normal puberty and may present later with infertility. Confirmation is by chromosomal analysis. Treatment is androgen replacement therapy unless testosterone levels are normal. No treatment is possible for the abnormal seminiferous tubules and infertility.

Kallmann’s syndrome

This is isolated GnRH deficiency. It is associated with decreased or absent sense of smell (anosmia), and sometimes with other bony (cleft palate), renal and cerebral abnormalities (e.g. colour blindness). It is often familial and is usually X-linked, resulting from a mutation in the KAL1 gene which encodes anosmin-1 (producing loss of smell); one sex-linked form is due to an abnormality of a cell adhesion molecule. Management is that of secondary hypogonadism (see p. 976). Fertility is possible.

Normosmic idiopathic hypogonadotropic hypogonadism

This refers to isolated GnRH deficiency in the absence of anosmia. Known mutations account for less than 15% of normosmic idiopathic hypogonadotropic hypogonadism (nIHH). Mutations include the KISS1 gene which codes for kisspeptin, the protein which acts on GPR54 receptor, and the FGFR1 gene.

Oligospermia or azoospermia

These may be secondary to gonadotrophin deficiency and can be corrected by gonadotrophin therapy. More often they result from primary testicular diseases, in which case they are rarely treatable.

Azoospermia with normal testicular size and low FSH levels suggests a vas deferens block, which is sometimes reversible by surgical intervention.

Lack of libido and erectile dysfunction

Lack of libido is a loss of sexual desire; erectile dysfunction (ED) is inability to achieve or maintain erection; they may occur together or separately, and each can precipitate the other. Both are common symptoms in hypogonadism, but most people with either symptom have normal hormones and many have no definable organic cause. ED may be psychological, neurogenic, vascular, endocrine or related to drugs, and often includes contributions from several causes. Vascular disease is a common etiology, especially in smokers, and is often associated with vascular problems elsewhere. Autonomic neuropathy, most commonly from diabetes mellitus, is a common contributory cause (see p. 1025) and many drugs produce ED. The endocrine causes are those of hypogonadism (see above) and can be excluded by normal testosterone, gonadotrophin and prolactin levels. The

presence of nocturnal emissions and frequent satisfactory morning erections make endocrine disease unlikely.

Psychogenic erectile dysfunction is frequently a diagnosis of exclusion, though complex tests of penile vasculature and function are available in some centres.

**Treatment.** Offending drugs should be stopped. Phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, vardenafl) which increase penile blood flow (see p. 1027) are first choice for therapy. Other treatments include apomorphine, intracavernosal injections of alprostadil, papaverine or phentolamine, vacuum expanders and penile implants.

If no organic disease is found, or if there is clear evidence of psychological problems, the couple should receive psychosexual counselling.

### Gynaecomastia

Gynaecomastia is development of breast tissue in the male. Causes are shown in Table 19.23. It is due to an imbalance between free oestrogen and free androgen effects on breast tissue.

**Pubertal gynaecomastia** occurs in perhaps 50% of normal boys, often asymptomatically. It usually resolves spontaneously within 6–18 months, but after this duration may require surgical removal, as fibrous tissue will have been laid down. The cause is thought to be relative oestrogen excess, and the oestrogen antagonist tamoxifen is occasionally helpful.

**Gynaecomastia in the older male** requires a full assessment to exclude potentially serious underlying disease, such as bronchial carcinoma and testicular tumours (e.g. Leydig cell tumour). However, aromatase activity (p. 972) increases with age and may be the cause of gynaecomastia in this group. Aromatase is an enzyme of the cytochrome P450 family and converts androgens to produce oestrogens. Drug effects are common (especially digoxin and spironolactone), and once these and significant liver disease are excluded most cases have no definable cause. Surgery is occasionally necessary.

### Disorders in the female

### Hypogonadism

Impaired ovarian function, whether primary or secondary, will lead both to oestrogen deficiency and abnormalities of the menstrual cycle. The latter is very sensitive to disruption, cycles becoming anovulatory and irregular before disappearing altogether. Symptoms will depend on the age at which the failure develops. Thus, before puberty, primary amenorrhoea will occur, possibly with delayed puberty; if after puberty, secondary amenorrhoea and hypogonadism will result.

### Oestrogen deficiency

The physiological effects of oestrogens and symptoms/signs of deficiency are shown in Table 19.24.

### Amenorrhoea

Absence of periods or markedly irregular infrequent periods (oligomenorrhoea) is the commonest presentation of female gonadal disease. The clinical assessment of such patients is shown in Box 19.8, and common causes are listed in Table 19.25.

*These conditions may present as primary amenorrhoea. LH, luteinizing hormone; FSH, follicle-stimulating hormone; E2, oestradiol; PRL, prolactin; T, testosterone; DHEAS, dehydroepiandrosterone sulphate; SHBG, sex hormone-binding globulin; HCG, human chorionic gonadotrophin; LHRH, luteinizing hormone-releasing hormone; nIHH, normosmic idiopathic hypogonadotropic hypogonadism; EUA, examination under anaesthesia.

Polycystic ovary syndrome is the common cause of oligomenorrhoea and amenorrhoea (see below).

Weight-related amenorrhoea
A minimum body weight is necessary for regular menstruation. While anorexia nervosa is the extreme form of weight loss (see p. 1222), amenorrhoea is common and may be seen at weights within the ‘normal’ range. The biochemistry is indistinguishable from gonadotrophin deficiency and some patients have additional mild endocrine disease (e.g. polycystic ovarian disease). It is possible that alterations in lepton levels are responsible for the hypothalamic dysfunction seen in this situation. Restoration of body weight to above the 50th centile for height is usually effective in restoring menstruation, but in the many cases where this cannot be achieved then oestrogen replacement is necessary. Similar problems occur with intensive physical training in athletes and dancers.

Hypothalamic amenorrhoea
Amenorrhoea with low oestrogen and gonadotrophins in the absence of organic pituitary disease, weight loss or excessive exercise is described as hypothalamic amenorrhoea. This may be related to ‘stress’, to previous weight loss or stopping the contraceptive pill, but some patients appear to have defective cycling mechanisms without apparent explanation.

Hypothyroidism
Oligomenorrhoea and amenorrhoea are frequent findings in severe hypothyroidism in young women.

Other
Other causes include pregnancy, genital tract abnormalities, such as an imperforate hymen, cause primary amenorrhoea. Severe illness, even in the absence of weight loss, can lead to amenorrhoea.

Turner’s syndrome (p. 983) is a cause of primary amenorrhoea. The phenotype is female with female external
Reproduction and sex

There is gonadal dysgenesis with streak ovaries. Features include short stature, webbing of the neck (up to 40%), a wide carrying angle of the elbows, high arched palate and low-set ears. These patients also have an increased incidence of autoimmune disease (2%), bicuspid aortic valves, aortic coarctation and dissection and coronary artery disease, hypertension, type 2 diabetes, horseshoe kidneys, lymphoedema, reduced bone density, hearing problems and inflammatory bowel disease (0.3%).

**Investigations**

Basal levels of FSH, LH, oestrogen and prolactin allow initial distinction between primary gonadal and hypothalamic–pituitary causes (Table 19.25). Ovarian biopsy may occasionally be necessary to confirm the diagnosis of primary ovarian failure, although elevation of LH and FSH to menopausal levels is usually adequate. Subsequent investigations are shown in Table 19.25.

**Treatment**

Treatment is that of the cause wherever possible (e.g. hypothyroidism, low weight, stress, excessive exercise).

Primary ovarian disease is rarely treatable except in the rare condition of ‘resistant’ ovary, where high-dose gonadotrophin therapy can occasionally lead to folliculogenesis. Hyperprolactinaemia should be corrected (see below). Polycystic ovary syndrome is discussed in detail below. In all other cases oestrogen replacement is usually indicated to prevent the long-term consequences of deficiency.

**Hirsutism and polycystic ovary syndrome**

**Normal hair versus hirsutism**

The extent of normal hair growth varies between individuals, families and races, being more extensive in the Mediterranean and some Asian subcontinent populations. These normal variations in body hair, and the more extensive hair growth seen in patients complaining of hirsutism, represent a continuum from no visible hair to extensive cover with thick dark hair. It is therefore impossible to draw an absolute dividing line between ‘normal’ and ‘abnormal’ degrees of facial and body hair in the female. Soft vellus hair is normally present all over the body, and this type of hair on the face and elsewhere is ‘normal’ and is not sex hormone dependent. Hair in the beard, moustache, breast, chest, axilla, abdominal midline, pubic and thigh areas is sex hormone dependent. Any excess in the latter regions is thus a marker of increased ovarian or adrenal androgen production, most commonly polycystic ovary syndrome (PCOS) but occasionally other rarer causes.

**Causes of hirsutism**

**Polycystic ovary syndrome.** PCOS is the most common cause of hirsutism in clinical practice, affecting about 1 in 5 women worldwide. It is characterized by multiple small cysts within the ovary (Fig. 19.23) (which represent arrested follicular development) and by excess androgen production from the ovaries (and to a lesser extent from the adrenals). It was originally described in its severe form as the Stein–Leventhal syndrome.

Measured levels of androgens in blood vary widely from patient to patient and may remain within the normal range but SHBG levels are often low (due to high insulin levels), leading to high free androgen levels. In PCOS there is thought to be increased frequency of the GnRH pulse generator, leading to an increase in LH pulses and androgen secretion.

The response of the hair follicle to circulating androgens also seems to vary between individuals with otherwise identical clinical and biochemical features, and the reason for this variation in end-organ response remains poorly understood.

PCOS is frequently associated with:

- hyperinsulinaemia and insulin resistance, the prevalence of type 2 diabetes being 10 times higher than in normal women
- hypertension, hyperlipidaemia and increased cardiovascular risk (the metabolic syndrome, p. 201), which is 2–3 times higher in PCOS, although it is currently unclear whether PCOS per se confers an absolute increase in cardiovascular mortality.
Obesity with PCOS is an additional risk factor for insulin resistance. The precise mechanisms which link the aetiology of polycystic ovaries, hyperandrogenism, anovulation and insulin resistance remain to be elucidated and whether the basic defect is in the ovary, adrenal, pituitary or a more generalized metabolic defect remains unknown.

In routine clinical practice, the majority of people with objective signs of androgen-dependent hirsutism will have PCOS, and investigation is mainly required to exclude rarer and more serious causes of virilization.

**Idiopathic hirsutism.** People with hirsutism, no elevation of serum androgen levels and no other clinical features are sometimes labelled as having ‘idiopathic hirsutism’. However, studies suggest that most people with ‘idiopathic hirsutism’ have some radiological or biochemical evidence of PCOS on more detailed investigation, and several studies have demonstrated evidence of mild PCOS in up to 20% of the normal female population.

Familial or idiopathic hirsutism does occur, but usually involves a distribution of hair growth which is not typically androgenic.

**Other causes.** Rarer and more serious endocrine causes of hirsutism and virilization include congenital adrenal hyperplasia (CAH, see p. 987), Cushing’s syndrome (p. 957) and virilizing tumours of the ovary and adrenal.

**Ovarian hyperthecosis** is a non-malignant ovarian disorder characterized by luteinized thecal cells in the ovarian stroma which secrete testosterone. The clinical features are similar to PCOS but tend to present in perimenopausal women, and serum testosterone levels are higher than typically seen in PCOS.

**Iatrogenic hirsutism** also occurs after treatment with androgens, or more weakly androgenic drugs such as progestogens or danazol.

**Non-androgen-dependent hair growth (hypertrichosis)** occurs with drugs such as phenytoin, diazoxide, minoxidil and ciclosporin.

**Clinical features of PCOS**

PCOS presents with amenorrhoea/oligomenorrhoea, hirsutism and acne (alone or in combination), shortly after menarche. Clinical, biochemical and radiological features of PCOS merge imperceptibly into those of the normal populations. The development of hirsutism commonly provokes severe distress in young women and may lead to avoidance of normal social activities.

- **Hirsutism** should be recorded objectively, ideally using a scoring system, to document the problem and to monitor treatment. The method and frequency of physical removal (e.g. shaving, plucking) should also be recorded. Most patients who complain of hirsutism will have an objective excess of hair on examination, but occasionally very little will be found (and appropriate counselling is then indicated).

- **Age and speed of onset.** Hirsutism related to PCOS usually begins around the time of the menarche and increases slowly and steadily in the teens and twenties. Rapid progression and prepubertal or late onset suggest a more serious cause.

- **Accompanying virilization.** Hirsutism due to PCOS may be severe and affect all androgen-dependent areas on the face and body. However, more severe virilization (clitoromegaly, recent-onset frontal balding, male phenotype) implies substantial androgen excess, and usually indicates a rarer cause rather than PCOS. Thinning of head hair in a male pattern – androgenic alopecia – occurs in a proportion of women with uncomplicated PCOS, typically with a familial tendency for premature androgen-related hair loss in both sexes.

- **Menstruation.** Most people with hirsutism will have some disturbance of menstruation, typically oligo-/amenorrhoea, although more frequent erratic bleeding can also occur. However, PCOS can present as hirsutism with regular periods or as irregular periods, with no evidence of hirsutism or acne.

- **Weight.** Many people with hirsutism are also overweight or obese. This worsens the underlying androgen excess and insulin resistance and inhibits the response to treatment, and is an indication for appropriate advice on diet and exercise. In severe cases the insulin resistance may have a visible manifestation as acanthosis nigricans on the neck and in the axillae (see Fig. 24.24).

**Investigations and differential diagnosis**

A variety of investigations aid the diagnosis of people with hirsutism:

- **Serum total testosterone** is often elevated in PCOS and is invariably substantially raised in virilizing tumours (usually >5 nmol/L). People with hirsutism and normal testosterone levels frequently have low levels of sex hormone-binding globulin (SHBG), leading to high free androgen levels. The free androgen index ([testosterone/SHBG] ×100) is often used and is high; free testosterone is difficult to measure directly.

- **Other androgens.** Androstenedione and dehydroepiandrosterone sulphate are frequently elevated in PCOS, and even more elevated in congenital adrenal hyperplasia (CAH) and virilizing tumours.

- **17α-Hydroxyprogesterone** is elevated in classical CAH, but may be apparent in late-onset CAH only after stimulation tests.

- **Gonadotrophin levels.** LH hypersecretion is a frequent feature of PCOS, but the pulsatile nature of secretion of this hormone means that a ‘classic’ increased LH/FSH ratio is not always observed on a random sample.

- **Oestrogen levels.** Oestradiol is usually normal in PCOS, but oestrone levels (which are rarely measured) are elevated because of peripheral conversion. Levels are variable in other causes.

- **Ovarian ultrasound** is a useful investigation (Fig. 19.23). Typical features are those of a thickened capsule, multiple 3–5 mm cysts and a hypertrophic stroma. Prolonged hyperandrogenization from any cause may lead to polycystic changes in the ovary. Ultrasound may also reveal virilizing ovarian tumours, although these are often small.

- **Serum prolactin.** Mild hyperprolactinaemia is common in PCOS but rarely exceeds 1500 mU/L.

If a virilizing tumour is suspected clinically or after investigation, then more complex tests include dexamethasone suppression tests, CT or MRI of adrenals, and selective venous sampling.

**Diagnosis**

Most patients presenting with a combination of hirsutism and menstrual disturbance will be shown to have polycystic ovary syndrome, but the rarer alternative diagnoses should be excluded, e.g. late-onset congenital adrenal hyperplasia (early-onset, raised serum 17α-OH-progesterone), Cushing’s
syndrome (look for other clinical features) and virilizing tumours of the ovary or adrenals (severe virilization, markedly elevated serum testosterone).

The consensus (Rotterdam) criteria 2003 for diagnosis of PCOS are at least two of:
- Clinical or biochemical evidence of hyperandrogenism
- Evidence of oligo- or anovulation
- Presence of polycystic ovaries on ultrasound.

**Treatment**

The underlying cause should be removed in the rare instances where this is possible (e.g. drugs, adrenal or ovarian tumours). Treatment of CAH and Cushing’s is discussed on page 987 and page 957, respectively. Other therapy depends upon whether the aim is to reduce hirsutism, regularize periods or produce fertility.

**Local therapy for hirsutism**

Regular plucking, bleaching, depilatory cream, waxing or shaving is used. Such removal neither worsens nor improves the underlying severity of hirsutism. More ‘permanent’ solutions include electrolysis and a variety of ‘laser’ hair removal systems – all appear effective but have not been evaluated in long-term studies, are expensive, and still often require repeated long-term treatment. Eflornithine cream (an antiprotozoal) inhibits hair growth by inhibiting ornithine decarboxylase but is effective in only a minority of cases and should be discontinued if there is no improvement after 4 months.

**Systemic therapy for hirsutism**

This always requires a year or more of treatment for maximal benefit, and long-term treatment is frequently required as the problem tends to recur when treatment is stopped. The patient must therefore always be an active participant in the decision to use systemic therapy and must understand the rare risks as well as the benefits.

- **Oestrogens** (e.g. oral contraceptives) suppress ovarian androgen production and reduce free androgens by increasing SHBG levels. Combined hormone pills, which contain ethinylestradiol and a non-androgenic progestogen, e.g. desogestrel dospirenone, or cyproterone acetate plus ethinylestradiol (co-cyprindiol), will result in a slow improvement in hirsutism in a majority of cases and should normally be used first unless there is a contraindication, e.g. history of thrombosis. The risk of venous thrombosis appears to be 2–4-fold higher than on other low-dose oral contraceptive pills. After the menopause, HRT preparations which contain medroxyprogesterone (rather than more androgenic progestogens) may be helpful.

- **Cyproterone acetate** (50–100 mg daily) is an antiandrogen but is also a progestogen, teratogenic and a weak glucocorticoid. Given continuously it produces amenorrhoea, and so is normally given for days 1–14 of each cycle. In women of childbearing age, contraception is essential.

- **Spironolactone** (200 mg daily) also has antiandrogen activity and can cause useful improvements in hirsutism.

- **Finasteride** (5 mg daily), a 5α-reductase inhibitor which prevents the formation of dihydrotestosterone in the skin, has also been shown to be effective but long-term experience is limited.

- **Flutamide**, another antiandrogen, is less commonly used owing to the high incidence of hepatic side-effects.

**Treatment of menstrual disturbance**

- Cyclical oestrogen/progestogen administration will regulate the menstrual cycle and remove the symptom of oligo- or amenorrhoea. This is most frequently an additional benefit of the treatment of hirsutism, but may also be used when menstrual disturbance is the only symptom.

- Drugs to improve the hyperinsulinaemia associated with PCOS and obesity are increasingly used (and requested by patients). Metformin (500 mg three times daily) improves menstrual cyclicity and ovulation in short-term studies, and some patients also report improvement in hirsutism and ease of weight loss, but gastrointestinal upset may limit use.

- Thiazolidinediones are also effective, but concerns about the long-term cardiovascular effects of these agents now preclude their use.

**Treatment for fertility**

- Metformin alone may improve ovulation and achieve conception.

- Clomifene 50–100 mg can be given daily on days 2–6 of the cycle and is more effective than metformin alone in achieving ovulation. This can occasionally cause the ovarian hyperstimulation syndrome, an iatrogenic complication of ovulation induction therapy, consisting of ovarian enlargement, oedema, hypovolaemia, acute kidney injury, and possibly shock; specialist supervision is essential. It is recommended that clomifene should not normally be used for longer than six cycles (owing to a possible increased risk of ovarian cancer in patients treated for longer than recommended).

- **Reverse circadian rhythm.** Prednisolone (2.5 mg in the morning, 5 mg at night) suppresses pituitary production of ACTH, upon which adrenal androgens partly depend. Regular ovulatory cycles often ensue. A steroid instruction leaflet and a card must be supplied.

- More intensive techniques to stimulate ovulation may also be indicated in specialist hands, including low-dose gonadotrophin therapy, and ovarian hyperstimulation techniques associated with in vitro fertilization.

- Side-effects of these preparations are shown in Box 19.9. Most of the serious ones are rare and are less common with typical modern 20–30 μg oestrogen pills, although evidence suggests that thromboembolism may be slightly more common with ‘third-generation pills’ containing desogestrel.
Endocrine disease

and gestodene (approximately 30/100 000 woman-years compared with 15/100 000 on older pills and 5/100 000 on no treatment). While some problems require immediate cessation of the pill, other milder side-effects must be judged against the hazards of pregnancy occurring with inadequate contraception, especially if other effective methods are not practicable or acceptable.

Hazes of the combined pill are increased in smokers, in obesity and in those with other risk factors for cardiovascular disease (e.g. hypertension, hyperlipidaemia, diabetes) especially in women aged over 35 years (avoid if over 50 years). The ‘mini-pill’ (progestogen only, usually norethisterone) is less effective but is often suitable where oestrogens are contraindicated (Box 19.9). A progestrone antagonist, mifepristone, in combination with a prostaglandin analogue (vaginal gemeprost), induces abortion of pregnancy at up to 9 weeks’ gestation. It prevents progesterone-induced inhibition of uterine contraction.

Subfertility

Subfertility, or ‘infertility’, is defined as the inability of a couple to conceive after 1 year of unprotected intercourse. Investigation requires the combined skills of gynaecologist, endocrinologist and, ideally, andrologist. Both partners must be involved and every aspect of the physiology critically examined.

Causes (Fig. 19.24)

A significant proportion of couples have both male and female contributing factors.

Figure 19.24 Major factors involved in subfertility and their investigation. LH, luteinizing hormone; FSH, follicle-stimulating hormone; PCOS, polycystic ovarian syndrome; PID, pelvic inflammatory disease; GC, gonorrhoea; STI, sexually transmitted infection.
Inadequate intercourse, hostile cervical mucus and vaginal factors are uncommon (5%). 15% of cases appear to be idiopathic, and natural fertility decreases with increasing age. Conception over 40 years of age for both males and females is reduced to below 30%.

**Male factors**
About 30–40% of couples have a major identifiable male factor. There is some evidence that male sperm counts are declining in many populations. Untreated male hypogonadism of any cause (see Table 19.21) is likely to be associated with subfertility.

**Female factors**
Female tubal problems due to pathologies such as pelvic inflammatory disease and endometriosis account for perhaps 20%; a similar proportion have ovulatory disorders. Any cause of oligomenorrhea or amenorrhoea (see Table 19.25) is likely to be associated with suboptimal ovulation or anovulation.

**Clinical assessment**
Both partners should be seen and the following factors checked:
- **The man.** Look for previous testicular damage (orchitis, trauma), undescended testes, urethral symptoms and evidence of sexually transmitted infection, local surgery, and use of alcohol and drugs. A semen analysis early in the investigations is essential.
- **The woman.** Look for previous pelvic infection, regularity of periods, previous surgery, alcohol intake and smoking and body weight (see p. 978).
- **Together.** Check the frequency and adequacy of intercourse, and the use of lubricants.

**Investigations**
See Figure 19.24.

**Treatment**
Counselling of both partners is essential. Any defect(s) found should be treated if possible. Ovulation can usually be induced by exogenous hormones if simpler measures fail, while in vitro fertilization (IVF) and similar techniques are widely used, especially where there is tubal blockage, oligospermia or ‘idiopathic subfertility’. Intracytoplasmic sperm injection (ICSI) appears particularly effective for severe oligospermia and poor sperm function.

**Disorders of sexual differentiation**
Disorders of sexual differentiation are rare but may affect chromosomal, gonadal, endocrine and phenotypic development (Table 19.26). Such cases always require extensive, multidisciplinary clinical management. An individual's sex can be defined in several ways:
- **Chromosomal sex.** The normal female is 46XX, the normal male 46XY. The Y chromosome confers male sex; if it is not present, development follows female lines.
- **Gonadal sex.** This is determined predominantly by chromosomal sex, but requires normal embryological development.
- **Phenotypic sex.** This describes the normal physical appearance and characteristics of male and female body shape. This in turn is a manifestation of gonadal sex and subsequent sex hormone production.
- **Social sex (gender).** This is heavily dependent on phenotypic sex and normally assigned on appearance of the external genitalia at birth.
- **Sexual orientation** – heterosexual, homosexual or bisexual.

*Gonadectomy advised because of high risk of malignancy, i, isochromosome.
The zona glomerulosa, which secretes aldosterone under the control of the renin-angiotensin system, and the zona reticularis and zona fasciculata, which produce cortisol and androgens under feedback control of the hypothalamic-pituitary-adrenal (HPA) axis. The inner medulla synthesizes, stores and secretes catecholamines (see below and Fig. 19.25).

**The adrenal cortex**

The steroids produced by the adrenal cortex are grouped into three classes based on their predominant physiological effects: glucocorticoids, mineralocorticoids and androgens.

**Glucocorticoids**

These are so named after their effects on carbohydrate metabolism. Major actions are listed in Table 19.27. They act on intracellular corticosteroid receptors and combine with coactivating proteins to bind the ‘glucocorticoid response element’ (GRE) in specific regions of DNA to cause gene transcription. Glucocorticoid action is modified locally by the action of 11β-hydroxysteroid dehydrogenase (11βHSD). 11βHSD type 1 converts inactive cortisol to cortisone in cortisol, hence amplifying the hormone signal, whilst 11βHSD type 2 does the opposite.

The relative potency of common steroids is shown in Table 19.28.

**Mineralocorticoids**

The predominant effect of mineralocorticoids is on the extracellular balance of sodium and potassium in the distal tubule of the kidney. Aldosterone, produced solely in the zona glomerulosa, is the predominant mineralocorticoid in humans (about 50%); corticosterone makes a small contribution to overall mineralocorticoid activity. Mineralocorticoids act on type 1 corticosteroid receptors, whilst glucocorticoids act on type 2 receptors, both having a very similar structure. The mineralocorticoid activity of cortisol is weak but cortisol is present in considerable excess. The mineralocorticoid receptor in the kidney is largely protected from this excess by the intrarenal conversion (‘shuttle’) of cortisol to cortisone by 11β-hydroxysteroid dehydrogenase type 2.

**Androgens**

Although secreted in considerable quantities, most androgens have only relatively weak intrinsic androgenic activity until metabolized peripherally to testosterone or dihydrotestosterone. Dihydrotestosterone is metabolized from testosterone by 5α-reductase and is a potent androgen receptor agonist. The androgen receptor has been well characterized and mutations within this gene may cause androgen insensitivity syndromes.

**Biochemistry**

All steroids have the same basic skeleton (Fig. 19.26b) and the chemical differences between them are slight. The major biosynthetic pathways are shown in Fig. 19.22a.

**Physiology**

**Glucocorticoid** production by the adrenal is under hypothalamic-pituitary control (Fig. 19.27). Corticotrophin-releasing hormone (CRH) is secreted in the hypothalamus in response to circadian rhythm, stress and other stimuli. CRH travels down the portal system to stimulate adrenocorticotrophin (ACTH) release from the anterior pituitary. Hypothalamic vasopressin (ADH) also stimulates ACTH secretion and acts synergistically. ACTH is derived from the prohormone pro-opiomelanocortin (POMC), which undergoes complex processing within the pituitary to produce ACTH and a number of other peptides including beta-lipotrophin and beta-endorphin. Many of these peptides, including ACTH, contain melanocyte-stimulating hormone (MSH)-like sequences which cause pigmentation when levels of ACTH are markedly raised.

Circulating ACTH stimulates cortisol production in the adrenal. The secreted cortisol (or any other synthetic corticosteroid administered to the patient) causes negative feedback on the hypothalamus and pituitary to inhibit further CRH/ACTH release. The set-point of this system clearly varies through the day according to the circadian rhythm, and is usually overridden by severe stress. Unlike cortisol, mineralocorticoids and sex steroids do not cause negative feedback on the CRH/ACTH axis.

Following adrenalectomy or other adrenal damage (e.g. Addison’s disease), cortisol secretion will be absent or reduced; ACTH levels will therefore rise.

**Mineralocorticoid secretion** is mainly controlled by the renin-angiotensin system (see p. 566).

---

**Figure 19.25** The adrenal gland and its hormones.
The adrenal axis

Figure 19.26 (a) The major steroid biosynthetic pathways. Steroid hormones are synthesized in adrenal and gonads from the initial substrate via a series of interconnected enzymatic steps. The reactions catalysed are shown by shaded boxes with italic labels. The molecular identity of the enzymes is shown in red – some catalyse more than one reaction. p450 enzymes are in mitochondria, 3βHSD (hydroxysteroid dehydrogenase) in cytoplasm. 17βHSD and p450aro (aromatase) are found mainly in gonads. (b) The steroid molecule.

Investigation of glucocorticoid abnormalities
Basal levels
ACTH and cortisol are released episodically and in response to stress. When taking a blood sample, remember:
- Sampling time should be recorded. Basal levels should be taken between 08:00 hours and 09:00 hours near the peak of the circadian variation.
- Stress should be minimized.
- Appropriate reference ranges (for time and assay method) should be used.

Suppression and stimulation tests are used in suspected excess and deficient cortisol production, respectively.

Dexamethasone suppression tests
Administration of a synthetic glucocorticoid (dexamethasone) to a normal subject produces prompt feedback suppression of CRH and ACTH levels and thus of endogenous cortisol secretion (dexamethasone is not measured by most cortisol assays). Three forms of the test, used in the diagnosis and differential diagnosis of Cushing’s syndrome, are available (see Table 19.11).

ACTH stimulation tests
Synthetic ACTH (tetracosactide, which consists of the first 24 amino acids of human ACTH) is given to stimulate adrenal cortisol production. Details are given in Box 19.1 and Figure 19.5 (p. 944).

Addison’s disease: primary hypoadrenalism
Pathophysiology and causes
In this condition, there is destruction of the entire adrenal cortex. Glucocorticoid, mineralocorticoid and sex steroid
blood pressure is normal. Mineralocorticoid deficiency is the cause of the hypotension.

**Investigations**

Once Addison’s disease is suspected, investigation is urgent. If the patient is seriously ill or hypotensive, hydrocortisone 100 mg should be given intravenously or intramuscularly together with intravenous 0.9% saline. Ideally this should be done immediately after a blood sample is taken for later measurement of plasma cortisol. Alternatively, an ACTH stimulation test can be performed immediately. Full investigation should be delayed until emergency treatment (see below) has improved the patient’s condition. Otherwise, tests are as follows:

- **Single cortisol measurements** are of little value, although a random cortisol below 100 nmol/L during the day is highly suggestive, and a random cortisol >550 nmol/L makes the diagnosis unlikely.

- **The short ACTH stimulation test** should be performed (see Box 19.11 and Fig. 19.5). Note that an absent or impaired cortisol response confirms the presence of hypoadrenalism but does not differentiate Addison’s disease from ACTH deficiency or iatrogenic suppression by steroid medication.

- **A 09:00 hours plasma ACTH level** – a high level (>80 ng/L) with low or low-normal cortisol confirms primary hypoadrenalism.

- **Electrolytes and urea** classically show hyponatraemia, hyperkalaemia and a high urea, but they can be normal.

- **Blood glucose** may be low, with hypoglycaemia.

- **Adrenal antibodies** are present in many cases of autoimmune adrenalitis.

- **Chest and abdominal X-rays** may show evidence of tuberculosis and/or calcified adrenals.

- **Plasma renin activity** is high due to low serum aldosterone.

- **Hypercalcaemia and anaemia** (after rehydration) are sometimes seen.

**Treatment**

Acute hypoadrenalism needs urgent treatment ([Emergency Box 19.1](#)).
Management of acute hypoadrenalism

Clinical context
Hypotension, hyponaetraemia, hyperkalaemia, hypoglycaemia, dehydration, pigmentation often with precipitating infection, infarction, trauma or operation. The major deficiencies are of salt, steroid and glucose.

Assuming normal cardiovascular function, the following are required:
- 1 litre of 0.9% saline should be given over 30–60 min with 100 mg of intravenous bolus hydrocortisone.
- Subsequent requirements are several litres of saline within 24 hours (assessing with central venous pressure line if necessary) plus hydrocortisone, 100 mg i.m., 6-hourly, until the patient is clinically stable.
- Glucose should be infused if there is hypoglycaemia.
- Oral replacement medication is then started, unless unable to take oral medication, initially hydrocortisone 20 mg, 8-hourly, reducing to 20–30 mg in divided doses over a few days (Table 19.30).
- Fludrocortisone is unnecessary acutely as the high cortisol doses provide sufficient mineralocorticoid activity – it should be introduced later.

Long-term treatment is with replacement glucocorticoid and mineralocorticoid; tuberculosis must be treated if present or suspected. Replacement dosage details are shown in Table 19.30. Dehydroepiandrosterone (DHEA) replacement has also been advocated, and some studies suggest that this may cause symptomatic improvements, although others show no clear benefit.

Adequacy of glucocorticoid dose is judged by:
- Clinical wellbeing and restoration of normal, but not excessive, weight
- Normal cortisol levels during the day while on replacement hydrocortisone (cortisol levels cannot be used for synthetic steroids).
- Adequacy of fludrocortisone replacement is assessed by:
  - Restoration of serum electrolytes to normal
  - Blood pressure response to posture (it should not fall >10 mmHg systolic after 2 minutes’ standing)
  - Suppression of plasma renin activity to normal.

Patient advice
All patients requiring replacement steroids should:
- know how to increase steroid replacement dose for intercurrent illness
- carry a ‘Steroid Card’
- wear a Medic-Alert bracelet (or similar), which gives details of their condition so that emergency replacement therapy can be given if found unconscious
- keep an (up-to-date) ampoule of hydrocortisone at home in case oral therapy is impossible, for administration by self, family or doctor.

Secondary hypoadrenalism
This may arise from:
- hypothalamic-pituitary disease (inadequate ACTH production) or
- long-term steroid therapy leading to hypothalamic-pituitary-adrenal suppression.

Most people with hypothalamic-pituitary disease have panhypopituitarism (see p. 950) and need T₄ replacement as well as cortisol; in this case hydrocortisone must be started before T₄.

Long-term corticosteroid medication for non-endocrine disease is the most common cause of secondary hypoadrenalism. The hypothalamic-pituitary axis and the adrenal may both be suppressed and the patient may have vague symptoms of feeling unwell. ACTH levels are low in secondary hypoadrenalism. Weaning off steroids is often a long and difficult process.

Congenital adrenal hyperplasia (CAH)
Pathophysiology
This condition results from an autosomal recessive deficiency of an enzyme in the cortisol synthetic pathways. There are six major types, but most common is 21-hydroxylase deficiency (CYP21A2), which occurs in about 1 in 15000 births and which has been shown to be due to defects on chromosome 6 near the HLA region affecting one of the cytochrome p450 enzymes (p450C21).

As a result, cortisol secretion is reduced and feedback leads to increased ACTH secretion to maintain adequate cortisol – leading to adrenal hyperplasia. Diversion of the steroid precursors into the androgenic steroid pathways occurs (see Fig. 19.26a). Thus, 17-hydroxyprogesterone, androstenedione and testosterone levels are increased, leading to virilization. Aldosterone synthesis may be impaired with resultant salt wasting.

The other forms affect 11β-hydroxylase, 17α-hydroxylase, 3β-hydroxysteroid dehydrogenase and a cholesterol side-chain cleavage enzyme (p450scd) (see Fig. 19.26a).

Clinical features
If severe, CAH presents at birth with sexual ambiguity or adrenal failure (collapse, hypotension, hypoglycaemia), sometimes with a salt-losing state (hypotension, hyponatraemia). In the female, clitoral hypertrophy, urogenital abnormalities and labioscrotal fusion are common, but the syndrome may be unrecognized in the male.

Precocious puberty with hirsutism is a later presentation, whereas rare, milder cases only present in adult life, usually accompanied by primary amenorrhoea. Hirsutism developing before puberty is suggestive of CAH.

Investigations
Expert advice is essential in the confirmation and differential diagnosis of 21-hydroxylase deficiency, and with ambiguous genitalia such advice must be sought urgently before any assignment of gender is made.
A profile of adrenocortical hormones is measured before and one hour after ACTH administration.
- 17-Hydroxyprogesterone levels are increased
- Urinary pregnanetriol excretion is increased
- Androstenedione levels are raised
- Basal ACTH levels are raised.

Treatment
Glucocorticoid activity must be replaced, as must mineralocorticoid activity if deficient. In CAH the larger dose of glucocorticoid is often given at night to suppress the morning ACTH peak with a smaller dose in the morning (cf. Addison’s disease, p. 987; Table 19.30). Correct dosage is often difficult to establish in the child but should ensure normal 17-hydroxyprogesterone levels while allowing normal growth; excessive replacement leads to stunting of growth. In adults, clinical features and biochemistry (plasma renin, androstenedione and 17-OH-progesterone) are used to modify treatment. Genetic counselling (p. 43) and antenatal diagnosis is essential, particularly in 21-hydroxylase deficiency. The mother of an affected fetus can take dexamethasone daily to prevent virilization.

Uses and problems of therapeutic steroid therapy
Apart from their use as therapeutic replacement for endocrine deficiency states, synthetic glucocorticoids are widely used for many non-endocrine conditions (Box 19.10). Short-term use (e.g. for acute asthma) carries only small risks of significant side-effects except for the simultaneous suppression of immune responses. The danger lies in their continued, often through medical oversight or patient default. In general, therapy for 3 weeks or less, or a dose of prednisolone less than 5 mg per day, will not result in significant long-term suppression of the normal adrenal axis.

Long-term therapy with synthetic or natural steroids will, in most respects, mimic endogenous Cushing’s syndrome. Exceptions are the relative absence of hirsutism, acne, hypertension and severe sodium retention, as the common synthetic steroids have low androgenic and mineralocorticoid activity.

Excessive doses of steroids may also be absorbed from skin when strong dermatological preparations are used, but inhaled steroids rarely cause Cushing’s syndrome, although they commonly cause adrenal suppression.

The major hazards are detailed in Box 19.11. In the long term, many are of such severity that the clinical need for high-dose steroids should be continually and critically assessed. Steroid-sparing agents (e.g. azathioprine) should always be considered and screening and prophylactic therapy for osteoporosis introduced (see p. 556). New targeted biological therapies for inflammatory conditions may reduce the incidence of steroid-induced adrenal suppression.

Supervision of steroid therapy
All patients receiving steroids should carry a ‘Steroid Card’. They should be made aware of the following points:
- Long-term steroid therapy must never be stopped suddenly.
- Doses should be reduced very gradually, with most being given in the morning at the time of withdrawal – this minimizes adrenal suppression. Many authorities believe that ‘alternate-day therapy’ produces less suppression.
- Doses need to be increased in times of serious intercurrent illness (defined as presence of a fever), accident and stress. Double doses should be taken during these times.
- Other physicians, anaesthetists and dentists must be told about steroid therapy.

Patients should also be informed of potential side-effects, and all this information should be documented in the clinical record. If prophylactic use of bisphosphonate therapy is required to prevent the development of osteoporosis (NICE guidance), they should be informed of the rationale.

Steroids and surgery
Any patient receiving steroids or who has recently received them (within the last 12 months) and may still have adrenal
suppression requires special control of steroid medication around the time of surgery. Details are shown in Table 19.31.

### Incidental adrenal tumours (‘incidentalomas’)

With the advent of abdominal CT, MRI and high-resolution ultrasound scanning, unsuspected adrenal masses have been discovered in 3–10% of scans (increasing with age). The two issues of concern with an incidental adrenal mass are:

- whether the lesion is functional or non-functional, and
- whether it is benign or malignant.

Most incidentalomas are asymptomatic and benign, but direct questioning may reveal symptoms of endocrine hypersecretion such as cushingoid features, catecholamine excess, virilization in women, or evidence of endocrine hypertension (p. 943). Even in the absence of symptoms, functional tests to exclude secretory activity should be performed as adrenal adenomas often secrete cortisol at a low level, ‘sub-clinical Cushing’s syndrome’, which may confer increased cardiovascular risk. If no endocrine activity is found then most authorities recommend removal only of large adrenal tumours (>4–5 cm) because of the risk of malignancy. Smaller hormonally inactive lesions are usually observed as long as there are no worrying radiological features.

Phaeochromocytoma must be excluded before surgery due to the risk of perioperative hypertensive or hypotensive crises (see p. 991).

### Primary hyperaldosteronism

Increased mineralocorticoid secretion from the adrenal cortex, termed primary hyperaldosteronism, is thought to account for 5–10% of all hypertension. Other endocrine causes of hypertension should also be considered if there is clinical suspicion (Table 19.32). It is impracticable and unnecessary to screen all hypertensive patients for secondary endocrine causes. The highest chances of detecting such causes are in patients:

- under 35 years, especially those without a family history of hypertension
- with accelerated (malignant) hypertension
- with hypokalaemia before diuretic therapy
- resistant to conventional antihypertensive therapy (e.g. more than three drugs) or
- with unusual symptoms (e.g. sweating attacks or weakness).

### Pathophysiology

Primary hyperaldosteronism is a disorder of the adrenal cortex characterized by excess aldosterone production leading to sodium retention, potassium loss and the combination of hypokalaemia and hypertension. This must be distinguished from secondary hyperaldosteronism, which arises when there is excess renin (and hence angiotensin II) stimulation of the zona glomerulosa. Common causes of secondary hyperaldosteronism are accelerated hypertension and renal artery stenosis, when the patient will also be hypertensive. Causes associated with normotension include congestive cardiac failure and cirrhosis, where excess aldosterone production contributes to sodium retention.

### Causes (see Table 19.32)

Adrenal adenomas (Conn’s syndrome) originally accounted for 60% of cases of in series of primary hyperaldosteronism but represented a rare cause of hypertension. The use of the aldosterone:renin ratio in the routine investigation of hypertension now suggests that hyperaldosteronism due to bilateral adrenal hyperplasia (idiopathic hyperaldosteronism) is

</table>

much more common than the classical Conn's adenoma. Some claim that idiopathic hyperaldosteronism is the cause of up to 10% of cases of 'essential' hypertension.

**Clinical features**

The usual presentation is simply hypertension; hypokalaemia (<3.5 mmol/L) is not frequently present. The few symptoms are nonspecific; rarely muscle weakness, nocturia and tetany are seen. The hypertension may be severe and associated with renal, cardiac and retinal damage.

Adenomas, often very small, are more common in young females, while bilateral hyperplasia rarely occurs before age 40 years and is more common in males.

**Investigations**

Beta-blockers and other drugs may interfere with renin activity, and spironolactone, ACE inhibitors and angiotensin II receptor antagonists will all affect results and all should be discontinued if possible. The characteristic features are as follows:

- **Plasma aldosterone:renin ratio (ARR)** is now most frequently used as a screening test for the condition, but raised ARR alone does not confirm the diagnosis (if the renin is low enough ARR will always be high). Note that normal ranges are highly assay-dependent.

- **Elevated plasma aldosterone levels** that are not suppressed with 0.9% saline infusion (2 L over 4 hours) or fludrocortisone administration. Between 30% and 50% of people with raised ARR on screening will suppress normally, excluding the diagnosis.

- **Suppressed plasma renin activity** or immunoreactivity.

- **Hypokalaemia** is often present but a normal serum potassium does not exclude the diagnosis.

- **Urinary potassium loss.** Levels >30 mmol daily during hypokalaemia are inappropriate.

Once a diagnosis of hyperaldosteronism is established, differentiation of adenoma from hyperplasia involves adrenal CT or MRI, but small adenomas may be missed and non-functioning incidentomomas also occur. Further information is obtained from diurnal/postural changes in plasma aldosterone levels (which tend to rise with adenomas between 09:00 hours supine and 13:00 hours erect samples; in contrast, they fall with hyperplasia), measurement of 18-OH cortisol levels (raised in adenoma) and venous catheterization for aldosterone levels. All of these tests have their pitfalls and exceptions.

**Treatment**

An adenoma can be removed surgically – usually laparoscopically; blood pressure falls in 70% of patients. Those with hyperplasia should be treated with the aldosterone antagonist spironolactone (100–400 mg daily); frequent side-effects include nausea, rashes and gynaecomastia, and the pure aldosterone receptor antagonist eplerenone can be a useful alternative if side-effects preclude the use of spironolactone (p. 640). Spironolactone metabolites have been linked with tumour development in animals but this has not been described in humans. Amiloride and calcium-channel blockers are moderately effective in controlling the hypertension but do not correct the hyperaldosteronism.

**Glucocorticoid (or dexamethasone)-suppressible hyperaldosteronism**

This rare condition is caused by a chimeric gene on chromosome 8. A fusion gene resulting from an unusual cross-over at meiosis between the genes encoding aldosterone synthase and adrenal 11β-hydroxylase produces aldosterone which is under ACTH control. Treatment with glucocorticoid resolves the problem.

**Syndrome of apparent mineralocorticoid excess**

This causes the clinical syndrome of primary hyperaldosteronism but with low renin and aldosterone levels. Reduced activity of the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) prevents the normal conversion in the kidney of cortisol (which is active at the mineralocorticoid receptor) to cortisone (which is not) and therefore ‘exposes’ the mineralocorticoid receptor in the kidney to the usual molar excess of cortisol over aldosterone in the blood. While the inherited syndrome is rare, the same clinical syndrome can occur with excessive ingestion of liquorice, which inhibits the 11β-HSD2 enzyme.

**The adrenal medulla**

The adrenal medulla is the innermost part of the adrenal gland, consisting of cells that secrete the major catecholamines, noradrenaline (norepinephrine) and adrenaline (epinephrine), which produce the sympathetic nervous response. The catecholamines are interconverted in the adrenal medulla and an increase in levels of their metabolites in the urine is a marker of abnormal hypersecretion (Fig. 19.29).

**Phaeochromocytoma and paraganglioma**

These are very rare tumours of the sympathetic nervous system (less than 1 in 1000 cases of hypertension) that secrete catecholamines, noradrenaline (norepinephrine) adrenaline (epinephrine) and their metabolites (Fig. 19.29):

- 90% arise in the adrenal medulla (phaeochromocytomas)
- 10% occur elsewhere in the sympathetic chain (paragangliomas).

![Diagram of the adrenal medulla and catecholamines metabolism](image)
Some are associated with MEN 2 syndromes (see below) and the von Hippel–Lindau (VHL) syndrome (p. 1143). Most tumours release both noradrenaline (norepinephrine) and adrenaline (epinephrine) but large tumours and extra-adrenal tumours produce almost entirely noradrenaline.

Paragangliomas typically occur in the head and neck but are also found in the thorax, pelvis and bladder. They are more closely associated with other genetic associations than is phaeochromocytoma. The association of paraganglioma, bilateral adrenal phaeochromocytomas, positive family history or young age at presentation is seen in multiple endocrine neoplasms (p. 997). Mutations in the succinate dehydrogenase (SDH) gene have been shown to be strongly associated with the development of paraganglioma.

Pathology

Oval groups of cells occur in clusters and stain for chromogranin A. Some 25% are multiple and 10% malignant, the latter being more frequent in the extra-adrenal tumours. Malignancy cannot be determined on simple histological examination alone.

Clinical features

The clinical features are those of catecholamine excess and are frequently, but not necessarily, intermittent (Table 19.33). All people with suspected phaeochromocytomas must be investigated because phaeochromocytomas may cause acute cardiovascular compromise during routine medical procedures, and can also present with sudden death if the diagnosis is missed.

Diagnosis

Specific tests are:

- **Measurement of urinary catecholamines and metabolites** (metanephrines are most sensitive and specific – Fig. 19.29) is a useful screening test; normal levels on three 24-hour collections of metanephrines virtually exclude the diagnosis. Many drugs and dietary vanilla interfere with these tests.
- **Resting plasma catecholamines** are raised.
- **Plasma chromogranin A** (a storage vesicle protein) is raised.
- **Clonidine suppression test** may be appropriate, but should only be performed in specialist centres.
- **CT scans**, initially of the abdomen, are helpful to localize the tumours, which are often large.
- **MRI** usually shows the lesion clearly.

**Scanning with** $^{123}$I*meta-iodobenzylguanidine (MIBG)** produces specific uptake in sites of sympathetic activity with about 90% success. It is particularly useful with extra-adrenal tumours. $^{18}$F-deoxyglucose PET is also used by some centres in the localization of phaeochromocytomas.

**Genetic testing** for MEN2, VHL and SDHD mutations should be performed in all people with confirmed phaeochromocytoma or paraganglioma.

### Treatment

Tumours should be removed if this is possible; 5-year survival is about 95% for non-malignant tumours. Medical preoperative and perioperative treatment is vital and includes complete alpha- and beta-blockade with phenoxybenzamine (20–80 mg daily initially in divided doses), then propranolol (120–240 mg daily), plus transfusion of whole blood to re-expand the contracted plasma volume. The alpha-blockade must precede the beta-blockade, as worsened hypertension may otherwise result. Labetalol is not recommended. Surgery in the unprepared patient is fraught with dangers of both hypertension and hypotension; expert anaesthesia and an experienced surgeon are both vital, and sodium nitroprusside and phentolamine (a rapid acting alpha blocker) should be available in case sudden severe hypertension develops.

When operation is not possible, combined alpha- and beta-blockade can be used long term. Radionucleotide treatment with MIBG has been used but with limited success in malignant phaeochromocytoma.

Patients should be kept under clinical and biochemical review after tumour resection as over 10% recur or develop a further tumour. Catecholamine excretion measurements should be performed at least annually.

### THE THIRST AXIS

Thirst and water regulation are largely controlled by vasopressin, also known as antidiuretic hormone (ADH), which is synthesized in the hypothalamus and then migrates in neurosecretory granules along axonal pathways to the posterior pituitary. Pituitary disease alone without hypothalamic involvement therefore does not lead to ADH deficiency as the hormone can still ‘leak’ from the damaged end of the intact axon.

At normal concentrations the kidney is the predominant site of action of vasopressin. Vasopressin stimulation of the $V_2$ receptors allows the collecting ducts to become permeable to water via the migration of aquaporin-2 water channels, thus permitting reabsorption of hypotonic luminal fluid (p. 640). Vasopressin therefore reduces diuresis and results in overall retention of water. At high concentrations vasopressin also causes vasoconstriction via the $V_1$ receptors in vascular tissue.

Changes in plasma osmolality are sensed by osmoreceptors in the anterior hypothalamus. Vasopressin secretion is suppressed at levels below 280 mOsm/kg, thus allowing maximal water diuresis. Above this level, plasma vasopressin increases in direct proportion to plasma osmolality. At the upper limit of normal (295 mOsm/kg) maximum antidiuresis is achieved and thirst is experienced at about 298 mOsm/kg (Fig. 19.30).

Other factors affecting vasopressin release are shown in Table 19.34.

Disorders of vasopressin secretion or activity include:

- deficiency as a result of hypothalamic disease (‘cranial’ diabetes insipidus)
Biochemistry

- High or high-normal plasma osmolality with low urine osmolality (in primary polydipsia plasma osmolality tends to be low).
- Resultant high or high-normal plasma sodium (hypermotriaemia).
- High 24-h urine volumes (less than 2 L excludes the need for further investigation).
- Failure of urinary concentration with fluid deprivation.
- Restoration of urinary concentration with vasopressin or an analogue.

The latter two points are studied with a formal water deprivation test (Box 19.12). In normal subjects, plasma osmolality remains normal while urine osmolality rises above 600 mOsm/kg. In DI, plasma osmolality rises while the urine remains dilute, only concentrating after exogenous vasopressin is given (in ‘cranial’ DI) or not concentrating after vasopressin if nephrogenic DI is present. An alternative is measurement of plasma vasopressin during hypertonic saline infusion, but these measurements are not widely available.

**Treatment**

The synthetic vasopressin (ADH) analogue desmopressin is the treatment of choice. It has a longer duration of action than vasopressin and has no vasconstrictive effects. It is most reliably given intranasally as a spray 10–40 μg once or twice daily, but can also be given orally as 100–200 μg three times daily.
times daily, or intramuscularly 2–4 μg daily. Response is variable and must be monitored carefully with enquiry about fluid input/output and plasma osmolality measurements. The main problem is avoiding water overload and consequent hyponatraemia (p. 650). Where there is a reversible underlying cause (e.g. a hypothalamic tumour) this should be investigated and treated.

Alternative agents in mild DI, probably working by sensitizing the renal tubules to endogenous vasopressin, include thiazide diuretics, carbamazepine (200–400 mg daily) or chlorpropamide (200–350 mg daily) but these are rarely used.

**Nephrogenic diabetes insipidus**

In this condition, renal tubules are resistant to normal or high levels of plasma vasopressin (ADH). It may be inherited as a rare sex-linked recessive, with an abnormality in the vasopressin-2 receptor, or as an autosomal post-receptor defect in an ADH-sensitive water channel, aquaporin-2. More commonly it can be acquired as a result of renal disease, sickle cell disease, drug ingestion (e.g. lithium), hypercalcaemia or hypokalaemia. Wherever possible the cause should be reversed. Polyuria is helped by thiazide diuretics.

**Other causes of polyuria and polydipsia**

Diabetes mellitus, hypokalaemia and hypercalcaemia should be excluded. In the case of diabetes mellitus the cause is an osmotic diuresis secondary to glycosuria which leads to dehydration and an increased perception of thirst owing to hypertonicity of the extracellular fluid.

**Primary polydipsia**

This is a relatively common cause of thirst and polyuria. It is a psychiatric disturbance characterized by the excessive intake of water. Plasma sodium and osmolality fall as a result and the urine produced is appropriately dilute. Vasopressin levels become virtually undetectable. Prolonged primary polydipsia may lead to the phenomenon of 'renal medullary washout', with a fall in the concentrating ability of the kidney.

---

**Box 19.12 Water deprivation test**

**Indication**
- Diagnosis or exclusion of diabetes insipidus.

**Procedure**
- Fasting and no fluids from 07:30 hours (or overnight if only mild DI is expected and polyuria is only modest).
- Monitor serum and urine osmolality, urine volume and weight hourly for up to 8 hours.
- Abandon fluid deprivation if weight loss >3% occurs.
- If serum osmolality <300 mOsm/kg and/or urine osmolality <600 mOsm/kg give desmopressin 2 μg i.m. at end of test. Allow free fluid but measure urine osmolality for 2–4 hours.

**Interpretation**
- **Normal response.** Serum osmolality remains within normal range (275–295 mOsm/kg). Urine osmolality rises to >600 mOsm/kg.
- **Diabetes insipidus (DI).** Serum osmolality rises above normal without adequate concentration of urine osmolality (i.e. serum osmolality >300 mOsm/kg; urine osmolality <600 mOsm/kg).
- **Nephrogenic DI** – if desmopressin does not concentrate urine.
- **Cranial DI** – if urine osmolality rises by >50% after desmopressin.

Characteristically the diagnosis is made by a water deprivation test. A low plasma osmolality is usual at the start of the test, and since vasopressin secretion and action can be stimulated, the patient’s urine becomes concentrated (albeit ‘maximum’ concentrating ability may be impaired); the initially low urine osmolality gradually increases with the duration of the water deprivation.

**Syndrome of inappropriate antidiuretic hormone (SIADH)**

**Clinical features**

Inappropriate secretion of ADH (also called vasopressin) leads to retention of water and hyponatraemia. The presentation is usually vague, with confusion, nausea, irritability and, later, fits and coma. There is no oedema. Mild symptoms usually occur with plasma sodium levels below 125 mmol/L and serious manifestations are likely below 115 mmol/L. The elderly may show symptoms with milder abnormalities.

The syndrome must be distinguished from dilutional hyponatraemia due to excess infusion of glucose/water solutions or diuretic administration (thiazides or amiloride, see p. 651).

**Diagnosis**

The usual features are:
- Dilutional hyponatraemia due to excessive water retention
- Euvolaemia (in contrast to hypovolaemia of sodium and water depletion states)
- Low plasma osmolality with ‘inappropriate’ urine osmolality >100 mOsm/kg (and typically higher than plasma osmolality)
- Continued urinary sodium excretion >30 mmol/L (lower levels suggest sodium depletion and should respond to 0.9% saline infusion)
- Absence of hypokalaemia (or hypotension)
- Normal renal and adrenal and thyroid function.

The causes are listed in Table 19.36.

Hyponatraemia is very common during illness in frail elderly patients and it may sometimes be clinically difficult to distinguish SIADH from salt and water depletion, particularly when mixed clinical features are present. Under these circumstances, a trial infusion of 1–2 L 0.9% saline is given.
SIADH will not respond (but will excrete the sodium and water load effectively) – sodium depletion will respond. ACTH deficiency can give a very similar biochemical picture to SIADH, therefore it is necessary to ensure the hypothalamic-pituitary-adrenal axis is intact, particularly in neurosurgical patients, in whom ACTH deficiency may be relatively common.

Treatment
The underlying cause should be corrected where possible. Symptomatic relief can be obtained by the following measures:

- Fluid intake should be restricted to 500–1000 mL daily. If tolerated, and complied with, this will correct the biochemical abnormalities in almost every case.
- Plasma osmolality, serum sodium and body weight should be measured frequently.
- If water restriction is poorly tolerated or ineffective, demeclocycline (600–1200 mg daily) is given; this inhibits the action of vasopressin on the kidney, causing a reversible form of nephrogenic diabetes insipidus. It often, however, causes photosensitive rashes.
- When the syndrome is very severe (i.e. acute and symptomatic), hypertonic saline may be indicated but this is potentially dangerous and should only be used with extreme caution (p. 650).
- Vasopressin V₂ antagonists, e.g. tolvaptan 15 mg daily, are being used with good results.

### DISORDERS OF CALCIUM METABOLISM

Serum calcium levels are mainly controlled by parathyroid hormone (PTH) and vitamin D. Hypercalcaemia is much more common than hypocalcaemia and is frequently detected incidentally with multichannel biochemical analysers. Mild asymptomatic hypercalcaemia occurs in about 1 in 1000 of the population, with an incidence of 25–30 per 100 000 population. It occurs mainly in elderly females, and is usually due to primary hyperparathyroidism (primary HPT).

#### Parathyroid hormone

There are normally four parathyroid glands which are situated posterior to the thyroid, but occasionally additional glands exist or they may be found elsewhere in the neck or mediastinum. PTH, an 84-amino-acid hormone derived from the 115-residue preprohormone, is secreted from the chief cells of the parathyroid glands. PTH levels rise as serum ionized calcium falls. The latter is detected by specific G protein coupled calcium-sensing receptors on the plasma membrane of the parathyroid cells. PTH has several major actions, all serving to increase plasma calcium by:

- increasing osteoclastic resorption of bone (occurring rapidly)
- increasing intestinal absorption of calcium (a slow response)
- increasing synthesis of 1,25-(OH)₂D₃
- increasing renal tubular reabsorption of calcium
- increasing excretion of phosphate.

PTH effects are mediated at specific membrane receptors on the target cells, resulting in an increase of adenyl cyclase messenger activity.

Vitamin D metabolism is discussed on page 550.

PTH measurements use two-site immunometric assays that measure only the intact PTH molecule; interpretation requires a simultaneous calcium measurement in order to differentiate most causes of hyper- and hypocalcaemia.

### Hypercalcaemia

#### Pathophysiology and causes

The major causes of hypercalcaemia are listed in Table 19.37; primary hyperparathyroidism and malignancies are by far the most common (>90% of cases). Hyperparathyroidism itself may be primary, secondary or tertiary. Primary hyperparathyroidism is caused by single (>80%) parathyroid adenomas or by diffuse hyperplasia of all the glands (15–20%); multiple parathyroid adenomas are rare. Involvement of multiple parathyroid glands may be part of a familial syndrome (e.g. multiple endocrine neoplasia (MEN) syndrome type 1 or 2a). Parathyroid carcinoma is rare (<1%), though it usually produces severe and intractable hypercalcaemia. Hyperparathyroidism-jaw tumour syndrome is a rare familial cause of hyperparathyroidism which may be associated with parathyroid carcinoma and maxillary or mandibular tumours.

Primary hyperparathyroidism is of unknown cause, though it appears that adenomas are monoclonal. Hypercalcaemia may also be monoclonal. Chromosomal rearrangements in the 5 regulatory region of the parathyroid hormone gene have been identified, and inactivation of some tumour suppressor genes at a variety of sites may also be involved.

Secondary hyperparathyroidism (see p. 618) is physiological compensatory hypertrophy of all parathyroids because of hypocalcaemia, such as occurs in chronic kidney disease or vitamin D deficiency. PTH levels are raised but calcium levels are low or normal, and PTH falls to normal after correction of the cause of hypocalcaemia where this is possible.

</table>
Tertiary hyperparathyroidism is the development of apparently autonomous parathyroid hyperplasia after longstanding secondary hyperparathyroidism, most often in renal failure. Plasma calcium and phosphate are both raised, the latter often grossly so. Parathyroidectomy is necessary at this stage.

Symptoms and signs
Mild hypercalcaemia (e.g. adjusted calcium <3 mmol/L) is frequently asymptomatic, but more severe hypercalcaemia can produce a number of symptoms:
- **General.** There may be tiredness, malaise, dehydration and depression.
- **Renal.** Renal colic from stones, polyuria or nocturia, haematuria and hypertension occurs. The polyuria results from the effect of hypercalcaemia on renal tubules, reducing their concentrating ability – a form of mild nephrogenic diabetes insipidus. Primary hyperparathyroidism is present in about 5% of patients who present with renal calculi.
- **Bones.** There may be bone pain. Hyperparathyroidism mainly affects cortical bone, and bone cysts and locally destructive ‘brown tumours’ occur but only in advanced disease. Only 5–10% of all cases have definite bony lesions even when sought. Bone disease may be more apparent when there is co-existing vitamin D deficiency.
- **Abdomen.** There may be abdominal pain.
- **Chondrocalcinosis** and ectopic calcification. These are occasional features.
- **Corneal calcification.** This is a marker of longstanding hypercalcaemia but causes no symptoms. There may also be symptoms from the underlying cause. Malignant disease is usually advanced by the time hypercalcaemia occurs, typically with bony metastases. The common primary tumours are bronchus, breast, myeloma, oesophagus, thyroid, prostate, lymphoma and renal cell carcinoma. True ‘ectopic PTH secretion’ by the tumour is very rare, and most cases are associated with raised levels of PTH-related protein. This is a 144-amino-acid polypeptide, the initial sequence of which shows an approximate homology with the biologically active part of PTH, which is necessary in fetal development but does not have a clearly defined role in the adult. Local bone-resorbing cytokines and prostaglandins may be involved locally where there are metastatic skeletal lesions, leading to local mobilization of calcium by osteolysis with subsequent hypercalcaemia. Severe hypercalcaemia (>3 mmol/L) is usually associated with malignant disease, hyperparathyroidism, chronic kidney disease or vitamin D therapy.

Investigations and differential diagnosis
**Biochemistry**
Several fasting serum calcium and phosphate samples should be performed.
- **Serum PTH.** The hallmark of primary hyperparathyroidism is hypercalcaemia and hypophosphataemia with detectable or elevated intact PTH levels during hypercalcaemia. When this combination is present in an asymptomatic patient then further investigation is usually unnecessary. However, an undetectable PTH level in the context of hypercalcaemia always requires further investigation to exclude malignancy or other pathology (Table 19.37).

- **Hyperchloraemic acidosis – often mild.**
- **Renal function** is usually normal but should be measured as a baseline.
- **24-hour urinary calcium** or single calcium creatinine ratio should be measured in a young patient with modest elevation in calcium and PTH to exclude familial hypocalciuric hypercalcaemia (see p. 996).
- **Elevated serum alkaline phosphatase** is found in severe parathyroid bone disease, but otherwise it suggests an alternative cause for hypercalcaemia. Where PTH is undetectable or equivocal, a number of other tests may lead to the diagnosis:
  - Protein electrophoresis/immunofixation: to exclude myeloma
  - Serum TSH: to exclude hyperthyroidism
  - 09:00 hours cortisol and/or ACTH test: to exclude Addison’s disease
  - Serum ACE: helpful in the diagnosis of sarcoidosis
  - Hydrocortisone suppression test: hydrocortisone 40 mg three times daily for 10 days leads to suppression of plasma calcium in sarcoidosis, vitamin D-mediated hypercalcaemia and some malignancies.

**Imaging**
Abdominal X-rays may show renal calculi or nephrocalcinosis. High-definition hand X-rays can show subperiosteal erosions in the middle or terminal phalanges. DXA bone density scan is useful to detect bone effects in asymptomatic people with hyperparathyroidism (HPT) in whom conservative management is planned.

The success of parathyroid imaging is highly operator dependent and choice therefore depends on local skills and experience. Imaging is frequently far less accurate than parathyroid exploration by an expert surgeon where the success rate is at least 90%. Methods include:
- Ultrasound, which, although insensitive for small tumours, is simple and safe
- High-resolution CT scan or MRI (more sensitive)
- Radioisotope scanning using 99mTc-sestamibi, which is approximately 90% sensitive in detecting adenomas.

**Treatment of hypercalcaemia**
Details of emergency treatment for severe hypercalcaemia are given in Emergency Box 19.2. This should be followed by oral therapy unless the underlying disease can be treated.

**Treatment of primary hyperparathyroidism**

**Medical management**
There are no effective medical therapies at present for primary hyperparathyroidism, but a high fluid intake should be maintained, a high calcium or vitamin D intake avoided, and exercise encouraged. New therapeutic agents that target the calcium-sensing receptors (e.g. cinacalcet) are of proven value in parathyroid carcinoma and in dialysis patients (p. 631), and are used in primary hyperparathyroidism where surgical intervention is contraindicated.

**Surgery**
There is agreement that surgery is indicated in primary hyperparathyroidism for:
- people with renal stones or impaired renal function
- bone involvement or marked reduction in cortical bone density
Hypocalcaemia and hypoparathyroidism
Pathophysiology
Hypocalcaemia may be due to deficiencies of calcium homeostatic mechanisms, secondary to high phosphate levels or other causes of hypocalcaemia (Table 19.38). All forms of hypoparathyroidism, except transient surgical effects, are uncommon.

Postoperative care
The major danger after operation is hypocalcaemia, which is more common in patients who have significant bone disease and/or vitamin D deficiency – the ‘hungry bone’ syndrome. Some authorities pre-treat such patients, with alfacalcidol 2 μg daily from 2 days preoperatively for 10–14 days, and routine vitamin D replacement (preferably without calcium) is always indicated if deficiency is diagnosed. Chvostek’s and Trousseau’s signs (see p. 997) are monitored as well as biochemistry. Plasma calcium measurements are performed at least daily until stable – with or without replacement – a mild transient hypoparathyroidism often continues for 1–2 weeks. Depending on its severity, oral or intravenous calcium should be given temporarily, as only a few patients (<1%) will develop longstanding surgical hypoparathyroidism.

Familial hypocalciuric hypercalcaemia
This uncommon autosomal dominant, and usually asymptomatic, condition demonstrates increased renal reabsorption of calcium despite hypercalcaemia. PTH levels are normal or slightly raised and urinary calcium is low. It is caused by loss of function mutations in the gene on the long arm of chromosome 3 encoding for the calcium-ion-sensing G-protein coupled receptor in the kidney and parathyroid gland. Family members are often affected, detected by genetic analysis. Parathyroid surgery is not indicated as the course appears benign. This diagnosis can be differentiated from hyperparathyroidism in an isolated case by the calcium creatinine ratio in blood and urine.

Emergency Box 19.2
Treatment of acute severe hypercalcaemia
Acute hypercalcaemia often presents with dehydration, nausea and vomiting, nocturia and polyuria, drowsiness and altered consciousness. The serum Ca²⁺ is over 3 mmol/L, and sometimes as high as 5 mmol/L. While investigation of the cause is under way, immediate treatment is mandatory if the patient is seriously ill or if the Ca²⁺ is above 3.5 mmol/L.
- **Rehydrate** at least 4–6 L of 0.9% saline on day 1, and 3–4 L for several days thereafter. Central venous pressure (CVP) may need to be monitored to control the hydration rate.
- **Intravenous bisphosphonates** are the treatment of choice for hypercalcaemia of malignancy or of undiagnosed cause. Pamidronate is preferred (60–90 mg as an intravenous infusion in 0.9% saline or glucose over 2–4 hours or, if less urgent, over 2–4 days). Levels fall after 24–72 hours, lasting for approximately two weeks. Zoledronate is an alternative.
- **Prednisolone** (30–60 mg daily) is effective in some instances (e.g. in myeloma, sarcoidosis and vitamin D excess) but in most cases is ineffective.
- **Calcitonin** (200 units i.v. 6-hourly) has a short-lived action and is little used.
- **Oral phosphate** (sodium cellulose phosphate 5 g three times daily) produces diarrhoea.

- unequivocal marked hypercalcaemia (in UK typically >3.0 mmol/L; USA guidelines state >1 mg/dL above reference range)
- the uncommon younger patient, below age 50 years
- a previous episode of severe acute hypercalcaemia.

The situation where plasma calcium is mildly raised (2.65–3.00 mmol/L) is more controversial. Most authorities feel that young patients should be operated on, as should those who have reduced cortical bone density or significant hypercalciuria, as this is associated with stone formation.

In older patients without these problems, or in those unfit for or unwilling to have surgery, conservative management is indicated. Regular measurement of serum calcium and of renal function is necessary. Bone density of cortical bone should be monitored if conservative management is used. Hyperparathyroidism can cause nonspecific symptoms of weakness, fatigue and depression, and it can be difficult to determine whether these symptoms are related to hypercalcaemia or coincidental.

Surgical technique and complications
Parathyroid surgery should be performed only by experienced surgeons, as the minute glands may be very difficult to define, and it is difficult to distinguish between an adenoma and normal parathyroid. In expert centres over 90% of operations are successful, involving removal of the adenoma, or removal of all four hyperplastic parathyroids. Minimal access surgery is used, and some centres measure PTH levels intraoperatively to ensure the adenoma has been removed.

Other than postoperative hypocalcaemia (see below), the other rare complications are those of thyroid surgery – bleeding and recurrent laryngeal nerve palsies (<1%). Vocal cord function should be checked preoperatively.

If initial exploration is unsuccessful, a full work-up including venous catheterization and scanning is essential, remembering that parathyroid tissue can be ectopic.
Causes

- Chronic kidney disease is the most common cause of hypocalcaemia.
- Severe vitamin D deficiency may cause mild, and occasionally severe, hypocalcaemia.
- Hypocalcaemia after thyroid or parathyroid surgery is common but usually transient – fewer than 1% of thyroidectomies leave permanent damage (see above).
- Idiopathic hypoparathyroidism is one of the rarer autoimmune disorders, often accompanied by vitiligo, cutaneous candidiasis and other autoimmune disease.
- DiGeorge’s syndrome (p. 66) is a familial condition in which the hypoparathyroidism is associated with intellectual impairment, cataracts and calcified basal ganglia, and occasionally with specific autoimmune disease.
- Pseudohypoparathyroidism is a syndrome of end-organ resistance to PTH owing to a mutation in the G protein (GNAS1) which couples to the PTH receptor. It is associated with short stature, short metacarpals, subcutaneous calcification and sometimes intellectual impairment. Variable degrees of resistance involving other G protein-linked hormone receptors may also be seen (TSH, LH, FSH).
- Pseudo-pseudohypoparathyroidism describes the phenotypic defects but without any abnormalities of calcium metabolism. These individuals may share the same gene defect as individuals with pseudohypoparathyroidism and be members of the same families.

Clinical features

Hypoparathyroidism presents as neuromuscular irritability and neuropsychiatric manifestations. Paraesthesias, circumoral numbness, cramps, anxiety and tetany (Box 19.13) are frequently seen in idiopathic hypoparathyroidism. Two signs of hypocalcaemia are Chvostek’s sign (gentle tapping over the facial nerve causes twitching of the ipsilateral facial muscles) and Trousseau’s sign, where inflation of the sphygmomanometer cuff above systolic pressure for 3 min induces tetanic spasm of the fingers and wrist. Severe hypocalcaemia may cause papilloedema and frequently a prolonged QT interval on the ECG.

Investigations

The clinical history and picture is usually diagnostic and is confirmed by a low serum calcium (after correction for any albumin abnormality). Additional tests include:

- Serum and urine creatinine for renal disease
- PTH levels in the serum: absent or inappropriately low in hypoparathyroidism, high in other causes of hypocalcaemia
- Parathyroid antibodies (present in idiopathic hypoparathyroidism)
- 25-hydroxy vitamin D serum level (low in vitamin D deficiency)
- Magnesium level: severe hypomagnesaemia results in functional hypoparathyroidism which is reversed by magnesium replacement
- X-rays of metacarpals, showing short fourth metacarpals which occur in pseudohypoparathyroidism.

Diseases of many glands

Multiple gland failure (polyglandular autoimmune syndromes)

These are caused by autoimmune disease as detailed in Table 19.2 on page 939. Most common are the associations of primary hypothyroidism and type 1 diabetes, and either of these with Addison's disease or pernicious anaemia.

Autoimmune polyendocrinopathy type 1 (APS-1) is an autosomal recessive disorder and is caused by AIRE gene mutations. The AIRE gene is present in the epithelium of the thymus and is involved in the presentation of self-antigens to thymocytes. Mutations will allow persistence of thymic lymphocytes, which react against self-antigens and cause development of autoimmune disorders. Mucocutaneous candidiasis often develops before the onset of endocrine deficiencies, such as Addison’s disease, type 1 diabetes, hypoparathyroidism, nail dystrophy, vitiligo and dental enamel hypoplasia.

APS-2 is not associated with candidiasis and is also known as Schmidt’s syndrome, typically when hypothyroidism, Addison’s disease and type 1 diabetes are present in combination; coeliac disease is also an association.

Multiple endocrine neoplasias

This is the name given to the simultaneous or metachronous occurrence of tumours involving a number of endocrine glands (Table 19.39). The condition is inherited in an autosomal dominant manner and arises from the expression of recessive oncogenic mutations, most of which have been isolated. Affected persons may pass on the mutation to their offspring in the germ cell, but for the disease to become evident a somatic mutation must also occur, such as deletion or loss of a normal homologous chromosome.

MEN 1

The defect in MEN 1 is in a novel gene (menin) on the long arm of chromosome 11 which encodes for a 610-amino-acid protein. Menin represses a transcription factor (JunD) and lack of JunD suppression leads to decreased apoptosis and oncogenesis. People with the MEN1 gene carry one mutant

Multiple liver metastases from a pancreatic endocrine tumour in multiple endocrine neoplasia type 1.

gene and a wild type gene (i.e. are heterozygous). When the wild type gene undergoes a random somatic mutation during life, this leads to loss of heterozygosity and explains the late onset of tumours at any stage (the ‘two hit’ hypothesis). MEN 1 is classically associated with pancreatic, parathyroid and pituitary tumours, although other glands may be affected (Table 19.39).

**MEN 2a and 2b**

MEN 2a and 2b are caused by mutations of the RET proto-oncogene on chromosome 10 (see medullary thyroid cancer, p. 971). This gene encodes for a transmembrane glycoprotein receptor. For MEN 2a the mutation is in the extracellular domain; for 2b it is in the intracellular domain. MEN 2 is classically associated with parathyroid tumours, phaeochromocytoma and medullary thyroid carcinoma (Table 19.39). Unlike MEN 2a, MEN 2b is associated with a marfanoid phenotype and intestinal and visceral ganglioneuromas, as well as neuromas around the lips and tongue.

**Management**

Treatment of established tumours in MEN is largely the same as treatment for similar tumours occurring sporadically. In MEN 1 four-gland parathyroidectomy is usually recommended when surgery is needed since all glands are typically involved. However, the essence of management in MEN is annual screening to detect tumours at an early, treatable stage.

**Screening**

A careful family history is essential. If the precise gene mutation has been identified in a particular family, then family members at risk can be offered genetic screening for the presence of the mutation, ideally in childhood. In affected individuals, biochemical screening and periodic imaging is then required.

**Screening for MEN 1**

Hyperparathyroidism is usually the first manifestation, and serum calcium is the simplest screening test in families with no identified mutation. In an established case (or gene-positive family member) other screening bloods include prolactin, GH/IGF-1 and ‘gut hormones’ (p. 247). Periodic imaging of pancreas, adrenals and pituitary is usually performed. People with MEN 1 can develop metastases to the liver from non-functional pancreatic tumours which are clinically silent; this emphasizes the need for regular screening imaging.

**Screening for MEN 2**

Serum calcium levels will easily detect hyperparathyroidism.

- **Medullary carcinoma of thyroid (MCT)** – with the known presence of the gene defect, total thyroidectomy is recommended in early childhood or as soon as the gene defect is identified. Calcitonin is a useful tumour marker.

- **Phaeochromocytoma** – metanephrine or catecholamine estimations.

**McCune–Albright syndrome**

This condition is associated with autonomous hypersecretion of a number of endocrine glands at a young age. Gonadotrophin-independent puberty with Leydig cell hyperplasia in males and ovarian oestrogen production in girls occurs. Pituitary hypersecretion may lead to hyperprolactinaemia, acromegaly or gigantism. Cushing’s syndrome due to nodular hyperplasia of the adrenal cortex is observed, as well as autonomous functioning thyroid nodules. Non-endocrine manifestations include café-au-lait patches and increased bone deformity and fractures due to polyostotic fibrous dysplasia. The pathological basis is a point mutation of the GNAS1 gene that inhibits GTPase activity, leading to persistent activation of cAMP-mediated endocrine secretion.

**Ectopic hormone secretion**

This term refers to hormone synthesis, and normally secretion, from a neoplastic non-endocrine cell, most usually seen in tumours that have some degree of embryological resemblance to specialist endocrine cells. The clinical effects are those of the hormone produced, with or without manifestations of systemic malignancy. The most common situations seen are the following:

- **Hypercalcaemia of malignant disease**, often from squamous cell tumours of lung and breast, often with bone metastases. Where metastases are not present, most cases are mediated by secretion of PTH-related...
protein (PTHrP), which has considerable sequence homology to PTH; a variety of other factors may sometimes be involved, but very rarely PTH itself (see p. 995). Treatment is also discussed on page 995.

- **SIADH** (see p. 993). Again, this is most common from a primary lung tumour.

- **Ectopic ACTH syndrome** (see p. 953). Small-cell carcinoma of the lung, carcinoid tumours and medullary thyroid carcinomas are the most common causes, though many other tumours rarely cause it.

- **Production of insulin-like activity** may result in hypoglycaemia (see p. 1029).

### Other endocrine disorders

**Endocrine treatment of other malignancies**

See Chapter 9.

Introduction

*Diabetes mellitus* (DM) is a syndrome of chronic hyperglycaemia due to relative insulin deficiency, resistance or both. It affects more than 220 million people worldwide, and it is estimated that it will affect 440 million by the year 2030. Diabetes is usually irreversible and, although patients can lead a reasonably normal lifestyle, its late complications result in reduced life expectancy and major health costs. These include macrovascular disease, leading to an increased prevalence of coronary artery disease, peripheral vascular disease and stroke, and microvascular damage causing diabetic retinopathy and nephropathy. Neuropathy is another major complication.

Insulin structure and secretion

Insulin is the key hormone involved in the storage and controlled release within the body of the chemical energy available from food. It is coded for on chromosome 11 and synthesized in the beta cells of the pancreatic islets (Fig. 20.1). The synthesis, intracellular processing and secretion of insulin by the beta cell is typical of the way that the body produces and manipulates many peptide hormones. Figure 20.2 illustrates the cellular events triggering the release of insulin-containing granules. After secretion, insulin enters the portal circulation and is carried to the liver, its prime target organ. About 50% of secreted insulin is extracted and degraded in the liver; the residue is broken down by the kidneys. C-peptide is only partially extracted by the liver (and hence provides a useful index of the rate of insulin secretion) but is mainly degraded by the kidneys.

An outline of glucose metabolism

Blood glucose levels are closely regulated in health and rarely stray outside the range of 3.5–8.0 mmol/L (63–144 mg/dL), despite the varying demands of food, fasting and exercise. The principal organ of glucose homeostasis is the liver, which absorbs and stores glucose (as glycogen) in the post-absorptive state and releases it into the circulation between meals to match the rate of glucose utilization by peripheral tissues. The liver also combines 3-carbon molecules derived from breakdown of fat (glycerol), muscle glycogen (lactate) and protein (e.g. alanine) into the 6-carbon glucose molecule by the process of gluconeogenesis.

Glucose production

About 200 g of glucose is produced and utilized each day. More than 90% is derived from liver glycogen and hepatic gluconeogenesis, and the remainder from renal gluconeogenesis.

Glucose utilization

The brain is the major consumer of glucose, and its function depends upon an uninterrupted supply of this substrate. Its requirement is 1 mg/kg bodyweight per minute, or 100 g daily in a 70 kg man. Glucose uptake by the brain is obligatory and is not dependent on insulin, and the glucose used is oxidized to carbon dioxide and water. Other tissues, such as muscle and fat, are facultative glucose consumers. The effect of insulin peaks associated with meals is to lower
Figure 20.1 Part of a beta cell. The ribosomes manufacture pre-proinsulin from insulin mRNA. The hydrophobic ‘pre’ portion of pre-proinsulin allows it to transfer to the Golgi apparatus, and is subsequently enzymatically cleaved off. Proinsulin is parcelled into secretory granules in the Golgi apparatus. These mature and pass towards the cell membrane where they are stored before release. The proinsulin molecule folds back on itself and is stabilized by disulphide bonds. Equimolar quantities of insulin and C-peptide are released into the circulation via the ‘regulated pathway’. A small amount of insulin is secreted by the beta cell directly via the ‘constitutive pathway’, which bypasses the secretory granules.

Figure 20.2 Local forces regulating insulin secretion from beta cells. Glucose enters the beta cell via the GLUT-2 transporter protein, which is closely associated with the glycolytic enzyme glucokinase. Metabolism of glucose within the beta cell generates ATP. ATP closes potassium channels in the cell membrane (a). If a sulfonylurea binds to its receptor, this also closes potassium channels. Closure of potassium channels predisposes to cell membrane depolarization, allowing calcium ions to enter the cell via calcium channels in the cell membrane (b). The rise in intracellular calcium triggers activation of calcium-dependent phospholipid protein kinase which, via intermediary phosphorylation steps, leads to fusion of the insulin-containing granules with the cell membrane and exocytosis of the insulin-rich granule contents. Similar mechanisms produce hormone-granule secretion in many other endocrine cells.

the threshold for glucose entry into cells; at other times, energy requirements are largely met by fatty-acid oxidation. Glucose taken up by muscle is stored as glycogen or metabolized to lactate or carbon dioxide and water. Fat uses glucose as a source of energy and as a substrate for triglyceride synthesis; lipolysis releases fatty acids from triglyceride together with glycerol, a substrate for hepatic gluconeogenesis.

Hormonal regulation

Insulin is a major regulator of intermediary metabolism, although its actions are modified in many respects by other hormones. Its actions in the fasting and postprandial states differ (Fig. 20.3). In the fasting state, its main action is to regulate glucose release by the liver, and in the postprandial state, it additionally promotes glucose uptake by fat and muscle. The effect of counter-regulatory hormones (glucagon, epinephrine (adrenaline), cortisol and growth hormone) is to cause greater production of glucose from the liver and less utilization of glucose in fat and muscle for a given level of insulin.

Glucose transport

Cell membranes are not inherently permeable to glucose. A family of specialized glucose-transporter (GLUT) proteins carry glucose through the membrane into cells.

- GLUT-1 – enables basal non-insulin-stimulated glucose uptake into many cells (see Fig. 6.29).
- GLUT-2 – transports glucose into the beta cell, a prerequisite for glucose sensing, and is also present in the renal tubules and hepatocytes.
- GLUT-3 – enables non-insulin-mediated glucose uptake into brain neurones and placenta.
- GLUT-4 – enables much of the peripheral action of insulin. It is the channel through which glucose is taken up into muscle and adipose tissue cells following stimulation of the insulin receptor (Fig. 20.4).
The key clinical features of the two main forms of diabetes are listed in Table 20.2. Type 1 and type 2 diabetes represent two distinct diseases from the epidemiological point of view, but clinical distinction can sometimes be difficult. The two diseases should from a clinical point of view be seen as a spectrum, distinct at the two ends but overlapping to some extent in the middle. Hybrid forms are increasingly recognized, and patients with immune-mediated diabetes (type 1) may, for example, also be overweight and insulin resistant. This is sometimes referred to as ‘double diabetes’. It is more relevant to give the patient the right treatment on clinical grounds than to worry about how to label their diabetes. The classification of primary diabetes continues to evolve. Monogenic forms have been identified (see p. 1007), in some cases with significant therapeutic implications. Although secondary diabetes accounts for barely 1–2% of all new cases at presentation, it should not be missed because the cause can sometimes be treated. All forms of diabetes derive from inadequate insulin secretion relative to the needs of the body, and progressive insulin secretory failure is characteristic of both common forms of diabetes. Thus, some patients with immune-mediated diabetes type 1 may not at first require insulin, whereas many with type 2 diabetes will eventually do so.

**Type 1 diabetes mellitus**

**Epidemiology**

Type 1 diabetes is a disease of insulin deficiency. In western countries almost all patients have the immune-mediated form of the disease, otherwise known as type 1A. Type 1 diabetes is a disease of childhood, reaching a peak incidence around the time of puberty, but can present at any age. A ‘slow-burning’ variant with slower progress to insulin deficiency occurs in later life and is sometimes called latent autoimmune diabetes in adults (LADA). LADA may be difficult to distinguish from type 2 diabetes. Clinical clues are: leaner build, rapid progression to insulin therapy following an initial response to other therapies, and the presence of circulating islet autoantibodies. The highest rates of type 1 diabetes in the world are seen in Finland and other Northern European countries, and on the island of Sardinia, which for unknown reasons, has the second highest rate in the world (Fig. 20.5). The incidence of type 1 diabetes appears to be increasing in most populations. In Europe, the annual increase is of the order of 2–3%, and is most marked in children under the age of 5 years. WHO estimated in 1995 that there were 19.4 million people with type 1 diabetes and that the number will rise to 57.2 million by 2025.
Diabetes mellitus and other disorders of metabolism

Note: Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not, of itself, classify the patient. (Adapted from ADA. Diagnosis and classification of diabetes mellitus. Diabetes Care 2008; 31(Suppl 1):S55–S60.)

Table 20.2 The spectrum of diabetes: a comparison of type 1 and type 2 diabetes mellitus

<table>
<thead>
<tr>
<th>Causes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Type 1 diabetes belongs to a family of HLA-associated immune-mediated organ-specific diseases. Genetic susceptibility is polygenic, with the greatest contribution from the HLA region. Autoantibodies directed against pancreatic islet constituents appear in the circulation within the first few years of life, and often predate clinical onset by many years. Autoantibodies are also found in older patients with LADA and carry an increased risk of progression to insulin therapy.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Genetic susceptibility and inheritance</th>
</tr>
</thead>
<tbody>
<tr>
<td>Increased susceptibility to type 1 diabetes is inherited, but the disease is not genetically predetermined. The identical twin of a patient with type 1 diabetes has a 30–50% chance of developing the disease, which implies that non-genetic factors must also be involved. The risk of developing diabetes by age 20, curiously, is greater with a diabetic father (3–7%) than with a diabetic mother (2–3%). If one child in a family has type 1 diabetes, each sibling has a ~6% risk of developing diabetes by age 20. This risk rises to about 20% in HLA-identical siblings who have the same HLA type as the proband. Since type 1 diabetes can present at any age, the lifetime risk for a sibling or child is at least double the risk by age 20.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>HLA system</th>
</tr>
</thead>
<tbody>
<tr>
<td>The HLA genes on chromosome 6 are highly polymorphic and modulate the immune defence system of the body.</td>
</tr>
</tbody>
</table>
Type 1 diabetes is associated with other organ-specific autoimmune diseases including autoimmune thyroid disease, coeliac disease, Addison’s disease and pernicious anaemia. Autopsies of patients who died following diagnosis of type 1 diabetes show infiltration of the pancreatic islets by mononuclear cells. This appearance, known as insulitis, resembles that in other autoimmune diseases such as thyroiditis. Several islet antigens have been characterized, and these include insulin itself, the enzyme glutamic acid decarboxylase (GAD), protein tyrosine phosphatase (IA-2) (also known as ICA512). Not all the staining seen with ICA is due to these two autoantibodies, so it is assumed that other islet autoantibodies are also involved. Insulin autoantibodies also appear in the circulation but do not contribute to the ICA reaction.

Environmental factors
The incidence of childhood type 1 diabetes is rising across Europe at the rate of 2–3% each year, suggesting that environmental factor(s) are involved in its pathogenesis. Islet autoantibodies (see above) appear in the first few years of life, indicating prenatal or early postnatal interactions with the environment. Exposures to dietary constituents, enteroviruses such as Coxsackie B4 and relative deficiency of vitamin D are possible candidates, but their role in the causation of the disease has yet to be confirmed. A cleaner environment with less early stimulation of the immune system in childhood may increase susceptibility for type 1 diabetes, as for atopic/allergic conditions (the hygiene hypothesis) (see p. 824), and more rapid weight gain in childhood and adolescence leading to increased insulin resistance might accelerate clinical onset (the accelerator hypothesis).

Pre-type 1 diabetes and prevention of type 1 diabetes
Children who test positive for two or more autoantibodies have a >80% risk of progression to diabetes, and the risk approaches 100% in those who additionally lose their first phase insulin response to intravenous glucose and/or develop glucose intolerance. The ability to predict type 1 diabetes with this degree of precision has opened the way to trials of disease prevention, but intervention before clinical onset of diabetes has so far proved unsuccessful.
Type 2 diabetes mellitus

Epidemiology

Type 2 diabetes is a common condition in all populations enjoying an affluent lifestyle, and has increased in parallel with the adoption of a western lifestyle and increasing obesity. The four major determinants are increasing age, obesity, ethnicity and family history. In poor countries, diabetes is a disease of the rich, but in rich countries, it is a disease of the poor; obesity being the common factor. Glucose intolerance or frank diabetes may be present in a subclinical or undiagnosed form for years before diagnosis, and 25–50% of patients already have some evidence of vascular complications at the time of diagnosis. Onset may be accelerated by the stress of pregnancy, drug treatment or intercurrent illness. The overall prevalence within the UK is 4–6%, and the lifetime risk is around 15–20%. Type 2 diabetes is 2–4 times as prevalent in people of South Asian, African and Caribbean ancestry who live in the UK, and the life-time risk in these groups exceeds 30%. High rates also affect people of Middle Eastern and Hispanic American origin living western lifestyles. Obesity increases the risk of type 2 diabetes 80–100 fold, and this is reflected by the increasing prevalence of diabetes in different populations. On average, the inhabitants of affluent countries gain almost 1 g daily between the ages of 25 and 55 years. This gain, due to a tiny excess in energy intake over expenditure (~ 90 kcal or one chocolate-coated digestive biscuit per day) is often due to reduced exercise rather than increased food intake. Further, our sedentary lifestyle means that the proportion of obese young adults is rising rapidly, and epidemic obesity will create a huge public health problem for the future. The increasing numbers of obese adolescents presenting with type 2 diabetes, particularly within high-risk ethnic groups, is a matter for concern.

Type 2 diabetes is associated with central obesity, hypertension, hypertriglyceridaemia, a decreased HDL-cholesterol, disturbed haemostatic variables and modest increases in a number of pro-inflammatory markers. Insulin resistance is strongly associated with many of these variables, as is increased cardiovascular risk. This group of conditions is referred to as the metabolic syndrome (see p. 223). The International Diabetes Federation has proposed criteria based on increased waist circumference (or BMI >30) plus two of the following: diabetes (or fasting glucose >7.0 mmol/L), hypertension, raised triglycerides or low HDL cholesterol. On this definition, about one-third of the adult population has features of the syndrome, not necessarily associated with diabetes. Critics would argue that the metabolic syndrome is not a distinct entity, but one end of a continuum in the relationship between exercise, lifestyle and bodyweight on the one hand, and genetic make-up on the other, and that diagnosis adds little to standard clinical practice in terms of diagnosis, prognosis or therapy.

Causes

Inheritance

Identical twins of patients with type 2 diabetes have >50% chance of developing diabetes; the risk to non-identical twins or siblings is of the order of 25%, confirming a strong inherited component to the disease. Type 2 diabetes is a polygenic disorder, and, as with type 1 diabetes, genome-wide studies of associations between common DNA variants and disease have allowed identification of numerous susceptibility loci. Several of these loci subserve beta-cell development or function, and there is no overlap with the immune function genes identified for type 1 diabetes. There is no major gene susceptibility, involving the HLA region. However, transcription factor-7-like (TCF7-L2) is the most common variant observed in type 2 diabetes in Europeans, and KCNQ1 (a potassium voltage-gated channel) in Asians. TCF7-L2 carries an increased risk of around 35%, while other common variants account for no more than 10–20%. TCF7-L2 has now been shown to modulate pancreatic islet cell function. Paradoxically, the genes for type 2 diabetes account for a relatively small fraction of its observed heritability. They do not allow subtypes of the condition to be identified with any confidence, or provide useful disease prediction.

Environmental factors: early and late

An association has been noted between low weight at birth and at 12 months of age and glucose intolerance later in life, particularly in those who gain excess weight as adults. The concept is that poor nutrition early in life impairs beta-cell development and function, predisposing to diabetes in later life. Low birthweight has also been shown to predispose to heart disease and hypertension.

Inflammation

Subclinical inflammatory changes are characteristic of both type 2 diabetes and obesity, and in diabetes, high-sensitivity C-reactive protein (CRP) levels are modestly elevated in association with raised fibrinogen and increased plasminogen activator inhibitor-1 (PAI-1), and contribute to cardiovascular risk. Circulating levels of the pro-inflammatory cytokines TNF-α and IL-6 are elevated in both diabetes and obesity.

Abnormalities of insulin secretion and action

The relative role of secretory failure versus insulin resistance in the pathogenesis of type 2 diabetes has been much debated, but even massively obese individuals with a fully functioning beta-cell mass do not necessarily develop diabetes, which implies that some degree of beta-cell dysfunction is necessary. Insulin binds normally to its receptor on the surface of cells in type 2 diabetes, and the mechanisms of ‘insulin resistance’ are still poorly understood. Insulin resistance is, however, associated with central obesity and accumulation of intracellular triglyceride in muscle and liver in type 2 diabetes, and a high proportion of patients have non-alcoholic fatty liver disease (NAFLD), see page 303. It has long been stated that patients with type 2 diabetes retain up to 50% of their beta-cell mass at the time of diagnosis, as compared with healthy controls, but the shortfall is greater than this when they are matched with healthy individuals who are equally obese. In addition, patients with type 2 diabetes almost all show islet amyloid deposition at autopsy, derived from a peptide known as amylin or islet amyloid polypeptide (IAPP), which is co-secreted with insulin. It is not known if this is a cause or consequence of beta-cell secretory failure.

Abnormalities of insulin secretion manifest early in the course of type 2 diabetes. An early sign is loss of the first phase of the normal biphasic response to intravenous insulin. Established diabetes is associated with hyposecre-
The genetic causes of some rare forms of diabetes are discussed. Type 2 diabetes is thus a condition in which insulin deficiency relative to increased demand leads to hypersecretion of insulin by a depleted beta-cell mass and progression towards absolute insulin deficiency requiring insulin therapy. Its time course varies widely between individuals.

Overview and prevention
Genetic predisposition determines whether an individual is susceptible to type 2 diabetes; if and when diabetes develops largely depends upon lifestyle. A dramatic reduction in the incidence of new cases of adult-onset diabetes was documented in the Second World War when food was scarce, and clinical trials in individuals with impaired glucose tolerance have shown that diet, exercise or agents such as metformin have a marked effect in deferring the onset of type 2 diabetes. Established diabetes can be reversed, even if temporarily, by successful diet and weight loss or by bariatric surgery. Diabetes is therefore largely preventable, although obesity, marked insulin resistance, hyperandrogenism in women, acanthosis nigricans (areas of hyperpigmented skin) and 50% of cases ultimately relapse later in life. Most have an abnormality of imprinting of the ZAC and HYMAI genes on chromosome 6q. The commonest cause of permanent neonatal diabetes mellitus (PNDM) is mutations in the KCNJ11 gene encoding the Kir6.2 subunit of the beta-cell potassium-ATP channel.

Neurological features are seen in 20% of patients. Diabetes is due to defective insulin release rather than beta-cell failure. The glucokinase gene is intimately involved in the glucose-sensing mechanism within the pancreatic beta cell. The hepatic nuclear factor (HNF) genes and the insulin promoter factor-1 (IPF-1) gene control nuclear transcription in the beta cell where they regulate its development and function. Abnormal nuclear transcription genes may cause pancreatic agenesis or more subtle progressive pancreatic damage. A handful of families with autosomal dominant diabetes have been described with mutations in neurogenic differentiation factor-1 (NeuroD1). (see: http://projects.exeter.ex.ac.uk/diabetesgenes/mody/)

The glucokinase gene is intimately involved in the glucose-sensing mechanism within the pancreatic beta cell. The hepatic nuclear factor (HNF) genes and the insulin promoter factor-1 (IPF-1) gene control nuclear transcription in the beta cell where they regulate its development and function. Abnormal nuclear transcription genes may cause pancreatic agenesis or more subtle progressive pancreatic damage. A handful of families with autosomal dominant diabetes have been described with mutations in neurogenic differentiation factor-1 (NeuroD1). (see: http://projects.exeter.ex.ac.uk/diabetesgenes/mody/)
CLINICAL PRESENTATION OF DIABETES

Presentation may be acute, subacute or asymptomatic.

Acute presentation
Young people often present with a 2–6-week history and report the classic triad of symptoms:
- Polyuria – due to the osmotic diuresis that results when blood glucose levels exceed the renal threshold
- Thirst – due to the resulting loss of fluid and electrolytes
- Weight loss – due to fluid depletion and the accelerated breakdown of fat and muscle secondary to insulin deficiency

Ketonuria is often present in young people and may progress to ketoacidosis if these early symptoms are not recognized and treated.

Subacute presentation
The clinical onset may be over several months or years, particularly in older patients. Thirst, polyuria and weight loss are typically present but patients may complain of such symptoms as lack of energy, visual blurring (owing to glucose-induced changes in refraction) or pruritus vulvae or balanitis that is due to Candida infection.

Complications as the presenting feature
These include:
- Staphylococcal skin infections
- Retinopathy noted during a visit to the optician
- A polyneuropathy causing tingling and numbness in the feet
- Erectile dysfunction
- Arterial disease, resulting in myocardial infarction or peripheral gangrene.

Asymptomatic diabetes
Glycosuria or a raised blood glucose may be detected on routine examination (e.g. for insurance purposes) in individuals who have no symptoms of ill-health. Glycosuria is not diagnostic of diabetes but indicates the need for further investigations. About 1% of the population have renal glycosuria. This is an inherited low renal threshold for glucose, transmitted either as a Mendelian dominant or recessive trait.

Physical examination at diagnosis
Evidence of weight loss and dehydration may be present, and the breath may smell of ketones. Older patients may present with established complications, and the presence of the characteristic retinopathy is diagnostic of diabetes. In occasional patients, there will be physical signs of an illness causing secondary diabetes (see Table 20.1). Patients with severe insulin resistance may have acanthosis nigricans, which is characterized by blackish pigmentation at the nape of the neck and in the axillae (p. 1217).

DIAGNOSIS AND INVESTIGATION OF DIABETES

Diabetes is easy to diagnose when overt symptoms are present, and a glucose tolerance test is hardly ever necessary for clinical purposes. The oral glucose tolerance test has, however, allowed more detailed epidemiological characterization based on the existence of separate glucose thresholds for macrovascular and microvascular disease. These correspond with the levels for the diagnosis of impaired glucose tolerance (IGT) and diabetes as specified by the WHO criteria set out in Box 20.1. Epidemiological studies show that for every person with known diabetes, there is another undiagnosed in the population. A much larger proportion fall into the intermediate category of impaired glucose tolerance.

Impaired glucose tolerance (IGT)
This is not a clinical entity but a risk factor for future diabetes and cardiovascular disease. The diagnosis can only be made with a glucose tolerance test, and is complicated by poor reproducibility of the key 2-hour value in this test. The group is heterogeneous; some patients are obese, some have liver disease and others are on medication that impairs glucose tolerance. Individuals with IGT have the same risk of cardiovascular disease as those with frank diabetes, but do not develop the specific microvascular complications.

Box 20.1 WHO diagnostic criteria

<table>
<thead>
<tr>
<th>WHO criteria for the diagnosis of diabetes are:</th>
</tr>
</thead>
<tbody>
<tr>
<td>- Fasting plasma glucose &gt;7.0 mmol/L (126 mg/dL)</td>
</tr>
<tr>
<td>- Random plasma glucose &gt;11.1 mmol/L (200 mg/dL)</td>
</tr>
<tr>
<td>- One abnormal laboratory value is diagnostic in symptomatic individuals; two values are needed in asymptomatic people. The glucose tolerance test is only required for borderline cases and for diagnosis of gestational diabetes.</td>
</tr>
<tr>
<td>- HbA1c &gt;6.5 (48 mmol/mol)</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>The glucose tolerance test – WHO criteria</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Normal</strong></td>
</tr>
<tr>
<td>Fasting</td>
</tr>
<tr>
<td>2 h after glucose</td>
</tr>
<tr>
<td>- Adult: 75 g glucose in 300 mL water</td>
</tr>
<tr>
<td>- Only a fasting and a 120-min sample are needed</td>
</tr>
<tr>
<td>- Results are for venous plasma – whole blood values are lower.</td>
</tr>
</tbody>
</table>

Note: There is no such thing as mild diabetes. All patients who meet the criteria for diabetes are liable to disabling long-term complications.
Impaired fasting glucose (IFG)

This diagnostic category (fasting plasma glucose between 6.1 and 6.9 mmol/L) has the practical advantage that it avoids the need for a glucose tolerance test. It is not a clinical entity, but indicates future risk of frank diabetes and cardiovascular disease. IFG only overlaps with IGT to a limited extent, and the associated risks of cardiovascular disease and future diabetes are not directly comparable. A lower cut-off of 5.6 mmol/L (rather than 6.1 mmol/L) has been recommended by the American Diabetes Association (ADA) and would, if implemented, greatly increase the number of those in this category.

Haemoglobin A\textsubscript{1c} (HbA\textsubscript{1c})

HbA\textsubscript{1c} is an integrated measure of an individual’s prevailing blood glucose concentration over several weeks (see below). Standardization of this measure has enabled it to be proposed as an alternative diagnostic test for diabetes by the American Diabetes Association. As currently proposed, an HbA\textsubscript{1c} > 6.5% (48 mmol/mol) would be considered diagnostic of diabetes, whereas a level of 5.7–6.4% (39–46 mmol/mol) would denote increased risk of diabetes. A WHO Consultation recently also concluded that HbA\textsubscript{1c} ‘can be used as a diagnostic test for diabetes’. Unfortunately, there is relatively little concordance between IGT, IFG and HbA\textsubscript{1c} as markers of ‘prediabetes’. Furthermore, there will be many people in a mixed population who are ‘diabetic’ using the HbA\textsubscript{1c} criteria but ‘normal’ on glucose tolerance testing. Many are uncomfortable with this concept.

Other investigations

No further tests are needed to diagnose diabetes. Other routine investigations include urine testing for protein, a full blood count, urea and electrolytes, liver biochemistry and random lipids. The latter test is useful to exclude an associated hyperlipidaemia and, if elevated, should be repeated fasting after diabetes has been brought under control. Diabetes may be secondary to other conditions (see Table 20.1), may be precipitated by underlying illness and be associated with autoimmune disease or hyperlipidaemia. Hypertension is present in 50% of patients with type 2 diabetes and a higher proportion of African and Caribbean patients.

TREATMENT OF DIABETES

The role of patient education and community care

The care of diabetes is based on self-management by the patient, who is helped and advised by those with specialized knowledge. The quest for improved glycaemic control has made it clear that whatever the technical expertise applied, the outcome depends on willing cooperation by the patient. This in turn depends on an understanding of the risks of diabetes and the potential benefits of glycaemic control and other measures such as maintaining a lean weight, stopping smoking and taking care of the feet. If accurate information is not supplied, misinformation from friends and other patients will take its place. For this reason the best time to educate the patient is soon after diagnosis. Organized education programmes involve all healthcare workers, including nurse specialists, dieticians and podiatrists, and should include ongoing support and updates wherever possible.

Diet

The diet for people with diabetes is no different from that considered healthy for everyone. Table 20.5 lists recommendations on the ideal composition of this diet. To achieve this, food for people with diabetes should be:

- low in sugar (though not sugar free)
- high in starchy carbohydrate (especially foods with a low glycaemic index), i.e. slower absorption
- high in fibre
- low in fat (especially saturated fat).

<table>
<thead>
<tr>
<th>Component of diet</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Protein</td>
<td>1 g/kg ideal bodyweight (approx.)</td>
</tr>
<tr>
<td>Total fat</td>
<td>&lt;35% of energy intake. Limit: fat/oil in cooking, fried foods, processed meats (burgers, salami, sausages), high-fat snacks (crisps, cake, nuts, chocolate, biscuits, pastry). Encourage: lower-fat dairy products (skimmed milk, reduced-fat cheese, low-fat yoghurt), lean meat.</td>
</tr>
<tr>
<td>Saturated and trans-unsaturated fat</td>
<td>&lt;10% of total energy intake</td>
</tr>
<tr>
<td>n-6 polyunsaturated fat</td>
<td>No absolute quantity recommended. Eat fish, especially oily fish, once or twice weekly. Fish oil supplements not recommended</td>
</tr>
<tr>
<td>n-3 polyunsaturated fat</td>
<td>&lt;10% of total energy intake</td>
</tr>
<tr>
<td>Cis-monounsaturated fat</td>
<td>10–20% of total energy intake (olive oil, avocado)</td>
</tr>
<tr>
<td>Total carbohydrate</td>
<td>40–60% of total energy intake. Encourage: artificial (intense) sweeteners instead of sugar (sugar-free fizzy drinks, squashes and cordials). Limit: fruit juices, confectionery, cake, biscuits</td>
</tr>
<tr>
<td>Sucrose</td>
<td>Up to 10% of total energy intake, provided this is eaten in the context of a healthy diet (examples: fibre-rich breakfast cereals, baked beans)</td>
</tr>
<tr>
<td>Fibre</td>
<td>No absolute quantity recommended. Soluble fibre has beneficial effects on glycaemic and lipid metabolism. Insoluble fibre has no direct effects on glycaemic metabolism, but benefits satiety and gastrointestinal health</td>
</tr>
<tr>
<td>Vitamins and antioxidants</td>
<td>Best taken as fruit and vegetables (five portions per day) in a mixed diet. There is no evidence for the use of supplements</td>
</tr>
<tr>
<td>Alcohol</td>
<td>Not forbidden. Its energy content should be taken into account, as should its tendency to cause delayed hypoglycaemia in those treated with insulin</td>
</tr>
<tr>
<td>Salt</td>
<td>&lt;6 g/day (lower in hypertension)</td>
</tr>
</tbody>
</table>
The overweight or obese should be encouraged to lose weight by a combination of changes in food intake and physical activity.

Carbohydrates

The glucose peak seen in the blood after eating pasta is much flatter than that seen after eating the same amount of carbohydrate as white potato. Pasta has a lower ‘glycaemic index’. Foods with a low glycaemic index prevent rapid swings in circulating glucose, and are thus preferred to those with a higher glycaemic index.

Prescribing a diet

Most people find it extremely difficult to modify their eating habits, and repeated advice and encouragement are needed if this is to be achieved. A diet history is taken, and the diet prescribed should involve the least possible interference with the person’s lifestyle. Advice from dieticians is more likely to affect medium-term outcome than advice from doctors. People taking insulin or oral agents have traditionally been advised to eat roughly the same amount of food (particularly carbohydrate) at roughly the same time each day, so that treatment can be balanced against food intake and exercise. Knowledgeable and motivated patients with type 1 diabetes, who get feedback from regular blood glucose monitoring, can vary the amount of carbohydrate consumed, or meal times, by learning to adjust their exercise pattern and treatment. This is the basis of the DAFNE (Dose Adjustment For Normal Eating) regimen.

Exercise

Diet treatment is incomplete without exercise. Any increase in activity levels is to be encouraged, but participation in more formal exercise programmes is best. Where facilities for this exist, exercise should be prescribed for everyone with diabetes. Several trials have shown that regular exercise reduces the risk of progression to type 2 diabetes by 30–60%, and the lowest long-term morbidity and mortality is seen in those with established disease who have the highest levels of cardiorespiratory fitness. Both aerobic and resistance training improve insulin sensitivity and metabolic control in type 1 and type 2 diabetes, although reported effects on metabolic control are inconsistent. Patients on insulin or sulfonylureas should be warned that there is an increased risk of hypoglycaemia for up to 6–12 h following heavy exertion.

Tablet treatment for type 2 diabetes

Diet and lifestyle changes are the key to successful treatment of type 2 diabetes, and no amount of medication will succeed where these have failed. The concept is that controlling diabetes is not just a matter of swallowing tablets, and these should in general never be prescribed until lifestyle changes have been implemented. Tablets will however be needed if satisfactory metabolic control (see ‘Measuring control’ below) is not established within 4–6 weeks. A consensus treatment pathway is shown in Figure 20.9 (p. 1013). The three main options are metformin, a sulfonylurea or a thiazolidinedione.

Biguanide (metformin)

Metformin is the only biguanide currently in use, and remains the best validated primary treatment for type 2 diabetes. It activates the enzyme AMP-kinase, which is involved in regulation of cellular energy metabolism, but its precise mechanism of action remains unclear. Its effect is to reduce the rate of gluconeogenesis, and hence hepatic glucose output, and to increase insulin sensitivity. It does not affect insulin secretion, does not induce hypoglycaemia and does not predispose to weight gain. It is thus particularly helpful in the overweight, although normal weight individuals also benefit, and may be given in combination with sulfonylureas, thiazolidinediones, dipeptidyl peptidase-4 (DPP4) inhibitors or insulin. Metformin was as effective as sulfonylurea or insulin in glucose control and reduction of microvascular risk in the UK Prospective Diabetic Study (UKPDS), but proved unexpectedly beneficial in reducing cardiovascular risk, an effect that could not be fully explained by its glucose-lowering actions. Adverse effects include anorexia, epigastric discomfort and diarrhoea, and these prohibit its use in 5–10% of patients. Diarrhoea should never be investigated in a diabetic patient without testing the effect of stopping metformin or changing to a slow release preparation. Lactic acidosis has occurred in patients with severe hepatic or renal disease, and metformin is contraindicated when these are present. A Cochrane review showed little risk of lactic acidosis with standard clinical use, but most clinicians withdraw the drug when serum creatinine exceeds 150 μmol/L.

Sulfonylureas (Table 20.6)

These act upon the beta cell to promote insulin secretion in response to glucose and other secretagogues. They are ineffective in patients without a functional beta-cell mass, and they are usually avoided in pregnancy. Their action is to bind to the sulfonylurea receptor on the cell membrane, which closes ATP-sensitive potassium channels and blocks potassium efflux. The resulting depolarization promotes influx of calcium, a signal for insulin release (Fig. 20.2). Sulfonylureas are cheap and more effective than the other agents in achieving short-term (1–3 years) glucose control, but their effect wears off as the beta-cell mass declines. There are theoretical concerns that they might hasten beta-cell apoptosis and they promote weight gain, and are best avoided in the overweight. They can also cause

hypoglycaemia and although the episodes are generally mild, fatal hypoglycaemia may occur. Severe cases should always be admitted to hospital, monitored carefully, and treated with a continuous glucose infusion since some sulfonylureas have long half-lives. Sulfonylureas should be used with care in patients with liver disease. Patients with renal impairment should only be given those primarily excreted by the liver. Tolbutamide is the safest drug in the very elderly because of its short duration of action.

**Meglitinides**

Meglitinides, e.g. repaglinide and nateglinide, are insulin secretagogues. Meglitinides are the non-sulfonylurea moiety of glibenclamide. As with the sulfonylureas, they act via closure of the K⁺-ATP channel in the beta cells (see Fig. 20.2). They are short-acting agents that promote insulin secretion in response to meals. Their effects are similar to that of the short-acting sulfonylurea tolbutamide, but they are much more costly.

**Thiazolidinediones**

The thiazolidinediones (more conveniently known as the ‘glitazones’) reduce insulin resistance by interaction with peroxisome proliferator-activated receptor-gamma (PPAR-γ), a nuclear receptor which regulates large numbers of genes including those involved in lipid metabolism and insulin action. The paradox that glucose metabolism should respond to a drug that binds to nuclear receptors mainly found in fat cells is still not fully understood. One suggestion is that they act indirectly via the glucose-fatty acid cycle, lowering free fatty acid levels and thus promoting glucose consumption by muscle. They reduce hepatic glucose production, an effect that is synergistic with that of metformin, and also enhance peripheral glucose uptake. Like metformin, the glitazones potentiate the effect of endogenous or injected insulin. The glitazones have yet to demonstrate unique advantages in the treatment of diabetes, and their place in routine diabetes care remains uncertain. Troglitazone and rosiglitazone have been withdrawn for safety concerns (liver failure and increased cardiovascular risk, respectively), and pioglitazone is the only remaining agent in this class. **Unwanted effects** of pioglitazone include weight gain of 5–6 kg, together with fluid retention and heart failure. Mild anaemia and osteoporosis resulting in peripheral bone fractures have also been reported, and there is a possible increase in the risk of bladder cancer.

**Dipeptidyl peptidase-4 (DPP4) inhibitors**

These enhance the incretin effect (Box 20.2). The enzyme dipeptidyl peptidase 4 (DPP4) rapidly inactivates GLP-1 as this is released into the circulation. Inhibition of this enzyme thus potentiates the effect of endogenous GLP-1 secretion. Four agents are currently available (linagliptin, saxagliptin, sitagliptin and vildagliptin) with more likely to be available in the future. They have a moderate effect in lowering blood glucose and are weight neutral. They are most effective in the early stages of type 2 diabetes when insulin secretion is relatively preserved, and are currently recommended for second-line use in combination with metformin or a sulfonylurea. Adverse events are uncommon: the main side-effect is nausea, and there have been occasional reports of acute pancreatitis. Their place in the management of type 2 diabetes has yet to be fully established. Although the short-term safety record is good, DPP4 is widely distributed in the body, and the long-term consequences of inhibition of this enzyme in other tissues are unknown.

**Injection therapies for type 2 diabetes**

**GLP-1 agonists**

Exenatide and liraglutide are injectable long-acting analogues of GLP-1, which enhance the incretin effect (Box 20.2). They promote insulin release, inhibit glucagon release, reduce appetite and delay gastric emptying, thus blunting the post-prandial rise in plasma glucose and promoting weight loss. Their main clinical disadvantage is the need for subcutaneous injection (twice daily for exenatide and once daily for liraglutide), and their major advantage is improving glucose control whilst inducing useful weight reduction. They work well in 70% but have limited benefit in 30% of those treated. **Side-effects** include nausea, acute pancreatitis and acute kidney injury. At present they are used as an alternative to insulin, particularly in the overweight. A once weekly version of exenatide has been developed.

GLP-1 promotes beta-cell replication in immature rodents, but there is no evidence to suggest that it can do so in adult humans. GLP-1 receptors are also present in the exocrine pancreas, and the long-term clinical implications of this observation remain unclear.

**Other therapies**

- **Intestinal enzyme inhibitors** include acarbose, a sham sugar that competitively inhibits α-glucosidase enzymes situated in the brush border of the intestine, reducing absorption of dietary carbohydrate. Undigested starch may then enter the large intestine where it will be broken down by fermentation. Abdominal discomfort, flatulence and diarrhoea can result, and dosage needs careful adjustment to avoid these side-effects.

- **Orlistat** is a lipase inhibitor which reduces the absorption of fat from the diet. It benefits diabetes indirectly by promoting weight loss in patients under careful dietary supervision on a low fat diet. This is necessary to avoid unpleasant steatorrhoea.

- **Gastric banding and gastric bypass surgery** (see p. 220) have been used in those with marked obesity unresponsive to 6 months’ intensive attempts at dieting and graded exercise. NICE recommends consideration of surgery in those with a BMI >40, or in those with BMI >35 and co-morbidities such as diabetes or hypertension which will be alleviated by weight loss. In the USA, the FDA-recommended BMI thresholds are lower. The risks of surgery are not insignificant, and long-term specialist care and follow-up are needed, including psychological support and nutritional supplements for those with bowel resection, but these...
insulin treatment

Insulin is found in every vertebrate, and the key parts of the molecule show few species differences. Small differences in the amino acid sequence may alter the antigenicity of the molecule. The glucose and insulin profiles in normal subjects are shown in Figure 20.7.

**Short-acting insulins**

Insulins derived from beef or pig pancreas have been replaced in most countries by biosynthetic human insulin. This is produced by adding a DNA sequence coding for insulin or proinsulin into cultured yeast or bacterial cells. Short-acting insulins are used for pre-meal injection in multiple dose regimens, for continuous intravenous infusion in labour or during medical emergencies, and in patients using insulin pumps. Human insulin is absorbed slowly, reaching a peak 60–90 min after subcutaneous injection, and its action tends to persist after meals, predisposing to hypoglycaemia. Absorption is delayed because soluble insulin is in the form of stable hexamers (six insulin molecules around a zinc core) and needs to dissociate to monomers or dimers before it can enter the circulation. **Short-acting insulin analogues** have been engineered to dissociate more rapidly following injection without altering the biological effect. **Insulin analogues** (Fig. 20.8) such as the rapid-acting insulins (**insulin lispro, insulin aspart and insulin glulisine**) enter the circulation more rapidly than human soluble insulin, and also disappear more rapidly. Although widely used, the short-acting analogues have little effect upon overall glucose control in most patients, mainly because improved postprandial glucose is balanced by higher levels before the next meal. A Cochrane review has concluded that there is little evidence as to their benefit in type 2 diabetes.

**Intermediate and longer-acting insulins**

The action of human insulin can be prolonged by the addition of zinc or protamine derived from fish sperm. The most widely used form is NPH (isophane insulin), which has the advantage that it can be premixed with soluble insulin to form stable mixtures (biphasic insulins), of which the combination of 30% soluble with 70% NPH is most widely used. Long-acting analogues have their structure modified to delay absorption or to prolong their duration of action. **Insulin glargine** is soluble in the vial as a slightly acidic (pH 4) solution, but precipitates at subcutaneous pH, thus prolonging its duration of action. **Insulin detemir** has a fatty acid ‘tail’ which allows it to bind to serum albumin, and its slow dissociation from the bound state prolongs its duration of action. Although popular and widely used, these insulins have little demonstrated advantage over NPH in many clinical situations, although useful in those on intensified therapy or with troublesome hypoglycaemia.

**Inhaled insulin**

The first inhaled insulin was withdrawn from the market in 2007 on the grounds of limited clinical demand, although lung cancer was also observed.
Practical management of diabetes
All patients with diabetes require advice about diet and lifestyle. Lifestyle changes, i.e. controlling weight, stopping smoking and taking regular exercise, can prevent or delay the onset of type 2 diabetes in people with glucose intolerance. Good glycaemic control is unlikely to be achieved with insulin or oral therapy when diet is neglected, especially when the patient is also overweight. Regular exercise helps to control weight and reduces cardiovascular risk. Blood pressure control is vital using an angiotensin converting enzyme (ACE) inhibitor or angiotensin II receptor (AIIR) antagonist (see p. 782); Most patients will also benefit from a statin and low-dose aspirin (see p. 1022). Most patients will also benefit from a statin and low-dose aspirin (see p. 1022).

Type 2 diabetes
The great majority of patients presenting over the age of 40 will have type 2 diabetes, but do not miss the occasional type 1 patient presenting late. An approach to their management is illustrated in Figure 20.9. Goals of treatment are described on page 1016. Type 2 diabetes is characterized by progressive beta-cell failure, and glucose control deteriorates over time, requiring a progressive and pre-emptive escalation of diabetes therapy. Regular review is essential for this to be achieved. Most patients on tablets will eventually require insulin, and it is helpful to explain this from the outset. The most widespread error in management at this stage is procrastination; the patient whose control is inadequate on oral therapy should start insulin without undue delay. Targets for glucose control are discussed later (p. 1016).

There is little consensus regarding the optimal insulin regimen in type 2 diabetes, but an intermediate insulin given at night with metformin during the day is initially as effective as multidose insulin regimens in controlling glucose levels, and is less likely to promote weight gain, which is a common complication of insulin therapy. Metformin is a useful adjunct to insulin in those able to tolerate it. Addition of a morning dose of insulin may become necessary to control postprandial hyperglycaemia. Twice-daily injections of pre-mixed soluble and isophane insulins (i.e. biphasic isophane insulin) are widely used and reasonably effective (Fig. 20.10a). More aggressive treatment, with multiple injections or continuous infusion pumps, is increasingly used in younger patients with type 2 diabetes.

Type 1 diabetes
Insulin is always indicated in a patient who has been in ketoacidosis, and is usually indicated in lean patients who present under the age of 40 years.

Principles of insulin treatment

Injections
The needles used to inject insulin are very fine and sharp. Even though most injections are virtually painless, patients are understandably apprehensive and treatment begins with a lesson in injection technique. Insulin is usually administered by a pen injection device but can be drawn up from a vial into special plastic insulin syringes marked in units (100 U in 1 mL). Injections are given into the fat below the skin on the abdomen, thighs or upper arm, and the needle is usually inserted to its full length. Slim adults and children usually use a 31 gauge 6 mm needle and fatter adults a 30 gauge 8 mm needle. Both reusable and disposable pen devices are available, together with a range of devices to aid injection. The

**Further Reading**

Insulin administration

In healthy individuals, a sharp increase in insulin occurs after meals; this is superimposed on a constant background of secretion (Fig. 20.7). Insulin therapy attempts to reproduce this pattern, but ideal control is difficult to achieve for four reasons:

- In normal subjects, insulin is secreted directly into the portal circulation and reaches the liver in high concentration; about 50% of the insulin produced by the pancreas is cleared by the liver. By contrast, insulin injected subcutaneously passes into the systemic circulation before passage to the liver. Insulin-treated patients therefore have lower portal levels of insulin and higher systemic levels relative to the physiological situation.

- Subcutaneous soluble insulin takes 60–90 min to achieve peak plasma levels, so the onset and offset of action are too slow.

- The absorption of subcutaneous insulin into the circulation is variable.

- Basal insulin levels are constant in normal people, but injected insulin invariably peaks and declines in people with diabetes, with resulting swings in metabolic control.

A multiple injection regimen with short-acting insulin and a longer-acting insulin at night is appropriate for most younger patients (Fig. 20.10b). The advantages of multiple injection regimens are that the insulin and the food go in at roughly the same time so that meal times and sizes can vary, without greatly disturbing metabolic control.

The flexibility of multiple injection regimens is of great value to patients with busy jobs, shift workers and those who travel regularly. Some recovery of endogenous insulin secretion may occur over the first few months (the ‘honeymoon period’) in type 1 patients and the insulin dose may need to be reduced or even stopped for a period. Requirements rise thereafter. Strict glucose control from diagnosis in type 1 diabetes prolongs beta-cell function, resulting in better glucose levels and less hypoglycaemia. Target blood glucose values should normally be 4–7 mmol/L before meals and 4–10 mmol/L after meals, assuming that this can be achieved without troublesome hypoglycaemia.

All patients need careful training for a life with insulin. This is best achieved outside hospital, provided that adequate facilities exist for outpatient diabetes education. A scheme for adjusting insulin regimens is given in Table 20.7. DAFNE is described on page 1010.

When to use insulin analogues

Hypoglycaemia between meals and particularly at night is the limiting factor for many patients on multiple injection regimens. The more expensive rapid-acting insulin analogues (Fig. 20.10c) are a useful substitute for soluble insulin in some patients. They reduce the frequency of nocturnal hypoglycaemia due to reduced carry-over effect from the daytime. They are often used on grounds of convenience, since patients can inject shortly before meals but standard insulins injected at the same time give equivalent overall control. High or erratic morning blood sugar readings can prove a problem for about a quarter of all patients on conventional multiple injection regimens, because the bedtime intermediate-acting insulin falls and the absorption is variable. The long-acting insulin analogues insulin glargine and insulin detemir may help to overcome these problems and reduce the risk of nocturnal hypoglycaemia.

Infusion devices

CSII (continuous subcutaneous insulin infusion) is delivered by a small pump strapped around the waist that infuses a constant trickle of insulin via a needle in the subcutaneous tissues. Meal-time doses are delivered by the user telling the pump to deliver a bolus of insulin at the start of a meal.

This approach is particularly useful in the overnight period, since the basal overnight infusion rate can be programmed to fit each patient’s needs. Disadvantages include the nuisance of being attached to a gadget, skin infections, the risk of ketoacidosis if the flow of insulin is broken (since these patients have no protective reservoir of injected depot insulin) and cost. Infusion pumps should only be used by specialized centres able to offer a round-the-clock service to their patients. This form of treatment has revolutionized the lives of some people with type 1 diabetes.

Complications of insulin therapy

At the injection site

Shallow injections result in intradermal insulin delivery and painful, reddened lesions or even scarring. Injection site abscesses occur but are extremely rare.

Local allergic responses sometimes occur early in therapy but usually resolve spontaneously. Generalized allergic responses are exceptionally rare. Fatty lumps, known as lipohypertrophy, may occur as the result of overuse of a single injection site with any type of insulin.

Insulin resistance

The most common cause of mild insulin resistance is obesity. Occasional unstable patients require massive insulin doses, sometimes with a fluctuating requirement. Rare syndromes of insulin resistance may be present, but most cases are unexplained. Insulin resistance associated with antibodies directed against the insulin receptor has been reported in patients with acanthosis nigricans (Table 20.3).

Weight gain
Many patients show weight gain on insulin treatment, especially if the insulin dose is increased inappropriately, but this can to some extent be overcome by emphasis on the need for diet and exercise, plus addition of metformin. Patients who are in poor control when insulin is started tend to gain (or regain) most weight.

Hypoglycaemia during insulin treatment
This is the most common complication of insulin therapy, and limits what can be achieved with insulin treatment. It is a major cause of anxiety for patients and relatives. It results from an imbalance between injected insulin and a patient’s normal diet, activity and basal insulin requirement. The times of greatest risk are before meals, during the night, and during exercise. Irregular eating habits, unusual exertion and alcohol excess may precipitate episodes; other cases appear to be due simply to variation in insulin absorption.

Symptoms develop when the blood glucose level falls below 3 mmol/L and typically develop over a few minutes, with most patients experiencing ‘adrenergic’ features of sweating, tremor and a pounding heartbeat. Virtually all patients with type 1 diabetes experience intermittent hypoglycaemia and one in three will go into a coma at some stage in their lives. A small minority suffer attacks that are so frequent and severe as to be virtually disabling.

Physical signs include pallor and a cold sweat. Many patients with longstanding diabetes report loss of these warning symptoms (hypoglycaemic unawareness) and are at a greater risk of central nervous dysfunction (neuroglycopenia) resulting in altered behaviour or conscious level. Such patients appear pale, drowsy or detached, signs that their relatives quickly learn to recognize. Behaviour is clumsy or inappropriate, and some become irritable or even aggressive. Others slip rapidly into hypoglycaemic coma. Occasionally, patients develop convulsions during hypoglycaemic coma, especially at night. This must not be confused with idiopathic epilepsy. Another presentation is with a hemiparesis that resolves when glucose is administered.

People with diabetes have an impaired ability to counter-regulate glucose levels after hypoglycaemia. The glucagon response is invariably deficient, even though the α cells are preserved and respond normally to other stimuli. The epinephrine (adrenaline) response may also fail in patients with a long duration of diabetes, and this is associated with hypoglycaemia unawareness. Recurrent hypoglycaemia may itself induce a state of hypoglycaemia unawareness, and the ability to recognize the condition may sometimes be restored by relaxing control for a few weeks.

Nocturnal hypoglycaemia. Basal insulin requirements fall during the night but increase again from about 4 a.m. onwards, at a time when levels of injected insulin are falling. As a result many patients wake with high blood glucose levels, but find that injecting more insulin at night increases the risk of hypoglycaemia in the early hours of the morning. The problem may be helped by the following:

- Checking that a bedtime snack is taken regularly
- Patients taking twice-daily mixed insulin can separate their evening dose and take the intermediate insulin at bedtime rather than before supper
- Reducing the dose of soluble insulin before supper, since the effects of this persist well into the night
- Changing to a rapid-acting insulin analogue, with a long-lasting insulin analogue at night.

Changing to an insulin infusion pump which can be programmed to deliver lower doses of insulin at the time of night when a patient has been experiencing hypoglycaemia.

Mild hypoglycaemia
Any form of rapidly absorbed carbohydrate will relieve the early symptoms, and glucose or sweets should always be carried. Drowsy individuals will be able to take carbohydrate in liquid form (e.g. Lucozade). All patients and their close relatives need training about the risks of hypoglycaemia. More carbohydrate than necessary should not be taken during the recovery period, since this causes a rebound to hyperglycaemia. Alcohol excess increases the risk of hypoglycaemia, and this requires careful explanation, together with the need to guard against hypoglycaemia while driving.

Severe hypoglycaemia
The diagnosis of severe hypoglycaemia resulting in confusion or coma is simple and can usually be made on clinical grounds, backed by a bedside blood test. If real doubt exists, blood should be taken for glucose estimation before treatment is given. Patients should carry a card or wear a bracelet or necklace to say that they have diabetes, and these should be looked for in unconscious patients.

Unconscious patients should be given either intramuscular glucagon (1 mg) or intravenous glucose (25–50 mL of 50% glucose solution) followed by a flush of 0.9% saline to preserve the vein (since 50% glucose scleroses veins). Glucagon acts by mobilizing hepatic glycogen, and works almost as rapidly as glucose. It is simple to administer and can be given at home by relatives. It does not work when liver glycogen levels are low, as after a prolonged fast. Oral glucose is given to replenish glycogen reserves once the patient revives.

Whole pancreas and pancreatic islet transplantation
Whole pancreas transplantation has been performed for some 30 years, usually in diabetic patients who require immunosuppression for a kidney transplant. Surgical advances have greatly improved the outcome of this procedure. In experienced hands graft function lasts longer with considerable improvement in quality of life. Patient survival is better in those who receive simultaneous pancreas and kidney grafts, mainly because of the delay involved in waiting for a pancreas to become available following renal transplantation. There is some evidence of protection against or reversal of some complications of diabetes, but this comes at the cost of long-term immunosuppression.

Islet transplantation is performed by harvesting pancreatic islets from cadavers (two or three pancreata are usually needed); these are then injected into the portal vein and seed themselves into the liver. This form of treatment had limited success for many years, but improved treatment protocols have now achieved more promising results. The main indication is disabling hypoglycaemia, and the main disadvantage is the need for powerful immunosuppressive therapy, with its associated costs and complications.

Measuring the metabolic control of diabetes

Urine tests
Urine dipstick tests, although less informative than blood tests, offer some feedback on metabolic control. Patients
with consistently negative tests and no symptoms of hypoglycaemia are generally well controlled. Nevertheless, the correlation between urine tests and simultaneous blood glucose is poor for three reasons:

- Changes in urine glucose lag behind changes in blood glucose.
- The mean renal threshold is around 10 mmol/L but the range is wide (7–13 mmol/L). The threshold also rises with age.
- Urine tests can give no guidance concerning blood glucose levels below the renal threshold.

**Home blood glucose testing**

Blood tests offer invaluable feedback to everyone affected by diabetes, but their routine use varies according to need. Patients soon learn to provide their own profiles using finger-prick blood samples and reagent strips which can be read with the aid of a meter. Blood is taken from the side of a finger tip (not from the tip, which is densely innervated) using a special lancet usually fitted to a spring-loaded device, a range of which are available. The fasting blood glucose concentration is reproducible in diet or tablet-treated type 2 diabetes, and is therefore a useful guide to therapy, supplemented by occasional tests after meals. Those on insulin treatment require more frequent testing in order to adjust their therapy and avoid hypoglycaemia. Regular profiles (e.g. four daily samples on at least two days each week) are needed in those on intensified therapy, and should be recorded electronically or in a record book. Patients on insulin are encouraged to adjust their insulin dose as appropriate (Table 20.7) and should be able to obtain advice over the telephone when needed. Blood glucose monitoring does not in itself result in better control, but is essential to those wishing to achieve it.

**Glycosylated haemoglobin (HbA₁c) and fructosamine**

Glycosylation of haemoglobin occurs as a two-step reaction, resulting in the formation of a covalent bond between the glucose molecule and the terminal valine of the β chain of the haemoglobin molecule. The rate at which this reaction occurs is related to the prevailing glucose concentration. Glycosylated haemoglobin is expressed as a percentage of the normal haemoglobin (standardized range 4–6.1%; 20–44 mmol/mol). This test provides an index of the average blood glucose concentration over the life of the haemoglobin molecule (approximately 6 weeks). The figure will be misleading if the life-span of the red cell is reduced or if an abnormal haemoglobin or thalassaemia is present. There is considerable interindividual variation in HbA₁c levels, even in health. Although the glycosylated haemoglobin test provides a rapid assessment of glycaemic control in a given patient, blood glucose testing is needed before the clinician can know what to do about it.

Glycosylated plasma proteins (‘fructosamine’) may also be measured as an index of control. Glycosylated albumin is the major component, and fructosamine measurement relates to glycaemic control over the preceding 2–3 weeks. It is useful in patients with anaemia or haemoglobinopathy and in pregnancy (when haemoglobin turnover is changeable) and other situations where changes of treatment need a swift means of assessing progress.

**Targets for glucose control**

Data from the UK Prospective Diabetic Study (UKPDS) and the Diabetes Control and Complications Trial (DCCT) suggest that patients with both type 1 diabetes and type 2 diabetes should ideally aim to run their glycosylated haemoglobin readings below 7.0% (53 mmol/mol) in order to reduce the risk of long-term microvascular complications (Table 20.8). Hypoglycaemia, patterns of eating and lifestyle, weight problems and problems accepting and coping with diabetes limit what can be achieved (see p. 1017). Some will, but most will not, be able to reach these target values, particularly as their duration of diabetes increases. Realistic goals should be set for each patient, taking into account what is likely to be achievable, and this applies in particular to elderly patients and those with a limited prognosis.

**Does good glucose control matter?**

Blood glucose is just one measure of the diverse metabolic consequences of diabetes which not only affect carbohydrate metabolism but also the metabolism of lipids and proteins.

The DCCT in the USA compared standard and intensive insulin therapy in a large prospective controlled trial of young patients with type 1 diabetes. Despite intensive therapy, mean blood glucose levels were still 40% above the nondiabetic range, but even at this level of control, the risk of progression to retinopathy was reduced by 60%, nephropathy by 30% and neuropathy by 20% over the 7 years of the study. Near-normoglycaemia should, therefore, be the goal for all young patients with type 1 diabetes. The unwanted effects of this policy include weight gain and a two- to three-fold increase in the risk of severe hypoglycaemia. Control should be less strict in those with a history of recurrent severe hypoglycaemia.

The UKPDS compared standard and intensive treatment in a large prospective controlled trial of type 2 diabetes patients. There was a 25% overall reduction in microvascular disease end-points, a 33% reduction in albuminuria and a 30% reduction in the need for laser treatment for retinopathy in the more intensively treated patients. These benefits persisted for many years after conclusion of the trial (the ‘legacy effect’). This study also showed blood pressure control to be equally necessary in the prevention of retinopathy, but there is no legacy effect and good blood pressure control needs to be maintained. There appeared to be little difference in outcome between the agents used to achieve good metabolic control (metformin, sulfonylurea or insulin). Intensive blood pressure control very considerably reduced the cardiovascular risk.

**Recent trials in type 2 diabetes.** Three large outcome studies in type 2 diabetes have confirmed the benefits of

FURTHER READING

good glucose control upon microvascular complications, although these benefits diminish with increasing age. Glucose control appears to be of less value in prevention of arterial disease, and the current trend is to aim for more relaxed glucose control in older patients (e.g. HbA1c <8% (<64 mmol/mol)), while attention to blood pressure and lipids should take priority. In the recent ACCORD study the use of intensive therapy to target a glycated hemoglobin level below 6% in people with type 2 diabetes increased 5-year mortality. Such an intensive strategy cannot be recommended, particularly for high-risk patients with advanced type 2 diabetes.

PSYCHOSOCIAL IMPLICATIONS OF DIABETES

Patients starting tablet or insulin treatment should live as normal a life as possible, but this is not always easy. Tact, empathy, encouragement and practical support are needed from all members of the clinical team. Diabetes, like any chronic disease, has psychological sequelae. Most patients will experience periods of not coping, of helplessness, of denial and of acceptance often fluctuating over time. Other problems include:

- **You cannot take a ‘holiday’ from diabetes** – yet the human psyche is poorly developed to cope with unremitting adversity.
- **Concessions or sympathy are often denied** to the person with diabetes, since its presence is invisible.
- **The treatment is complex and demanding**, and the person with diabetes must make trade-offs between short-term and long-term wellbeing.
- **Embarassing loss of control over personal behaviour** or consciousness can occur in insulin-treated patients when minor miscalculation leads to hypoglycaemia.
- **Risk-taking behaviour** is indulged in by all humans when emotion is in conflict with logical thought, but its effects can be much greater for the person with diabetes (particularly the risks of unplanned pregnancy, alcohol and tobacco).

- **Poor self-image** is a very common problem.
- **Eating disorders** are more common in people with diabetes – 30–40% of young women will report disordered eating at some stage of their diabetes.
- **Omission of tablets or insulin** is common since non-adherence to treatment regimens is universal in all illness. Between one in four and one in five tablets prescribed for diabetes is not consumed within the designated treatment period. Insulin omission is very common in young women in whom the pressure to lose weight may overcome concerns about long-term complications.

**Adolescence**

A period of poor metabolic control, or dropping out of medical care for a time and re-emerging with complications, is very common in adolescence. Diabetic Summer Camps (e.g. run by Diabetes UK) help prevent a feeling of isolation and not knowing anyone else with the same problem. Separate adolescent clinics allow:

- **Treatment without marginalization** in a larger group of older people
- **Meeting peers with similar problems** in the waiting room
- **Gradual separation from parents** and assumption of personal responsibility for the illness
- **Age-appropriate literature** should be available.

**Practical aspects**

Patients need to inform the driving and vehicle licensing authority and their insurance companies after diagnosis. They would also be wise to inform their family, friends and employers in case unexpected hypoglycaemia occurs. Insulin treatment can be undertaken by people in most walks of life. A few jobs are unsuitable; these include driving Heavy Goods or Public Service vehicles; working at heights; piloting aircraft or working close to dangerous machinery in motion. Certain professions such as the police and the armed forces are designated treatment period. Insulin omission is very common since prescribed for diabetes is not consumed within the marital period. In a larger group of diabetics, the ACCORD study demonstrated that newly diagnosed diabetics four years after a trial of intensive insulin therapy, the prevalence of diabetes four years after a trial of intensive insulin therapy, N Engl J Med 2000; 342:381-389.

**Diabetic metabolic emergencies**

The main terms used are defined in Table 20.9.

**Diabetic ketoacidosis**

Diabetic ketoacidosis (DKA) is the hallmark of type 1 diabetes. It is usually seen in the following circumstances:

- Previously undiagnosed diabetes (10%)
- Interruption of insulin therapy (15%)
- The stress of intercurrent illness (30%).

The majority of cases reaching hospital could have been prevented by earlier diagnosis, better communication between patient and doctor and better patient education. The most common error of management is for patients to reduce or omit insulin because they feel unable to eat, owing to nausea or vomiting. This is a factor in at least 25% of all
hospital admissions. Insulin may need adjusting up or down but should never be stopped.

Pathogenesis
Ketoacidosis is a state of uncontrolled catabolism associated with insulin deficiency. Insulin deficiency is a necessary precondition since only a modest elevation in insulin levels is sufficient to inhibit hepatic ketogenesis, and stable patients do not readily develop ketoacidosis when insulin is withdrawn. Other factors include counter-regulatory hormone excess and fluid depletion. The combination of insulin deficiency with excess of its hormonal antagonists leads to the parallel processes shown in Figure 20.11. In the absence of insulin, hepatic glucose production accelerates, and peripheral uptake by tissues such as muscle is reduced. Rising glucose levels lead to an osmotic diuresis, loss of fluid and electrolytes, and dehydration. Plasma osmolality rises and renal perfusion fails. In parallel, rapid lipolysis occurs, leading to elevated circulating free fatty-acid levels. The free fatty acids are broken down to fatty acyl-CoA within the liver cells, and this in turn is converted to ketone bodies within the mitochondria (Fig. 20.12). Accumulation of ketone bodies produces a metabolic acidosis. Vomiting leads to further loss of fluid and electrolytes. The excess ketones are excreted in the urine but also appear in the breath, producing a distinctive smell similar to that of acetone. Respiratory compensation for the acidosis leads to hyperventilation, graphically described as ‘air hunger’. Progressive dehydration impairs renal excretion of hydrogen ions and ketones, aggravating the acidosis. As the pH falls below 7.0 ([H⁺] >100 nmol/L), pH-dependent enzyme systems in many cells function less effectively. Untreated, severe ketoacidosis is invariably fatal.

Clinical features
The features of ketoacidosis are those of uncontrolled diabetes with acidosis, and include prostration, hyperventilation (Kussmaul respiration), nausea, vomiting and, occasionally, abdominal pain. The latter is sometimes so severe that it can be confused with a surgical acute abdomen.

</tr>
</tbody>
</table>

Some patients are mentally alert at presentation, but confusion and stupor are present in more severe cases. Up to 5% present in coma. Evidence of marked dehydration is present and the eyeball is lax to pressure in severe cases. Hyperventilation is present but becomes less marked in very severe acidosis owing to respiratory depression. The smell of ketones on the breath allows an instant diagnosis to be made by those able to detect the odour. The skin is dry and the body temperature is often subnormal, even in the presence of infection; in such cases, pyrexia may develop later.
Diabetic metabolic emergencies

Diagnosis
This is confirmed by demonstrating hyperglycaemia with ketonaemia or heavy ketonuria, and acidosis. No time should be lost, and treatment is started as soon as the first blood sample has been taken. Hyperglycaemia is demonstrated by dipstick, while a venous blood sample is sent to the laboratory for confirmation. Ketonaemia is confirmed by centrifuging a blood sample and testing the plasma with a dipstick that measures ketones. Hand-held sensors measuring β-hydroxybutyrate in 30 s are available. An arterial blood sample is taken for blood gas analysis.

The severity of DKA can be assessed as follows. One or more suggest severe DKA.

Clinical
- Pulse >100 b.p.m. or <60 b.p.m.
- Systolic BP <90 mmHg
- Glasgow Coma Score of <12 (see Table 22.10, p. 1092) or abnormal ‘Alert, Voice, Pain, Unresponsive’ scale (AVPU)
- O₂ saturation <92% on air (if normal respiratory function)

Bloods
- Blood ketones >6 mmol/L
- Bicarbonate <12 mmol/L
- Venous/arterial pH <7.1
- Hypokalaemia on admission <3.5 mmol/L

Management (pathophysiology)
The principles of management are as follows (Emergency Box 20.1); these should be carried out in a high-dependency area.

- Replace the fluid losses with 0.9% saline. Average loss of water is 5–7 litres with a sodium loss of 500 mmol.
- Replace the electrolyte losses. Patients have a total body potassium deficit of 350 mmol, although initial plasma levels may not be low. Insulin therapy leads to uptake of potassium by the cells with a consequent fall in plasma K⁺ levels. Potassium is therefore given as soon as insulin is started.

*Restore the acid-base balance*. A patient with healthy kidneys will rapidly compensate for the metabolic acidosis.

Emergency Box 20.1
Guidelines for the diagnosis and management of diabetic ketoacidosis

**Diagnosis**
- Hyperglycaemia: measure blood glucose.
- Ketonuria: measure urine ketone levels where plasma ketone measurements are not available.
- Acidosis: measure
  - pH in arterial blood
  - bicarbonate in venous blood.

**What to do immediately**
1. Assess
2. Send bloods to laboratory
3. Set up i.v. infusion
   - Blood glucose
     - measure baseline and hourly initially
     - aim for fall of 3–6 mmol/L (55–110 mg/dL) per hour
   - Urea and electrolytes – do at baseline and hourly until 6 hours, then at 12 hours and 24 hours
     - Potassium – add when K⁺ <3.5 mmol/L. Give 20 mmol/h in infusion. 10 mmol/h when K⁺ = 3.5–5 mmol
   - Full blood count
   - Blood gases – at 0, 2 hours, 6 hours
   - Creatinine – at 0, 6, 12, 24 hours
   - Bicarbonate – at 0, 1, 2, 3, 6, 12, 24 hours.

**Phase 1**
- Admit to Level 2 HDU.
- **INSULIN**: soluble insulin i.v. 0.1 U/kg/h by infusion, or 20 units i.m. stat. followed by 6 units i.m. hourly.
- **FLUID AND ELECTROLYTE REPLACEMENT**: i.v. 0.9% sodium chloride with 20 mmol KCl/L.
  - 1 L in 30 min, then
    - 1 L in 1 h
    - 1 L in 2 h
    - 1 L in 4 h
    - 1 L in 8 h.
  - Adjust KCl concentration depending on results of regular blood K⁺ measurement.

**Phase 2**
**INSULIN AND GLUCOSE**: When blood glucose falls to 10–12 mmol/L, change infusion fluid to 1 L 5% glucose plus 20 mmol KCl 6-hourly. Continue insulin with dose adjusted according to hourly blood glucose test results (e.g. i.v. 3 U/h glucose 15 mmol/L; 2 U/h when glucose 10 mmol/L).

**Phase 3**
Once stable and able to eat and drink normally, transfer patient to four times daily subcutaneous insulin regimen (based on previous 24 hours’ insulin consumption and trend in consumption).

**Other semi-urgent procedures**
- Blood and urine culture
- Cardiac enzymes
- CXR
- ECG (monitor if electrolyte problems or severe DKA)
- Catheterization if no urine passed after 3 hours of hydration
- If conscious – nasogastric tube
- Antibiotics if infection.

**Special measures**
- Broad-spectrum antibiotic if infection likely
- Bladder catheter if no urine passed in 2 hours
- Nasogastric tube if drowsy
- Consider CVP pressure monitoring if shocked or if previous cardiac or renal impairment
- Give s.c. prophylactic LMW heparin.

**Subsequent management**
- Monitor glucose hourly for 8 hours.
- Monitor electrolytes 2-hourly for 8 hours.
- Adjust K replacement according to results.

Note: The regimen of fluid replacement set out above is a guide for patients with severe ketoacidosis. Excessive fluid can precipitate pulmonary and cerebral oedema; inadequate replacement may cause renal failure. Fluid replacement must therefore be tailored to the individual and monitored carefully throughout treatment.
Problems of management

- **Hypotension.** This may lead to renal shutdown. Plasma expanders (or whole blood) are therefore given if the systolic blood pressure is below 80 mmHg. A central venous pressure line is useful in this situation. A bladder catheter is inserted if no urine is produced within 2 h, but routine catheterization is not necessary.

- **Coma.** The usual principles apply (see p. 1093). It is essential to pass a nasogastric tube to prevent aspiration, since gastric stasis is common and carries the risk of aspiration pneumonia if a drowsy patient vomits.

- **Cerebral oedema.** This is a rare, but serious complication and has mostly been reported in children or young adults. Excessive rehydration and use of hypertonic fluids such as 8.4% bicarbonate may sometimes be responsible. The mortality is high.

- **Hypothermia.** Severe hypothermia with a core temperature below 33°C may occur and can be overlooked unless a rectal temperature is taken with a low-reading thermometer.

- **Late complications.** These include pneumonia and deep-vein thrombosis (DVT prophylaxis, see p. 429) are essential and occur especially in the comatose or elderly patient.

- **Complications of therapy.** These include hypoglycaemia and hypokalaemia, due to loss of K⁺ in the urine from osmotic diuresis. Overenthusiastic fluid replacement may precipitate pulmonary oedema in the very young or the very old. Hyperchloraeic acidosis may develop in the course of treatment since patients have lost a large variety of negatively charged electrolytes, which are replaced with chloride. The kidneys usually correct this spontaneously within a few days.

**Subsequent management**

Intravenous glucose and insulin are continued until the patient feels able to eat and keep food down. The drip is then taken down and a similar amount of insulin is given as four injections of soluble insulin subcutaneously at meal times and a dose of intermediate-acting insulin at night.

Sliding-scale regimens are unnecessary and may even delay the establishment of stable blood glucose levels.

The mortality of diabetic ketoacidosis is around 5%, and is increased in older patients. Its treatment is incomplete without a careful enquiry into the causes of the episode and advice as to how to avoid its recurrence.

**Hyperosmolar hyperglycaemic state**

This condition, in which severe hyperglycaemia develops without significant ketosis, is the metabolic emergency characteristic of uncontrolled type 2 diabetes. Patients present in middle or later life, often with previously undiagnosed diabetes. Common precipitating factors include consumption of glucose-rich fluids, concurrent medication such as thiazide diuretics or steroids, and intercurrent illness. The hyperosmolar hyperglycaemic state and ketoacidosis represent two ends of a spectrum rather than two distinct disorders (Box 20.4). The biochemical differences may partly be explained as follows:

- **Age.** The extreme dehydration characteristic of hyperosmolar hyperglycaemic state may be related to age. Old people experience thirst less acutely, and more...

The normal range of osmolality is 285–300 mOsm/kg. It can be measured directly, or can be calculated approximately from the formula:

\[
\text{Osmolality} = \frac{2(\text{Na}^{+} + \text{K}^{+}) + \text{glucose} + \text{urea}}{2}
\]

For instance, in the example of severe ketoacidosis given above:

\[
\text{Osmolality} = \frac{2(140 + 5) + 30 + 8}{2} = 328 \text{ mOsm/kg}
\]

and in the example of the hyperosmolar hyperglycaemic state:

\[
\text{Osmolality} = \frac{2(155 + 5) + 50 + 15}{2} = 385 \text{ mOsm/kg}
\]

The normal anion gap is ±17. It is calculated as \(\text{Na}^{+} + \text{K}^{+}) – (\text{Cl}⁻ + \text{HCO₃⁻})\). In the example of ketoacidosis the anion gap is 40, and in the example of the hyperosmolar hyperglycaemic state, the anion gap is 25. Mild hyperchloremic acidosis may develop in the course of therapy. This will be shown by a rising plasma chloride and persistence of a low bicarbonate even though the anion gap has returned to normal.
readily become dehydrated. In addition, the mild renal impairment associated with age results in increased urinary losses of fluid and electrolytes.

- **The degree of insulin deficiency.** This is less severe in the hyperosmolar hyperglycaemic state. Endogenous insulin levels are sufficient to inhibit hepatic ketogenesis, but insufficient to inhibit hepatic glucose production.

**Clinical features**

The characteristic clinical features on presentation are dehydration and stupor or coma. Impairment of consciousness is directly related to the degree of hyperosmolality. Evidence of underlying illness such as pneumonia or pylonephritis may be present, and the hyperosmolar state may predispose to stroke, myocardial infarction or arterial insufficiency in the lower limbs.

**Investigations and treatment**

These are (with some exceptions) according to the guidelines for ketoacidosis. The plasma osmolality is usually extremely high. It can be measured directly or calculated as $2(Na^+ + K^+) + glucose + urea$, all in mmol/L. Many patients are extremely sensitive to insulin, and the glucose concentration may plummet. The resultant change in osmolality may cause cerebral damage. It is sometimes useful to infuse insulin at a rate of 3 U/hour for the first 2–3 hours, increasing to 6 U/hour if glucose is falling too slowly. The standard fluid for replacement is 0.9% saline. Avoid 0.45% saline, since rapid dilution of the blood may cause more cerebral damage than a few hours of exposure to hyperosmolar. Low-molecular-weight heparin should be given to counter the increased risk of thromboembolic complications associated with this condition.

**Prognosis**

The reported mortality ranges as high as 20–30%, mainly because of the more advanced age of the patients and the frequency of intercurrent illness. Unlike ketoacidosis, the hyperosmolar hyperglycaemia state is not an absolute indication for subsequent insulin therapy, and survivors may do well on diet and oral agents.

**Lactic acidosis**

Lactic acidosis may occur in diabetic patients on biguanide therapy. The risk in patients taking metformin is extremely low provided that the therapeutic dose is not exceeded and the drug is withheld in patients with advanced hepatic or renal dysfunction.

Patients present in severe metabolic acidosis with a large anion gap (normally <17 mmol/L), usually without significant hyperglycaemia or ketosis. Treatment is by rehydration and infusion of isotonic 1.26% bicarbonate. The mortality is in excess of 50%.

**Pathophysiology**

The mechanisms leading to damage are ill-defined. The following are consequences of hyperglycaemia and may play a role:

- **Non-enzymatic glycosylation** of a wide variety of proteins, e.g. haemoglobin, collagen, LDL and tubulin in peripheral nerves. This leads to an accumulation of advanced glycosylated end-products causing injury and inflammation via stimulation of pro-inflammatory factors, e.g. complement, cytokines.

- **Polol pathway.** The metabolism of glucose by increased intracellular aldose reductase leads to accumulation of sorbitol and fructose. This causes changes in vascular permeability, cell proliferation and capillary structure via stimulation of protein kinase C and TGF-β.

- **Abnormal microvascular blood flow** impairs supply of nutrients and oxygen. Microvascular occlusion is due to vasoconstrictors, e.g. endothelins and thrombogenesis, and leads to endothelial damage.

- **Other factors** include the formation of reactive oxygen species and growth factors stimulation (TGF-β) and vascular endothelial growth factor (VEGF). These growth factors are released by ischaemic tissues and cause endothelial cells to proliferate.

- **Haemodynamic changes,** e.g. in kidney (see p. 1025).

It has been proposed that all of the above mechanisms stem from a single hyperglycaemia-induced process of overproduction of superoxide by the mitochondrial electron chain. This paradigm offers an integrated explanation of how complications of diabetes develop.

**Macrovascular complications** (Table **20.10**)

Diabetes is a risk factor for the development of atherosclerosis. This risk is related to that of the background population. For example, people with diabetes in Japan are less likely than European patients to develop atherosclerosis, but more likely to develop it than non-diabetic Japanese.

- Stroke is twice as likely.
- Myocardial infarction is 3–5 times as likely, and women with diabetes lose their premenopausal protection from coronary artery disease.
- Amputation of a foot for gangrene is 50 times as likely.

Several large trials have shown that intensive glucose-lowering treatment of diabetes has a relatively minor effect upon cardiovascular risk. Since the effect of other cardiovascular risk factors is enhanced in diabetes, it is vital to tackle all cardiovascular risk factors together in diabetes, and not just to focus on glucose levels.

- **Hypertension.** The UKPDS demonstrated that aggressive treatment of hypertension produces a marked reduction in adverse cardiovascular outcomes,
both microvascular and macrovascular. To achieve the target for blood pressure (Table 20.8), the UKPDS found that one-third of patients needed three or more antihypertensive drugs in combination, and two-thirds of treated patients needed two or more.

- **Smoking**: the avoidable risk factor (see p. 806). Never give up efforts to help diabetic patients stop smoking.

- **Lipid abnormalities.** Clinical trials suggest that there is no ‘safe’ cut-off for serum cholesterol. The lowest achievable level seems best to aim for, and in practice this means that almost all people with type 2 diabetes will be treated with a statin.

- **Low-dose aspirin** can reduce macrovascular risk, but is associated with a morbidity and mortality from bleeding. The benefits of aspirin outweigh the bleeding risk when the risk of a cardiovascular end-point is >30% in the next 10 years. This risk is reached in patients aged under 45 with three strong additional cardiovascular risk factors, aged 45–54 with three additional risk factors, aged 54–65 with two additional risk factors or aged over 65 with just one additional risk factor.

- **ACE inhibitors/angiotensin II receptor antagonists.** Treating people with diabetes and at least one other major cardiovascular risk factor with an ACE inhibitor produces a 25–35% lowering of the risk of heart attack, stroke, overt nephropathy or cardiovascular death. Angiotensin II receptor antagonists are sometimes preferred initially and are also used for those intolerant to ACE inhibitors.

### Microvascular complications

In contrast to macrovascular disease, which is prevalent in the West as a whole, microvascular disease is specific to diabetes. Small blood vessels throughout the body are affected but the disease process is of particular danger in three sites:

- **Retina**
- **Renal glomerulus**
- **Nerve sheaths**

Diabetic retinopathy, nephropathy and neuropathy tend to manifest 10–20 years after diagnosis in young patients, but may present earlier in older patients, probably because these have had unrecognized diabetes for months or even years prior to diagnosis. Genetic factors appear to contribute to the susceptibility to microvascular disease. Diabetic siblings of diabetic patients with renal and eye disease have a three- to five-fold increased risk of the same complication in both type 1 and type 2 patients. There are racial differences in the overall prevalence of nephropathy. In the USA, prevalence is: Pima American Indians > Hispanic/Mexican > US black > US white patients.

### Diabetic eye disease

At least 90% of young patients with type 1 diabetes will develop retinal changes, but these only progress to sight-threatening retinopathy in a minority. Some 30–50% will require laser photocoagulation to prevent or limit progression to proliferative retinopathy, and good control of blood pressure is essential. Diabetes is still the commonest cause of blindness in under 65 year olds. It affects the eye in a variety of ways:

- **Diabetic retinopathy** is damage to the retina and iris caused by diabetes, which can lead to blindness.

- **Cataract** is denaturation of the protein and other components of the lens of the eye which render it opaque.

- **External ocular** palsies (p. 1081). The sixth and the third nerve are the most commonly affected. Third nerve palsy is not associated with pain. These nerve palsies usually recover spontaneously within a period of 3–6 months.

### Natural history

#### Cataracts

Cataract develops earlier in people with diabetes than in the general population. Sustained very poor diabetes control with a degree of ketosis can cause an acute cataract (snowflake cataract), which comes on rapidly. Fluctuations in blood glucose concentration can cause refractive variability, as a result of osmotic changes within the lens (the absorption of water into the lens causes temporary hypermetropia). This presents as fluctuating difficulty in reading. It resolves with better metabolic control of the diabetes.

#### Diabetic retinopathy

Diabetic retinopathy (Fig. 20.13) is the most commonly diagnosed diabetes-related complication. Its prevalence increases with the duration of diabetes (Fig. 20.14). Some 20% of people with type 1 diabetes will have retinal changes after 10 years, rising to >95% after 20 years (see Table 20.11); 20–30% of people with type 2 diabetes have retinopathy at diagnosis. The metabolic consequences of poorly-controlled diabetes cause intraretinal pericyte death, and thickening of the basement membrane in the small blood vessels of the retina. This leads initially to incompetence and increased permeability of the vascular walls, and later to occlusion of the vessels (capillary closure). This process has somewhat different consequences in the peripheral retina and in the macular area.

#### Peripheral retina

Damage to the wall of small vessels causes *microaneurysms* (small red dots) within the retina. When vessel walls are breached superficial (bloot) haemorrhages occur in the ganglion cell and outer plexiform layers. Damaged blood vessels leak fluid into the retina. The fluid is cleared into the retinal veins leaving behind protein and lipid deposits causing hard exudates. These are eventually cleared by macrophages.

Micro-infarcts within the retina due to occluded vessels cause *cotton wool spots*. The spot itself is due to the accumulation of axoplasmic debris. This debris is removed by macrophages. As this occurs, there may be white dots at the site of the previous cotton wool spot (*cytoid bodies*). Damage to the walls of veins causes their calibre to vary (*venous beading*), and elongation to occur causing *venous loops*. Blockage of blood vessels leads to areas of capillary non-perfusion. Ischaemia in these areas causes the release of vascular growth factors such as VEGF (*vascular endothelial growth factor*). These factors cause new blood vessels to grow in the retina (*neovascularization*). Some of these new blood vessels are inside the retina and are helpful. These new intraretinal vessels, and other vessels whose walls are damaged and dilated, give the appearance of *intranaretinal microvascular abnormalities (IRMAs)*.

Other new vessels emerge through the retina and lie on its surface, usually at the margin of an area of capillary closure. The normal shearing stresses that occur within the eye can cause these poorly supported new vessels to bleed. Small haemorrhages give rise to *pre-retinal haemorrhages* (boat-shaped haemorrhages). With further bleeding
Complications of diabetes

Macular area

Fluid from leaking vessels is cleared poorly in the macular area due to its anatomy differing from the rest of the retina. Above a certain rate of formation, clearance fails and macular oedema occurs. This distorts and thickens the retina at the macula. If sustained, this distortion causes loss of central vision. Macular oedema is not visible with the ophthalmoscope or with retinal photography. For this reason surrogate markers for the presence of macular oedema are used (Table 20.11). Capillary occlusion in the macular area will also cause loss of central vision.

Examination

Bedside examination of the eye. Visual acuity should be checked using both a pinhole and the patient’s distance spectacles. The ocular movements are assessed to detect any ocular motor palsies. The iris is examined for rubeosis and then the pupils dilated with 1% tropicamide. About 20 minutes later the eye is examined for the presence of a cataract by looking at the lens with a +10.00 lens in the ophthalmoscope and viewing the lens against the red reflex. The retina is then examined systematically looking at the disc, then all four quadrants, and finally the macula. The macula is examined last because this induces the greatest discomfort, and pupillary constriction.

Eye screening

Screening for sight-threatening eye disease with universal access is seen as offering the best hope of displacing diabetes as the commonest cause of blindness in those under 65 years of age. The National Screening Committee in the UK has helped establish digital photography-based screening across the country, based on a national set of standards. All people with diabetes, over the age of 12 are offered annual measurement of their acuity, and photographs of their retina. Box 20.5 shows standardized criteria for screening schemes; these are regularly inspected.

Management of diabetic eye disease (Table 20.11)

Cataract

Extraction and intraocular lens implantation is indicated if the cataract is causing visual disability to the patient or is giving rise to inability to view the retina adequately. Cataract extraction is straightforward if there is no retinopathy present. Pre-existing retinopathy may worsen after cataract extraction.

Retinopathy

The DCCT and UKPDS show that the risk of developing diabetic eye disease, and the risk of established retinopathy

Figure 20.13 Features of diabetic eye disease.
(a) The normal macula (centre) and optic disc (to left). (b) Microaneurysms (small circles) and blot haemorrhage (larger circle) – early background retinopathy. (c) Hard exudates (circled) and single cotton wool spot (arrowed) in addition to multiple blot haemorrhages in background retinopathy. (d) Intra-retinal microvascular abnormalities (IRMA) – pre-proliferative retinopathy (circled). (e) Venous loop (circled) also indicates pre-proliferative change. (f) Fronds of new vessels on the disc and elsewhere (proliferative). (g) Pre-retinal haemorrhage in proliferative disease. (h) Hard exudates within a disc-width of the macula (maculopathy). (i) Cortical and (j) central cataracts can be seen against the red reflex with the ophthalmoscope.

Vitreous haemorrhage occurs with consequent sudden loss of vision. Later collagen tissue grows along the margins of the new vessels and giving rise to fibrotic bands. These bands may contract and pull on the retina causing further haemorrhage and retinal detachment. Sometimes vessels may be induced to grow on the pupil margin (rubeosis) and in the angle of the anterior chamber of the eye giving rise to rapid increase in intraocular pressure (rubeotic glaucoma). These features of retinopathy in the peripheral retina are grouped, according to the risk of visual loss, into three stages (Table 20.11).

Note: Hard exudates have a bright yellowish-white colour and are often irregular in outline with a sharply defined margin. Cotton-wool spots are greyish-white, have indistinct margins and a dull matt surface, unlike the glossy appearance of hard exudates. R, retinopathy; M, maculopathy.

Box 20.5 Criteria for a successful local screening scheme for sight-threatening diabetic retinopathy

- Clearly defined geographical area for the screening programme
- Adequate number of people with diabetes for viability (>12 000)
- An identified screening programme manager
- An identified clinical screening lead
- An identified hospital eye service for diagnosis and laser treatment
- Computer software capable of supporting call/recall of patients and image grading
- Centralized appointment administration
- Single collated list of all people with diabetes in the area over the age of 12
- Equipment to obtain adequate disc and macula centred images of each eye
- Single image grading centre
- Process to manage people with poor quality images
- Clear route of referral for treatment, and for feedback from treatment centre to screening unit
- Accreditation of screening staff
- Annual reporting of service performance

Diabetes mellitus and other disorders of metabolism

Table 20.11 - Grading of pathological changes in the retina in diabetic retinopathy: the action needed

- Developing further, can be reduced by tight metabolic control of both diabetes and blood pressure. Development or progression of retinopathy may be accelerated by rapid improvement in glycaemic control, pregnancy and in those with nephropathy, and these groups need frequent monitoring. Fluorescein angiography (a fluorescent dye is injected into an arm vein and photographed in transit through the retinal vessels) is used to define the extent of the potentially sight-threatening diabetic retinopathy. Ocular coherence tomography (OCT) is used to image the content of the layers of the retina at the macula, and in particular to measure retinal thickness. It can detect macular oedema and other macular abnormalities.

**Treatment of proliferative retinopathy**

New vessels are an indication for laser photocoagulation therapy. New vessels on the disc carry the worst prognosis and warrant urgent laser therapy. The laser should be directed at the new vessels and, in addition, to the associated areas of capillary non-perfusion (ischaemia). If the proliferative retinopathy has progressed to new vessels developing on the optic disc then a technique known as panretinal photocoagulation (PRP) is carried out. This involves multiple laser burns to the peripheral retina, especially in the areas of capillary non-perfusion. Ruberosis is also treated with panretinal photoocoagulation. If some bleeding has occurred but there is a good view then laser treatment should be applied. Vitreoretinal surgery is used if bleeding is recurrent and preventing laser therapy. It is also used to try to salvage some vision after vitreous haemorrhage and to treat fibrotic traction retinal detachment in advanced retinopathy.

**Treatment of maculopathy**

Extrafoveal exudates can be watched. However, if they are beginning to encroach on the fovea then the centre of any rings of exudates, should be treated by laser photocoagulation. If oedema has spread into the centre of the macula, then a technique known as grid photocoagulation is used, where a number of laser burns are scattered around the macula. This limits deterioration in vision, and on occasion results in some visual improvement. Ischaemic maculopathy is not treatable, and leads to central visual loss.

**The future**

Anti-VEGF drugs, such as bevacizumab and ranibizumab (see p. 1064) are being used to control diabetic retinopathy and diabetic maculopathy, particularly that which involves the centre of the macula and is causing sight loss. Recent studies have shown benefit over laser for this type of maculopathy.

**The diabetic kidney**

The kidney may be damaged by diabetes in three main ways:

- Glomerular damage
- Ischaemia resulting from hypertrophy of afferent and efferent arterioles
- Ascending infection
Diabetic nephropathy

Epidemiology
Clinical nephropathy secondary to glomerular disease usually manifests 15–25 years after diagnosis of diabetes and affects 25–35% of patients diagnosed under the age of 30 years. It is the leading cause of premature death in young diabetic patients. Older patients also develop nephropathy, but the proportion affected is smaller. The incidence of end-stage kidney disease has fallen in recent decades, probably due to better control of blood glucose and blood pressure, but this benefit has been cancelled out by the rising incidence of both types of diabetes.

Pathophysiology
The earliest functional abnormality in the diabetic kidney is renal hypertrophy associated with a raised glomerular filtration rate. This appears soon after diagnosis and is related to poor glycaemic control. As the kidney becomes damaged by diabetes, the afferent arteriole (leading to the glomerulus) becomes vasodilated to a greater extent than the efferent glomerular arteriole. This increases the intraglomerular filtration pressure, further damaging the glomerular capillaries. This increased intraglomerular pressure also leads to increased local shearing forces which are thought to contribute to mesangial cell hypertrophy and increased secretion of extracellular mesangial matrix material. This process eventually leads to glomerular sclerosis. The initial structural lesion in the glomerulus is thickening of the basement membrane. Associated changes result in disruption of the protein cross-linkages which normally make the membrane an effective filter. In consequence, there is a progressive leak of large molecules (particularly protein) into the urine.

Albuminuria
The earliest evidence of this is ‘microalbuminuria’ – amounts of urinary albumin so small as to be undetectable by standard dipsticks (see p. 309). Microalbuminuria may be tested for by radioimmunoassay or by using special dipsticks. It is a predictive marker of progression to nephropathy in type 1 diabetes, and of increased cardiovascular risk in type 2 diabetes. Microalbuminuria may, after some years, progress to intermittent albuminuria followed by persistent proteinuria. Light-microscopic changes of glomerulosclerosis become manifest; both diffuse and nodular glomerulosclerosis can occur. The latter is sometimes known as the Kimmerstedt–Wilson lesion. At the later stage of glomerulosclerosis, the glomerulus is replaced by hyaline material.

At the stage of persistent proteinuria, the plasma creatinine is normal but the average patient is only some 5–10 years from end-stage kidney disease. The proteinuria may become so heavy as to induce a transient nephrotic syndrome, with peripheral oedema and hypoalbuminaemia.

Patients with nephropathy typically show a normochromic normocytic anaemia and a raised erythrocyte sedimentation rate (ESR). Hypertension is a common development and may itself damage the kidney still further. A rise in plasma creatinine is a late feature that progresses inevitably to renal failure, although the rate of progression may vary widely between individuals.

The natural history of this process is shown in Figure 20.15.

Ischaemic lesions
Arteriolar lesions, with hypertrophy and hyalinization of the vessels, can occur in patients with diabetes. The appearances are similar to those of hypertensive disease and lead to ischaemic damage to the kidneys.

Infective lesions
Urinary tract infections are relatively more common in women with diabetes, but not in men. Ascending infection may occur because of bladder stasis resulting from autonomic neuropathy, and infections more easily become established in damaged renal tissue. Autopsy material frequently reveals interstitial changes suggestive of infection, but ischaemia may produce similar changes and the true frequency of pyelonephritis in diabetes is uncertain. Untreated infections in diabetics can result in renal papillary necrosis, in which renal papillae are shed in the urine, but this complication is now very rare.

Diagnosis
The urine of all diabetic patients should be checked regularly (at least annually) for the presence of protein. Many centres also screen younger patients for microalbuminuria since there is evidence that meticulous glycaemic control and early antihypertensive treatment, particularly with ACE inhibitors and angiotensin 2 blockers, may delay the onset of frank proteinuria. The albumin creatinine ratio (ACR) (tested on a mid-stream first morning urine sample) is <2.5 in healthy men, <3.5 mg/mmol in healthy women. Once proteinuria is present, other possible causes should be considered (see below), but once these are excluded, a presumptive diagnosis of diabetic nephropathy can be made. For practical purposes this implies inevitable progression to end-stage kidney disease, although the time course can be markedly slowed by early aggressive antihypertensive therapy. Clinical suspicion of a non-diabetic cause of nephropathy may be provoked by an atypical history, the absence of diabetic retinopathy (usually but not invariably present with diabetic nephropathy) and the presence of red-cell casts in the urine. Renal biopsy should be considered in such cases, but is rarely necessary or helpful. A 24-hour urine collection is often performed to quantify protein loss. Regular measurement is made of the plasma creatinine level with estimated glomerular filtration rate (eGFR).

Figure 20.15 Schematic representation of the natural history of nephropathy. The typical onset is 15 years after diagnosis. Intermittent proteinuria leads to persistent proteinuria. In time, the plasma creatinine rises as the glomerular filtration rate falls.
Diabetes mellitus and other disorders of metabolism

The earliest functional change in diabetic nerves is delayed nerve conduction velocity; the earliest histological change is segmental demyelination, caused by damage to Schwann cells. In the early stages axons are preserved, implying prospects of recovery, but at a later stage irreversible axonal degeneration develops.

The following varieties of neuropathy occur (Fig. 20.16):
- Symmetrical mainly sensory polyneuropathy (distal)
- Acute painful neuropathy
- Mononeuropathy and mononeuritis multiplex
  - cranial nerve lesions
  - isolated peripheral nerve lesions
- Diabetic amyotrophy (asymmetrical motor diabetic neuropathy)
- Autonomic neuropathy.

Symmetrical mainly sensory polyneuropathy
This is often unrecognized by the patient in its early stages. Early clinical signs are loss of vibration sense, pain sensation (deep before superficial) and temperature sensation in the feet. At later stages patients may complain of a feeling of 'walking on cotton wool' and can lose their balance when washing the face or walking in the dark owing to impaired proprioception. Involvement of the hands is much less common and should prompt a search for non-diabetic causes. Complications include unrecognized trauma, beginning as blistering due to an ill-fitting shoe or a hot-water bottle, and leading to ulceration.

Diabetic neuropathy
Diabetes can damage peripheral nervous tissue in a number of ways. The vascular hypothesis postulates occlusion of the vasa nervorum as the prime cause. This seems likely in isolated mononeuropathies, but the diffuse symmetrical nature of the common forms of neuropathy implies a metabolic cause. Since hyperglycaemia leads to increased formation of sorbitol and fructose in Schwann cells, accumulation of these sugars may disrupt function and structure.
Acute painful neuropathy
A diffuse, painful neuropathy is less common. The patient describes burning or crawling pains in the feet, shins and anterior thighs. These symptoms are typically worse at night, and pressure from bedclothes may be intolerable. It may present at diagnosis or develop after sudden improvement in glycaemic control (e.g. when insulin is started). It usually remits spontaneously after 3–12 months if good control is maintained. A more chronic form, developing later in the course of the disease, is sometimes resistant to almost all forms of therapy. Neurological assessment is difficult because of the hyperaesthesia experienced by the patient, but muscle wasting is not a feature and objective signs can be minimal.

Management is firstly to explore for non-diabetic causes (see p. 1146). Explanation and reassurance about the high likelihood of remission within months may be all that is needed. Duloxetine (NICE recommend as first-line therapy), tricyclics, gabapentin or pregabalin, mexitelaine, valproate and carbamazepine all reduce the perception of neuritic pain somewhat, but usually not as much as patients hope for. Transdermal nerve stimulation (TENS) benefits some patients. Topical capsaicin-containing creams help occasionally. A few report that acupuncture has helped.

Mononeuritis and mononeuritis multiplex (multiple mononeuropathy)
Any nerve in the body can be involved in diabetic mononeuropathy; the onset is typically abrupt and sometimes painful. Radiculopathy (i.e. involvement of a spinal root) may also occur.

Isolated palsies of nerves to the external eye muscles, especially the third and sixth nerves, are more common in diabetes. A characteristic feature of diabetic third nerve lesions is that pupillary reflexes are retained owing to sparing of pupillomotor fibres. Full spontaneous recovery is the rule for most episodes of mononeuritis over 3–6 months. Lesions are more likely to occur at common sites for external pressure palsies or nerve entrapment (e.g. the median nerve in the carpal tunnel, see p. 1074).

Diabetic amyotrophy
This condition is usually seen in older men with diabetes. Presentation is with painful wasting, usually asymmetrical, of the quadriceps muscles or occasionally in the shoulders. The wasting may be very marked and knee reflexes are diminished or absent. The affected area is often extremely tender. Extensor plantar responses sometimes develop and CSF protein content is elevated. Diabetic amyotrophy is usually associated with periods of poor glycaemic control and may be present at diagnosis. It often resolves in time with careful metabolic control of the diabetes.

Autonomic neuropathy
Asymptomatic autonomic disturbances can be demonstrated on testing in many patients (Box 20.6), but symptomatic autonomic neuropathy is rare. It affects both the sympathetic and parasympathetic nervous systems and can cause disabling postural hypotension.

The cardiovascular system
Vagal neuropathy results in tachycardia at rest and loss of sinus arrhythmia. At a later stage, the heart may become denervated (resembling a transplanted heart). Cardiovascular reflexes such as theValsalva manoeuvre are impaired. Postural hypotension occurs owing to loss of sympathetic tone to peripheral arterioles. A warm foot with a bounding pulse is sometimes seen in a polyneuropathy as a result of peripheral vasodilatation.

Gastrointestinal tract
Vagal damage can lead to gastroparesis, often asymptomatic, but sometimes leading to intractable vomiting. Implantable devices which stimulate gastric emptying, and injections of botulinum toxin into the pylorus (to partly paralyse the sphincter), have each shown benefit in cases of this previously intractable problem. Autonomic diarrhoea characteristically occurs at night accompanied by urgency and incontinence. Diarrhoea and steatorrhoea may occur owing to small bowel bacterial overgrowth; treatment is with antibiotics such as tetracycline.

Bladder involvement
Loss of tone, incomplete emptying and stasis (predisposing to infection) can occur, and may ultimately result in an atomic, painless, distended bladder. Treatment is with intermittent self-catheterization, permanent catheterization if that fails and prophylactic antibiotic therapy for those prone to recurrent infection.

Male erectile dysfunction
This is common. The first manifestation is incomplete erection which may in time progress to total failure; retrograde ejaculation also occurs in patients with autonomic neuropathy. Erectile dysfunction in diabetes has many causes including anxiety, depression, alcohol excess, drugs (e.g. thiazides and beta-blockers), primary or secondary gonadal failure, hypothyroidism and inadequate vascular supply owing to atheroma in pudendal arteries. The history and examination should focus on these possible causes. Blood is taken for LH, FSH, testosterone, prolactin and thyroid function. Treatment should ideally include sympathetic counselling of both partners.

Phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, vardenafil, avanafil), which enhance the effects of nitric oxide on smooth muscle and increase penile blood flow, are used in those who do not take nitrates for angina. Some 60% of patients can be expected to benefit from this therapy.

Alternatives for those who fail to improve with a phosphodiesterase inhibitor, who dislike the side-effects (headache and a green tinge to vision the next day) or those in whom it is contraindicated, are:
- Apomorphine 2 or 3 mg sublingually 20 min before sexual activity
- Alprostadil (prostaglandin E1 preparation) given as a small pellet inserted with a device into the urethra (125 μg initially with a maximum of 500 μg). If the

### The diabetic foot

A total of 10–15% of diabetic patients develop foot ulcers at some stage in their lives. Diabetic foot problems are responsible for nearly 50% of all diabetes-related hospital admissions. Many diabetic limb amputations could be delayed or prevented by more effective patient education and medical supervision. Ischaemia, infection and neuropathy combine to produce tissue necrosis. Although all these factors may co-exist, the ischaemic and the neuropathic foot (Table 20.12) can be distinguished. In rural India, foot ulcers are commonly due to neuropathic and infective causes rather than vascular causes.

#### Management

Many diabetic foot problems are avoidable, so patients need to learn the principles of foot care (Table 20.13). Older patients should visit a chiropodist/podiatrist regularly and should not cut their own toenails. Once tissue damage has occurred in the form of ulceration or gangrene, the aim is preservation of viable tissue. The four main threats to the skin and subcutaneous tissues are:

- **Infection.** This can take hold rapidly in a diabetic foot. Early antibiotic treatment is essential, with antibiotic therapy adjusted in the light of culture results. The organisms grown from the skin surface may not be the organism causing deeper infection. Collections of pus are drained and excision of infected bone is needed if osteomyelitis develops and does not respond to appropriate antibiotic therapy. Regular X-rays of the foot are needed to check on progress.
- **Ischaemia.** The blood flow to the feet is assessed clinically and with Doppler ultrasound. Femoral angiography is used to localize areas of occlusion amenable to bypass surgery or angioplasty. Relatively few patients fall into this category.
- **Abnormal pressure.** An ulcerated site must be kept non-weight-bearing. Resting the affected leg may need to be supplemented with special deep shoes and insoles to move pressure away from critical sites, or by removable or non-removable casts of the leg. After healing, special shoes and insoles are likely to continue to be needed to protect the feet and prevent abnormal pressure repeating damage to a healed area. In neuropathic feet particularly, sharp surgical debridement by a chiropodist is necessary to prevent callus distorting the local wound architecture and causing damage through abnormal pressure on normal skin nearby.
- **Wound environment.** Dressings are used to absorb or remove exudate, maintain moisture, and protect the wound from contaminating agents, and should be easily removable. Expensive new dressings containing growth factors and other biologically active agents may have a role to play in future, but their place is still being assessed.

Good liaison between physician, chiropodist/podiatrist and surgeon is essential if periods in hospital are to be used efficiently. When irreversible arterial insufficiency is present, it is often quicker and kinder to opt for an early major amputation rather than subject the patient to a debilitating sequence of conservative procedures.

#### Infections

There is no evidence that diabetic patients with good glycaemic control are more prone to infection than normal subjects. However, poorly-controlled diabetes entails increased susceptibility to the following infections:

- **Skin**
  - staphylococcal infections (boils, abscesses, carbuncles)
  - mucocutaneous candidiasis
- **Gastrointestinal tract**
  - periodontal disease
  - rectal and ischiorectal abscess formation (when control very poor)
- **Urinary tract**
  - urinary tract infections (in women)
  - pyelonephritis
  - perinephric abscess
- **Lungs**
  - staphylococcal and pneumococcal pneumonia
  - Gram-negative bacterial pneumonia
  - tuberculosis
- **Bone**
  - spontaneous staphylococcal spinal osteomyelitis.

One reason why poor control leads to infection is that chemotaxis and phagocytosis by polymorphonuclear leukocytes are impaired because at high blood glucose concentrations neutrophil superoxide generation is impaired. Conversely, infections may lead to loss of glycaemic control, and are a common cause of ketoacidosis. Insulin-treated patients need to increase their dose by up to 25% in the face of infection, and non-insulin-treated patients may need insulin cover while the infection lasts. Patients should

**Table 20.13** Principles of diabetic foot care

- Inspect feet daily
- Moisturize dry skin
- Seek early advice for any damage
- Check shoes inside and out for sharp bodies/areas before wearing
- Use lace-up shoes with plenty of room for the toes
- Keep feet away from sources of heat (hot sand, hot-water bottles, radiators, fires)
- Check the bath temperature before stepping in
- Regular podiatrist care
be told never to omit their insulin dose, even if they are nauseated and unable to eat; instead they should test their blood glucose frequently and seek urgent medical advice. Diabetic patients should receive pneumococcal vaccine and yearly influenza vaccine.

**Diabetes and cancer**

Certain types of cancer are more common in type 2 diabetes. The risk of carcinoma of the uterus and of the pancreas is approximately doubled, and there is a 20–50% increase in the risk of colorectal and breast cancer. These associations appear to be mediated by obesity, which confers similar levels of risk in the absence of hyperglycaemia, although there is also an element of reverse causation with carcinoma of the pancreas, which can precipitate or cause diabetes. Metformin-treated patients have been reported to have a lower cancer risk than those on other therapies, and this agent is under investigation for possible anti-tumour properties.

**Skin and joints**

Joint contractures in the hands are a common consequence of childhood diabetes. The sign may be demonstrated by asking the patient to join the hands as if in prayer; the metacarpophalangeal and interphalangeal joints cannot be opposed. Thickened, waxy skin can be noted on the backs of the fingers. These features may be due to glycosylation of collagen and are not progressive (see also p. 1220). The condition is sometimes referred to as diabetic cheiroarthropathy. Osteopenia in the extremities is also described in type 1 diabetes but rarely leads to clinical consequences.

**NOTES ON SPECIAL SITUATIONS IN DIABETES**

**Surgery**

Smooth control of diabetes minimizes the risk of infection and balances the catabolic response to anaesthesia and surgery. The procedure for insulin-treated patients is simple:

- Long-acting and/or intermediate insulin should be stopped the day before surgery, with soluble insulin substituted.
- Whenever possible, diabetic patients should be first on the morning theatre list.
- An infusion of glucose, insulin and potassium is given during surgery. The insulin can be mixed into the glucose solution or administered separately by syringe pump. A standard combination is 16 U of soluble insulin with 10 mmol of KCl in 500 mL of 10% glucose, infused at 100 mL/hour.
- Postoperatively, the infusion is maintained until the patient is able to eat. Other fluids needed in the perioperative period must be given through a separate intravenous line and must not interrupt the glucose/insulin/potassium infusion. Glucose levels are checked every 2–4 hours and potassium levels are monitored. The amount of insulin and potassium in each infusion bag is adjusted either upwards or downwards according to the results of regular monitoring of the blood glucose and serum potassium concentrations.

The same approach is used in the emergency situation, with the exception that a separate variable-rate insulin infusion may be needed to bring blood glucose under control before surgery.

Non-insulin-treated patients should stop medication 2 days before the operation. Patients with mild hyperglycaemia (fasting blood glucose below 8 mmol/L) can be treated as non-diabetic. Those with higher levels are treated with soluble insulin prior to surgery, and with glucose, insulin and potassium during and after the procedure, as for insulin-treated patients.

**Pregnancy in established diabetes**

Pregnancy in diabetes was in the past associated with high fetal mortality, which has been dramatically reduced by meticulous metabolic control of the diabetes and careful obstetric management. Despite this, the rates of congenital malformation and perinatal mortality remain several times higher than in the non-diabetic population. Type 2 diabetes is now much more prevalent in the maternal population as a result of the changing natural history of this condition.

**Metabolic control of diabetes in pregnancy**

Congenital malformations are associated with poor glucose control in the early weeks of pregnancy, and good control should therefore be in place before conception wherever possible. The mother should perform daily home blood glucose profiles, recording blood tests before and 2 hours after meals. The renal threshold for glucose falls in pregnancy, and urine tests are therefore of little value. Insulin requirements rise progressively, and intensified insulin regimens are generally used. The aim is to maintain blood glucose and fructosamine (or HbA1c) levels as close to the normal range as can be tolerated. Oral antidiabetic therapy should be avoided, except for metformin which is recognized to be safe in pregnancy.

**General management**

The patient is seen at intervals of 2 weeks or less at a clinic managed jointly by physician and obstetrician. Circumstances permitting, the aim should be outpatient management with a spontaneous vaginal delivery at term. Retinopathy and nephropathy may deteriorate during pregnancy. Digital photographic eye screening and urine testing for protein should be undertaken at booking, at 28 weeks and before delivery.

**Obstetric problems associated with diabetes**

Congenital malformations associated with maternal diabetes affect cardiac and skeletal development, of which the caudal regression syndrome is an example. Poorly-controlled diabetes later in gestation is associated with stillbirth, mechanical problems in the birth canal owing to fetal macrosomia, hydramnios and pre-eclampsia. Ketoacidosis in pregnancy carries a 50% fetal mortality, but maternal hypoglycaemia, although highly undesirable, is relatively well tolerated by the fetus.

**Neonatal problems**

Maternal diabetes, especially when poorly controlled, is associated with fetal macrosomia. The infant of a diabetic mother is more susceptible to hyaline membrane disease than non-diabetic infants of similar maturity. In addition, neonatal hypoglycaemia may occur. The mechanism is as follows: maternal glucose crosses the placenta, but insulin does not; the fetal islets hypersecrete to combat maternal hyperglycaemia, and a rebound to hypoglycaemic levels occurs when the umbilical cord is severed. These complications are due to hyperglycaemia in the third trimester.

**References**

Gestational diabetes
This term refers to glucose intolerance that develops or is first recognized in the course of pregnancy; it is typically asymptomatic and usually remits following delivery. Gestational diabetes has been estimated to complicate about 7% of all pregnancies, with wide variation due to differences between populations and diagnostic criteria. Women with a previous history of gestational diabetes, older or overweight women, those with a history of large for gestational age babies and women from certain ethnic groups are at particular risk, but many affected women are not in any of these categories. For this reason some advocate screening of all pregnant women on the basis of random plasma glucose testing in each trimester and by oral glucose tolerance testing if the glucose concentration is, for example, 7 mmol/L or more. The Hyperglycaemia and Adverse Pregnancy Outcomes (HAPO) study found that the risk of adverse outcomes increased as a function of maternal glucose levels at 24–28 weeks of pregnancy, even when these were within the normal reference range. This has added to the controversy concerning the appropriate cut-off levels for screening and intervention, since the benefits of intervention are marginal at lower glucose levels, while labelling a mother as diabetic may have unwanted consequences such as a higher rate of caesarean section.

Those who meet the diagnostic criteria for diabetes at first presentation are treated with insulin. Treatment for the remainder is with diet in the first instance, although most patients require insulin cover at some stage during pregnancy (target levels: fasting <4.9 mmol/L; postprandial <6.5 mmol/L). Insulin does not cross the placenta. Many oral agents cross the placenta and are usually avoided because of the potential risk to the fetus, although metformin has been used with success when healthcare facilities are limited.

Gestational diabetes has been associated with all the obstetric and neonatal problems described above for pre-existing diabetes, except that there is no increase in the rate of congenital abnormalities. Gestational diabetes typically remits after delivery but signals an increased risk of type 2 diabetes in later life; maintaining a low bodyweight and keeping physically active reduce this risk.

Not all diabetes presenting in pregnancy is gestational. True type 1 diabetes may develop, and swift diagnosis is essential to prevent the development of ketoacidosis. Hospital admission is required if the patient is symptomatic, or has ketonuria or a markedly elevated blood glucose level.

Unstable diabetes
This term is used to describe patients with recurrent ketoacidosis and/or recurrent hypoglycaemia coma. Of these, the largest group is made up of those who experience recurrent severe hypoglycaemia.

Recurrent severe hypoglycaemia
This affects 1–3% of insulin-dependent patients. Most are adults who have had diabetes for >10 years. By this stage, endogenous insulin secretion is negligible in the great majority of patients. Pancreatic α cells are still present in undiminished numbers, but the glucagon response to hypoglycaemia is virtually absent. Long-term patients are thus subject to fluctuating hyperinsulininaemia owing to erratic absorption of insulin from injection sites, and lack a major component of the hormonal defence against hypoglycaemia. In this situation adrenaline (epinephrine) secretion becomes vital, but this too may become impaired in the course of diabetes. Loss of adrenaline (epinephrine) secretion has been attributed to autonomic neuropathy, but this is unlikely to be the sole cause; central adaptation to recurrent hypoglycaemia may also be a factor.

The following factors may also predispose to recurrent hypoglycaemia:
- **Overtreatment with insulin.** Frequent biochemical hypoglycaemia lowers the glucose level at which symptoms develop. Symptoms often reappear when overall glucose control is relaxed.
- **An unrecognized low renal threshold for glucose.** Attempts to render the urine sugar-free will inevitably produce hypoglycaemia.
- **Excessive insulin doses.** A common error is to increase the dose when a patient needs more frequent injections to overcome a problem of timing.
- **Endocrine causes.** These include pituitary insufficiency, adrenal insufficiency and premenstrual insulin sensitivity.
- **Alimentary causes.** These include exocrine pancreatic failure and diabetic gastroparesis.
- **Chronic kidney disease.** Clearance of insulin is diminished.
- **Patient causes.** Patients may be unintelligent, uncooperative or may manipulate their therapy.

Recurrent ketoacidosis
This usually occurs in adolescents or young adults, particularly girls. Metabolic decompensation may develop very rapidly. A combination of chaotic food intake and insulin omission, whether conscious or unconscious, is now regarded as the primary cause of this problem. It almost always occurs in the context of considerable psychosocial problems, particularly eating disorders. This area needs careful and sympathetic exploration in any patient with recurrent ketoacidosis. It is perhaps not surprising that in an illness where much of one’s life is spent thinking of and controlling food intake, 30% of women with diabetes have had some features of an eating disorder at some time. Other causes include:
- **Iatrogenic.** Inappropriate insulin combinations may be a cause of swinging glycaemic control. For example, a once-daily regimen may cause hypoglycaemia during the afternoon or evening and pre-breakfast hyperglycaemia due to insulin deficiency.
- **Intercurrent illness.** Unsuspected infections, including urinary tract infections and tuberculosis, may be present. Thyrotoxicosis can also manifest as unstable glycaemic control.

Hypoglycaemia develops when hepatic glucose output falls below the rate of glucose uptake by peripheral tissues. Hepatic glucose output may be reduced by:
- The inhibition of hepatic glycogenolysis and gluconeogenesis by insulin
- Depletion of hepatic glycogen reserves by malnutrition, fasting, exercise or advanced liver disease
- Impaired gluconeogenesis (e.g. following alcohol ingestion).

In the first of these categories, insulin levels are raised, the liver contains adequate glycogen stores and the hypoglycaemia can be reversed by injection of glucagon. In the other
two situations, insulin levels are low and glucagon is ineffective. Peripheral glucose uptake is accelerated by high insulin levels and by exercise, but these conditions are normally balanced by increased hepatic glucose output.

The most common symptoms and signs of hypoglycaemia are neurological. The brain consumes about 50% of the total glucose produced by the liver. This high energy requirement is needed to generate ATP used to maintain the potential difference across axonal membranes.

**Insulinomas**

Insulinomas are pancreatic islet cell tumours that secrete insulin. Most are sporadic but some patients have multiple tumours arising from neural crest tissue (multiple endocrine neoplasia). Some 95% of these tumours are benign. The classic presentation is with fasting hypoglycaemia, but early symptoms may also develop in the late morning or afternoon. Recurrent hypoglycaemia is often present for months or years before the diagnosis is made, and the symptoms may be atypical or even bizarre; the presenting features in one series are given in Table 20.14. Common misdiagnoses include psychiatric disorders, particularly pseudodementia in elderly people, epilepsy and cerebrovascular disease. Whipple’s triad remains the basis of clinical diagnosis. This is satisfied when:

- Symptoms are associated with fasting or exercise
- Hypoglycaemia is confirmed during these episodes
- Glucose relieves the symptoms.

A fourth criterion – demonstration of inappropriately high insulin levels during hypoglycaemia – may usefully be added to these.

The diagnosis is confirmed by the demonstration of hypoglycaemia in association with inappropriate and excessive insulin secretion. Hypoglycaemia is demonstrated by:

- Measurement of overnight fasting (16 hours) glucose and insulin levels on three occasions. About 90% of patients with insulinomas will have low glucose and non-suppressed (normal or elevated) insulin levels.
- A prolonged 72-hour supervised fast if overnight testing is inconclusive and symptoms persist.

Autonomous insulin secretion is demonstrated by lack of the normal feedback suppression during hypoglycaemia. This may be shown by measuring insulin, C-peptide or proinsulin during a spontaneous episode of hypoglycaemia.

**Treatment of insulinoma**

The most effective therapy is surgical excision of the tumour, but insulinomas are often very small and difficult to localize. Many techniques can be used to attempt to localize insulinomas. Sensitivity and specificity vary between centres and between operators. These include highly selective angiography, contrast-enhanced high-resolution CT scanning, scanning with radiolabelled somatostatin (some insulinomas express somatostatin receptors) and endoscopic and intraoperative ultrasound scanning. Venous sampling for the detection of ‘hot spots’ of high insulin concentration in the various intra-abdominal veins is still used occasionally.

Medical treatment with diazoxide is useful when the insulinoma is malignant, in patients in whom a tumour cannot be located and in elderly patients with mild symptoms. Symptoms may also remit on treatment with a somatostatin analogue (octreotide or lanreotide).

**Hypoglycaemia with other tumours**

Hypoglycaemia may develop in the course of advanced neoplasia and cachexia, and has been described in association with many tumour types. Certain massive tumours, especially sarcomas, may produce hypoglycaemia owing to the secretion of insulin-like growth factor-1. True ectopic insulin secretion is extremely rare.

**Postprandial hypoglycaemia**

If frequent venous blood glucose samples are taken following a prolonged glucose tolerance test, about one in four subjects will have at least one value below 3 mmol/L. The arteriovenous glucose difference is quite marked during this phase, so that very few are truly hypoglycaemic in terms of arterial (or capillary) blood glucose content. Failure to appreciate this simple fact led some authorities to believe that postprandial (or reactive) hypoglycaemia was a potential ‘organic’ explanation for a variety of complaints that might otherwise have been considered psychosomatic. An epidemic of false ‘hypoglycaemia’ followed, particularly in the USA. Later work showed a poor correlation between symptoms and biochemical hypoglycaemia. Even so, a number of otherwise normal people occasionally become pale, weak and sweaty at times when meals are due, and report benefit from advice to take regular snacks between meals.

True postprandial hypoglycaemia may develop in the presence of alcohol, which ‘primes’ the cells to produce an exaggerated insulin response to carbohydrate. The person who substitutes alcoholic beverages for lunch is particularly at risk. Postprandial hypoglycaemia sometimes occurs after gastric surgery, owing to rapid gastric emptying and mismatching of nutrient absorption and insulin secretion. This is referred to as ‘dumping’ but it is now rarely encountered (see p. 251).

**Hepatic and renal causes of hypoglycaemia**

The liver can maintain a normal glucose output despite extensive damage, and hepatic hypoglycaemia is uncommon. It is particularly a problem with fulminant hepatic failure.

The kidney has a subsidiary role in glucose production (via gluconeogenesis in the renal cortex), and hypoglycaemia is sometimes a problem in terminal renal failure.

Hereditary fructose intolerance occurs in 1 in 20 000 live births and can cause hypoglycaemia (see p. 1040).

**Endocrine causes of hypoglycaemia**

Deficiencies of hormones antagonistic to insulin are rare but well-recognized causes of hypoglycaemia. These include hypopituitarism, isolated adrenocorticotropic hormone (ACTH) deficiency and Addison’s disease.

**Drug-induced hypoglycaemia**

Many drugs have been reported to produce isolated cases of hypoglycaemia, but usually only when other predisposing factors are present.

Hypoglycaemia may develop in the course of advanced neoplasia and cachexia, and has been described in association with many tumour types. Certain massive tumours, especially sarcomas, may produce hypoglycaemia owing to the secretion of insulin-like growth factor-1. True ectopic insulin secretion is extremely rare.

**Postprandial hypoglycaemia**

If frequent venous blood glucose samples are taken following a prolonged glucose tolerance test, about one in four subjects will have at least one value below 3 mmol/L. The arteriovenous glucose difference is quite marked during this phase, so that very few are truly hypoglycaemic in terms of arterial (or capillary) blood glucose content. Failure to appreciate this simple fact led some authorities to believe that postprandial (or reactive) hypoglycaemia was a potential ‘organic’ explanation for a variety of complaints that might otherwise have been considered psychosomatic. An epidemic of false ‘hypoglycaemia’ followed, particularly in the USA. Later work showed a poor correlation between symptoms and biochemical hypoglycaemia. Even so, a number of otherwise normal people occasionally become pale, weak and sweaty at times when meals are due, and report benefit from advice to take regular snacks between meals.

True postprandial hypoglycaemia may develop in the presence of alcohol, which ‘primes’ the cells to produce an exaggerated insulin response to carbohydrate. The person who substitutes alcoholic beverages for lunch is particularly at risk. Postprandial hypoglycaemia sometimes occurs after gastric surgery, owing to rapid gastric emptying and mismatching of nutrient absorption and insulin secretion. This is referred to as ‘dumping’ but it is now rarely encountered (see p. 251).

**Hepatic and renal causes of hypoglycaemia**

The liver can maintain a normal glucose output despite extensive damage, and hepatic hypoglycaemia is uncommon. It is particularly a problem with fulminant hepatic failure.

The kidney has a subsidiary role in glucose production (via gluconeogenesis in the renal cortex), and hypoglycaemia is sometimes a problem in terminal renal failure.

Hereditary fructose intolerance occurs in 1 in 20 000 live births and can cause hypoglycaemia (see p. 1040).

**Endocrine causes of hypoglycaemia**

Deficiencies of hormones antagonistic to insulin are rare but well-recognized causes of hypoglycaemia. These include hypopituitarism, isolated adrenocorticotropic hormone (ACTH) deficiency and Addison’s disease.

**Drug-induced hypoglycaemia**

Many drugs have been reported to produce isolated cases of hypoglycaemia, but usually only when other predisposing factors are present.
Alcohol-induced hypoglycaemia

Alcohol inhibits gluconeogenesis. Alcohol-induced hypoglycaemia occurs in poorly-nourished chronic alcoholics, binge drinkers and in children who have taken relatively small amounts of alcohol, since they have a diminished hepatic glycogen reserve. They present with coma and hypothermia (hypothermia is a feature of hypoglycaemia, due to the suppression of central thermoregulation, particularly the shivering response: children manifest hypothermia more frequently due to their high surface area to body mass ratio).

Factitious hypoglycaemia

This is a relatively common variant of self-induced disease and is more common than an insulinoma. Hypoglycaemia is produced by surreptitious self-administration of insulin or sulfonylureas. Many patients in this category have been extensively investigated for an insulinoma. Measurement of C-peptide levels during hypoglycaemia should identify patients who are injecting insulin; sulfonylurea abuse can be detected by chromatography of plasma or urine.

Sulfonylureas may be used in the treatment of diabetes or may be taken by non-diabetics in suicide attempts.

Quinine may produce severe hypoglycaemia in the course of treatment for falciparum malaria.

Salicylates may cause hypoglycaemia; usually accidental ingestion by children.

Propranolol can induce hypoglycaemia in the presence of strenuous exercise or starvation.

Pentamidine used in the treatment of resistant pneumocystis pneumonia (see p. 188).

DISORDERS OF LIPID METABOLISM

Lipid physiology

Lipids are insoluble in water, and are transported in the bloodstream as macromolecular complexes. In these complexes, lipids (principally triglyceride, cholesterol and cholesterol esters) are surrounded by a stabilizing coat of phospholipid. Proteins (called apoproteins) embedded into the surface of these ‘lipoprotein’ particles exert a stabilizing function and allow the particles to be recognized by receptors in the liver and the peripheral tissues. The structure of a chylomicron (one type of lipoprotein particle) is illustrated in Figure 20.17.

Five principal types of lipoprotein particles are found in the blood (Fig. 20.18). They are structurally different and can be separated in the laboratory by their density and electrophoretic mobility. The larger particles give postprandial plasma its cloudy appearance. More than half of all patients aged under 60 with angiographically confirmed coronary artery disease have a lipoprotein disorder.

The genes for all the major apoproteins and that for the low-density lipoprotein (LDL) receptor have been isolated, sequenced and their chromosomal sites mapped. Production of abnormal apoproteins is known to produce, or predispose to, several types of lipid disorder, and it is likely that others will be discovered.

Chylomicrons

Chylomicrons (Fig. 20.18) are synthesized in the small intestine postprandially, passing initially into the intestinal lymphatic drainage, then along the thoracic duct into the bloodstream. They contain triglyceride and a small amount of cholesterol and its ester, and provide the main mechanism for transporting the digestion products of dietary fat to the liver and peripheral tissues. Each newly formed chylomicron contains several different apoproteins (B-48, A-I, A-II), and acquires apoproteins C-II and E by transfer from high-density lipoprotein (HDL) particles in the bloodstream. Apoprotein C-II binds to specific receptors in adipose tissue and skeletal muscle and the liver, where the endothelial enzyme, lipoprotein lipase, hydrolyses most of the triglyceride into fatty acids.

Figure 20.17 Schematic diagram of a chylomicron particle (75–1200 nm) showing apoproteins lying in the surface membrane.

Figure 20.18 Schematic representation of the sites of origin, interaction between, and fate of, the major lipoprotein particles.
which are used as an energy source or stored. The remaining chylomicron remnant particle, which contains the bulk of the original cholesterol, is taken up by the liver. Apoprotein E on the particle’s surface binds with liver clearance receptors.

**Very-low-density lipoprotein (VLDL) particles**

These are synthesized continuously in the liver and contain most of the body’s endogenously synthesized triglyceride and a smaller quantity of cholesterol. They are the body’s main source of energy during prolonged fasting. Apoprotein B-100 is an essential component of VLDL. Apoproteins C-II and E are incorporated later into VLDL by transfer from HDL particles. As they pass round the circulation, VLDL particles bind through apoprotein C-II allowing triglyceride to be progressively removed by lipoprotein lipase in the capillary endothelium. This leaves a particle, now depleted of triglyceride and apoprotein C-II, called an intermediate-density lipoprotein (IDL) particle.

**Intermediate-density lipoprotein (IDL) particles**

These have apoprotein B-100 and apoprotein E molecules on the particle surface. Most IDL particles bind to liver LDL receptors through the apoprotein E molecule and are then catabolized. Some IDL particles have further triglyceride removed (by the enzyme hepatic lipase), producing LDL particles.

**Low-density lipoprotein (LDL) particles**

LDL particles are the main carrier of cholesterol, and deliver it both to the liver and to peripheral cells. The surface of the LDL particle contains apoprotein B-100, and also apoprotein E. The apoprotein B-100 is the principal ligand for the LDL clearance receptor. This receptor lies within coated pits on the surface of the hepatocyte. Once bound to the receptor, the coated pit invaginates and fuses with liposomes which destroy the LDL particle (Fig. 20.19). The number of hepatic LDL clearance receptors regulates the circulating LDL concentration, which is also influenced by controlling the activity of the rate-limiting enzyme in the cholesterol synthetic pathway, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase.

LDL particles can deposit lipid into the walls of the peripheral vasculature. Not all the cholesterol synthesized by the liver is packaged immediately into lipoprotein particles. Some is oxidized into bile salts. Both bile salts and cholesterol are excreted in the bile: both are then reabsorbed through the terminal ileum and recirculated (enterohepatic circulation).

LDL particles become Lp(a) lipoproteins as a result of the linkage of apoprotein (a) to apoprotein B-100 with a single disulphide bond. Raised levels of Lp(a) lipoprotein are a risk factor for cardiovascular disease.

**High-density lipoprotein (HDL) particles**

Nascent HDL particles are produced in both the liver and intestine. They are disc shaped, seemingly inert and contain apoprotein A-I. They are transmuted into mature particles by the acquisition of phospholipids, and the E and C apoproteins from chylomicrons and VLDL particles in the circulation. The more mature HDL particles take up cholesterol from cells in the peripheral tissues aided by cholesterol- efflux regulatory protein – a product of the ABC1 gene. As it is taken up, the enzyme lecithin cholesterol acyltransferase (LCAT), activated by the apoprotein A on the particle’s surface, esterifies the sequestered cholesterol. The HDL particle transports cholesterol away from the periphery and may transfer it indirectly to other particles such as VLDL in the circulation or deliver its cholesterol directly to the liver (reverse cholesterol transport) and steroid-synthetic tissues (ovaries, testes, adrenal cortex).

This direct delivery takes place through scavenger-receptor B1. In experimental animals the absence of scavenger-receptor B1 dramatically accelerates the development of atheroma, and genetically programmed overproduction suppresses atheroma formation.

**Measurement**

When a laboratory measures fasting serum lipids, the majority of the total cholesterol concentration consists of LDL particles with a 20–30% contribution from HDL particles. The triglyceride concentration largely reflects the circulating number of VLDL particles, since chylomicrons are not normally present in the fasted state. If the patient is not fasted, the total triglyceride concentration will be raised owing to the additional presence of triglyceride-rich chylomicrons.

**Epidemiology and lipids**

**LDL and total cholesterol**

Population studies have repeatedly demonstrated a strong association between both total and LDL cholesterol concentration and coronary heart risk. There is a strong link between mean fat consumption, mean serum cholesterol concentration and the prevalence of coronary heart disease between countries. The exception is France where the cardiovascular risk is only moderate – perhaps owing to high alcohol consumption. Studies of migrants, particularly of Japanese men migrating to Hawaii, have shown that as diet changes, and cholesterol concentrations rise, so does the cardiovascular risk. Such studies show the role of the environment rather than the genetic make-up of a population.

The Multiple Risk Factor Intervention Trial (MRFIT) screened one-third of a million American men for various cardiovascular risk factors and then followed them for 6 years. Data from this study have shown that although cardiovascular risk rises...
HYPERLIPIDAEMIA

Hyperlipidaemia results from genetic predisposition interacting with an individual’s diet.

Secondary hyperlipidaemia

If a lipid disorder has been detected it is vital to carry out a clinical history, examination and simple special investigations to detect causes of secondary hyperlipidaemia (Table 20.15), which may need treatment in their own right. Hypothyroidism, diabetes, renal disease and abnormal liver function can all raise plasma lipid levels.

**Classification, clinical features and investigation of primary hyperlipidaemias**

We have used the functional/genetic classification which has the advantage that the genetic disorders may be grouped by the results of simple lipid biochemistry into causes of:

- Disorders of VLDL and chylomicrons – hypertriglyceridaemia alone
- Disorders of LDL – hypercholesterolaemia alone
- Disorders of HDL
- Combined hyperlipidaemia.

**Disorders of VLDL and chylomicrons – hypertriglyceridaemia alone**

The majority of cases appear to be due to multiple genes acting together to produce a modest excess of circulating concentration of VLDL particles, such cases being termed polygenic hypertriglyceridaemia.

In a proportion of cases, there will be a family history of a lipid disorder or its effects (e.g. pancreatitis). Such cases are often classified as familial hypertriglyceridaemia. The defect underlying the majority of such cases is not understood. Apoprotein A5 deficiency underlies some cases. The main clinical feature is a history of attacks of pancreatitis or retinal vein thrombosis in some individuals.

**Lipoprotein lipase deficiency and apoprotein C-II deficiency**

These are rare diseases which produce greatly elevated triglyceride concentrations owing to the persistence of chylomicrons (and not VLDL particles) in the circulation. The chylomicrons persist because the triglyceride within cannot be metabolized if the enzyme lipoprotein lipase is defective, or because the triglycerides cannot gain access to the normal enzyme owing to deficiency of the apoprotein C-II on their surface. Patients present in childhood with eruptive xanthomatosis, lipaemia retinalis and retinal vein thrombosis, pancreatitis and hepatosplenomegaly. If not identified in childhood, it can present in adults with gross hypertriglyceridaemia resistant to simple measures. The presence of chylomicrons floating like cream on top of fasting plasma suggests this diagnosis. It is confirmed by plasma electrophoresis or ultracentrifugation. An abnormality of apoprotein C can be deduced if the hypertriglyceridaemia improves temporarily after infusing fresh frozen plasma, and lipoprotein lipase deficiency is likely if it does not.

Findings in 366 222 primary screenees of the Multiple Risk Factor Intervention Trial (MRFIT). JAMA 1986; 256:2823.)
Disorders of LDL – hypercholesterolaemia alone

**Heterozygous familial hypercholesterolaemia** is an autosomal dominant monogenic disorder present in 1 in 500 of the normal population. The average primary care physician would therefore be expected to have four such patients, but because of clustering within families the prevalence varies. There is an increased prevalence in some racial groups (e.g., French Canadians, Finns, South Africans). Surprisingly, most individuals with this disorder remain undetected. Patients may have no physical signs, in which case the diagnosis is made on the presence of very high plasma cholesterol concentrations which are unresponsive to dietary modification and are associated with a typical family history of early cardiovascular disease. Diagnosis can more easily be made if typical clinical features are present. These include xanthomatous thickening of the Achilles tendons and xanthomas over the extensor tendons of the fingers. Xanthelasma may be present, but is not diagnostic of familial hypercholesterolaemia.

The genetic defect is the underproduction or malproduction of the LDL cholesterol clearance receptor in the liver (Table 20.16). Over 150 different mutations in the LDL receptor have been described to date. Fifty per cent of men with the disease will die by the age of 60, most from coronary artery disease, if untreated.

**Homozgyous familial hypercholesterolaemia** is very rare indeed. Affected children have no LDL receptors in the liver. They have a hugely elevated LDL cholesterol concentration, and massive deposition of lipid in arterial walls, the aorta and the skin. The natural history is for death from ischaemic heart disease in late childhood or adolescence. Repeated plasmapheresis has been used to remove LDL cholesterol with some success. Liver transplantation is a ‘cure’. Plasma lipids normalize and xanthomas regress after transplantation, but the number of patients having undergone this procedure is small.

**Mutations in the apoprotein B-100 gene** cause another relatively common single gene disorder. Since LDL particles bind to their clearance receptor in the liver through apoprotein B-100, this defect also results in high LDL concentrations in the blood, and a clinical picture which closely resembles classical heterozygous familial hypercholesterolaemia. The two disorders can be distinguished clearly only by genetic tests. The approach to treatment is the same.

**Polygenic hypercholesterolaemia** is a term used to lump together patients with raised serum cholesterol concentrations, but without one of the monogenic disorders above. They exist in the right-hand tail of the normal distribution of cholesterol concentration. The precise nature of the polygenic variation in plasma cholesterol concentration remains unknown. Variations in the apoprotein E gene (chromosome 19), and in sterol-regulatory element-binding protein (SREBP)-2 gene, are involved in some individuals in this heterogeneous group.

### Disorders of HDL (very low HDL, low total cholesterol)

**Tangier disease** is an autosomal recessive disorder characterized by a low HDL cholesterol concentration. Cholesterol accumulates in reticuloendothelial tissue and arteries causing enlarged orange-coloured tonsils and hepatosplenomegaly. Cardiovascular disease, corneal opacities and a polynuropathy also occur. It is due to a gene mutation (ABC1 gene, see HDL physiology above and Table 20.16) which normally promotes cholesterol uptake from cells by HDL particles.

Other mutations in this gene have been found in a few families with autosomal dominant HDL deficiency. It is as yet unknown whether abnormalities of this gene contribute to the low HDL cholesterol concentrations commonly seen in cardiovascular disease patients.

**Combined hyperlipidaemia**

The most common patient group is a polygenic combined hyperlipidaemia. Patients have an increased cardiovascular risk due to both high LDL concentrations and suppression of HDL by the hypertriglyceridaemia.

**Familial combined hyperlipidaemia**

This is relatively common, affecting 1 in 200 of the general population. The genetic basis for the disorder has not yet been characterized. It is diagnosed by finding raised cholesterol and triglyceride concentrations in association with a typical family history. There are no typical physical signs.

**Remnant hyperlipidaemia**

This is a rare (1 in 5000) cause of combined hyperlipidaemia. It is due to accumulation of LDL remnant particles and is associated with an extremely high risk of cardiovascular disease. It may be suspected in a patient with raised total cholesterol and triglyceride concentrations by finding xanthomas in the palmar creases (diagnostic) and the presence of tuberous xanthomas, typically over the knees and elbows.

Table 20.16 The genetic defects underlying some lipoprotein disorders
Remnant hyperlipidaemia is almost always due to the inheritance of a variant of the apoprotein E allele (apoprotein E2) together with an aggravating factor such as another primary hyperlipidaemia. When suspected clinically the diagnosis can be confirmed using ultracentrifugation of plasma, or phenotyping apoprotein E.

**Therapies available to treat hyperlipidaemia**

**The lipid-lowering diet**

Studies have shown that dieticians helping patients to adjust their own diet to meet the nutritional targets set out below produce a better lipid-lowering effect than does the issuing of standard diet sheets and advice from a doctor. The main elements of a lipid-lowering diet are similar to those for people with diabetes (Table 20.5). Additional specific measures are to:

- reduce consumption of liver, offal and fish roes to reduce dietary cholesterol
- reduce alcohol consumption, since this may worsen primary lipid disorders at doses that would not affect normal individuals
- include foods containing plant stanols in the diet. Plant stanols reduce the absorption of cholesterol from the intestine by competing for space in the micelles that deliver lipid to the mucosal cells of the gut. They are largely unabsorbed and excreted in the stool. Increasing the amount of plant stanol in the diet 10-fold by using a margarine (e.g. Benecol) containing added stanol esters lowers LDL cholesterol by approximately 0.35–0.5 mmol/L. A reduction in the risk of heart disease of about 25% would be expected if this reduction in LDL cholesterol was applied to a population.

**Drugs**

The classes of drugs used to treat hyperlipidaemia are described in Table 20.17. How they are used is set out in Table 20.18. Statins are the most widely used lipid-lowering agents. Generalized muscular aches are the commonest adverse effect, occasionally leading to a frank myopathy. These adverse events occur more frequently in people with a SNP in a gene region coding for a liver-specific organic anion transporter protein (Solute Carrier Organic anion transporter IBI – SLCOIB1), which leads to a decreased hepatic uptake of the statin and higher statin levels in the serum.

**Other specific issues in the management of hyperlipidaemias**

**Screening**

Most patients with hyperlipidaemia are asymptomatic and have no clinical signs. Many are discovered during the screening of high-risk individuals. Whose lipids should be measured?

There are great doubts as to whether blanket screening of plasma lipids is warranted. Selective screening of people at high risk of cardiovascular disease should be undertaken:

- A family history of coronary heart disease (especially below 50 years of age)
- A family history of lipid disorders
- The presence of a xanthoma
- The presence of xanthelasma or corneal arcus before the age of 40 years
- Obesity
- Diabetes mellitus
- Hypertension
- Acute pancreatitis
- Those undergoing renal replacement therapy.

Where one family member is known to have a monogenic disorder such as familial hypercholesterolaemia (1 in 500 of the population), siblings and children must have their plasma lipid concentrations measured. It is also worth screening the prospective partners of any patients with this heterozygous monogenic lipid disorder because of the small risk of producing children homozygous for the condition.

Acute severe illnesses such as myocardial infarction can derange plasma lipid concentrations for up to 3 months. Plasma lipid concentrations should be measured either within 48 hours of an acute myocardial infarction (before derangement has had time to occur) or 3 months later.

Serum cholesterol concentration does not change significantly after a meal and as a screening test a random blood sample is sufficient. If the total cholesterol concentration is raised, HDL cholesterol, triglyceride and LDL cholesterol concentrations should be quantitated on a fasting sample. If a test for hypertriglyceridaemia is needed, a fasting blood sample is mandatory.

**Treatment of hypertriglyceridaemia**

A serum triglyceride concentration below 2.0 mmol/L is normal. In the range 2.0–6.0 mmol/L, no specific intervention will be needed unless there are coincident cardiovascular risk factors, and in particular a strong family history of early cardiovascular death. In general, patients should be advised that they have a minor lipid problem, offered advice on weight reduction if obese, and advice on correcting other cardiovascular risk factors.

If the triglyceride concentration is above 6.0 mmol/L, there is a risk of pancreatitis and retinal vein thrombosis. Patients should be advised to reduce their weight if overweight and start a formal lipid-lowering diet (see below). A proportion of individuals with hypertriglyceridaemia have livers which respond to even moderate degrees of alcohol intake by allowing accumulation or excess production of VLDL particles. If hypertriglyceridaemia persists, lipid measurements should be repeated before and after a 3-week interval of complete abstinence from alcohol. If a considerable improvement results, lifelong abstinence may prove necessary. Other drugs, including thiazides, oestrogens and glucocorticoids, can have a similar effect to alcohol in susceptible patients.

</table>
If the triglyceride concentration remains above 6.0 mmol/L, despite the above measures, drug therapy is warranted (Table 20.18). The severe hypertriglyceridaemia associated with the rare disorders of lipoprotein lipase deficiency and apoprotein C-II deficiency may require restriction of dietary fat to 10–20% of total energy intake and the use of special preparations of medium-chain triglycerides in cooking in place of oil or fat. Medium-chain triglycerides are not absorbed via chylomicrons (see p. 260).

**Treatment of hypercholesterolaemia (without hypertriglyceridaemia)**

**Familial hypercholesterolaemia**

Individuals often require treatment with diet and more than one cholesterol-lowering drug. The cholesterol absorption inhibitor ezetimibe is a logical addition to a statin and has a low side-effect profile (Tables 20.17 and 20.18). Bile acid sequestrants are an alternative to ezetimibe, but there are problems with tolerability. Concurrent therapy with statins and fibrates, particularly fenofibrate, can be used in severe cases. Checking for muscle symptoms and measuring creatine kinase is necessary.

**Primary prevention for people with risk factors**

Lipid-lowering therapy using a statin, or alternatives as above is used in asymptomatic individuals irrespective of the total or LDL cholesterol level in type 2 diabetes alone or with two or more of: positive family history of cardiovascular disease, albuminuria, hypertension, smoking.

**Primary prevention for people without risk factors**

In the absence of risk factors, lipid-lowering therapy should be used in asymptomatic men with LDL cholesterol levels persistently above 6.5 mmol/L despite dietary change. The situation for women is less clear.

**Secondary prevention**

As a generality, statin treatment is warranted for any patient with known macrovascular disease (coronary artery disease, TIA or stroke, peripheral vascular disease), irrespective of the total or LDL cholesterol level (treatment target is total cholesterol under 4.0, LDL under 2 mmol/L). If a statin is not tolerated, combinations of other agents are tried (Table 20.18).

**Risk prevention tables**

An array of risk prediction tables (see p. 669) are available to allow quantification of the risk of a patient having a cardiovascular event within the next 10 years. Some advocate the use of these risk tables as a guide to treatment, e.g. if the 10-year risk reaches the 15% or the 30% level. The authors side with those who have reservations over their use. Such risk analyses are a useful approach in helping to decide whether to use treatments such as aspirin. Aspirin probably has no effect until the day an atherosclerotic plaque ruptures, when it may then prevent thrombosis leading to a heart attack or stroke. Furthermore, it has a significant associated morbidity and mortality (from bleeding). At a 10-year cardiovascular risk level of 15% the benefit: risk ratio for aspirin becomes favourable. At the 30% level the benefits are clear.

By contrast, the use of lipid-lowering agents, if initially tolerated, has a low associated morbidity and mortality. These agents probably reduce the rate of atheroma accumulation over a period of decades. When a patient is young, the chance that atheroma will be bad enough to cause a heart attack or stroke within the next 10 years will be small, even if atheroma is accumulating at a swift rate. The level of cardiovascular risk will only rise to the 15% or 30% level when the patient gets older. Yet it seems bizarre not to treat the gradual accumulation of atheroma when the patient is young with a low 10-year risk, and then to start treatment when age causes the 10-year risk levels to rise to a particular threshold, if all other factors are the same. In choosing whether or not to prescribe, we prefer to consider, ‘will he/she live long enough to collect some pension and see his/her grandchildren?,’ rather than, ‘will he/she have a heart attack or stroke within the next 10 years?’ The answers to these two questions are very different.

**Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia)**

Treatment is the same for all varieties of combined hyperlipidaemia. For any given cholesterol concentration the hypertriglyceridaemia found in the combined hyperlipidaemias increases the cardiovascular risk considerably. Treatment is aimed at reducing serum cholesterol below 4.0 mmol/L and triglycerides below 2.0 mmol/L. Therapy is with diet in the first instance and with drugs if an adequate response has not occurred. Fibrates are the treatment of choice since these reduce both cholesterol and triglyceride concentrations, and also have the benefit of raising cardioprotective HDL concentrations. Combination with other agents is often needed (Table 20.18).

**Other lipid disorders**

**Hypolipidaemia**

Low lipid levels can be found in severe protein-energy malnutrition. They are also seen occasionally with severe malabsorption and in intestinal lymphangiectasia.
Hypobetalipoproteinaemia (Table 20.16) is a benign familial condition which is being increasingly recognized. The cholesterol levels are in the range 1–3.5 mmol/L.

Abetalipoproteinaemia
This is described on page 270.

INBORN ERRORS OF CARBOHYDRATE METABOLISM

Glycogen storage disease
All mammalian cells can manufacture glycogen, but the main sites of its production are the liver and muscle. Glycogen is a high-molecular-weight glucose polymer made up of 1–4 linked glucose units, with a 1–6 branch point every 4–10 residues. In glycogen storage disease there is either an abnormality in the molecular structure or an increase in glycogen concentration owing to a specific enzyme defect. Almost all these conditions are autosomal recessive in inheritance and present in infancy, except for McArdle’s disease, which presents in adults.

Table 20.19 shows the classification and clinical features of some of these diseases.

Galactosaemia
Galactose is normally converted to glucose. However, a deficiency of the enzyme galactose-1-phosphate aTissue obtained is used for the biochemical assay of the enzyme. % = percentage of total number of cases in USA and Europe.

FURTHER READING

Defects of fructose metabolism

Absorbed fructose is chiefly metabolized in the liver to lactic acid or glucose. Three defects of metabolism in the liver and intestine occur; all are inherited as autosomal recessive traits:

- **Fructosuria** is due to fructokinase deficiency. It is a benign asymptomatic condition.
- **Hereditary fructose intolerance** is due to fructose-1-phosphate aldolase deficiency. Fructose-1-phosphate accumulates after fructose ingestion, inhibiting both glycolysis and gluconeogenesis, resulting in symptoms of severe hypoglycaemia. Hepatomegaly and renal tubular defects occur but are reversible on a fructose- and sucrose-free diet. Intelligence is normal and there is an absence of dental caries.
- **Hereditary fructose-1,6-diphosphatase deficiency** leads to a failure of gluconeogenesis. Infants present with hypoglycaemia, ketosis and lactic acidosis. Dietary control can lead to normal growth.

INBORN ERRORS OF AMINO ACID METABOLISM

Inborn errors of amino acid metabolism are chiefly inherited as autosomal recessive conditions. The major ones are shown in Table 20.20.

Amino acid transport defects

Amino acids are filtered by the glomerulus, but 95% of the filtered load is reabsorbed in the proximal convoluted tubule by an active transport mechanism. Aminoaciduria results from:

- abnormally high plasma amino acid levels (e.g. phenylketonuria)
- any inherited disorder that damages the tubules secondarily (e.g. galactosaemia)
- tubular reabsorptive defects, either generalized (e.g. Fanconi’s syndrome) or specific (e.g. cystinuria).

Amino acid transport defects can be congenital or acquired.

Generalized aminoacidurias

Fanconi’s syndrome

This occurs in a juvenile form (De Toni–Fanconi–Debré syndrome); in adult life it is often acquired through, for example, heavy metal poisoning, drugs or some renal diseases. There is a generalized defective proximal tubular reabsorption of: most amino acids, glucose, urate, phosphate, resulting in hypophosphatemia, rickets and bicarbonate, with failure to transport hydrogen ions, causing a renal tubular acidosis that then produces a hyperchloreaemic acidosis (see p. 664).

Other abnormalities include potassium depletion, primary or secondary to the acidosis, polyuria, increased excretion of immunoglobulins and other low-molecular-weight proteins.

Various combinations of the above abnormalities have been described.

The juvenile form begins at the age of 6–9 months, with failure to thrive, vomiting and thirst. The clinical features are as a result of fluid and electrolyte loss and the characteristic vitamin D-resistant rickets.

In the adult, the disease is similar to the juvenile form, but osteomalacia is a major feature.

Treatment of the bone disease is with large doses of vitamin D (e.g. 1–2 mg of 1α-hydroxylcholecalciferol with regular blood calcium monitoring). Fluid and electrolyte loss needs to be corrected.

Specific aminoacidurias

Cystinuria

There is a defective tubular reabsorption and jejunal absorption of cystine and the dibasic amino acids, lysine, ornithine and arginine. Cystinuria is either a completely or incompletely autosomal recessive disorder with mutations in two genes, SLC3A1 and SLC7A9. Cystine absorption from the jejunum is impaired but, nevertheless, cystine in peptide form can be absorbed. Cystinuria leads to urinary stones and is responsible for approximately 1–2% of all urinary calculi. The disease often starts in childhood, although most cases present in adult life.

Treatment is described on page 603.

The condition cystinosis must not be confused with cystinuria. Cystinosis is characterized by the accumulation of cystine in different organs leading to organ dysfunction, e.g. photophobia and ocular problems, chronic kidney disease. Treatment is with cysteamine.

Hartnup’s disease

There is defective tubular reabsorption and jejunal absorption of most neutral amino acids but not their peptides. The resulting tryptophan malabsorption produces nicotinamide deficiency (see p. 210). Patients can be asymptomatic, but others develop evidence of pellagra (p. 210). Treatment is with nicotinamide.

Other aminoacidurias

Tryptophan malabsorption syndrome (blue diaper syndrome), familial iminoglu cinuria and methionine malabsorption syndrome have all been described.

LYSOSOMAL STORAGE DISEASES

Lysosomal storage diseases are due to inborn errors of metabolism which are mainly inherited in an autosomal recessive manner (see Table 20.19).
Glucosylceramide lipidoses: Gaucher’s disease

This is the most prevalent lysosomal storage disease and is due to a deficiency in glucocerebrosidase, a specialized lysosomal acid β-glucosidase. This results in accumulation of glucosylceramide in the lysosomes of the reticuloendothelial system, particularly the liver, bone marrow and spleen. Over 200 mutations have been characterized in the glucocerebrosidase gene (1g21), the most common being a single base change (N370S) causing the substitution of arginine for serine; this is seen in 70% of Jewish patients. The typical Gaucher cell, a glucocerebroside-containing reticuloendothelial histiocyte, is found in the bone marrow, producing many cytokines such as CD14.

There are three clinical types, the most common presenting in childhood or adult life with an insidious onset of hepatosplenomegaly (Type 1). There is a high incidence in Ashkenazi Jews (1 in 3000 births), and patients have a characteristic pigmentation on exposed parts, particularly the forehead and hands. The clinical spectrum is variable, with patients developing anaemia, evidence of hypersplenism and pathological fractures that are due to bone involvement. Nevertheless, many have a normal life-span.

The diagnosis is made on finding reduced glucocerebrosidase in leucocytes. Mutational analysis will confirm the diagnosis. Plasma chitotriosidase (an enzyme secreted by activated macrophages) is grossly elevated in Gaucher’s disease and other lysosomal disorders: it is used to monitor enzyme replacement therapy.

Acute Gaucher’s disease (Type 2) presents in infancy with rapid onset of hepatosplenomegaly, with neurological involvement owing to the presence of Gaucher cells in the brain. The outlook is very poor.

Type 3 presents in childhood or adolescence with a variable progression of hepatosplenomegaly, neurodegeneration and bone disease. Again, the outlook is poor.

Some patients with non-neuropathic (Type 1) Gaucher’s disease show considerable improvement with infusion of human recombinant glucocerebrosidase (imiglucerase – a
human recombinant enzyme). Velaglucerase alfa is also used. Oral miglustat (an inhibitor of glucosylceramide synthase) is used for mild to moderate type 1 Gaucher’s disease.

Sphingomyelin cholesterol lipidosis: Niemann-Pick disease

The disease is due to a deficiency of lysosomal sphingomyelinase which results in the accumulation of sphingomyelin cholesterol and glycosphingolipids in the reticuloendothelial macrophages of many organs, particularly the liver, spleen, bone marrow and lymph nodes. The disease usually presents within the first 6 months of life with mental retardation and hepatosplenomegaly; a particular type (11c) presents in adults with dementia. The gene frequency is 1:100 in Ashkenazi Jews, the diagnosis being made in the group by targeted mutation analysis. Typical foam cells are found in the marrow, lymph nodes, liver and spleen.

The mucopolysaccharidoses (MPS)

This is a group of disorders caused by the deficiency of lysosomal enzymes (e.g. α-L-iduronidase) required for the catalysis of glycosaminoglycans (mucopolysaccharides).

The catabolism of dermatan sulphate, heparan sulphate, keratin sulphate or chondroitin sulphate may be affected either singularly or together.

Accumulation of glycosaminoglycans in the lysosomes of various tissues results in the disease. Ten forms of MPS have been described; all are chronic but progressive, and a wide spectrum of clinical severity can be seen within a single enzyme defect. The MPS types show many clinical features though in variable amounts, with dysostosis, abnormal facies, poor vision and hearing and joint dysmobility (either stiff or hypermobile) being frequently seen. Mental retardation is present in, e.g. Hurler (MPS IH) and San Filippo A (MPS IIIA) types, but normal intelligence and life-span are seen in, e.g. Hurler (MPS IH) and San Filippo A (MPS IIIA) types, but normal intelligence and life-span are seen in Scheie (MPS IS). L-arosidase infusion reduces lysosomal storage, resulting in clinical improvement.

The GM2 gangliosidoses

In these conditions there is accumulation of GM2 gangliosides in the central nervous system and peripheral nerves. It is particularly common (1 in 2000) in Ashkenazi Jews. Tay–Sachs disease is the severest form, where there is a progressive degeneration of all cerebral function, with fits, epilepsy, dementia and blindness, and death usually occurs before 2 years of age. The macula has a characteristic cherry spot appearance.

Fabry’s disease

This X-linked recessive condition involves the glycosphingolipid pathway. There is a deficiency of lysosomal hydrolase (α-galactosidase A). This enzyme is encoded by the gene on the Xq22.1 region of the X chromosome. Many mutations have been described and genetic analysis is used in the diagnosis, causing an accumulation of globotriaosylceramide with terminal α-galactosyl moieties in the lysosomes of various tissues including the liver, kidney, blood vessels and the ganglion cells of the nervous system. The patients present with peripheral nerve involvement, gastrointestinal symptoms/abdominal pain, diarrhoea and early satiety, but eventually most patients have a cardiomyopathy, strokes and kidney disease in adult life. An absent or very low level of α-gal A in leucocytes confirms the diagnosis. Genetic testing is available. Treatment is with agalsidase α-β infusions.

Diagnosis

Many of the sphingolipidoses can be diagnosed by demonstrating the enzyme deficiency, usually in peripheral blood leucocytes.

Prenatal diagnosis is possible in a number of the conditions by obtaining specimens of amniotic cells. Carrier states can also be identified, so that sensible genetic counselling can be given.

Amyloidosis

Amyloidosis is a disorder of protein metabolism in which there is an extracellular deposition of pathological insoluble fibrillar proteins in organs and tissues. Characteristically, the amyloid protein consists of β-sheet that are responsible for its insolubility and resistance to proteolysis.

Amyloidosis can be acquired or inherited. Classification is based on the nature of the precursor plasma proteins (at least 20) that form the fibrillar deposits. The process for the production of these fibrils appears to be multifactorial and differs amongst the various types of amyloid.

AL amyloidosis (immunoglobulin light chain-associated)

This is a plasma cell dyscrasia, related to multiple myeloma, in which clonal plasma cells in the bone marrow produce immunoglobulins that are amyloidogenic. This may be the outcome of destabilization of light chains owing to substitution of particular amino acids into the light chain variable region. There is a clonal dominance of amyloid light (AL) chains – either the dominant κ or γ isotype – which are excreted in the urine (Bence Jones proteins). This type of amyloid is often associated with lymphoproliferative disorders, such as myeloma, Waldenstrom’s macroglobulinaemia or non-Hodgkin’s lymphoma. It rarely occurs before the age of 40 years.

The clinical features are related to the organs involved. These include the kidneys (presenting with proteinuria and the nephrotic syndrome) and the heart (presenting with heart failure). Autonomic and sensory neuropathies are relatively common, and carpal tunnel syndrome with weakness and paraesthesia of the hands may be an early feature. Sensory neuropathy is common. There is an absence of central nervous system involvement.

On examination, hepatomegaly and rarely splenomegaly, cardiomyopathy, polyneuropathy and bruising may be seen. MacroGLOSSIA occurs in about 10% of cases and peri orbital purpura in 15%.

Familial amyloidosis (transthyretin-associated, ATTR)

These are autosomal dominant transmitted diseases where the mutant protein forms amyloid fibrils, starting usually in middle age. The most common form is due to a mutant – transthyretin – which is a tetrameric protein with four identical subunits. It is a transport protein for thyroxine and retinol-binding protein and mainly synthesized in the liver. Over 80 amino acid substitutions have been described; for example, a common substitution is that of methionine for valine at position 30 (Met 30) in all racial groups, and alanine for threonine (Ala 60) in the English and Irish. These substitutions destabilize the protein, which precipitates following stimulation, and can cause disorders such as familial amyloidotic polyneuropathy (FAP), cardiomyopathy or the...
nephrotic syndrome. Major foci of FAP occur in Portugal, Japan and Sweden.

Other less common variants include mutations of apoprotein A1, gelsolin, fibrinogen Ax and lysozyme.

Clinically, peripheral sensorimotor and autonomic neuropathy are common, with symptoms of autonomic dysfunction, diarrhoea and weight loss. Renal disease is less prevalent than with AA amyloidosis. Macroglossia does not occur. Cardiac problems are usually those of conduction. There may be a family history of unidentified neurological disease.

Other hereditary systemic amyloidoses include other familial amyloid polyneuropathies (e.g. Portuguese, Icelandic, Dutch). There is a familial Creutzfeldt–Jakob disease. In familial Mediterranean fever, renal amyloidosis is a common serious complication.

Reactive systemic (secondary AA) amyloidoses

These are due to amyloid formed from serum amyloid A (SAA), which is an acute phase protein. It is, therefore, related to chronic inflammatory disorders and chronic infection.

Clinical features depend on the nature of the underlying disorder. Chronic inflammatory disorders include rheumatoid arthritis, inflammatory bowel disease and untreated familial Mediterranean fever. In developing countries, it is still associated with infectious diseases such as tuberculosis, bronchiectasis and osteomyelitis. AA amyloidosis often presents with chronic kidney disease, with hepato megaly and splenomegaly. Macroglossia is not a feature and cardiac involvement is rare. The degree of renal failure correlates with the SAA level in a more favourable outcome in patients with low normal levels.

Other amyloids

Cerebral amyloidosis, Alzheimer’s disease and transmissible spongiform encephalopathy

The brain is a common site of amyloid deposition, although it is not directly affected in any form of acquired systemic amyloidosis. Intracerebral and cerebrovascular amyloid deposits are seen in Alzheimer’s disease. Most cases are sporadic, but hereditary forms caused by mutations have been reported. In hereditary spongiform encephalopathies several amyloid plaques have been seen.

Amyloid deposits are frequently found in the elderly, particularly cerebral deposits of A4 protein. This is also seen in Down’s syndrome. Approtein E (involved in LDL transport, see p. 1033) interacts directly with β-A4 protein in senile plaques and neurofibrillary tangles in the brain. The gene for approtein E is on chromosome 19 and may be a susceptibility factor in the aetiology of Alzheimer’s disease.

Local amyloidosis

Deposits of amyloid fibrils of various types can be localized to various organs or tissues (e.g. skin, heart and brain).

Dialysis-related amyloidosis

This is due to the β2-microglobulin producing amyloid fibrils in chronic dialysis patients (see p. 628). It frequently presents with the carpal tunnel syndrome.

Diagnosis

This is based on clinical suspicion and, if possible, on tissue histology. Amyloid in tissues appears as an amorphous, homogeneous substance that stains pink with haematoxylin and eosin and stains red with Congo red. It also has a green fluorescence in polarized light. Tissue can be obtained from the rectum, gums or fat pad. The bone marrow may show plasma cells in amyloidosis or a lymphoproliferative disorder. A paraproteinaemia and proteinuria with light chains in the urine may also be seen in AL amyloidosis. In secondary or reactive amyloidosis there will be an underlying disorder. Scintigraphy using 123I-labelled serum amyloid P component is useful for the assessment of AL, ATTR and AA amyloidosis, but it is not widely available and is expensive.

Treatment

This is symptomatic or the treatment of the associated disorder. The nephrotic syndrome and congestive cardiac failure require the relevant therapies. Treatment of any inflammatory source or infection should be instituted. Colchicine may help familial Mediterranean fever. Eprodisate, which interferes with interactions between amyloid proteins and glycosaminoglycans, inhibits polymerization of amyloid fibrils; it slows the fall in renal function in AA amyloidosis. Chemotherapy is with melphalan plus dexamethasone in AL amyloidosis. Stem cell therapy is also used. In ATTR amyloidosis where transthyretin is predominantly synthesized in the liver, liver transplantation (when there would be a disappearance of the mutant protein from the blood) is considered as the definitive therapy.

THE PORPHYRIAS

This heterogeneous group of rare inborn errors of metabolism is caused by abnormalities of enzymes involved in the biosynthesis of haem, resulting in overproduction of the intermediate compounds called ‘porphyrins’ (Fig. 20.22). The porphyrias show extreme genetic heterogeneity. For example, in acute intermittent porphyria, more than 90 mutations have been identified in the porphobilinogen deaminase gene. One mutation has a high prevalence in patients in northern Sweden, suggesting a common ancestor.

Structurally, porphyrins consist of four pyrrole rings. These pyrrole rings are formed from the precursors glycine and succinyl-CoA, which are converted to δ-aminolevulinic acid (δ-ALA) in a reaction catalysed by the enzyme δ-ALA synthase. Two molecules of δ-ALA condense to form a pyrrole ring.

Porphyrins can be divided into uroporphyrins, coproporphyrins or protoporphyrins depending on the structure of the side-chain. They are termed type I if the structure is symmetrical and type III if it is asymmetrical. Both uroporphyrins and coproporphyrins can be excreted in the urine.

The sequence of enzymatic changes in the production of haem is shown in Figure 20.22. The chief rate-limiting step is the enzyme δ-ALA synthase. This has two isoforms, ALA-N (non-erythroid) and ALA-E (erythroid). ALA-N is under negative feedback by haem but is upregulated by drugs and chemicals; there is no known inherited deficiency and the gene is on 3p21. Conversely ALA-E, encoded by Xp11.21, is unaffected by drugs or haem, and an inherited deficiency causes X-linked sideroblastic anaemia (Fig. 20.22).

Consequently:

- Haem (endogenous or exogenous) produces remission of hepatic porphyria.
- Chemicals and drugs can produce disease.
- Erythropoietic porphyria gives constant symptoms and is affected by sunlight.
Diabetes mellitus and other disorders of metabolism

Investigations
A rapid semi-quantitative spot urine test for porphobilinogen (PBG) is often available.

1. Blood count. This is usually normal, with occasional neutrophil leucocytosis.
2. Liver biochemical tests. There is elevated bilirubin and aminotransferases.
3. Serum urea is often raised.
4. ALA and PBG are raised (24 h collection).
5. Erythrocyte PBG deaminase is decreased.

Screening
Family members should be screened to detect latent cases.

Urinalysis is not adequate but measurement of erythrocyte porphobilinogen deaminase and ALA synthase is extremely sensitive.

Clinical features
All of the haem intermediates shown in Figure 20.22 are potentially toxic. Three patterns of symptoms occur in the various types of porphyria:

- Neurovisceral (Table 20.21)
- Photosensitive
- Haemolytic anaemia.

The most common types of porphyria are acute intermittent porphyria (AIP), porphyria cutanea tarda (PCT) and erythropoietic porphyria (EPP).

Neurovisceral

**Acute intermittent porphyria (AIP)**

AIP is an autosomal dominant disorder (Fig. 20.22). Presentation is in early adult life, usually around the age of 30 years, and women are affected more than men. It may be precipitated by alcohol and drugs such as barbiturates and oral contraceptives, but a wide range of lipid-soluble drugs have also been incriminated. Acute attacks present with neurovisceral symptoms (Table 20.21). Symptoms of the rare, autosomal recessive aminolaevulinic acid dehydrogenase porphyria (ADP) are similar.

**Investigations**

A rapid semi-quantitative spot urine test for porphobilinogen (PBG) is often available.

- The urine turns red–brown or red on standing.
- Blood count. This is usually normal, with occasional neutrophil leucocytosis.
- Liver biochemical tests. There is elevated bilirubin and aminotransferases.
- Serum urea is often raised.
- ALA and PBG are raised (24 h collection).
- Erythrocyte PBG deaminase is decreased.

**Screening**

Family members should be screened to detect latent cases. Urinalysis is not adequate but measurement of erythrocyte porphobilinogen deaminase and ALA synthase is extremely sensitive.

**Mixed neurovisceral and photocutaneous Variegate porphyria (VP)**

This combines neurovisceral symptoms with those of a cutaneous photosensitive porphyria (Fig. 20.22). A bullous eruption develops on exposure to sunlight owing to the activation of porphyrins deposited in the skin.

Investigation shows an elevated urinary ALA and PBG. Fluorescence emission spectroscopy of plasma differentiates this from other cutaneous porphyrias.

**Hereditary coproporphyria (HCP)**

This is extremely rare and broadly similar in presentation to variegate porphyria.

---

Photocutaneous

Porphyria cutanea tarda (cutaneous hepatic porphyria) (PCT)

This condition, which has a genetic predisposition, presents with a bullous eruption on exposure to sunlight; the eruption heals with scarring. Alcohol is the most common aetiological agent but hepatitis C, iron overload or HIV can also precipitate the disease. Evidence of biochemical or clinical liver disease may also be present. Polychlorinated hydrocarbons have been implicated and porphyria cutanea tarda has been seen in association with benign or malignant tumours of the liver.

Hepatoerythropoietic porphyria (HEP, Fig. 20.22) is a rare disease clinically very similar to congenital erythropoietic porphyria presenting in childhood; haemolytic anaemia occurs. The defect of HEP is similar to that of PCT.

The diagnosis depends on demonstration of increased levels of urinary uroporphyrin. Histology of the skin shows subepidermal blisters with perivascular deposition of periodic acid–Schiff-staining material. The serum iron and transferrin saturation are often raised. Liver biopsy shows mild iron overload as well as features of alcoholic liver disease.

Congenital erythropoietic porphyria (CEP)

This is extremely rare and is transmitted as an autosomal recessive trait. Its victims show extreme sensitivity to sunlight and develop disfiguring scars. Dystrophy of the nails, blindness due to lenticular scarring, and brownish discoloration of the teeth also occur.

Erythropoietic protoporphyria (EPP)

This is more common than congenital erythropoietic porphyria and is inherited as an autosomal dominant trait. It presents with irritation and a burning pain in the skin on exposure to sunlight. The liver is usually normal but protoporphyrin deposition can occur. Diagnosis is made by fluorescence of the peripheral red blood cells and by increased protoporphyrin in the red cells and stools.

Management of porphyrias

Neurovisceral

Acute. The management of acute episodes is largely supportive. Precipitating factors, e.g. drugs, should be stopped. Analgesics should be given (avoiding drugs that may aggravate an attack). Intravenous carbohydrates, e.g. glucose, inhibit ALA synthase activity. Intravenous haem arginate (human haemin) infusion reduces ALA and PBG excretion by having a negative effect on ALA synthase-N activity (Fig. 20.22) and decreases the duration of an attack; this is useful in a severe attack. Calorie and fluid intake should be maintained.

Prevention in remission period. This is by avoidance of possible precipitating factors, e.g. drugs and alcohol.

Stopping smoking, treatment of infections and stress avoidance are helpful. Surgery can precipitate attacks. A high-carbohydrate diet should be maintained and haemin infusions may also help.

Photocutaneous episodes

Acute attacks following exposure to UV light can only be treated symptomatically. However, venesection, which reduces urinary porphyrina, can be used for PCT in both acute and remission phases. Chloroquine can also aid excretion by forming a water-soluble complex with uroporphyrins. Liver transplantation is used for severe cases.

Prevention is with avoidance of sunlight, and use of zinc-containing sunscreens and protective clothing.

Oral β-carotene, which quenches free radicals, provides effective protection against solar sensitivity in EPP.

#### THE EAR

**Anatomy and physiology**

The ear can be divided into three parts: outer, middle and inner (Fig. 21.1).

- **The outer ear** has a skin-lined tube 2.5 cm long leading down to the tympanic membrane (the ear drum). Its outer third is cartilaginous and contains hair, sebaceous and ceruminous glands, but the walls of the inner two-thirds are bony. The outer ear is self-cleaning as the skin is migratory and there are no indications to use cotton wool buds. Wax should only be seen in the outer third.

- **The middle ear** is an air-containing cavity derived from the branchial clefts. It communicates with the mastoid air cells superiorly, and the Eustachian tube connects it to the nasopharynx medially. The Eustachian tube ventilates the middle ear and maintains equal air pressure across the tympanic membrane. It is normally closed but opens via the action of the palatal muscles to allow air entry when swallowing or yawning. A defect in this mechanism, such as with a cleft palate, will prevent air entering the middle ear cleft which may then fill with fluid. Lying within the middle ear cavity are the three ossicles (malleus, incus and stapes) that transmit sound from the tympanic membrane to the inner ear. On the medial wall of the cavity is the horizontal segment of the facial nerve, which can be damaged during surgery or by direct extension of infection in the middle ear.

- **The inner ear** contains the cochlea for hearing and the vestibule and semicircular canals for balance. There is a semicircular canal arranged in each body plane and these are stimulated by rotatory movement. The facial, cochlear and vestibular nerves emerge from the inner ear and run through the internal acoustic meatus to the brainstem (see Fig. 22.7, p. 1076).

#### Physiology of hearing

The ossicles, in the middle ear, transmit sound waves from the tympanic membrane to the cochlea. They amplify the waves by about 18-fold to compensate for the loss of sound waves moving from the air-filled middle ear to the fluid-filled cochlea. Hair cells in the basilar membrane of the cochlea detect the vibrations and transduce these into nerve impulses which pass to the cochlear nucleus and then eventually to the superior olivary nuclei of both sides; thus lesions central to the cochlear nucleus do not cause unilateral hearing loss.

If the ossicles are diseased, sound can also reach the cochlea by vibration of the temporal bone (bone conduction).

#### Examination

The pinna and postauricular region should first be examined for scars or swellings. An auroscope is used to examine the external ear canal whilst the pinna is retracted backwards and upwards to straighten the canal. Look for wax, discharge or foreign bodies. The tympanic membrane should always be seen with a light reflex anteroinferiorly. Previous repeated infections may cause a thickened, whitish drum but fluid in

---

**Normal tympanic membrane.**

- a, Lateral process of malleus.
- b, Long process of malleus.
- c, Umbo.
- d, Light reflex.
the middle ear may show as dullness of the drum. Perforations are marginal or central.

**Common disorders**

**The discharging ear (otorrhoea)**

Discharge from the ear is usually due to infection of the outer or middle ear.

**Otitis externa**

This is a diffuse inflammation of the skin of the ear canal. The cause is bacterial, viral or fungal and the patient usually complains of severe pain. Gentle pulling of the pinna is tender and there may be lymphadenopathy of the preauricular nodes.

Examination often reveals debris in the canal which needs to be removed either by gentle mopping or preferably by suction viewed directly under a microscope. In severe cases the canal may be swollen and a view of the tympanic membrane impossible. Any foreign body seen should be removed with great care by trained personnel.

**Treatment** is with topical antibiotics in the first instance (drops such as dexamethasone 0.05%, framycetin sulphate 0.5%, gramicidin 0.005% drops or hydrocortisone acetate 0.5%, neomycin sulphate 3250 units). If it does not resolve in 3–4 days then microsuction in an ENT department is necessary.

**Otitis media**

Otitis media can also present with discharge from the middle ear through a perforation of the tympanic membrane. There are no mucous glands in the external ear canal, however; if the discharge is serous, then middle ear pathology is unlikely.

**Treatment** for the acute case is initially with non-steroidal anti-inflammatory drugs then, if it is not resolving, with systemic antibiotics.

**Cholesteatoma**

Cholesteatoma is defined as keratinizing squamous epithelium within the middle ear cleft and can present with foul-smelling otorrhoea. Examination shows a defect in the tympanic membrane full of white cheesy material. Mastoid surgery is required to remove this sac of squamous debris as it can erode local structures such as the facial nerve or even extend intracranially.

**Hearing loss**

Deafness can be conductive or sensorineural and these can be differentiated at the bedside by the Rinne and the Weber tests (Box 21.1) or with pure-tone audiometry. Conductive hearing loss has many causes (Table 21.1) but wax is the commonest.

**Rinne test**

- Normally a tuning fork, 512 Hz, will be heard as louder if held next to the ear (i.e. air conduction) than it will if placed on the mastoid bone (Rinne positive).
- If the tuning fork is perceived louder when placed on the mastoid (i.e. via bone conduction), then a defect in the conducting mechanism of the external or middle ear is present (true Rinne negative).

**Weber test**

A tuning fork placed on the forehead or vertex of a patient with normal hearing (or with symmetrical hearing loss) should be perceived centrally.

**Pure tone audiometry**

The patient is asked to respond to a series of pure tones presented to each ear, in turn, in a soundproof room. An audiogram is produced (see Fig. 21.2).

**Perforated tympanic membrane**

This arises from trauma or chronic middle ear disease where recurrent infection results in a permanent defect. Surgical
repair is only indicated if the patient is symptomatic with hearing loss or recurrent discharge.

**Otitis media**
This is an acute inflammation of the middle ear, causing severe pain (otalgia) and conductive hearing loss. This occurs because fluid accumulation in the middle ear impairs sound conduction to the cochlea. Otitis media is often viral in origin, e.g. following a cold, and will settle within 72 hours without antibacterial treatment. In people with systemic features or after 72 hours, a systemic antibiotic, e.g. amoxicillin, should be given, particularly in the under 2 year olds. Topical therapy is of no value. Complications include infection of the mastoid bone.

Acute otitis media can spread to the mastoid area. If there is tenderness and swelling over the mastoid then an urgent ENT opinion should be obtained.

**Secretory otitis media with effusion (‘serous otitis media’ or ‘glue ear’)**
This is common in children because of Eustachian tube dysfunction. The effusion resolves naturally in the majority of cases but can persist giving hearing loss, and it predisposes to recurrent attacks of acute otitis media. A grommet (tympanostomy tube) is inserted into the tympanic membrane and ventilates the middle ear cavity, i.e. takes over the Eustachian tube’s function. Grommets are extruded from the tympanic membrane as it heals (over 6 months to 2 years). Developmental outcomes are not improved by grommet insertions. In most children the middle third of the face grows around the age of 7–14 years and Eustachian tube dysfunction is rare after this.

**Otosclerosis**
This is usually a hereditary disorder in which new bony deposits occur within the stapes footplate and the cochlea. Characteristically seen in the second and third decades, it is commoner in females and can become worse during pregnancy. The hearing loss may be mixed, and treatment is commoner in females and can become worse during pregnancy. The hearing loss may be mixed, and treatment is commoner in females and can become worse during pregnancy.

**Presbycusis**
This is the commonest cause of deafness. It is a degenerative disorder of the cochlea and is typically seen in old age. It can be due to the loss of outer hair cells (sensory), loss of the ganglion cells (neural), strial atrophy (metabolic) or it can be a mixed picture. Ageing itself does not cause outer hair cell loss but environmental noise toxicity over the years is a major factor.

Vertigo
Vertigo is usually rotatory when it arises from the ear. The presence of otalgia, otorrhoea, tinnitus or hearing loss suggests an otologic aetiology. Vestibular causes can be classified according to the duration of the vertigo. Common causes are summarized below.

- Seconds to minutes – benign paroxysmal positional vertigo
- Minutes to hours – Ménière’s disease
- Hours to days – labyrinthine or central pathology.

**Benign paroxysmal positional vertigo (BPPV)**
BPPV is thought to be due to loose otoliths in the semicircular canals, commonly the posterior canal. Positional vertigo is precipitated by head movements, usually to a particular position, and often occurs when turning in bed or on sitting up. The onset is typically sudden and distressing. The vertigo lasts seconds or minutes and the phenomenon becomes less severe on repeated movements (fatigue). There is no serious underlying cause but it sometimes follows vestibular neuritis (see p. 1079), head injury or ear infection.

**Diagnosis**
Diagnosis is made on the basis of the history and by the Hallpike manoeuvre (Fig 21.3). A positive Hallpike test confirms BPPV, which can be cured in over 90% of cases by the Epley manoeuvre. This involves gentle but specific manipulation and rotation of the patient’s head to shift the loose otoliths from the semicircular canals.

---

**Figure 21.2 Audiogram showing presbycusis (high frequency loss).**

**Figure 21.3**

Secretory otitis media (glue ear). Auroscopic view of the tympanic membrane, which is dull with loss of light reflex.

FURTHER READING
A differential diagnosis is a cerebellar mass, but here positional nystagmus (and vertigo) is immediately apparent (no latent interval) and does not fatigue.

**Ménière’s disease**

This condition is characterized by recurring episodic rotatory vertigo lasting 30 minutes to a few hours; attacks are recurrent over months or years. Classically, it is associated with a low frequency sensorineural hearing loss, feeling of fullness in the affected ear, loss of balance, tinnitus and vomiting. There is a build-up of endolymphatic fluid in the inner ear, although its precise aetiology is still unclear.

**Treatment**

Vestibular sedatives, e.g. cinnarizine, are used in the acute phase. Preventative measures, such as a low-salt diet, beta-histine and avoidance of caffeine, are useful. If the disease cannot be controlled, then a chemical labyrinthectomy, perfusing the round window orifice with ototoxic drugs such as gentamicin, is used. Gentamicin destroys the vestibular epithelium; therefore the patient has severe vertigo for around 2 weeks until the body compensates for the lack of vestibular input on that side. The patient will happily trade occasional mild vertigo when the balance system is challenged to the unpredictable, severe and disabling attacks of vertigo of Ménière’s disease.

**Labyrinthine or central causes of vertigo**

(see Table 22.4)

These are managed with vestibular sedatives in the acute phase. Most patients will settle over a few days but continuous true vertigo with nystagmus suggests a central lesion. A patient with a deficit of vestibular function due to viral labyrinthitis or neuronitis should be able to cease vestibular sedatives within 2 weeks; long-term use can give parkinsonian side-effects, delay central compensation and thus prolong the vertigo. Vestibular rehabilitation by a physiotherapist or audiological scientist can speed up the compensation process, although most patients will be able to do this themselves with time.

**Tinnitus**

This is a sensation of a sound when there is no auditory stimulus. It can occur without hearing loss and results from heightened awareness of neural activity in the auditory pathways. Patients describe a hissing or ringing in their ears and this can cause much distress. It usually does not have a serious cause but vascular malformation, e.g. aneurysms, or vascular tumours can be associated. Tinnitus occurs due to awareness of neural activity in the auditory pathways that our brains are made more conscious of.

**Treatment**

This is difficult. A tinnitus masker (a mechanically produced continuous soft sound) can help. Specialist audiological services are of use and rehabilitate patients well.

**THE NOSE**

**Anatomy and physiology** (Fig. 21.4)

The function of the nose is to facilitate smell and respiration:

- Smell is a sensation conveyed by the olfactory epithelium in the roof of the nose. The olfactory epithelium is supplied by the first cranial nerve (see p. 1071).
- The nose also filters, moistens and warms inspired air and in doing so assists the normal process of respiration.

The external portion of the nose consists of two nasal bones attached to the rest of the facial skeleton and to the upper and lower lateral cartilages. The internal nose is divided by a midline septum that comprises both cartilage and bone. This divides the internal nose in two, from the external nostril to the posterior choanae. The posterior choanae are in continuity with the nasopharynx posteriorly.
Nasal obstruction is a symptom and not a diagnosis. It can significantly affect a patient’s quality of life. Causes include:

- **Rhinitis** (see p. 808). If an allergen is identified, then allergen avoidance is the mainstay of treatment. Topical steroids and/or antihistamines can be tried. If severe, then oral antihistamines or referral to an allergy clinic for immunotherapy is warranted.

- **Septal deviation**. Correction of this deviation can be undertaken surgically.

- **Nasal polyps**. This condition occurs with inflammation and oedema of the sinus nasal mucosa. This oedematous mucosa prolapses into the nasal cavity and can cause significant nasal obstruction. In allergic rhinitis (see p. 798) the mucosa lining the nasal septum and inferior turbinates are swollen and a dark red or plum colour. Nasal polyps can be identified as glistening swellings which are not tender. Treatment with intranasal steroids helps but if polyps are large or unresponsive to medical treatment then surgery is necessary.

- **Foreign bodies**. These are usually seen in children who present with unilateral nasal discharge. Clinical examination of the nose with a light source often reveals the foreign body, which requires removal either in clinic or in theatre with a general anaesthetic.

- **Sinonasal malignancy**. This is extremely rare. The diagnosis must be considered if unusual unilateral

**Figure 21.5** (a) Blood supply of Little’s area on the septum of the nose. (b) Nasal pack.
Symptoms are seen, including nasal obstruction, epistaxis, pain, epiphora, cheek swelling, paraesthesia of the cheek and proptosis of the orbit.

Sinusitis

Sinusitis is an infection of the paranasal sinuses that either is bacterial (mainly Streptococcus pneumoniae and Haemophilus influenzae) or is occasionally fungal. It is most commonly associated with an upper respiratory tract infection and can occur with asthma. Symptoms include frontal headache, purulent rhinorrhea, facial pain with tenderness and fever. It can be confused with a variety of other conditions such as migraine, trigeminal neuralgia and cranial arteritis.

Treatment

Treatment for a bacterial sinusitis includes nasal decongestants, e.g. xylometazoline, broad-spectrum antibiotics, e.g. co-amoxiclav because H. influenzae can be resistant to amoxicillin, anti-inflammatory therapy with topical corticosteroids such as fluticasone propionate (nasal spray) to reduce mucosal swelling, and steam inhalations.

If the symptoms of sinusitis are recurrent (Box 21.2) or complications such as orbital cellulitis arise, then an ENT opinion is appropriate and a CT scan of the paranasal sinuses is undertaken. Plain sinus X-rays are now rarely used to image the sinuses.

CT scan of the sinuses or an MRI scan can demonstrate bony landmarks and soft tissue planes.

Functional endoscopic sinus surgery (FESS) is used for ventilation and drainage of the sinuses.

Anosmia

Olfaction is mainly under the control of cranial nerve I, although irritant, unpleasant nasal sensations are carried by cranial nerves V, IX and X. Anosmia is a complete loss of the sense of smell and hyposmia is a decreased sense of smell:

- A conductive deficit of smell occurs if odorant molecules do not reach the olfactory epithelium high in the nose.
- A sensorineural loss of smell is incurred if the neural transmission of smell is affected.
- Some conditions predispose to a mixed (conductive and sensorineural) loss of smell.

The main cause of a loss of smell is nasal obstruction due to upper respiratory infection or nasal polyps. Other causes include sinonasal disease, old age, drug therapy and head injury/trauma. It is difficult to predict the speed and extent of recovery in the latter causes. In many patients anosmia is idiopathic, but before this diagnosis is accepted an assessment of the patient for the possibility of an intranasal tumour or intracranial mass should be undertaken.

Fractured nose

People with a fractured nose present with epistaxis, bruising of the eyes and nasal bridge swelling. Initially, it is often difficult to assess if the bones are deviated, particularly if there is significant swelling. Reduction of the fracture should be undertaken in the first 2 weeks after injury and can be achieved by manipulation. However, if the fracture sets, a more formal rhinoplasty may have to be undertaken at a later stage. The patient should be examined for a head injury and the nose should also be checked for a septal haematoma. This is painful, can cause nasal obstruction, is fluctuant to touch on the nasal septum and requires immediate drainage.

**The Throat**

### Anatomy and physiology

The throat can be considered as the oral cavity, the pharynx and the larynx (Fig. 21.6). The oral cavity extends from the lips to the tonsils. The pharynx can be divided into three areas:

- **The nasopharynx**: extending from the posterior nasal openings to the soft palate
- **The oropharynx**: extending from the soft palate to the tip of the epiglottis
- **The hypopharynx**: extending from the tip of the epiglottis to just below the level of the cricoid cartilage where it is continuous with the oesophagus.

Lying within the hypopharynx is the larynx. This consists of cartilaginous, ligamentous and muscular tissue with the primary function of protecting the distal airway. The pharynx is innervated from the pharyngeal plexus.

In the larynx, there are two vocal cords which abduct (open) during inspiration and adduct (close) to protect the airway and for voice production (phonation). The main nerve supply of the vocal cords comes from the recurrent laryngeal nerves (branches of the vagus nerve) which arise in the neck, but on the left side passes down around the aortic arch and then ascends in the tracheo-oesophageal groove to the larynx.

Normal vocal cords in phonation vibrate between 90 (male) and 180 (female) times per second, giving the voice its pitch or frequency. A healthy voice requires full closure of the vocal cords with a smooth, regular pattern of vibration, and any pathology that prevents full closure will result in air escaping between the vocal cords during phonation and a ‘breathy’ voice.
Examination

Good illumination is essential. Look at teeth, gums, tongue, floor of mouth and oral cavity. Tonsils, soft palate and uvula are easily seen, and a gag reflex (see p. 1080) is present. The remainder of the pharynx and larynx can be inspected with a laryngeal mirror or flexible nasendoscope.

Examination of the neck for lymph nodes and other masses is also performed.

Common disorders

Hoarseness (dysphonia)

There are three essential components for voice production: an air source (the lungs); a vibratory source (the vocal cords); and a resonating chamber (the pharynx, the nasal and oral cavities). Although chest and nasal disorders can affect the voice, the majority of hoarseness is due to laryngeal pathology.

Inflammation which increases the ‘mass’ of the vocal cords will cause the vocal cord frequency to fall, giving a much deeper voice. Thus listening to a patient’s voice can often give a diagnosis before the vocal cords are examined.

Nodules

Nodules (always bilateral and commoner in females) and polyps are found on the free edge of the vocal cord preventing full closure and giving a ‘breathy, harsh’ voice. They are commonly found in professions that rely on their voice for their livelihood, such as teachers, singers and lawyers. They are usually related to poor technique of voice production and can usually be cured with speech therapy. If surgery is needed, great care must be taken to remain in the superficial layers of the vocal cord in order to prevent deep scarring which leaves the voice permanently hoarse.

Reinke’s oedema

This is due to a collection of tissue fluid in the subepithelial layer of the vocal cord. The vocal cord has poor lymphatic drainage, predisposing it to oedema. Reinke’s oedema is associated with irritation of the vocal cords with smoking, voice abuse, acid reflux and very rarely hypothyroidism. Treatment is to remove the irritation in most cases but surgery to incise the cords and reduce the oedema will also allow the voice to return to its normal pitch.

Acute-onset hoarseness

Hoarseness, in a smoker, is a danger sign. Any patient with a hoarse voice for over 6 weeks should be seen by an ENT surgeon. Other red flag symptoms are also to be enquired about and will require urgent laryngoscopy (Emergency Box 21.1). The voice may be deep, harsh and breathy indicating incompetence of the larynx. This can be done under local anaesthesia, giving an immediate result whatever the long-term prognosis of the chest pathology.

Stridor

Stridor or noisy breathing can be divided into:
- **Inspiratory:** obstruction is at the level of the vocal cords or above
- **Mixed** (both inspiratory and expiratory): obstruction is in the subglottis or extrathoracic trachea
- **Expiratory:** obstruction is in the intrathoracic trachea or distal airways.

All people with stridor, both paediatric and adult, are potentially at risk of asphyxiation and should be investigated fully. Severe stridor may be an indication for either intubation or a tracheostomy (Table 21.3).

Tracheostomy

Tracheostomy tubes are:
- **Cuffed or uncuffed.** A high-volume, low-pressure cuff is used to prevent aspiration and to allow positive-pressure ventilation.
- **Fenestrated or unfenestrated.** A fenestrated cuff has a small hole on the greater curvature of the tube (both inspiratory and expiratory). A fenestrated cuff allows air to escape upwards to the vocal cords and therefore the patient can speak. This tube often has a valve which allows air to enter from the stoma but closes on expiration, directing the air through the fenestration.

Most long-term tracheostomy tubes have an inner and outer tube. The inner tube fits inside the outer tube and projects beyond its lower end. A major problem with a tracheostomy tube is crusting of its distal end with dried secretions, and this arrangement allows the inner tube to be removed, cleaned and replaced as frequently as required, without disrupting the outer tube.

When to decannulate a patient is often a difficult issue if laryngeal competence is unclear. Movement of the vocal cords requires an ENT examination but owing to the risk of aspiration, a speech therapist’s opinion can also be useful. The tracheostomy tube itself can also give problems due to compression of the oesophagus with a cuffed tube and by preventing the larynx from rising during normal swallowing.
**Special senses**

**Tonsillitis and pharyngitis**

Viral infections of the throat are common and, although many practitioners are under pressure from the patient to give antibiotics, the vast majority are usually self-limiting, settling with bed rest, analgesia and encouraging fluid intake. Fungal infections, usually candidiasis, are uncommon and may indicate an immunocompromised patient or undiagnosed diabetes.

**Tonsillitis**

Tonsillitis, with a good history of pyrexia, dysphagia, lymphadenopathy and severe malaise, is usually bacterial with β-haemolytic streptococcus the commonest organism.

**Glandular fever** (see p. 99)

This can also present with tonsillitis. Although clinically the tonsils have a white exudate, there is often a petechial rash on the soft palate and an accompanying lymphadenopathy.

**Quinsy**

Quinsy is a collection of pus outside the capsule of the tonsil usually located adjacent to its superior pole. The patient often has trismus making examination difficult but the pus pushes the uvula across the midline to the opposite side. The area is usually hyperaemic and smooth but unilateral tonsillar ulceration is more likely to be a malignancy. In either case urgent referral to an ENT specialist is essential.

**Indications for a tonsillectomy** are shown in Table 21.4. This is carried out under general anaesthetic and current surgical techniques include diathermy dissection, laser excision and coblation (using an ultrasonic dissecting probe). There are strong advocates for each technique and much will depend on the individual surgeon’s preference. Some departments now carry out tonsillectomy as a day case procedure as most reactionary bleeding will occur within the first 8 hours postoperatively.

**Snoring**

Snoring is due to vibration of soft tissue above the level of the larynx. It is a common condition (50% of 50-year-old males will snore to some extent) and can be considered to be related to obstruction of three potential areas: the nose, mouth and nasopharynx or hypopharynx. Difficulty in swallowing is a common symptom but can be due to a variety of causes.

**Figure 21.7 Pharyngeal pouch. (a) Position of pharyngeal pouch. (b) Stapling of the party wall between oesophagus and pouch.**

**A pharyngeal pouch** is a herniation of mucosa through the fibres of the inferior pharyngeal constrictor muscle (cricopharyngeus) (Fig. 21.7a). An area of weakness known as Killian’s dehiscence allows a pulsion diverticulum to form. This will collect food, which may regurgitate into the mouth or even down to the lungs at night with secondary pneumonia. Diagnosis is made with a barium swallow and treatment is surgical, either via an external approach through the neck where the pouch is excised or more commonly endoscopically with stapling of the party wall (Fig. 21.7b).

**Dysphagia**

Difficulty in swallowing is a common symptom but can be the presenting feature of carcinoma of the pharynx and therefore requires investigation. Dysphagia (see p. 237) occurs because of any lesion between the throat and stomach. The two conditions described here are the ones usually dealt with by ENT departments. Gastroenterology departments see causes further down the gut.

**Foreign bodies** in the pharynx can be divided into three general categories: soft food bolus, coins (smooth), bones (sharp). Soft food bolus can be initially treated conservatively with muscle relaxants for 24 hours. Impacted coins should be removed at the earliest opportunity but sharp objects require emergency removal to avoid perforation of the muscle wall.

If the patient perceives the foreign body to be to one side, then it should be above the cricopharyngeus and an ENT examination will locate it; common areas are the tonsillar fossae, base of tongue, posterior pharyngeal wall and valleculae. Radiology will identify coins, and it can be a clinical decision to see whether a coin will pass down to the stomach, in which case no further treatment is required as it will exit naturally. Some departments advocate the use of a metal detector to monitor the position of the coin in the patient, who is usually a child or has a mental disorder. Fish can be divided into those with a bony skeleton (teleosts) and those with a cartilaginous skeleton (elasmobranchs), and therefore radiology is useful only in some cases. Radiology can also
identify air in the cervical oesophagus indicating a radiolucent foreign body lying distally. A soft tissue lateral neck radiograph is the investigation of choice to delineate some of the features above.

**Globus pharyngeus**

This is a functional disorder and is not a true dysphagia. It is a condition with classic symptoms of an intermittent sensation of a lump in the throat. This is perceived to be in the midline at the level of the cricoid cartilage and is worse when swallowing saliva; indeed it often disappears when ingesting food or liquids. ENT examination is clear and normal laryngeal mobility can be felt when gently rocking the larynx across the postcricoid tissues. A contrast swallow will show not only the structures below the pharynx but also assess the swallowing dynamically. Any suspicious area will require an endoscopy with biopsy.

---

**DISORDERS OF THE EYE**

Most of the major and common types of eye disease are covered below. However, diabetic eye disease and hypertensive eye disease are discussed elsewhere.

**Applied anatomy and physiology**

The average length of the human eye is 24 mm. It is essentially made up of two segments:

- The anterior, smaller segment is transparent and coated by the cornea; its radius is approximately 8 mm
- The larger posterior segment is coated by the opaque sclera and is approximately 12 mm in radius

It is the cornea and the sclera that give the mechanical strength and shape to the exposed surface of the eye.

**The cornea** occupies the central aspect of the globe and is one of the most richly innervated tissues in the body. This clear, transparent and avascular structure, measuring 12 mm horizontally and 11 mm vertically, provides 78% of the focusing power of the eye. The eyelids prevent the cornea from drying and becoming an irregular surface by distributing the tear film over the surface of the globe with each blink.

Anatomically the cornea is made up of five layers:

- Epithelium
- Bowman’s layer (membrane)
- Stroma
- Descemet’s membrane
- Endothelium.

The endothelial cells lining the inner surface of the cornea are responsible for maintaining the clarity of the cornea by continuously pumping fluid out of the tissue. Any factor which alters the function of these cells will result in corneal oedema and cause blurred vision.

**The sclera** is a white opaque structure covering four-fifths of the globe and is continuous with the cornea at the limbus. The six extraocular muscles responsible for eye movements are attached to the sclera and the optic nerve perforates it posteriorly.

**The conjunctiva** covers the anterior surface of the sclera. This richly vascularized and innervated mucous membrane stretches from the limbus over the anterior sclera (where it is called the bulbar conjunctiva) and is then reflected onto the undersurface of the upper and lower lids (the tarsal conjunctiva). The area of conjunctival reflection under the lids makes up the upper and lower fornix.

**The anterior chamber** is the space between the cornea and the iris, and is filled with aqueous humour (Fig. 21.8). This fluid is produced by the ciliary body (2 μL/min) and provides nutrients and oxygen to the avascular cornea. The outflow of aqueous humour is through the trabecular meshwork and canal of Schlemm adjacent to the limbus. Any factor which impedes its outflow will increase the intraocular pressure. The upper range of normal for intraocular pressure is 21 mmHg.

**The uveal tract** is made up of the iris anteriorly, the ciliary body and the choroid.

The **iris** is the coloured part of the eye under the transparent cornea. The muscles of the iris diaphragm regulate the size of the pupil, thereby controlling the amount of light entering the eye. The muscles of the **ciliary** body control the accommodation of the lens and the secretory epithelium produces the aqueous humour (see above). The highly vascular **choroid** lines the inner aspect of the sclera and upon this lies the retina.

**The lens** lies immediately posterior to the pupil and anterior to the vitreous humour. It is a transparent biconvex structure and is responsible for 22% of the refractive power of the eye. By changing its shape it can alter its refractive power and help to focus objects at different distances from the eye. By the fourth decade of life this ability to change shape starts to decline and with time the lens starts to become less transparent and cataracts begin to develop.

**The vitreous humour** fills the cavity between the retina and the lens.

**The retina** is a multi-layered structure. The metabolically active region of the retina is represented in Figure 21.9. There are two types of photoreceptors in the retina, rods and cones. There are approximately 6 million cones mainly confined to the macula and these are responsible for detailed central vision and colour vision. The peripheral retina has around 125 million rods that are responsible for peripheral vision. The axons of the ganglion cells form the optic nerve (or disc) of the eye (Fig. 21.10).

**The blood supply to the eye** is via the ophthalmic artery and, in particular, the central retinal artery is responsible for supplying the inner retinal layers. Venous return is through the central retinal and ophthalmic veins. Local lymphatic drainage is to the preauricular and submental nodes.

**The sensory innervation of the eye** is through the trigeminal (V) nerve. The six extraocular muscles are supplied by different nerves.

- Oculomotor (III) nerve: medial, superior, inferior rectus and inferior oblique
- Trochlear (IV) nerve: superior oblique
- Abducentes (VI) nerve: lateral rectus.

The oculomotor (III) nerve also supplies the upper lid and indirectly the pupil (parasympathetic fibres are attached to it). The facial (VII) nerve supplies the orbicularis and other muscles of facial expression.
It is essential to adopt a systematic approach to the examination of the eye. Different approaches and instruments are necessary for examination of the lids, anterior and posterior segments as well as extraocular movements. It is vital that an accurate visual acuity is recorded in all people with an eye problem. The Snellen eye chart is the most commonly used, but use of the LogMAR chart (logarithm of the Minimum Angle of Resolution) is increasing, largely due to its necessity in studies or research. Unlike the Snellen and other visual acuity charts, the LogMAR chart has equal graduation between the letters on a line as well as the space between lines. There is also a fixed number of letters, five, on each line. Research done using a logarithmic progression in size of letters on a test chart gives most accurate visual acuity measurement.

**Visual acuity**

The visual acuity of each eye is recorded in two ways: distance visual acuity and near visual acuity. Distance vision is measured in Snellen letters or, ever more commonly, in LogMAR letters or figures of different sizes, constructed to subtend 5′ (5 min) of arc at the nodal point to give a value of visual acuity. The recording is given as an expression of the line of letters which can be discerned at a particular distance, usually 6 metres (or 20 feet). For example 6/60, where 6 equals the distance of the chart from the eye in metres and 60 equals the distance at which the letter subtends 5′ at the nodal point.

**Refractive errors**

The eye projects a sharp and focused image onto the retina. Refractive errors refer to any abnormality in the focusing mechanism of the eye and not to any opacity in the system such as a corneal or retinal scar.

The refraction of light in emmetropic (normal), myopic (short-sighted, negative lenses will correct) and hypermetropic (long-sighted, positive lenses will correct) eyes is shown in Figure 21.11.

**History and examination**

A careful and detailed history gives most of the facts needed to make a working diagnosis. The eye has limited mechanisms by which it can convey a diseased state. Common symptoms include alteration in visual acuity, redness, pain, discharge and photophobia.
Astigmatism is a retractive error of the eye in which there is a different degree of refraction in the different meridians of curvature. It may be myopic in one plane and hypermetropic or emmetropic in the other plane. In this situation the front surface of the eye is more rugby ball shaped than football shaped.

Presbyopia is the term used to describe the normal ageing of the lens and leads to a change in the refractive state of the eye. As the lens ages it becomes less able to alter its curvature and this causes difficulty with near vision, especially reading.

Treatment

Errors of refraction can be corrected by using spectacles or contact lenses. The latter often results in better quality vision, but carries the risk of infection. They may be the only option in some refractive states such as keratoconus, a degenerative disorder of the eye in which structural changes within the cornea cause it to thin and become a more conical shape than its normal gradual curve. A number of surgical techniques can correct these errors of refraction, with varying degrees of accuracy. The most popular method is to use an excimer laser to re-profile the corneal curvature (PRK, LASEK, LASIK). The laser either removes corneal tissue centrally to improve vision or reshapes the cornea by using radiofrequency ablation.

Disorders of the lids

The lids afford protection to the eyes and help to distribute the tear film over the front surface of the globe. Excess tears are drained via the punctae and lacrimal system to the nose (Fig. 21.12). Malposition of the lids, factors which affect blinking or lacrimal drainage, can all cause problems.

Entropion. The lid margin rolls inwards so that the lashes are against the globe (Fig. 21.13a). The lashes act as a foreign body and cause irritation, leading to a red eye which can mimic conjunctivitis. Occasionally the constant rubbing of lashes against the cornea causes an abrasion. The commonest cause is ageing and surgery is usually required.

Ectropion. The lid margin rolls outwards and is not apposed to the globe. As a result the lacrimal puncta is not in the correct anatomical position to drain tears and patients usually complain of a watery eye. Underlying factors include age, VII nerve palsy and cicatricial skin conditions. Surgery is usually required.

Dacryocystitis. Patients who have inflammation of the lacrimal sac usually present with a painful lump at the side of the nose adjacent to the lower lid (Fig. 21.13b). This should be treated with oral broad-spectrum antibiotics such as cefalexin, and patients should be watched carefully for signs of cellulitis. All patients should be referred to the ophthalmologist as some have an underlying mucocele or dilated sac, and will require surgery.

Blepharitis. This is an extremely common condition where inflammation of the lid margins may involve the lashes and lash follicles (Fig. 21.14a) resulting in styes, or inflammation and blockage of meibomian glands (Fig. 21.14b) leading to chalazion (Fig. 21.14c). Common underlying causes of blepharitis include meibomian gland dysfunction, seborrhoea and *Staphylococcus aureus* infection. Patients can be asymptomatic or complain of itchy, burning eyes because of tear film instability resulting from meibomian gland dysfunction. *Staphylococcus aureus* is frequently responsible for chronic blepharo-conjunctivitis and some patients may develop keratitis in the cornea (Fig. 21.15).

Treatment of blepharitis. Lid hygiene is the mainstay of treatment as it helps to reduce the bacterial load and unblock meibomian glands. A short course of topical chloramphenicol or fusidic acid is useful in chronic cases but in severe cases or cases where acne rosacea is suspected, oral doxycycline may be required. Some patients are left with a lump once the acute inflammatory phase has subsided. Most of these patients find the lump, or chalazion, cosmetically unacceptable and require incision and curettage. People with keratitis should be referred to the ophthalmologist for topical steroids.

Conjunctivitis

The commonest cause of a red eye, inflammation of the conjunctiva can arise from a number of causes, with viral, bacterial and allergic being the commonest. Common features in all types include soreness, redness and discharge, and in general the visual acuity is good. History should include the speed of onset of the inflammation, the colour and consistency of the discharge, whether the eye is itchy, and if there has been a recent history of a cold or sore throat. In the neonate it is vital to exclude gonococcal or chlamydial conjunctivitis associated with maternal sexually transmitted infection. The differential diagnosis of conjunctivitis is shown in Table 21.5.

![Figure 21.12 Photograph of the right eye.](image1)

![Figure 21.13 Disorders of the eyelid. (a) Lid entropion. The lower lid appears inverted. (b) Acute dacryocystitis showing a lump on the side of the nose.](image2)
Bacterial conjunctivitis

Bacterial conjunctivitis is uncommon, making up 5% of all cases of conjunctivitis. In the vast majority of patients it causes a sore or gritty eye in the presence of good vision. Bacterial conjunctivitis is invariably bilateral and should be suspected when conjunctival inflammation is associated with a purulent discharge.

Clinical features

Gonococcal conjunctivitis should be suspected when the onset of symptoms is rapid, the discharge is copious, and ocular inflammation includes chemosis (conjunctival oedema) and lid oedema. Gonococci are a cause of conjunctivitis giving rise to a palpable preauricular node. Less acute or subacute purulent conjunctivitis with moderate discharge can be attributed to organisms such as Haemophilus influenzae and Streptococcus pneumoniae. Chronic conjunctivitis is usually associated with mild conjunctival injection and scant purulent discharge. Common organisms include Staphylococcus aureus and Moraxella lacunata.

Treatment

Prompt treatment with oral and topical penicillin is given in gonococcal conjunctivitis to ensure a reduced rate of corneal perforation. A Gram-stain of the conjunctival swab can quickly confirm the presence of diplococci. Gonococcal conjunctivitis is a notifiable disease in the UK. Empirical treatment for both subacute and chronic conjunctivitis involves a topical broad-spectrum antibiotic such as chloramphenicol.

Chlamydial conjunctivitis

Chlamydia trachomatis (see p. 164) is seen in developed countries as a sexually transmitted infection that is most prevalent in sexually active adolescents and young adults. Direct or indirect contact with genital secretions is the usual route of infections but shared eye cosmetics can also be involved. Neonatal chlamydial conjunctivitis is a notifiable disease in the UK and should be suspected in newborns with a red eye. Mothers should be asked about sexually transmitted infections.

Trachoma caused by the same organism, but not usually sexually transmitted, is found mainly in the tropics and the Middle East and is a very common cause of blindness in the world (see p. 133). Chronic conjunctival inflammation causes progressive scarring, trichiasis, entropion and subsequent corneal scarring which leads to severe visual impairment or blindness from corneal opacification or ulceration.

Clinical features

The onset of symptoms is slow, and patients may complain of mild discomfort for weeks. In these cases the red eye is associated with a scanty mucopurulent discharge and a palpable preauricular node. In chronic cases it is not unusual to see superior corneal vascularization. In neonates the onset of the red eye is typically around 2 weeks after birth, whereas gonococcal conjunctivitis occurs within days of birth. Conjunctival swabs should be taken and a nucleic acid amplification test (NAAT) performed (p. 163) prior to commencement of treatment.

Treatment

Topical erythromycin twice daily is commenced and patients referred to the genitourinary physician. Neonates should be started on topical erythromycin and referred to the paediatrician as there may be associated otitis media or pneumonia.
Viral conjunctivitis

Adenoviral conjunctivitis
This is highly contagious and can cause epidemics in communities. Transmission is through direct or indirect contact with infected individuals. The onset of symptoms may be preceded by a cold or flu-like symptoms. Inflammation is commonly associated with chemosis, lid oedema and a palpable preauricular lymph node. Some patients develop a membrane on the tarsal conjunctiva and haemorrhage on the bulbar conjunctiva. Viral conjunctivitis can cause deterioration in visual acuity owing to corneal involvement (focal areas of inflammation). In 50% of the patients the conjunctivitis is unilateral.

Treatment
The condition is largely self-limiting in the majority of cases. Lubricants together with a cold compress can be soothing for patients. Strict hygiene and keeping towels separate from the rest of the household goes a long way towards reducing the spread of the infection. In people with corneal involvement or intense conjunctival inflammation, topical steroids are indicated.

Herpes simplex conjunctivitis
Primary ocular herpes simplex conjunctivitis is typically unilateral. It usually causes a palpable preauricular lymph node and cutaneous vesicles develop on the eyelids and the skin around the eyes in the majority of patients. Over 50% of these patients develop a dendritic corneal ulcer (Fig. 21.17). The organism responsible for this condition is the herpes simplex virus (HSV), which is usually HSV-1 but HSV-2 can give rise to ocular infection.

Treatment
Primary ocular HSV infection is self-limiting but most clinicians choose to treat it with topical aciclovir in order to limit the spread of the infection. In people with corneal involvement or intense conjunctival inflammation, topical steroids are indicated.

Molluscum contagiosum conjunctivitis
This is typically unilateral and produces a red eye that generally goes unrecognized and comes to the forefront because patients fail to improve and the cornea starts to become involved. On close inspection, pearly umbilicated nodules, filled with the DNA poxvirus, can be seen on the lid margin.

Treatment
This includes curett ing the central portion of the lesion, freezing the centre or completely excising the lesion. If the corneal involvement is severe or the eye is very inflamed, a short course of topical steroids such as prednisolone 0.5% or dexamethasone 0.1% is helpful.

Phthiriasis palpebrarum
Phthiriasis palpebrarum is an eyelid infestation caused by Phthirius pubis, or crab lice. Infestation of the cilia and eyelid is rare. It leads to blepharitis with marked conjunctival inflammation, preauricular lymphadenopathy, and rarely secondary infection at the site of lice bite.

Treatment
Mechanical removal of the lice with fine forceps, physostigmine 1.25% and pilocarpine gel 4% are all effective treatments.

Allergic conjunctivitis
There are five main types of allergic conjunctivitis: seasonal, perennial, vernal, atopic and giant papillary. Both seasonal and perennial allergic conjunctivitis are acute allergic conjunctival disorders. Symptoms include itching and pink to reddish eyes. These two eye conditions are mediated by mast cells and can be easily treated with cold compresses, eyewashes with tear substitutes, and avoidance of allergens. The last three are difficult to treat, chronic and can be sight-threatening. They should be referred to an ophthalmologist.

Seasonal/perennial conjunctivitis
Seasonal allergic conjunctivitis and perennial conjunctivitis, affecting 20% of the general population in the UK, is an allergic reaction to grass, pollen and fungal spores and occurs mainly in spring and summer. Perennial allergic conjunctivitis occurs all year round but peaks in the autumn and includes allergens such as house-dust mites.

The main symptoms include itching, redness, soreness, watering and a stringy discharge. Occasionally the conjunctiva may become so hyperaemic that chemosis results. This is usually associated with swollen lids.

Treatment
Reducing the allergen load (reducing dust, p. 825) is helpful. Medical treatment includes the use of antihistamine drops such as azelastine and emedastine together with topical mast cell-stabilizing agents such as sodium cromoglicate and nedocromil. Olopatadine (twice daily) has dual action and is very effective. Corticosteroid drops should be avoided. Oral antihistamines help the itching.

Corneal disorders

Trauma

Corneal abrasions
Trauma resulting in the removal of a focal area of epithelium on the cornea is very common. Abrasions usually occur
when the eye is accidentally poked with a finger, a foreign body (FB) flies into the eye or something brushes against the eye.

**Clinical features**

Symptoms include severe pain, due to exposure of the corneal nerve endings, lacrimation and inability to open the eye (blepharospasm). Blinking and eye movement can aggravate the pain and foreign body sensation. The visual acuity is usually reduced. Most cases will need topical anaesthetic drops such as oxybuprocaine or tetracaine to be administered before it is possible to examine the eye. The cornea should be inspected with a blue light after instillation of fluorescein drops. The orange dye will stain the area of the abrasion. Under blue light the abrasion lights up as green. Occasionally FBs can lodge on the undersurface of the upper lid and give rise to linear vertical abrasions. Eversion of the upper lid is necessary in all cases of abrasions (Fig. 21.18).

**Treatment**

Treatment consists of a broad-spectrum topical antibiotic such as chloramphenicol drops or ointment four times a day for 5 days. The role of padding is controversial but common practice is to pad the affected eye for 24 hours once chloramphenicol ointment has been applied to the eye.

**Corneal foreign body**

Occasionally when something flies into the eye it gets stuck on the cornea (Fig. 21.19a). It may be associated with lacrimation and photophobia. Examination is best attempted following instillation of a topical anaesthetic and should include evertting the upper lid (Fig. 21.19b). Corneal foreign bodies can usually be seen directly with a white light.

**Treatment**

The corneal FB should be removed and the patient given a topical antibiotic such as chloramphenicol four times a day for 5 days or fusidic acid twice a day for 5 days.

**Keratitis**

This is a general term to describe corneal inflammation. Common causes include herpes simplex virus, contact lens-associated infection and blepharitis. Symptoms include the sensation of a foreign body or pain (depending on the size and depth of the ulcer), photophobia and lacrimation. Vision is reduced if the ulcer affects the visual axis.

**Herpes simplex keratitis**

Corneal epithelial cells infected with the virus eventually undergo lysis and form an ulcer which is typically dendritic in shape (Fig. 21.17). The ulcer stains with fluorescein and can be observed easily with a blue light. Topical immunosuppression, e.g. steroid drops, or systemic immunosuppression, e.g. AIDS, can lead to the centrifugal spread of the virus such that the ulcer increases in area and is referred to as a geographic ulcer. Recurrent attacks of HSV keratitis can be triggered by ultraviolet light, stress and menstruation. All these factors are responsible for activating the virus, which normally lies dormant in the ganglion of the Vth nerve.

**Treatment**

Aciclovir ointment five times a day for 2 weeks is usually very effective.

**Contact lens-related keratitis**

A small number of contact lens wearers develop infective corneal ulcers which are potentially sight-threatening (Fig. 21.21). The organisms usually responsible include Gram-positive and Gram-negative bacteria. Patients should be referred to an ophthalmologist for scraping of the ulcer and commencement of antibiotic treatment.

**Corneal dystrophy**

Fuchs’ corneal dystrophy is a genetically associated degenerative disorder leading to corneal oedema and vision loss.
Disorders of the eye

The gene is TCF4. It affects both eyes, is commoner in females, and is of gradual onset leading to blindness in the 40–60 age group. There is an accumulation of deposits (guttae) in the cornea with thickening of Descemet’s membrane. Treatment is by corneal transplantation.

Cataracts

Cataract (Fig. 21.22a,b) is by far the commonest cause of preventable blindness in the world with an effective surgical treatment. In the UK, approximately 250,000 cataract operations are performed each year, making it the commonest surgical procedure.

Aetiology

Age-related opacification of the lens (cataract) is the commonest cause of visual impairment with 30% of people over 65 years having visual acuities below that required for driving (Snellen acuity less than 6/12). The common causes of cataracts are summarized in Table 21.6.

In young patients, familial or congenital causes should be excluded. Any history of ocular inflammation is noted. Cataracts diagnosed in infants demand urgent referral to the ophthalmologist in order to minimize the subsequent development of amblyopia.

Clinical features

Gradual painless deterioration of vision is the commonest symptom. Other symptoms are dependent upon the type of cataract, for example a posterior capsular type would lead to glare and problems with night driving. Early changes in the lens are correctable by spectacles but eventually the opacification needs surgical intervention.

Investigations

Blood glucose, serum calcium and liver biochemistry should be measured to diagnose metabolic disorders.

Treatment

Small incision extracapsular or phacoemulsification cataract extraction with the insertion of an intraocular lens is the treatment of choice (Fig. 21.22c).

Glaucoma

This is a group of diseases in which the pressure inside the eye is sufficiently elevated to cause optic nerve damage and result in visual field defects (Fig. 21.23). Normal intraocular pressure (IOP) is 10–21 mmHg. Some types of glaucoma can result in an IOP exceeding 70 mmHg. Glaucoma is the second commonest cause of blindness worldwide and the third commonest cause of blind registration in the UK.

Primary open-angle glaucoma (POAG)

This is the commonest form of glaucoma. High intraocular pressures result from reduced outflow of aqueous humour through the trabecular meshwork. Common risk factors include age (0.02% of 40-year-olds versus 10% of 80-year-olds), race (black Africans are at five times greater risk than whites), positive family history and myopia.

POAG causes a gradual, insidious, painless loss of peripheral visual field. It is initially asymptomatic and the central vision remains good until the end-stage of the disease. Usually glaucoma is identified during a routine ophthalmic

Further reading

Acute angle-closure glaucoma (AACG)

This is an ophthalmic emergency. There is a sudden rise in intraocular pressure to levels greater than 50 mmHg. This occurs due to reduced aqueous drainage as a result of the ageing lens pushing the iris forward against the trabecular meshwork. People most at risk of developing AACG are those with shallow anterior chambers such as hypermetropes and women. The attack is more likely to occur under reduced light conditions when the pupil is dilated.

Red eye and other signs and symptoms

AACG causes sudden onset of a red painful eye and blurred vision. Patients become unwell with nausea and vomiting and complain of headache and severe ocular pain. The eye is injected, tender and feels hard. The cornea is hazy and the pupil is semi-dilated (Fig. 21.24). Table 21.7 shows the differential diagnosis of the acute red eye. Emergency Box 21.2 shows features that require urgent referral to an ophthalmologist.

Treatment

Prompt treatment is required to preserve sight and includes:

- Intravenous acetazolamide 500 mg (provided there are no contraindications) to reduce IOP, and
- Instillation of pilocarpine 4% drops to constrict the pupil to improve aqueous outflow and prevent iris adhesion to the trabecular meshwork.

Other topical drops such as beta-blockers and prostaglandin analogues can also be instilled if available, provided there are no contraindications. Analgesia and antiemetics are given as required.

Patients must be referred to an ophthalmologist immediately so that reduction in IOP can be monitored and other agents such as oral glycerol or i.v. mannitol can be administered to non-responding patients. Definitive treatment involves making a hole in the periphery of the iris of both eyes either by laser or surgically.

Uveitis

Uveitis is inflammation of the uveal tract, which includes the iris, ciliary body and choroid. Inflammation confined to the anterior segment of the eye (in front of the iris) is referred to as iritis or anterior uveitis, that involving the ciliary body is referred to as intermediate uveitis whilst inflammation of the choroid is termed posterior uveitis. If all three regions are involved then the term panuveitis is used. For posterior uveitis, referral to an ophthalmologist is required.

The most common symptoms of uveitis are blurred vision, pain, redness, photophobia and floaters. Each symptom is
Disorders of the eye

Disorders of the retina

Central retinal vein occlusion (CRVO)

This usually leads to profound sudden painless loss of vision with thrombosis of the central retinal vein at or posterior to the lamina cribrosa where the optic nerve exits the globe. The thrombus causes obstruction to the outflow of blood leading to a rise in intravascular pressure. This results in dilated veins, retinal haemorrhage, cotton wool spots, and abnormal leakage of fluid from vessels resulting in retinal oedema (Fig. 21.26). In severe cases, an afferent papillary defect is present and this suggests the ischaemic variant. Predisposing factors include increasing age, hypertension and cardiovascular disease, diabetes, glaucoma, and in the younger age group, blood dyscrasias and vasculitis.

Treatment

Treatment of any underlying medical condition is mandatory. Referral to an ophthalmologist is essential to monitor the eye, as some patients can develop retinal ischaemia with resulting neovascularization of the retina and iris. Panretinal photocoagulation should be commenced if there is neovascularization, and intravitreal steroid or anti-vascular endothelial growth factor (anti-VEGF) therapy is also used if there is macular oedema. Patients who develop iris neovascularization, rubeosis, are at risk of developing rubeotic glaucoma.

Central retinal artery occlusion (CRAO)

This results in sudden painless severe loss of vision. Retinal arterial occlusion results in infarction of the inner two-thirds of the retina. The arteries become narrow and the retina becomes opaque and oedematous. A cherry red spot is seen at the fovea because the choroidal vasculature shows up through the thinnest part of the retina (Fig. 21.27). An afferent papillary defect is usually present.

Arteriosclerosis-related thrombosis is the most common cause of CRAO. Emboli from atheromas and diseased heart valves are other causes. Giant cell arteritis (see p. 543) must be excluded.

Treatment

CRAO is an ophthalmic emergency since studies have shown that irreversible retinal damage occurs after 90 minutes of onset. Ocular massage and 500 mg i.v. acetazolamide help to reduce ocular pressure and may help in dislodging the emboli. Breathing into a paper bag allows a build-up of carbon dioxide which acts as a vasodilator and so helps...
in dislodging the emboli. Other options include making a
corneal paracentesis to drain off some aqueous humour,
thereby reducing the intraocular pressure.

People with CRAO should have a thorough medical evalua-
tion to determine the aetiology of the emboli or thrombus.
Some patients may present with transient loss of vision or
amaurosis fugax (see p. 1098). All people with CRAO and
amaurosis fugax should be started on oral aspirin if it is not
medically contraindicated.

**Retinal detachment**

This causes a painless progressive visual field loss. The
shadow corresponds to the area of detached retina. If the
detachment affects the macula, central vision will be lost.
Following a tear in the retina, fluid collects in the potential
space between the sensory retina and the pigment epithelium
(Fig. 21.28). Patients usually report a sudden onset of floaters
often associated with flashes of light (photopsia) prior to the
detachment. These patients should be referred to an ophthal-
mologist for a detailed fundal examination.

**Retinitis pigmentosa**

This is a common chronic inherited degenerative disease of
the retina which can be primary or part of a syndrome and
leads to blindness. There is constriction of the peripheral
vision leading to tunnel vision and progressive loss of night
vision.

Ophthalmoscopy shows bone spicule deposits and attenu-
ated retinal vessels. Several genes are implicated.

There is no treatment but high-dose vitamin A supple-
mentation may slow progression. Gene therapy is being
investigated.

**Age-related macular degeneration (AMD)**

This is the commonest cause of visual impairment in patients
over 50 years in the western world, and blind registration in
this age group. It affects 10% of people over 65 years and
30% over 80 years. Mutations in various genes have been
reported; fibrulin 5, complement factor H, Arg 80 Gly variant
of complement C3.

The cause is unknown but suggested risk factors include
increasing age, smoking, hypertension, hypercholesterola-
emia and ultraviolet exposure.

There are two types:

- **Non-exudative (dry) macular degeneration** describes
  a painless and progressive loss of central vision. With
  age, lipofuscin deposits (drusen) are found between the
  retinal pigment epithelium (RPE) and Bruch’s membrane
  (see Fig. 21.9 and Fig. 21.29a). Drusen may be hard or
  soft and there may be focal RPE detachment. Not all
  people with these changes will be affected visually but
  some develop distortion and blurring of their central
  vision. Extensive atrophy of RPE can occur (geographic
  atrophy).

- **Exudative (wet) AMD** (10% of cases) occurs with the
devlopment of abnormal subfoveal choroidal
neovascularization in the region of the macula and
causes severe central visual loss (Fig. 21.29b).

**Treatment**

The Age-Related Eye Disease Study (AREDS) has shown that
vitamins C and E, β-carotene, zinc and copper slow progres-
sion of the disease. People with central distortion or with
frank macular pathology should be referred urgently to the
ophthalmologist for assessment of treatment.

Anti-vascular endothelial growth factors (anti-VEGF), such
as ranibizumab and bevacizumab, are given by intravitreal
injections with great success, although the latter is more
expensive. The treatment course should be commenced as
a matter of urgency as vision is maintained in up to 95% of
patients and improves in approximately a third. Monthly
monitoring with optical coherence tomography (OCT) is rec-
ommended (Fig. 21.30). Laser treatment and photodynamic
therapy with verteporfin were the treatment of choice in the
past for the treatment of wet AMD, but now have limited
roles.

Disorders of the eye

The initial history and examination in the patient presenting with sudden loss of vision

The common causes of blindness are similar across the world (Box 21.3). In developing countries, trachoma due to Chlamydia trachomatis (see p. 164) is also a major cause, accounting for 10% of global blindness, as is onchocerciasis (river blindness, due to Onchocerca volvulus – see p. 154), which accounts for blindness in about 1 million people, although this is decreasing with treatment. In leprosy, 70% of patients have ocular involvement, and blindness occurs in 5–10% of these. Ocular involvement is common in cerebral malaria (see p. 144), although loss of vision is rare.

HIV infection can produce uveitis but the major problem is severe opportunistic infection of the eye when the CD4 count falls (see p. 178) and HAART is not available.

Vitamin A deficiency and xerophthalmia affects millions each year; the WHO classification of xerophthalmia by ocular signs is shown in Table 5.10 (see p. 206).

WHO lists the commonest causes of blindness across the world as cataract, glaucoma, acute macular degeneration, corneal opacity, diabetic retinopathy and infections from bacteria or parasites.

Severe visual loss is possible and low-vision aids, such as magnifying glasses, may help to improve a patient’s independence.

Visual loss

Every patient with unexplained sudden visual loss requires ophthalmic referral. The initial history and examination are summarized in Emergency Box 21.3.

THE IMPACT OF NEUROLOGICAL DISEASE

Neurology is a large and diverse subject which covers many conditions that require long-term coordinated care and have serious effects on the daily lives of patients and their families.

**Box 22.1 Common gait abnormalities**

- Spasticity/hemiparesis
- Parkinson’s disease
- Cerebellar ataxia
- Position sense loss (stamping)
- Distal weakness (slapping)
- Proximal weakness (waddling)
- Apraxia of gait

**COMMON SYMPTOMS AND SIGNS**

Pattern recognition in neurology – interpretation of history, symptoms and examination – is very reliable. Practical experience is vital. There are three critical questions in formulating a clinical diagnosis:

- What is/are the site(s) of the lesion(s)?
- What is the likely pathology?
- Does a recognizable disease fit this pattern?

**Difficulty walking and falls**

Change in walking pattern is a common complaint (Box 22.1). Arthritis and muscle pain make walking painful and slow (antalgic gait). The pattern of gait is valuable diagnostically.

**Spasticity and hemiparesis**

Spasticity (p. 1082), more pronounced in extensor muscles, with or without weakness, causes stiff and jerky walking. Toes of shoes become scuffed, catching level ground. Pace shortens; a narrow base is maintained. Clonus – involuntary extensor rhythmic leg jerking – may occur.

In a hemiparesis when spasticity is unilateral and weakness marked, the stiff, weak leg is circumducted and drags.

**Parkinson’s disease: shuffling gait**

There is muscular rigidity (p. 1118) throughout extensors and flexors. Power is preserved; the pace shortens, and slows to a shuffle; its base remains narrow. A stoop and diminished arm swinging become apparent. Gait becomes festinant (hurried) with short rapid steps. There is difficulty turning quickly and initiating movement, sometimes with falls. Retropulsion means small backward steps, taken involuntarily when a patient is halted.

**Cerebellar ataxia: broad-based gait**

In lateral cerebellar lobe disease (p. 1083) stance becomes broad-based, unstable and tremulous. Ataxia describes this incoordination. When walking, the person tends to veer to the side of the affected cerebellar lobe.

In disease of midline structures (cerebellar vermis), the trunk becomes unsteady without limb ataxia, with a tendency to fall backwards or sideways – truncal ataxia.

**Sensory ataxia: stamping gait**

Peripheral sensory lesions (e.g. polyneuropathy, p. 1145) cause ataxia because of loss of proprioception (position sense). Broad-based, high-stepping, stamping gait develops.

This form of ataxia is exacerbated by removal of sensory input (e.g. vision) and worse in the dark. Romberg’s test, first described in sensory ataxia of tabes dorsalis (p. 1129), becomes positive.

**Lower limb weakness: slapping and waddling gaits**

When weakness is distal, each foot must be lifted over obstacles. When ankle dorsiflexors are weak, e.g. in a common peroneal nerve palsy (p. 1144), the sole returns to the ground with an audible slap.

Weakness of proximal lower limb muscles (e.g. polymyositis, muscular dystrophy) causes difficulty rising from sitting. Walking becomes a waddle, the pelvis being poorly supported by each leg.

**Gait apraxia**

With frontal lobe disease (e.g. tumour, hydrocephalus, infarction), acquired walking skills become disorganized. Leg movement is normal when sitting or lying but initiation and organization of walking fail. Shuffling small steps (marche à petits pas), gait ignition failure or undue hesitancy may predominate. Urinary incontinence and dementia are often present.

**Falls**

Falls in the elderly are a major cause of hospital admission, e.g. following fractures. Often no precise cause can be found. A multidisciplinary approach is essential, e.g. reviewing risk factors such as rugs, stairs, footwear and home circumstances.

**Dizziness, vertigo and blackouts**

Dizziness covers many complaints, from a vague feeling of unsteadiness to severe, acute vertigo. It is frequently used to describe light-headedness, panic, anxiety, palpitations and chronic ill-health. The real nature of this symptom must be determined.

Vertigo (p. 1078) means the illusion of movement, a sensation of rotation or tipping. The patient feels the surroundings are spinning or moving. This is distressing and often accompanied by nausea or vomiting.

Blackout, like dizziness, is simply descriptive, implying either altered consciousness, visual disturbance or falling. Epilepsy (p. 1112) and syncope are mentioned in detail (p. 1116); hypoglycaemia and anaemia must be considered. Commonly no sinister cause is found. A careful history is essential.

### Functional anatomy

#### The neurone and synapse

The neurone is the functional unit of the entire nervous system (Fig. 22.1). Its cell body and axon terminate in a synapse. Size and type of each group of neurones vary. A thoracic spinal cord α-motor neurone has an axonal length of >1 metre and innervates between several hundred and 2000 muscle fibres in one leg – a motor unit. By contrast, some spinal or intracerebral interneurones have axons under 100 μm long, terminating on one neuronal cell body.

#### Neurotransmitters

Neurotransmitters are excitatory (acetylcholine, noradrenaline, adrenaline, 5-hydroxytryptamine, dopamine, glutamate and aspartate) or inhibitory (γ-aminobutyric acid (GABA), histamine and glycine). Neuropeptides, e.g. vasopressin, ACTH, substance P and opioid peptides, as well as the purines (ATP and AMP) are both excitatory and inhibitory.

Synaptic transmission is mediated by neurotransmitters released by action potentials passing down an axon. Neurotransmitters activate postsynaptic receptors and are removed by transporter proteins. The neurotransmitter-receptor reaction increases ionic permeability and propagates a further action potential. Axonal electrical activity and synaptic chemical release is the basis of neurological function.

#### Clinical features of focal brain lesions: general mechanisms

The symptoms and signs suggest the area of the brain that is malfunctioning (e.g. aphasia – the left frontal lobe, hemiparesis – internal capsule or a Bell’s palsy – VIIth cranial (facial) nerve).

Focal lesions of the cortex, and lesions throughout the nervous system, cause symptoms and signs by two processes:
Suppression or destruction of neurones and surrounding structures (Fig. 22.2). This is the commonest process – part of the system simply fails to work.

Synchronous discharge of neurones by irritative lesions (Fig. 22.3), e.g. cortical lesions, causes epilepsy, either partial or generalized.

Localization within the cerebral cortex

This subject causes unnecessary difficulty. Work on neuronal networks, functional imaging and plasticity questions the traditional views of highly specific localization of cortical function. The following paragraphs summarize areas of clinical relevance.

The dominant hemisphere (usually left)

The concept of cerebral dominance arose from a simple observation: right-handed stroke patients with acquired language disorders had destructive lesions within the left hemisphere. Right-handed (and 70% of left-handed) people have language function on the left.

More specifically, destructive lesions within the left fronto-temporo-parietal region cause disorders of communication:

- Spoken language – aphasia, also called dysphasia
- Writing – agraphia
- Reading – acquired alexia.
Severe jargon aphasia is bizarre and often mistaken for psychotic behaviour.

Patients who recover from Wernicke’s aphasia say that they found speech, both their own and others’, like an unintelligible foreign language, i.e. incomprehensible, but they could neither stop speaking nor understand speech.

**Nominal (anomic, amnestic) aphasia**

This means difficulty naming familiar objects. Naming difficulty is an early feature in all types of aphasia.

**Global (central) aphasia**

This means the combination of the expressive problems of Broca’s aphasia and the loss of comprehension of Wernicke’s with loss of both language production and understanding. This is due to widespread damage to speech areas and is the commonest aphasia after a severe left hemisphere infarct. Writing and reading are also affected.

**Dysarthria**

Dysarthria is disordered articulation – slurred speech. Language is intact. Paralysis, slowing or incoordination of muscles of articulation or local discomfort causes various patterns of dysarthria. Examples are the gravelly speech of pseudobulbar palsy (p. 1080), the jerky, ataxic speech of cerebellar lesions, the monotone of Parkinson’s, and speech in myasthenia that fatigues and dies away. Many aphasic patients are also dysarthric.

**The non-dominant hemisphere**

Disorders in right-handed patients with right hemisphere lesions are often difficult to recognize. There are abnormalities of perception of internal and external space. Examples are losing the way in familiar surroundings, failing to put on clothing correctly (dressing apraxia), or failure to draw simple shapes – constructional apraxia.

**Memory and its disorders**

Disorders of memory follow damage to the medial surfaces of both temporal lobes and their brainstem connections –

**Box 22.2 Causes of an amnestic syndrome**

- Dementia
- Alcohol (Wernicke–Korsakoff syndrome)
- Head injury (severe)
- Anoxic brain damage and following carbon monoxide poisoning
- Posterior cerebral artery occlusion (bilateral)
- Herpes simplex encephalitis
- Chronic sedative and solvent abuse
- Bilateral invasive tumours
- Following hypoglycaemia
- Arsenic poisoning (very rare)

Memory loss (the amnestic syndrome) is part of dementia (p. 1137) but also occurs as an isolated entity (Box 22.2).

**Neuroanatomy: essential elements**

For clinical purposes the complexity of neuroanatomy must be reduced to its core elements:

- Cranial nerves
- Three systems of motor control:
  - corticospinal or pyramidal system
  - extrapyramidal system
  - cerebellum
- Motor unit
- Reflex arc
- Sensory pathways and pain
- Control of the bladder and sexual function.

**CRANIAL NERVES (Table 22.3)**

**I: Olfactory nerve**

This sensory nerve arises from olfactory (smell) receptors within nasal mucosa. Branches pierce the cribriform plate and synapse in the olfactory bulb. The olfactory tract passes to the olfactory cortex.

**Anosmia** (loss of sense of smell) is caused by head injury (shearing of olfactory neurones as they pass through the cribriform plate at the skull base) or tumours of the olfactory groove (e.g. meningioma). Olfaction is temporarily (occasionally permanently) lost or diminished after upper respiratory infections and with local disorders of the nose. Many patients with gradual onset anosmia over many years may be unaware of the deficit, e.g. in Parkinson’s disease where anosmia precedes motor symptoms by many years but is often not noticed by the patient.

Detailed smell testing is difficult in routine clinical practice and rarely performed. Adequate testing requires use of commercially available kits such as scratch and sniff cards or odour filled pens with forced multiple choice identification.

**II: Optic nerve and visual system (Fig. 22.4)**

Light regulated by the pupillary aperture is converted into action potentials by retinal rod, cone and ganglion cells (see page 1055). The lens, under control of the ciliary muscle, produces the image (inverted) on the retina. Axons in the
Neurological disease

Homonymous field defects, indicating involvement of the same part of the visual field in both eyes as information from the two visual hemifields is separated beyond this point. Lesions damaging decussating nasal fibres at the optic chiasm cause bitemporal defects.

Retinal and local eye lesions

See page 1063 in Chapter 21.

Optic nerve lesions

Unilateral visual loss, commencing with a central or paracentral (off-centre) scotoma, is the hallmark of an optic nerve lesion. Because most fibres in the optic nerve subserve macular vision, lesions within the nerve disproportionately affect central vision and colour vision. A total optic nerve lesion causes unilateral blindness with loss of pupillary light reflex. Examination findings in optic neuropathy:

- Reduced acuity in affected eye
- Scotoma (usually central)
- Impaired colour vision (assess with Ishihara plates)
- An afferent pupillary defect (see below)
- Optic atrophy – pale disc (develops late)
- Causes are listed in Box 22.3.

Papilloedema

Papilloedema means swelling of the optic disc. Causes are shown in Box 22.4. The earliest signs of swelling are disc pinkness, with blurring and heaping up of disc margins, nasal first. There is loss of spontaneous pulsation of retinal veins within the disc. The physiological cup becomes obliterated, the disc engorged with dilated vessels. Small haemorrhages often surround the disc.
Box 22.3 Causes of optic neuropathy
- Inflammatory (optic neuritis), e.g. demyelination, sarcoidosis, vasculitis
- Optic nerve trauma or compression, e.g. glioma, meningioma, aneurysm, bone disorders affecting orbit
- Toxic, e.g. tobacco-alcohol, ethambutol, methyl alcohol, quinine, hydroxy chloroquine, radiation
- Ischaemic optic neuropathy, e.g. giant cell arteritis
- Hereditary optic neuropathies, e.g. Leber's
- Nutritional deficiency, e.g. vitamin B₁ and B₁₂
- Infection, e.g. orbital cellulitis, syphilis, TB
- Neurodegenerative disorders, e.g. leucodystrophies
- Papilloedema and its causes (Box 22.4)

Box 22.4 Causes of optic disc swelling
- Raised intracranial pressure (papilloedema)
- Brain tumour, abscess, or haemorrhage. Idiopathic intracranial hypertension, hydrocephalus
- Optic nerve disease
- Optic neuritis, e.g. multiple sclerosis
- Ischaemic optic neuropathy, e.g. giant cell arteritis
- Toxic optic neuropathy, e.g. methanol
- Venous occlusion
- Venous sinus thrombosis
- Central retinal vein thrombosis
- Orbital mass lesions
- Retinal vascular disease
- Malignant hypertension
- Vasculitis, e.g. systemic lupus erythematosus
- Metabolic causes
- Hypercapnia, chronic hypoxia, hypocalcaemia
- Disc infiltration
- Leukaemia, sarcoidosis, optic nerve glioma

Various conditions simulate true disc swelling. Marked hypermetropic (long-sighted) refractive errors make a disc appear pink, distant and ill-defined. Myelinated nerve fibres at disc margins and hyaline bodies (drusen, p. 1064) can be mistaken for disc swelling.

Disc infiltration also causes a swollen disc with raised margins (e.g. in leukaemia).

When there is doubt about disc oedema, i.v. fluorescein angiography is diagnostic; retinal leakage is seen with papilloedema.

Papilloedema produces few if any visual symptoms other than momentary visual obscurations with changes in posture. The underlying disease is the source of the patient's symptoms. The blind spot is enlarged but this is not noticed by the patient. However, over time progressive and permanent visual loss occurs, ultimately culminating in optic atrophy.

Inflammatory optic neuropathy (optic neuritis)
Optic neuritis is one of the most common causes of subacute visual loss. Symptoms may vary from a mild fogging of central vision with colour desaturation to a dense central scotoma, but very rarely complete blindness. Pain on eye movements is almost universal. The optic disc usually appears normal despite severe visual loss (unless the inflammation is at the optic nerve head in which case the disc may appear swollen in the acute phase).

A plaque of demyelination within the optic nerve is the most common cause in Western populations. Dedicated MRI imaging of the optic nerves may show the inflammatory plaque and imaging of the brain may show additional inflammatory lesions which confer a higher risk of developing multiple sclerosis (MS). Approximately 50% of patients go on to develop MS with prolonged follow-up (see p. 1123). Recovery of visual acuity to 6/9 or better occurs in 95% of cases over months, with recovery time improved by high-dose i.v. steroids given acutely.

Optic neuritis may be caused by infective or other inflammatory disorders, e.g. sarcoidosis or vasculitides (see Box 22.3).

Anterior ischaemic optic neuropathy
The anterior part of the optic nerve is supplied by the posterior ciliary arteries, occlusion or hypoperfusion of which leads to infarction of all or part of the optic nerve head. There is sudden or stuttering altitudinal visual loss (typically the lower half of the visual field) with disc swelling, later replaced by optic atrophy. The other eye is later affected in one-third of cases.

Individuals with small hypermetropic discs seem to be predisposed, and often there are relatively few vascular risk factors. Less commonly arteritis is the cause (see p. 536).

Optic atrophy
Optic atrophy means disc pallor, from loss of axons, glial proliferation and decreased vascularity. This may eventually develop following any type of optic neuropathy of sufficient severity to extensively damage axons within the nerve, including chronic papilloedema.

Optic chiasm
Bitemporal hemianopia or quadrantanopia occurs with compression of the chiasm from above or below. Common causes are:
- Pituitary tumours (p. 946)
- Meningioma
- Cranialpharyngioma.

Optic tract and optic radiation
Optic tract lesions (rare) cause a homonymous hemianopia (loss of the contralateral visual field in both eyes). Optic radiation lesions cause homonymous quadrantanopic defects. Temporal lobe lesions (e.g. tumour, infarction) cause upper quadrantic defects, and parietal lobe, lower.

Occipital cortex
Homonymous hemianopic defects are produced by unilateral posterior cerebral artery infarction (see p. 1101 stroke). The macular cortex (at each occipital pole) may be spared.

Widespread bilateral occipital lobe damage by infarction (‘top of the basilar’ syndrome), trauma or coning causes cortical blindness (Anton’s syndrome). The patient cannot see but characteristically lacks insight into this; he or she may even deny it. Pupillary responses remain normal (p. 1101).

The pupils
A slight difference between the size of each pupil (up to 1 mm) is common (physiological anisocoria) and does not vary with differing light levels. The pupil tends to become smaller and irregular in old age (senile miosis); anisocoria is more pronounced. Convergence becomes sluggish with ageing.

Pupillary reactions to light and accommodation may be tested (Fig. 22.5). A bright torch (not an ophthalmoscope light!) should be used to test the pupillary light reaction.
A complete optic nerve lesion
This occurs

Westphal nuclei of IIIrd nerve, then, neurones in IIIrd nerves to cause
Efferent pathway:

(1) geniculate body, and
decussating at the chiasm) pass through each lateral
recovery of vision. For a left RAPD:

and can provide evidence of an optic nerve lesion even after
other. An RAPD is a sensitive sign of optic nerve pathology
with incomplete damage to one optic nerve relative to the

(APD). For a left APD:

Direct and indirect reflexes are intact in each eye but
differ in relative strength.

When the light is swung from one eye to the other, the
left pupil dilates slightly when illuminated and constricts
slightly when the right eye is illuminated (the consensual
reflex is stronger than the direct).

**Horner's syndrome** (see Box 22.5)
The sympathetic nervous supply to the eye is a three
nerone pathway originating in the hypothalamus and
descending by way of the brainstem and cervical cord to T1
tome root, paraverbral sympathetic chain and, on via the
carotid artery wall, to the eye. Damage to any part of
the pathway results in Horner's syndrome. This is significant not
only because it affects vision but also because it may indi-
cate a serious underlying pathology.

The clinical features of Horner's syndrome are:
- Unilateral miosis (constricted pupil)
- Partial ptosis

**Myotonic pupil (Holmes–Adie pupil)**
This is a dilated, often irregular, pupil, more frequent in
women; it is common and usually unilateral. There is no (or
very slow) reaction to bright light and also incomplete con-
triction to convergence. This is due to denervation in the
ciliary ganglion, of unknown cause, and has no other patho-
logical significance. A myotonic pupil is sometimes associ-
ated with diminished or absent tendon reflexes.

**Argyll Robertson pupil**
Now rarely seen in clinical practice. A small, irregular pupil is
fixed to light but constricts on convergence. The lesion is in
the brainstem surrounding the aqueduct of Sylvius. Once
considered diagnostic of neurosyphilis, it is now only occa-
sionally seen in diabetes or MS.

**III, IV, VI: Oculomotor, trochlear and abducens nerves**
These cranial nerves supply the extraocular muscles and
disorders commonly result in abnormal eye movements
and diplopia (double vision) due to breakdown of conjugate
(yoked) eye movements. Diplopia may also occur with local
orbital lesions or myasthenia gravis.

**Examining eye movements**
Pursuit (slow) eye movements and saccadic eye movements
are tested separately. The examiner assesses the range of
eye movements in all directions and asks the patient to report
double vision. Jerky pursuit movements with saccadic intru-
sion (i.e. brief fast saccades interspersed with slower pursuit
movements), overshoot on saccadic movements and nystag-
mos may indicate cerebellar or brainstem pathology.
Control of eye movements

Fast voluntary eye movements originate in the frontal lobes. Fibres descend and cross in the pons to end in the centre for lateral gaze (paramedian pontine reticular formation – PPRF), close to the VIth nerve nucleus. Each PPRF also receives input from:

- the ipsilateral occipital cortex – pathway concerned with tracking objects
- the vestibular nuclei – pathways linking eye movements with position of the head and neck (vestibulo-ocular reflex, p. 1072).

Conjugate lateral eye movements are coordinated from each PPRF via the medial longitudinal fasciculus (MLF, Fig. 22.6). Fibres from the PPRF pass both to the ipsilateral VIth nerve nucleus (lateral rectus) and, having crossed the midline, to the opposite IIIrd nerve nucleus (medial rectus and other muscles) via the MLF, thus linking the eyes for lateral gaze.

Abnormalities of conjugate lateral gaze

A destructive lesion on one side allows the eyes to be driven by the intact opposite pathway. A left frontal destructive lesion (e.g. an infarct) leads to failure of conjugate lateral gaze to the right. In an acute lesion the eyes are often deviated to the side of the lesion, past the midline and therefore look towards the left (normal) limbs; there is usually a contralateral (i.e. right) hemiparesis.

In the brainstem a unilateral destructive lesion involving the PPRF leads to failure of conjugate lateral gaze towards that side. There is usually a contralateral hemiparesis and lateral gaze is deviated towards the side of the paralysed limbs.

**Figure 22.6 PPRF and INO.** Impulses from PPRF pass via ipsilateral VIth nerve nucleus to lateral rectus muscle (ADduction) and via medial longitudinal fasciculus to opposite IIIrd nerve nucleus and thus to opposite medial rectus muscle (ADduction). A lesion of the MLF (X) causes failure of or slow ADduction in the right eye and nystagmus in the left eye with left lateral gaze. PPRF, para-median pontine reticular formation; INO, internuclear ophthalmoplegia; MLF, medial longitudinal fasciculus.

Internuclear ophthalmoplegia (INO)

Damage to one MLF causes internuclear ophthalmoplegia (INO), a common complex brainstem eye movement disorder seen frequently in MS. In a right INO there is a lesion of the right MLF (Fig. 22.6). On attempted left lateral gaze the right eye fails to ADduct. The left eye develops nystagmus in ABduction. The side of the lesion is on the side of impaired ADduction, not on the side of the (obvious, unilateral) nystagmus. When present bilaterally, INO is almost pathognomonic of MS.

**One and a half syndrome**

Pontine infarction involving the PPRF, VIth nerve nucleus and MLF on one side results in an ipsilateral horizontal gaze palsy and an INO so that abduction of the opposite eye (with nystagmus) is the only horizontal eye movement possible. Vertical gaze and convergence are preserved as they have distinct neural control mechanisms.

Vestibulo-ocular (Doll’s eye) reflexes

Examination is of diagnostic value in coma (p. 898) and assessment of vertigo (p. 1079).

Abnormalities of vertical gaze

Failure of up-gaze may be caused by dorsal midbrain lesions, e.g. pinealoma or infarcts. When the pupillary light reflex fails in addition, this is called Parinaud’s syndrome. Defective up-gaze also develops in certain degenerative disorders (e.g. progressive supranuclear palsy). Some impairment of up-gaze occurs as part of normal ageing.

Nystagmus

Nystagmus is rhythmic oscillation of eye movement, and a sign of disease of the retina, cerebellum and/or vestibular systems and their connections. Nystagmus is either jerk or pendular. Nystagmus must be sustained within binocular gaze to be of diagnostic value – a few beats at the extremes of gaze are normal.

**Jerk nystagmus**

Jerk nystagmus (usual in neurological disease) is a fast/slow oscillation. This is seen in vestibular, VIIIth nerve, brainstem, cerebellar lesions. Direction of nystagmus is decided by the fast component, a reflex attempt to correct the slower, primary movement.

- **Horizontal or rotary jerk nystagmus** may be either of peripheral (vestibular) or central origin (VIIIth nerve, brainstem, cerebellum and connections).
  - In peripheral lesions, nystagmus is usually acute and transient (minutes or hours) and associated with severe prostrating vertigo.
  - In central lesions nystagmus tends to be long-lasting (weeks, months or more). Vertigo caused by central lesions tends to wane after days or weeks, the nystagmus outlasting it.
- **Vertical jerk nystagmus** is caused typically by central lesions.
- **Down-beat jerk nystagmus** is a rarity caused by lesions around the foramen magnum (e.g. meningioma, cerebellar ectopia).

**Pendular nystagmus**

Pendular describes movements to and fro, similar in velocity and amplitude. Pendular nystagmus is usually vertical and present in all directions of gaze. The causes are generally
oculomotor (e.g. poor visual fixation from longstanding, severe visual impairment), or congenital.

### III: Oculomotor nerve

The nucleus of the IIIrd nerve lies ventral to the aqueduct in the midbrain. It supplies four external ocular muscles (superior, inferior and medial recti, and inferior oblique), levator palpebrae superioris (which lifts the eyelid) and parasympathetic constrictor of the pupil. Causes of a IIIrd nerve lesion are listed in Box 22.6.

**Signs of a complete IIIrd nerve palsy:**
- Unilateral complete ptosis (levator weakness)
- Eye deviated down and out (unopposed lateral rectus and superior oblique)
- A fixed and dilated pupil.

Patients do not complain of diplopia as the ptosis effectively covers the eye. *Sparing of the pupil* indicates parasympathetic fibres are undamaged; these run in a discrete bundle on the surface of the nerve, thus the pupil is of normal size and reacts normally. Diabetic IIIrd nerve infarction is usually painless and pupil sparing, unlike compression by a posterior communicating artery aneurysm.

### IV: Trochlear nerve

This supplies the superior oblique muscle. The patient complains of torsional diplopia (two objects at an angle) when attempting to look down (e.g. descending stairs); the head is tilted away from that side. The most common cause is head injury, often with bilateral trochlear nerve palsy occurring.

### VI: Abducens nerve

This supplies the lateral rectus muscle (ABduction). Lesions cause horizontal diplopia when looking into the distance, maximal when looking to the side of the lesion. The eye cannot be fully abducted and an esotropia (inwards eye deviation) may be visible in the primary position.

The VIth nerve has a long intracranial course. It can be damaged in the brainstem (e.g. by MS or infarction). In raised intracranial pressure, it is compressed against the tip of the petrous temporal bone (may be bilateral). The nerve sheath may be infiltrated by tumours, particularly nasopharyngeal carcinoma. Microvascular ischaemia of the nerve may occur in diabetes with acute onset followed by recovery within 3 months in most cases.

**Complete external ophthalmoplegia**

Complete external ophthalmoplegia describes an immobile eye when IIIrd, IVth and VIth nerves are paralysed at the orbital apex (e.g. by metastasis) or within the cavernous sinus (e.g. by sinus thrombosis or meningioma).

Wernicke’s encephalopathy due to thiamine deficiency (p. 1147) may cause a complex eye movement disorder or complete ophthalmoplegia, as may neuromuscular junction disorders such as myasthenia, botulism and some myopathies or metabolic disorders.

### V: Trigeminal nerve

The largest cranial nerve; mainly sensory with a motor component to the muscles of mastication.

Sensory fibres (Fig. 22.7; see also Figs 22.11 and 22.12) of the three divisions – ophthalmic (V₁), maxillary (V₂) and mandibular (V₃) – pass to the trigeminal (Gasserian) ganglion at the apex of the petrous temporal bone. Ascending fibres transmitting light touch enter the Vth nerve in the pons. Descending central fibres carrying pain and temperature form the spinal tract of V, to end in the spinal Vth nucleus that extends from the medulla into the cervical cord.

**Signs of a Vth nerve lesion**

A complete Vth nerve lesion causes unilateral sensory loss on the face, scalp anterior to the vertex, anterior two-thirds of the tongue and buccal mucosa; the jaw deviates to that side as the mouth opens (motor fibres). Diminution of the corneal reflex is an early and sometimes isolated sign of a Vth nerve lesion.

**Causes**

- **Brainstem pathology** (infarction, demyelination or tumour) may damage the nucleus, with light touch and spinothalamic pathways sometimes being differentially involved.
- **Cerebellopontine angle tumours** (acoustic neuroma or meningioma) may compress the nerve and also affect the Vth and VIIIth nerves producing facial weakness and deafness.
- **Cavernous sinus and skull base pathology** (tumour or infection) may affect the ganglion and proximal branches.
- **Peripheral branches** may be picked off individually, e.g. the ‘numb chin syndrome’ seen with a breast cancer metastasis in the mandible.
Trigeminal neuralgia
Trigeminal neuralgia is discussed with facial pain (p. 1110).

Trigeminal sensory neuropathy
Causes gradually progressive unilateral facial sensory loss and tingling with normal imaging. The condition is probably heterogeneous in aetiology but may have an autoimmune basis, with inflammation of the trigeminal ganglion, occurring mainly in association with mixed and undifferentiated connective tissue disease and primary Sjögren’s syndrome.

VII: Facial nerve
The VIIth nerve is largely motor, supplying muscles of facial expression. VII carries sensory taste fibres from the anterior two-thirds of the tongue via the chorda tympani and supplies motor fibres to the stapedius muscle. The VIIth nerve (Fig. 22.7) arises from its nucleus in the pons and leaves the skull through the stylomastoid foramen. Neurones in each VIIth nucleus supplying the upper face (principally frontalis) receive bilateral supranuclear innervation.

Unilateral facial weakness
Upper motor neurone (UMN lesions) cause weakness of the lower part of the face on the opposite side. Frontalis is spared: normal furrowing of the brow is preserved; eye closure and blinking are largely unaffected. The earliest sign is slowing of one side of the face, e.g. on baring teeth. There is sometimes relative preservation of spontaneous emotional movement (e.g. smiling) compared with voluntary movement.

Lower motor neurone (LMN) lesions. A complete unilateral LMN VIIth lesion causes weakness (ipsilateral) of all facial expression muscles. The angle of the mouth falls; unilateral dribbling develops. Frowning (frontalis) and eye closure are weak. Corneal exposure and ulceration occur if the eye does not close during sleep. Taste sensation is frequently also impaired.

Causes of facial weakness
The commonest cause of a UMN lesion is hemispheric stroke with hemiparesis on the opposite side. At lower levels, lesion sites are recognized by LMN weakness with additional signs.

Pons. Here the VIIth nerve loops around the Vth (abducens) nucleus (Fig. 22.7), leading to a lateral rectus palsy (see p. 1076) with unilateral LMN facial weakness. When the neighbouring PPRF and corticospinal tract are involved, there is the combination of:

- LMN facial weakness
- Failure of conjugate lateral gaze (towards lesion)
- Contralateral hemiparesis.

Causes include pontine tumours (e.g. glioma), MS and infarction.

Cerebellopontine angle (CPA). The neighbouring Vth, Vth and VIIth nerves are compressed with VII in the CPA, e.g. by acoustic neuroma, meningioma or metastasis.

Petrous temporal bone. The nerve may be damaged within the bony facial canal, within which lies the sensory geniculate ganglion (receiving taste fibres from the anterior two-thirds of the tongue via the chorda tympani). As well as LMN facial weakness, lesions in this region cause:

- Loss of taste on the anterior two-thirds of the tongue
- Hyperacusis (loud noise distortion – paralysis of stapedius).

Causes include:

- Bell’s palsy
- Trauma
- Middle ear infection
- Herpes zoster (Ramsay Hunt syndrome, p. 1077)

Skull base, parotid gland and within the face. The facial nerve can be compressed by skull base tumours and in Paget’s disease of bone. Branches of VII may be damaged by parotid gland tumours as the nerve traverses the parotid, sarcoidosis (p. 845) and trauma.

Bell’s palsy
This common (1 per 5000 incidence), acute facial palsy is thought to be due to viral infection (often herpes simplex) causing swelling of nerve within the tight petrous bone facial canal. There is unilateral LMN facial weakness developing over 24–48 hours, sometimes with lost or altered taste on the tongue, and hyperacusis. Pain behind the ear is common at onset. Patients often suspect a stroke and may be very distressed. Vague altered facial sensation is often reported although examination of facial sensation is normal.

Diagnosis is made on clinical grounds and tests are usually not required. The ear (and palate) should be examined for vesicles (see Ramsay Hunt syndrome below), hearing loss or evidence of local pathology such as cholesteatoma or malignant otitis externa and parotid tumours should be excluded. Involvement of other cranial nerves means facial weakness is not due to Bell’s palsy. Lyme disease may account for one-quarter of cases of facial palsy in endemic areas and HIV seroconversion is the commonest cause in parts of Africa.

(Bell’s phenomenon is the upward conjugate eye movement that occurs when the eyes are closed.)

Management and outcome
Complete, or almost complete, recovery over 3–8 weeks occurs in at least 85% of patients, even without specific treatment. Patients should be reassured that the prognosis is good and it is unlikely to recur.

Inability to blink in severe facial weakness may lead to exposure keratitis. Use of lubricating eye drops is often required and patients should be advised to carefully tape the eye closed at night. For more severe facial weakness with complete inability to close the eye, early ophthalmological assessment is required and lateral tarsorrhaphy and/or insertion of a gold weight into the upper lid may be required until recovery occurs.

Early treatment with corticosteroids (prednisolone 1 mg/kg for 7 days) improves outcome. Evidence to support use of antiviral agents is limited but aciclovir or valaciclovir is often given in combination with steroids.

Recovery sometimes takes up to a year if axons have to regrow rather than just remyelinate, in which case aberrant reinnervation of facial muscles (e.g. mouth twitching with blinking) is a frequent late complication. Cosmetic surgery may be helpful where recovery is not complete. Bell’s palsy rarely recurs and recurrence should prompt a search for an alternative cause.

Ramsay hunt syndrome
This is herpes zoster (shingles) of the geniculate ganglion. There is a facial palsy (identical to Bell’s) with vesicles around the external auditory meatus and/or the soft palate (sensory

Further reading
twigs from VII). Deafness and unsteadiness may occur. Complete recovery is less likely than in Bell’s. Antiviral treatment for shingles (above) should be given with steroids.

**Bilateral facial weakness**
Bilateral facial palsy is rare, accounting for fewer than 1% of cases of facial palsy, but is more likely than unilateral palsies to have an identifiable underlying cause. Paradoxically, bilateral weakness is often less obviously apparent than unilateral weakness as there is no facial asymmetry.

Causes include:
- Infections:
  - Lyme (bilateral in 25% – Bannwarth’s syndrome)
  - Viral: HIV seroconversion, EBV
  - Mastoiditis (bilateral)
  - Diphtheria and botulism (rare)
- Sarcoidosis
- Skull base trauma and tumours
- Pontine lesions, e.g. gliomas
- Neuromuscular disorders as part of more generalized weakness
  - Guillain–Barré syndrome
  - Myasthenia
  - Myotonic dystrophy and facioscapulohumeral dystrophy
- Congenital and genetic causes (Gelsolin gene mutations).

**Hemifacial spasm (HFS)**
This is an irregular, painless unilateral spasm of facial muscles, usually occurring after middle age. It starts in the orbicularis oculi and usually progresses gradually over the years to involve other facial muscles on the same side. It varies from a mild to a severe, disfiguring spasm.

HFS is usually caused by compression of the root entry zone of the facial nerve, generally by vascular structures such as the vertebral or basilar arteries or their branches (a mechanism similar to that of trigeminal neuralgia see p. 1050). Other mass lesions in the cerebellopontine angle, including tumours, are the cause in approximately 1% of cases.

Occasionally HFS may occur with ipsilateral trigeminal neuralgia, one symptom usually preceding the other, a combination called tic convulsif. The paroxysms of pain and spasm occur independently. A compressive cause such as a vascular loop or other structural lesion is usually identified.

**Management**
Mild cases require no treatment. Botulinum toxin injection into affected muscles every 3–4 months is now the standard treatment. Drugs (e.g. carbamazepine) are of little value. Decompression of the VIIth nerve in the CPA is sometimes helpful. Surgical decompression of the facial nerve in the posterior fossa involves interposing a non-resorbable sponge between the nerve and any adjacent vascular loop identified at operation. The procedure results in complete resolution of symptoms in up to 90% of cases but is associated with a risk of facial weakness or deafness.

**Other involuntary facial movements**
Myokymia of orbicularis oculi is an irritating twitch, usually of the lower eyelid. It is a normal phenomenon, but sometimes a cause of anxiety. More extensive facial myokymia may result from intrinsic brainstem pathology.

**VIII: Vestibulo-cochlear nerve; cochlear nerve**
Auditory fibres from the spiral organ of Corti within the cochlea pass to the cochlear nuclei in the pons. Fibres from these nuclei cross the midline and pass upwards via the medial lemnisci to the medial geniculate bodies and then to the temporal cortex.

Symptoms of a cochlear nerve lesion are deafness and tinnitus (p. 1050). Sensorineural and conductive deafness can be distinguished with tuning fork tests, e.g. Rinne’s and Weber’s (256 Hz, not 128 Hz tuning fork) (p. 1048).

**Basic investigations of cochlear lesions**
- Pure tone audiometry and auditory thresholds.
- Auditory evoked potentials (recording responses from repetitive clicks via scalp electrodes; lesion levels are determined from the response pattern).

**Causes of deafness** are listed in Table 22.4 and Table 21.1 (see p. 1048).

**Vertigo and the vestibular system**
The vestibular system of the inner ear detects head movements and has three primary functions:
- To stabilize gaze during head movements, e.g. looking ahead while running (the vestibulo-ocular reflex)
- To control posture and balance
- To facilitate perception of orientation and motion.

Nerve impulses generated by movement of hair cells within the three semicircular canals detect head motion in the three planes (yaw/pitch/roll). Balance is maintained by integrating information from:

V. vertigo; D. hearing loss.
The vestibular system
The visual system
The somatosensory system – proprioception from limbs, trunk and neck.

The main symptoms of vestibular lesions are vertigo and loss of balance.

Vertigo
Vertigo, is the illusion of movement of the subject or surroundings, typically rotatory, and should be distinguished from other causes of nonspecific dizziness. It can be described to patients as being similar to the sensation one feels after getting off a child’s roundabout or after spinning on the spot and suddenly stopping.

Vomiting frequently accompanies acute vertigo of any cause. Vertigo is always made worse by head movements and patients prefer to remain still and maintain visual fixation. Nystagmus (p. 1075) is the principal sign.

The dizzy patient
Complaints of ‘dizziness’ require careful history taking and may be due to:

- Vertigo
- Presyncopal sensations due to transient cerebral hypoperfusion, e.g. orthostatic light-headedness
- Unsteadiness or disequilibrium, e.g. cerebellar or postural stability disorders
- Nonspecific ‘dizziness’, e.g. due to medication or anxiety and hyperventilation.

Causes of vertigo
Vertigo indicates a disturbance of the vestibular apparatus or brainstem and associated neural pathways (Table 22.4).

Causes:

- Peripheral (vestibular system) causes are common. Deafness and tinnitus accompanying vertigo indicate involvement of the ear or cochlear nerve (p. 1048).
- Central causes (brainstem and connections) are rarer. Other clinical features such as diplopia, weakness, cerebellar signs or cranial nerve palsies may help localize the lesion.

Vestibular disorders
Vestibular disorders are fully discussed elsewhere (p. 1049). Attack duration and frequency and trigger factors help the clinician distinguish on history between different pathological causes. The ability to perform a Hallpike test, head impulse test and Epley particle repositioning manoeuvre are invaluable skills for all clinicians (p. 1049; see Fig. 22.8 and Fig. 21.3).

The most commonly encountered vestibular disorders presenting with vertigo are:

- **Benign positional vertigo** (BPPV) – frequent attacks lasting seconds only. Triggered by specific movements – lying down, sitting up or rolling over in bed, neck flexion or extension.
- **Vestibular neuronitis** – acute onset lasting days or weeks. Non-recurrent.
- **Migrainous vertigo** (p. 1108), really a central cause – lasting hours, occurring every few weeks or months
- **Meniere’s disease** – recurrent attacks lasting minutes or hours, usually accompanied by hearing loss, tinnitus and a feeling of fullness in the ear.
- **Trauma** – vestibular disruption following head injury

Central causes of vertigo
Vertigo may be a manifestation of brainstem pathology including:

- Infarcts involving the vestibular nuclei in the medulla (e.g. the lateral medullary syndrome)
- Demyelination involving the brainstem
- Posterior fossa mass lesions, e.g. tumours, haemorrhage or vascular malformations
- Migraine
- CPA mass lesions and tumours compressing the vestibular nerve (technically these should be classified as ‘peripheral’ disorders, but are distinct from disorders of the vestibular apparatus)
- Drugs, e.g. anticonvulsant toxicity and alcohol.

Although vertigo occasionally occurs in isolation with brainstem pathology, it is more typically a single component of a more complex clinical picture, associated with other symptoms or examination findings. The brainstem nuclei and tracts are tightly packed into a small space and most pathological processes affect multiple contiguous neural pathways, resulting, e.g. in diplopia, eye movement disorders, cranial nerve palsies, cerebellar signs or hemiparesis.

Slowly growing CPA tumours such as vestibular nerve schwannomas may cause vertigo but rarely do so in the absence of unilateral deafness and tinnitus.

Vertical nystagmus usually has a central cause.

Basic investigations for vestibular problems
Bedside assessment is usually sufficient to make a diagnosis in the majority of patients:

- Examination of eye movements for nystagmus (p. 1074)
- Assessment of hearing and otoscopic examination of the ear (p. 1047)
- Head impulse (thrust) test – to assess the vestibulo-ocular reflex (VOR) and identify a unilateral vestibulopathy
- Hallpike manoeuvre – a positioning test to stimulate the posterior semicircular canal and trigger an attack in BPPV (see Fig. 21.3)

Specialist testing is occasionally required to assess vestibular function and hearing. This includes:

- Caloric testing – irrigation of the external auditory meatus with cold and then warm water to stimulate the
horizontal semicircular canal and induce nystagmus. Test labyrinthine function in each ear separately.

- Electro-nystagmography – to quantify and characterize nystagmus under different conditions, e.g. in a rotating chair.
- Posturography – assesses body sway on a moving platform.
- Pure tone audiograms.
- High-definition MRI provides the best structural imaging of the brainstem and CPA and is useful where a central cause of vertigo is suspected.

**Vestibular neuronitis**

Vestibular neuronitis is a common, poorly understood problem. It is an acute attack of isolated vertigo with nystagmus, often with vomiting, believed to follow viral infections. The disturbance lasts for several days or weeks, is self-limiting and rarely recurs. Vestibular neuronitis is sometimes followed by benign positional vertigo (p. 1071). Deafness is absent. Acute treatment is with vestibular sedatives. Similar symptoms can be caused by MS or brainstem vascular lesions. Other signs are usually apparent.

**Lower cranial nerves IX, X, XI, XII**

The glossopharyngeal (IX), vagus (X) and accessory (XI) nerves arise in the medulla and leave the skull through the jugular foramen. The hypoglossal (XII) arises in the medulla, to leave the skull base via the hypoglossal foramen. Outside the skull, the four cranial nerves lie together, close to the carotid artery and sympathetic trunk.

**Glossopharyngeal (IX)**

This nerve is largely sensory, supplying sensation and taste from the posterior third of the tongue and the pharynx (afferent pathway of gag reflex). Motor fibres supply some pharyngeal muscles and parasympathetic fibres the parotid.

**Vagus (X)**

The vagus is a mixed nerve, largely motor, which supplies striated muscle of the pharynx (afferent gag reflex pathway), larynx (including vocal cords via recurrent laryngeal nerves) and upper oesophagus. There are sensory fibres from the larynx. Parasympathetic fibres supply the heart and abdominal viscera.

**Accessory (XI)**

The accessory nerve, a complex motor nerve, supplies the trapezius and sternomastoid muscles.

**Hypoglossal (XII)**

The hypoglossal nerve is a motor nerve to tongue muscles.

**IXth and Xth nerve lesions**

Principal causes of IXth, Xth, XIth and XIIth nerve lesions are listed in Box 22.7.

Isolated lesions of IXth and Xth nerves are unusual, since disease at the jugular foramen affects both nerves and sometimes XI.

A unilateral IXth nerve lesion causes diminished sensation on the same side of the pharynx, and is hard to recognize in isolation. A Xth nerve palsy produces ipsilateral failure of voluntary and reflex elevation of the soft palate (which is drawn to the opposite side) and ipsilateral vocal cords.

Bilateral lesions of IXth and Xth nerves cause palatal weakness, reduced palatal sensation, an absent gag reflex, dysphonia and choking with nasal regurgitation. **Bulbar palsy** is a general term describing palatal, pharyngeal and tongue weakness of LMN or muscle origin.

**Recurrent laryngeal nerve lesions.** Paralysis of this branch of each vagus causes hoarseness (dysphonia) and failure of the forceful, explosive part of coughing (‘bovine cough’). There is no visible palatal weakness; vocal cord paralysis is seen endoscopically. Bilateral acute lesions (e.g. postoperatively) cause respiratory obstruction – an emergency.

The left recurrent laryngeal nerve (looping beneath the aorta) is damaged more commonly than the right.

Causes of recurrent laryngeal nerve lesions include:

- Mediastinal primary tumours (e.g. thymoma)
- Secondary spread from bronchial carcinoma
- Aortic aneurysm
- Trauma or surgery of neck or thorax.

**XIth nerve lesions**

XIth nerve lesions cause weakness of sternomastoid (rotation of the head and neck to the opposite side) and trapezius (shoulder shrugging). Nerve section (e.g. following lymph node biopsy in the neck posterior triangle) is followed by persistent neuralgic pain.

**XIIth nerve lesions**

LMN lesions of XII lead to unilateral tongue weakness, wasting and fasciculation. The protruded tongue deviates towards the weaker side. Bilateral supranuclear (UMN) lesions produce slow, limited tongue movements and a stiff tongue that cannot be protruded far. Fasciculation is absent.

**Bulbar and pseudobulbar palsy**

**Bulbar palsy**

This is LMN weakness of muscles whose cranial nerve nuclei lie in the medulla (the bulb). Paralysis of bulbar muscles is caused by disease of lower cranial nerve nuclei, lesions of IXth, Xth and XIIth nerves (Box 22.7), malfunction of their neuromuscular junctions (e.g. myasthenia gravis, botulism) or disease of muscles themselves (e.g. dystrophies).

**Pseudobulbar palsy**

Describes bilateral supranuclear (UMN) lesions of lower cranial nerves producing weakness of the tongue and...
Motor control systems

There are three systems, each of which interacts by feedback loops with the other two, with sensory input and the reticular formation:

- **The corticospinal (or pyramidal) system** enables **purposive, skilled, intricate, strong and organized** movements. Defective function is recognized by a distinct pattern of signs – loss of skilled voluntary movement, spasticity and reflex change – seen, e.g. in a hemiparesis, hemiplegia or paraparesis.

- **The extrapyramidal system** facilitates **fast, fluid** movements that the corticospinal system has generated. Defective function produces slowness (bradykinesia), stiffness (rigidity) and/or disorders of movement (rest tremor, chorea and other dyskinesias). One feature (e.g. stiffness, tremor or chorea) will often predominate.

- **The cerebellum** and its connections have a role coordinating **smooth and learned** movement, initiated by the pyramidal system, and in posture and balance control. Cerebellar disease leads to unsteady and jerky movements (ataxia), with characteristic limb signs of past pointing, action tremor and incoordination, gait ataxia and/or truncal ataxia.

### Corticospinal (pyramidal) system

The corticospinal tracts originate in neurones of the cortex and terminate at motor nuclei of cranial nerves and spinal cord anterior horn cells. The pathways of particular clinical significance (Fig. 22.9) congregate in the internal capsule and cross in the medulla (decussation of the pyramids), passing to the contralateral cord as the lateral corticospinal tracts. This is the pyramidal system, disease of which causes upper motor neurone (UMN) lesions. ‘Pyramidal’ is simply a

---

**Box 22.8 Features of upper motor neurone lesions**

- Drift of upper limb
- Weakness with characteristic distribution
- Changes in tone: flaccid-spastic
- Exaggerated tendon reflexes
- Extensor plantar response
- Loss of skilled finger/toe movements
- Loss of abdominal reflexes
- No muscle wasting
- Normal electrical excitability of muscle

---

Signs of an early pyramidal lesion may be minimal. Weakness, spasticity or changes in superficial reflexes can predominate, or be present in isolation.

**Pyramidal drift of an upper limb**

Normally, the outstretched upper limbs are held symmetrically, when the eyes are closed. With a pyramidal lesion, when both upper limbs are held outstretched, palms
uppermost, the affected limb drifts downwards and medially. The forearm tends to pronate and the fingers flex slightly. This sign is often first to emerge, sometimes before weakness and/or reflex changes become apparent.

Weakness and loss of skilled movement
A unilateral pyramidal lesion above the decussation in the medulla causes weakness of the opposite limbs. When acute and complete, this weakness will be immediate and total, a hemiplegia, e.g. following an internal capsule infarct. With slowly progressive lesions (e.g. a hemisphere glioma) a characteristic pattern of weakness emerges – a hemiparesis.

In the upper limb, flexors remain stronger than extensors, whereas in the lower limb, extensors remain stronger than flexors. In the upper arm, weaker movements are thus shoulder abduction and elbow extension; in the forearm and hand, wrist and finger extensors and abductors are weaker than their antagonists. In the lower limb, weaker movements are hip flexion and abduction, knee flexion, ankle dorsiflexion and evasion. There is also loss of skilled movement – fine finger and toe control diminishes. Wasting (except from disuse) is not a feature. Muscles remain normally excitable electrically.

When a UMN lesion is below the decussation of the pyramids, e.g. in the cervical cord, hemiparesis is on the same side as the lesion, an unusual situation.

Changes in tone and tendon reflexes
An acute lesion of one pyramidal tract (e.g. internal capsule stroke) causes initially flaccid paralysis with loss of tendon reflexes. Increase in tone follows, usually within several days due to loss of inhibitory effects of the corticospinal pathways and an increase in spinal reflex activity. This increase in tone (spasticity) is detectable most easily in stronger muscles. Spasticity is characterized by sudden changing resistance to passive movement – the clasp-knife effect. Relevant tendon reflexes become exaggerated; clonus may emerge.

Changes in superficial reflexes
The normal flexor plantar response becomes extensor. In a severe acute lesion, this extensor response can be elicited from a wide area of the foot. As recovery progresses, the receptive area diminishes until the lateral posterior third of the sole remains receptive to an orange-stick stimulus (an appropriate instrument). An extensor plantar is certain when great toe dorsiflexion is accompanied by abduction of adjacent toes. Abdominal (and cremasteric) reflexes are abolished on the side affected.

Patterns of UMN disorders
There are three main patterns:

- **Hemiparesis** means weakness of the limbs on one side; it is usually caused by a lesion in the brain and occasionally in the cord.
- **Paraparesis** means weakness of both lower limbs and is usually diagnostic of a cord lesion; bilateral brain lesions occasionally cause paraparesis.
- **Tetraparesis** (syn. quadriparesis) means weakness of four limbs.

Hemiplegia, paraplegia and tetraplegia indicate (strictly total) paralysis, but are often used to describe severe weakness.

**Hemiparesis**
The level within the corticospinal system is recognized by particular features.

**Motor cortex.** Weakness and/or loss of skilled movement confined to one contralateral limb (an arm or a leg – monoparesis) or part of a limb (e.g. a clumsy hand) is typical of an isolated motor cortex lesion (e.g. a secondary neoplasm). A defect in cognitive function (e.g. aphasia) and focal epilepsy may occur.

**Internal capsule.** Corticospinal fibres are tightly packed in the internal capsule (about 1 cm²), thus a small lesion causes a large deficit. A middle cerebral arterial branch infarction (p. 1100) produces a sudden, dense, contralateral hemiplegia.

**Pons.** A pontine lesion (e.g. an MS plaque) is rarely confined to the corticospinal tract. Adjacent structures, e.g. VIIth and VIIIth nuclei, MLF and PPRF (p. 1075) are involved – diplopia, facial weakness, internuclear ophthalmoplegia (INO) and/or a lateral gaze palsy occur with contralateral hemiparesis.

**Spinal cord.** An isolated lesion of one lateral corticospinal tract (e.g. a cervical cord injury) causes an ipsilateral UMN lesion, the level indicated by changes in reflexes (e.g. absent biceps, C5/6), features of a Brown–Séquard syndrome (p. 1086) and muscle wasting at the level of the lesion (p. 1087).

**Spastic paraparesis**
Paraparesis indicates bilateral damage to corticospinal pathways causing weakness and spasticity (or flaccid weakness in the initial phase of spinal shock after an acute cord insult). Cord compression (p. 1135) or cord diseases are the usual causes; cerebral lesions occasionally produce paraparesis. Paraparesis is a feature of many neurological conditions; finding the cause is crucial (p. 1135).

**Extrapyramidal system**
The extrapyramidal system is a general term for basal ganglia motor systems, i.e. corpus striatum (caudate nucleus + globus pallidus + putamen), subthalamic nucleus, substantia nigra and parts of the thalamus. In basal ganglia/extrapyramidal disorders, two features (either or both) become apparent, in limbs and axial muscles:

- Reduction in speed (bradykinesia, meaning slow movement) or akinesia (no movement), with muscle rigidity
- Involuntary movements (e.g. tremor, chorea, hemiballismus, athetosis, dystonia).

Extrapyramidal disorders are classified broadly into akinetic-rigid syndromes (p. 1130) where poverty of movement predominates, and dyskinesias where there are involuntary movements (p. 1121).

The most common extrapyramidal disorder is Parkinson’s disease.

**Essential anatomy**
The corpus striatum lies close to the substantia nigra, thalami and subthalamic nuclei, lateral to the internal capsule (Figs 22.9, 22.10).

**Function and dysfunction**
Overall function of this system is modulation of cortical motor activity by a series of servo loops between cortex and basal ganglia (Fig. 22.10). In involuntary movement disorders there are specific changes in neurotransmitters (Table 22.5) rather than focal lesions seen on imaging or at autopsy.
The model helps explain how basal ganglia disease can either reduce excitatory thalamo-cortical activity at synapse H, i.e. movement – causing bradykinesia, or increase it, causing dyskinesias.

**Parkinson’s disease (PD).** This is characterized by slowness, stiffness and rest tremor (p. 1118). Degeneration in SNc causes loss of dopamine activity in the striatum. Dopamine is excitatory for synapse A and inhibitory for synapse B. Through the direct pathway there is reduced activity at synapse F, leading to increased inhibitory output (G) and decreased cortical activity (H).

Also in PD, in the indirect pathway, dopamine deficiency results in disinhibition of neurones synapsing at C. This leads to reduced activity at D, and to increased activity of neurones in the subthalamic nucleus. There is excess stimulation at synapse E, enhancing further inhibitory output of Gm-SNr.

The net effect via both pathways is to inhibit the ventral anterior (VA) and ventrolateral (VL) nuclei of the thalamus at synapse G. Cortical (motor) activity at H is thus reduced.

Levodopa helps slowness and tremor in PD (p. 1119) but induces unwanted dyskinesias by increasing dopamine activity at synapses A and B, it is thought by reversing sequences in both direct and indirect pathways.

**Hemiballismus** (p. 1121). Wild, flinging (ballistic) limb movements are caused by a lesion in the subthalamic nucleus, typically an infarct. This reduces excitatory activity at synapse E, reduces inhibition at G, with increased thalamo-cortical neuronal activity, and increases activity at H.

### Cerebellum

The third system of motor control modulates coordination and learned movement patterns, rather than speed. Ataxia, i.e. unsteadiness, is characteristic.

The cerebellum receives afferents from:
- proprioceptive receptors (joints and muscles)
- vestibular nuclei
- basal ganglia
- the corticospinal system
- olivary nuclei.

Efferents pass from the cerebellum to:
- each red nucleus
- vestibular nuclei
- basal ganglia
- corticospinal system.

Each lateral cerebellar lobe coordinates movement of the ipsilateral limbs. The vermis (a midline structure) is concerned with maintenance of axial (midline) posture and balance.

### Cerebellar lesions (Box 22.9)

Expanding lesions obstruct the aqueduct to cause hydrocephalus, with severe pressure headaches, vomiting and papilloedema. Coning of the cerebellar tonsils (p. 1133) through the foramen magnum leads to respiratory arrest, sometimes within minutes/hours. Rarely, tonic seizures (attacks of limb stiffness) occur.

### Lateral cerebellar hemisphere lesions

A lesion within one cerebellar lobe (e.g. tumour or infarction) causes disruption of the normal sequence of movements (dyssynergia) on the same side.
Posture and gait. The outstretched arm is held still in the early stages of a cerebellar lobar lesion (cf. the drift of pyramidal lesions) but there is rebound upward overshoot when the limb is pressed downwards and released. Gait becomes broad and ataxic, faltering towards the side of the lesion.

Tremor and ataxia. Movement is imprecise in direction, force and distance (dysmetria). Rapid alternating movements (tapping, clapping or rotary hand movements) become disorganized (dysdiadochokinesia). Intention tremor (action tremor with past-pointing) is seen, but speed of fine movement is preserved, cf. extrapyramidal and pyramidal lesions.

Nystagmus. Coarse horizontal nystagmus (p. 1075) develops with a lateral cerebellar lobe lesion. The fast component is always towards the side of the lesion.

Dysarthria. Halting, jerking speech develops – scanning speech.

Other signs. Titubation – rhythmic head tremor as either forward and back (yes-yes) movements or rotary (no-no) movements – can occur, mainly when cerebellar connections are involved (e.g. in essential tremor and MS, pp. 1080 and 1124). Hypotonia (floppy limbs) and depression of reflexes (with slow, pendular reflexes) are also sometimes seen.

Midline cerebellar lesions
Cerebellar vermis lesions have dramatic effects on trunk and axial muscles. There is difficulty standing and sitting unsupported (truncal ataxia), with a rolling, broad, ataxic gait. Lesions of the flocculonodular region cause vertigo and vomiting with gait ataxia if they extend to the roof of the IVth ventricle. Box 22.9 summarizes the main causes of cerebellar disease.

Tremor
Tremor means a regular and sinusoidal oscillation of the limbs, head or trunk.

Postural tremor
Everyone has a physiological tremor (often barely perceptible) of the outstretched hands at 8–12 Hz. This is increased with anxiety, caffeine, hyperthyroidism and drugs (e.g.

sympathomimetics, sodium valproate, lithium) and occurs in mercury poisoning. A coarser, postural tremor is seen in benign essential tremor (usually at 5–8 Hz) and in chronic alcohol use.

Intention tremor
Tremor exacerbated by action, with past-pointing and accompanying incoordination of rapid alternating movement (dysdiadochokinesia), occurs in cerebellar lobe disease and with lesions of cerebellar connections. Titubation and nystagmus may be present.

Rest tremor
Seen typically in Parkinson’s disease, this tremor is noticeably worse at rest, usually 4–7 Hz (pill-rolling, between thumb and forefinger).

Other tremors
Coarse tremor is seen following lesions of the red nucleus (e.g. infarction, multiple sclerosis) and rarely with frontal lesions.

LOWEER MOTOR NEURONE (LMN) LESIONS

The LMN is the pathway from anterior horn cell (or cranial nerve nucleus) via a peripheral nerve to muscle motor endplates. The motor unit consists of one anterior horn cell, its single fast-conducting axon that leaves the cord via the anterior root, and the group of muscle fibres (100–2000) supplied via the nerve. Anterior horn cell activity is modulated by impulses from:

- corticospinal tracts
- extrapyramidal system
- cerebellum
- afferents via posterior roots.

Signs of lower motor neurone lesions
These are seen in voluntary muscles that depend upon an intact nerve supply both for contraction and metabolic integrity. Signs follow rapidly if the LMN is interrupted (Box 22.10).

Causes
Examples of LMN lesions at various levels:

- Cranial nerve nuclei (Bell’s palsy) and anterior horn cell (motor neurone disease)
- Spinal root – cervical and lumbar disc protrusion, neuralgic amyotrophy (p. 1149)
- Peripheral (or cranial) nerve – trauma, entrapment (p. 1144), polyneuropathy (p. 1145).
Sensory pathways and pain

Peripheral nerves and spinal roots

Peripheral nerves carry all modalities of sensation from either free or specialized nerve endings to dorsal roots and thence to the cord. Sensory distribution of spinal roots (dermatomes) is shown in Figure 22.12.

Spinal reflex arc

Components are illustrated in Figure 22.11. The stretch reflex is the physiological basis for all tendon reflexes. In the knee jerk, a tap on the patellar tendon activates stretch receptors in the quadriceps. Impulses in first-order sensory neurones pass directly to LMNs (L3 and L4) that contract quadriceps. Loss of a tendon reflex is caused by a lesion anywhere along the spinal reflex path. The reflex lost indicates its level (Table 22.6).

Reinforcement. Distraction of the patient’s attention, clenching teeth or pulling interlocked fingers enhances reflex activity. Such reinforcement manoeuvres should be done before a reflex is recorded as absent.

SENSORY PATHWAYS AND PAIN

Peripheral nerves and spinal roots

Peripheral nerves carry all modalities of sensation from either free or specialized nerve endings to dorsal roots and thence to the cord. Sensory distribution of spinal roots (dermatomes) is shown in Figure 22.12.

Spinal cord

Posterior columns

Axons in the posterior columns whose cell bodies are in the ipsilateral gracile and cuneate nuclei in the medulla carry sensory modalities of vibration, joint position (proprioception), light touch and two-point discrimination. Axons from second-order neurones then cross in the brainstem to form the medial lemniscus, passing to the thalamus (Fig. 22.13).
Neurological disease

Neuralgia

Neuralgia refers to pain, usually of great severity, in the distribution of a damaged nerve. Examples are:

- Trigeminal neuralgia (p. 1110)
- Postherpetic neuralgia (p. 1129)
- Complex regional pain syndrome type II (causalgia) – chronic burning pain that occasionally follows nerve section.

Spinal root lesions

Root pain

Pain of root compression is felt in the myotome supplied by the root, and there is also a tingling discomfort in the dermatome. The pain is worsened by manoeuvres that either stretch the root (e.g. straight leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining). Cervical and lumbar disc protrusions (p. 1148) are common causes of root lesions.

Dorsal spinal root lesions

Section of a dorsal root causes loss of all modalities of sensation within a dermatome (see Fig. 22.12). However, overlap between adjacent dermatomes makes it difficult to detect anaesthesia when a single root is destroyed.

Lightning pains.

Tabes dorsalis (rare in the UK) is a form of neurosyphilis that causes low-grade inflammation.

Spinothalamic tracts

Axons carrying pain and temperature sensation synapse in the dorsal horn of the cord, cross within the cord and pass in the spinothalamic tracts to the thalamus and reticular formation.

Sensory cortex

Fibres from the thalamus pass to the parietal region sensory cortex (Fig. 22.13). Connections exist between the thalamus, sensory cortex and motor cortex.

Lesions of the sensory pathways

Altered sensation (paraesthesia), tingling, clumsiness, numbness and pain are the principal symptoms of sensory lesions. The pattern and distribution point to the site of pathology (Fig. 22.14).

Peripheral nerve lesions

Symptoms are felt within the distribution of a peripheral nerve (p. 1143). Section of a sensory nerve is followed by complete sensory loss. Nerve entrapment (p. 1144) causes numbness, pain and tingling. Tapping the site of compression sometimes causes a sharp, electric-shock-like pain in the distribution of the nerve, known as Tinel’s sign, e.g. in carpal tunnel syndrome (p. 1144).

Neuralgia

Neuralgia refers to pain, usually of great severity, in the distribution of a damaged nerve. Examples are:

- Trigeminal neuralgia (p. 1110)
- Postherpetic neuralgia (p. 1129)
- Complex regional pain syndrome type II (causalgia) – chronic burning pain that occasionally follows nerve section.

Spinal root lesions

Root pain

Pain of root compression is felt in the myotome supplied by the root, and there is also a tingling discomfort in the dermatome. The pain is worsened by manoeuvres that either stretch the root (e.g. straight leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining). Cervical and lumbar disc protrusions (p. 1148) are common causes of root lesions.

Dorsal spinal root lesions

Section of a dorsal root causes loss of all modalities of sensation within a dermatome (see Fig. 22.12). However, overlap between adjacent dermatomes makes it difficult to detect anaesthesia when a single root is destroyed.

Lightning pains.

Tabes dorsalis (rare in the UK) is a form of neurosyphilis that causes low-grade inflammation.

Spinothalamic tracts

Axons carrying pain and temperature sensation synapse in the dorsal horn of the cord, cross within the cord and pass in the spinothalamic tracts to the thalamus and reticular formation.

Sensory cortex

Fibres from the thalamus pass to the parietal region sensory cortex (Fig. 22.13). Connections exist between the thalamus, sensory cortex and motor cortex.

Lesions of the sensory pathways

Altered sensation (paraesthesia), tingling, clumsiness, numbness and pain are the principal symptoms of sensory lesions. The pattern and distribution point to the site of pathology (Fig. 22.14).

Peripheral nerve lesions

Symptoms are felt within the distribution of a peripheral nerve (p. 1143). Section of a sensory nerve is followed by complete sensory loss. Nerve entrapment (p. 1144) causes numbness, pain and tingling. Tapping the site of compression sometimes causes a sharp, electric-shock-like pain in the distribution of the nerve, known as Tinel’s sign, e.g. in carpal tunnel syndrome (p. 1144).

Neuralgia

Neuralgia refers to pain, usually of great severity, in the distribution of a damaged nerve. Examples are:

- Trigeminal neuralgia (p. 1110)
- Postherpetic neuralgia (p. 1129)
- Complex regional pain syndrome type II (causalgia) – chronic burning pain that occasionally follows nerve section.

Spinal root lesions

Root pain

Pain of root compression is felt in the myotome supplied by the root, and there is also a tingling discomfort in the dermatome. The pain is worsened by manoeuvres that either stretch the root (e.g. straight leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining). Cervical and lumbar disc protrusions (p. 1148) are common causes of root lesions.

Dorsal spinal root lesions

Section of a dorsal root causes loss of all modalities of sensation within a dermatome (see Fig. 22.12). However, overlap between adjacent dermatomes makes it difficult to detect anaesthesia when a single root is destroyed.

Lightning pains.

Tabes dorsalis (rare in the UK) is a form of neurosyphilis that causes low-grade inflammation.

Spinothalamic tracts

Axons carrying pain and temperature sensation synapse in the dorsal horn of the cord, cross within the cord and pass in the spinothalamic tracts to the thalamus and reticular formation.

Sensory cortex

Fibres from the thalamus pass to the parietal region sensory cortex (Fig. 22.13). Connections exist between the thalamus, sensory cortex and motor cortex.

Lesions of the sensory pathways

Altered sensation (paraesthesia), tingling, clumsiness, numbness and pain are the principal symptoms of sensory lesions. The pattern and distribution point to the site of pathology (Fig. 22.14).

Peripheral nerve lesions

Symptoms are felt within the distribution of a peripheral nerve (p. 1143). Section of a sensory nerve is followed by complete sensory loss. Nerve entrapment (p. 1144) causes numbness, pain and tingling. Tapping the site of compression sometimes causes a sharp, electric-shock-like pain in the distribution of the nerve, known as Tinel’s sign, e.g. in carpal tunnel syndrome (p. 1144).

Neuralgia

Neuralgia refers to pain, usually of great severity, in the distribution of a damaged nerve. Examples are:

- Trigeminal neuralgia (p. 1110)
- Postherpetic neuralgia (p. 1129)
- Complex regional pain syndrome type II (causalgia) – chronic burning pain that occasionally follows nerve section.

Spinal root lesions

Root pain

Pain of root compression is felt in the myotome supplied by the root, and there is also a tingling discomfort in the dermatome. The pain is worsened by manoeuvres that either stretch the root (e.g. straight leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining). Cervical and lumbar disc protrusions (p. 1148) are common causes of root lesions.

Dorsal spinal root lesions

Section of a dorsal root causes loss of all modalities of sensation within a dermatome (see Fig. 22.12). However, overlap between adjacent dermatomes makes it difficult to detect anaesthesia when a single root is destroyed.

Lightning pains.

Tabes dorsalis (rare in the UK) is a form of neurosyphilis that causes low-grade inflammation.
of dorsal roots and spinal cord root entry zones. Irregular, sharp, stabbing pains (like lightning) involve one or two spots, typically in a calf, thigh or ankle.

**Spinal cord lesions**

**Posterior column lesions**

These cause:
- Tingling
- Electric-shock-like sensations
- Clumsiness
- Numbness
- Band-like sensations.

These symptoms, though lateralized, are often felt vaguely without a clear sensory level. Position sense, vibration sense, light touch and two-point discrimination are diminished below the lesion. Position sense loss produces a stamping gait (sensory ataxia, p. 1068).

**Lhermitte's phenomenon**

Electric-shock-like sensations radiate down the trunk and limbs on neck flexion. This points to a cervical cord lesion. Lhermitte’s is common in acute exacerbations of MS (p. 1124), and also occurs in cervical myelopathy (p. 1149), subacute combined degeneration of the cord (p. 1147), radiation myelopathy (p. 1149) and cord compression.

**Spinothalamic tract lesions**

Pure spinothalamic spinal lesions cause contralateral loss of pain and temperature sensation with a clear level below the lesion. This is called dissociated sensory loss – pain and temperature are dissociated from light touch, which remains preserved. This is seen typically in syringomyelia where a cavity occupies the central cord (p. 1137).

The spinal level is modified by lamination of fibres within the spinothalamic tracts. Fibres from lower spinal roots lie superficially and are damaged first by compressive lesions from outside the cord. As an external compressive lesion (e.g. a midthoracic extradural meningioma): Fig. 22.15 enlarges, the spinal sensory level ascends as deeper fibres become involved. Conversely, a central cord lesion (e.g. a syrinx, p. 1137) affects deeper fibres first. Spinothalamic tract lesions cause loss of pain and temperature perception (e.g. painless burns). Perforating ulcers and neuropathic (Charcot) joints develop.

**Spinal cord compression** (Fig. 22.15)

Cord compression causes progressive spastic paraparesis (or tetraparesis/quadriparesis) with sensory loss below the level of compression. Sphincter disturbance is common. Root pain is frequent but not invariable, felt characteristically at the level of compression. With thoracic cord compression (e.g. an extradural meningioma), pain radiates around the chest, exacerbated by coughing and straining, as meningeval root sheaths are stretched.

Damage to one spinothalamic tract (contralateral loss of pain and temperature) with the ipsilateral corticospinal tract is known as the Brown-Séquard syndrome (originally, cord hemisection). The patient complains of numbness on one side and weakness on the other. Paraparesis/spinal cord lesions are discussed on page 1135.

**Pontine lesions**

Since lesions (e.g. an MS plaque) lie above the decussation of the posterior columns, and both medial lemniscus and spinothalamic tracts are close together, there is loss of all forms of sensation on the side opposite the lesion. Combinations of III, IV, V, VI and VII cranial nerve nuclei are seen, and may indicate a level (Fig. 22.13).

**Thalamic lesions**

Thalamic pain (also called central post-stroke pain or thalamic syndrome) follows a small thalamic infarct. The patient has a stroke (hemiparesis and sensory loss). Weakness improves, but deep-seated constant pain in the paretic limbs develops. Chorea-aethetic movements occur. Secondary depression may lead to self-harm. Thalamic lesions can also cause diminished sensation alone, on the opposite side; this is less usual.

**Parietal cortex lesions**

Sensory loss, neglect of one side, apraxia (p. 1068) and subtle disorders of sensation occur. Pain is not a feature of destructive cortical lesions. Irritative phenomena (e.g. partial sensory seizures from a parietal cortex glioma) cause tingling sensations in a limb, or elsewhere.

**Pain**

Pain is an unpleasant, unique physical and psychological experience. Acute pain serves a biological purpose (e.g. withdrawal) and is typically self-limiting, ceasing as healing ensues. Some forms of chronic pain (e.g. causalgia) outlast the period required for healing, and may be permanent.

**Essential physiology of pain**

Pain perception is mediated by free nerve endings, terminations of finely myelinated A-delta and of non-myelinated C fibres. Chemicals released following injury produce pain either by direct stimulation or by sensitizing nerve endings. A-delta fibres give rise to perception of sharp, immediate pain, then slower-onset, more diffuse and prolonged pain is mediated by slower-conducting C fibres.

Sensory impulses enter the cord via dorsal spinal roots. Impulses ascend either in each dorsal (posterior) column or in each spinothalamic tract. Grey matter neurones in the cord
are arranged in laminae labelled I–X (dorsal to ventral). A fibres terminate in laminae I and V and excite second-order neurones that project to the contralateral side via the anterior commissure and via the anterolateral column of the direct spinothalamic tract. C fibres mostly terminate in the substantia gelatinosa (laminae II and III); axons then pass through the anterior commissure to the contralateral side and rostrally, up the spino-reticulo-thalamic tract.

The spinothalamic tracts carry impulses that localize pain. Thalamic pathways to and from the cortex mediate emotional components. Sympathetic activity increases pain, e.g. hyperaemia in a painful limb.

**Gate theory of pain**

Gate theory, a useful way of thinking about pain, proposes that entry of afferent impulses is monitored first by the substantia gelatinosa. This gate determines whether or not sufficient activity penetrates to fire secondary neurones in the dorsal horn. This, and subsequent gates, are influenced by brain and cord regulators that alter how far a gate remains open.

Animal studies suggest that downstream regulators binding to calcium-regulated transcription factors control CNS endogenous opiate precursors (e.g. pro-dynorphin). These modulate pain.

**Endogenous opiates**

Endorphin peptides have opioid activity and probably account for placebo phenomena, effects of stress and acupuncture, and may explain in part why some patients develop chronic pain syndromes. Endorphins are CNS neurotransmitters acting at inhibitory synapses via δ, κ, and μ-receptors. Dynorphin (from the precursor, pro-dynorphin) is thought to modulate nociceptive (pain) impulses entering the cord.

**Management of chronic pain**

Chronic pain is gravely disabling, distressing, and taxing to treat (p. 509). Multidisciplinary pain-relief clinics provide specific and supportive therapy.

Management plans for intractable pain have seven components:

**Diagnostic**

Rigorous history must be paid to the diagnosis, reviewing the entire history and investigations. A specific surgical approach may become apparent (e.g. spinal stenosis, trigeminal neuralgia, glossopharyngeal neuralgia, or syringomyelia).

**Psychological**

Chronic pain influences quality of life. Depression (p. 1170) is commonly associated with pain when the pathology is benign; antidepressants can help. Of patients suffering pain from secondary cancer about one-third are clinically depressed.

**Analgesics**

Perseverance and compliance with therapy is a common problem. The WHO analgesic ladder (p. 487) is useful.

**Co-analgesics**

Co-analgesics have a primary use other than for pain but help either alone or when added to analgesics. Examples are:

- Tricyclic antidepressants, e.g. amitriptyline
- Duloxetine – a serotonin-norepinephrine reuptake blocker
- Anticonvulsants, e.g. carbamazepine, gabapentin and pregabalin (p. 486)
- Calcium-channel blockers, e.g. ziconotide used intrathecally in chronic refractory pain
- Muscle relaxants (spasticity)
- Capsaicin topical preparations – extracts from capsicum plants (chilli peppers) which bind to vanilloid receptors on pain neurones and deplete them of neurotransmitters such as substance P.

**Stimulation**

Acupuncture, ice, heat, ultrasound, massage, transcutaneous electrical nerve stimulation (TENS) and spinal cord stimulation all achieve analgesia by gating effects on large myelinated nerve fibres.

**Nerve blocks**

Pain pathways can be blocked either temporarily by local anaesthetic (by injection or with topical patches) or permanently with phenol, or radiofrequency lesions:

- Somatic blocks:
  - peripheral nerve and plexus injections
  - epidural and spinal analgesia
- Sympathetic blocks:
  - sympathetic ganglia injections
  - central epidural and spinal sympathetic blockade.

**Neurosurgery**

Highly specialized techniques have a place alongside drugs. Examples are dorsal rhizotomy, sympathectomy, cordotomy and neurostimulation.

**BLADDER CONTROL AND SEXUAL DYSFUNCTION**

Changes in micturition and failure of normal sexual activity due to neurological conditions are seen in sacral, spinal cord and cortical disease.

**Essential functions and anatomy**

The bladder has two functions: storage and voiding. Afferent pathways (T12–S4) respond to pressure within the bladder and sensation from the genitalia. As the bladder distends, continence is maintained by suppression of parasympathetic and reciprocal activation of sympathetic outflow. Both are under some voluntary control. Voiding takes place by parasympathetic activation of the detrusor, and relaxation of the internal sphincter (Table 22.7).

Cortical awareness of bladder fullness is located in the post-central gyrus, parasagittally, while initiation of
micturition is in the pre-central gyrus. Voluntary control of micturition is located in the frontal cortex, parasagittally.

Neurological disorders of micturition

Urogenital tract disease is dealt with largely by urologists. Incontinence is common and easy to recognize; neurological causes are sometimes not obvious. These are:

Cortical:
- Post-central lesions cause loss of sense of bladder fullness
- Pre-central lesions cause difficulty initiating micturition
- Frontal lesions cause socially inappropriate micturition.

Spinal cord. Bilateral UMN lesions (pyramidal tracts) cause urinary frequency and incontinence. The bladder is small and hypertonic, i.e. sensitive to small changes in intra-vesical pressure. Frontal lesions can also cause a hypertonic bladder.

LMN. Sacral lesions (conus medullaris, sacral root and pelvic nerve – bilateral) cause a flaccid, atonic bladder that overflows (cauda equina, p. 1149), often unexpectedly.

Management. Assessment of both urological causes (e.g. calculi, prostatism, gynaecological problems) and potential neurological causes of incontinence is necessary. Intermittent self-catheterization is used by many patients, with for example spinal cord lesions.

Male erectile dysfunction

Failure of penile erection often has mixed organic and psychological causes. Depression is common. Endocrine aspects of sexual dysfunction are described on page 977. Erectile dysfunction is sometimes helped by phosphodiesterase type 5 inhibitors, e.g. sildenafil.

NEUROLOGICAL TESTS

Skull-imaging

These show:
- Fractures of the vault or base
- Vault and skull base disease (e.g. metastases, osteomyelitis, Paget’s disease, abnormal skull foramina, fibrous dysplasia)
- Enlargement or destruction of the pituitary fossa-intrasellar tumour, raised intracranial pressure
- Intracranial calcification – tuberculoma, oligodendrogloma, wall of an aneurysm, cysticercosis.

Spinal X-rays show fractures, congenital and destructive lesions (bone cysts, infection, metastases) and degenerative spondylosis.

Imaging brain and spinal cord

Brain CT and MRI are widely available worldwide. Myelography (contrast imaging of the cord and ventricles; ventriculography) is obsolete.

Brain computed tomography (CT)

A collimated X-ray beam moves synchronously across a brain slice 2–13 mm thick. Transmitted X-irradiation from a pixel, an element <1 mm², is computer-processed to assign a Hounsfield number to its density (air = −1000 units; water = 0; bone = +1000 units). The digital data are converted to cross-sectional images to reconstruct brain anatomy. Helical CT (spiral or volumetric CT) provides greater definition in a shorter time. It is used for two-dimensional reconstruction.

Differences in attenuation (density) between bone, brain and CSF enable recognition of normal and infarcted tissue, tumour, blood, intracerebral haemorrhage, free subarachnoid blood, subdural and extradural haematoma and oedema.

Enhancement with i.v. contrast delineates areas of altered blood supply (CT angiography).

Safety. The irradiation involved is relatively small. There are occasional reactions to contrast.

Limitations of brain CT
- Lesions under 1 cm in diameter may be missed.
- Lesions with attenuation close to bone may be missed, if near the skull.
- Lesions with attenuation similar to brain are poorly displayed (e.g. MS plaques, isodense subdural haematoma).
- CT is not good at detecting posterior fossa lesions because of surrounding bone.
- Patient cooperation: an anaesthetic is very occasionally needed.

Magnetic resonance imaging: MRI

A hydrogen nucleus is a proton whose electrical charge creates a local electrical field. Protons are aligned by sudden strong magnetic impulses and then imaged with radio-frequency waves at right angles to their alignment. The protons resonate and spin, then revert to their normal alignment. As they do so, images are made at different phases of relaxation, known as T₁, T₂, T₂* STIR, FLAIR, diffusion-weighted imaging (DWI) and other sequences. From these sequences, often referred to as different weightings, recorded images are compared. Gadolinium is used as i.v. contrast to show areas of increased vascularity.

Advantages of MRI
- MR distinguishes between white and grey matter in the brain and cord.
- Cord and nerve roots are imaged directly.
- Pituitary imaging.
- MRI has resolution superior to CT (around 0.5 cm).
- No radiation is involved.
- MR angiography (MRA) images blood vessels without contrast.
- MR images soft tissues.
- Tumours, infarction, haemorrhage, MS plaques, posterior fossa, foramen magnum and cord are demonstrated well by MRI.

Limitations are principally time and cost. Patients need to keep still within a narrow tube: claustrophobia is an issue; open machines are available that are less claustrophobic. Patients with pacemakers or metallic fragments in the brain cannot be imaged. MR imaging frequently shows diffuse meningeal enhancement with gadolinium for some days after lumbar puncture (p. 1091).

Doppler studies

B-mode and colour ultrasound are valuable in detection of carotid stenosis.
Digital cerebral and spinal angiography
Where advanced MRI and CT are available, these techniques are little used. Contrast is injected intra-arterially or intravenously. Angiography carries a mortality and stroke risk (<1%). Images of aorta, carotid, vertebral and brain arteries demonstrate occlusion, stenoses, atheroma, aneurysms and arteriovenous malformations (AVMs). Spinal angiography images cord AVMs.

Positron emission tomography (PET), single proton emission computed tomography (SPECT), dopamine transporter imaging (DAT) and functional MRI (fMRI)
These functional imaging techniques track uptake of radioisotopes and/or metabolites. PET is used principally in the detection of occult neoplasms, outside the CNS. SPECT is little used in cerebrovascular disease and traumatic brain injury – there are issues of reliability. DAT is used in basal ganglia disease. fMRI is largely a research tool for mapping brain function, in health and disease.

Isotope bone scanning
The radioisotope $^{99m}$Tc-pertechnetate is given intravenously. The technique is used principally in detection of vertebral, skull and bone metastases.

Electroencephalography (EEG)
EEG (Fig. 22.16) recorded from scalp electrodes (16 channels simultaneously) is of value in epilepsy and diffuse brain diseases. Videotelemetry, combining EEG with video, is invaluable in attacks difficult to diagnose.

Epilepsy
Spikes, or spike-and-wave abnormalities, are hallmarks of epilepsy, but it should be emphasized that patients with epilepsy often have a normal EEG between seizures (p. 1092).

Diffuse brain disorders
Slow-wave EEG abnormalities appear in encephalitis, prion (Creutzfeldt–Jakob) diseases and metabolic states (e.g. hypoglycaemia, hepatic coma).

Brain death
The EEG is isoelectric (flat); EEG is no longer necessary to confirm brain death (p. 898).

Electromyography and conduction studies
Electromyography
A concentric needle electrode is inserted into voluntary muscle. Amplified recordings, on an oscilloscope, are also heard through a speaker. The main EMG features:

- Normal interference pattern
- Denervation and reinnervation changes
- Myopathic, myotonic and myasthenic changes (p. 1090).

Peripheral nerve conduction (Fig. 22.17)
Four measurements are of principal value in neuropathies and nerve entrapment:

- Mean nerve (motor and sensory) conduction velocity
- Distal motor latency
- Sensory action potentials
- Muscle action potentials.

Measurements differentiate between axonal and demyelinating damage and determine whether pathology is focal or diffuse.

Cerebral-evoked potentials
Visual-evoked potentials (VEPs) record the interval visual stimuli take to reach the occipital cortex, and the amplitude
**Lumbar puncture and CSF examination**

See Table 22.8 and Practical Box 22.3.

**Indications for lumbar puncture (LP):**

- Diagnosis of meningitis and encephalitis
- Diagnosis of subarachnoid haemorrhage (sometimes)
- Measurement of CSF pressure, e.g. idiopathic intracranial hypertension (p. 1110)
- Removal of CSF therapeutically, e.g. idiopathic intracranial hypertension
- Diagnosis of various conditions, e.g. MS, neurosyphilis, sarcoidosis, Behçet’s, neoplasmatic involvement, polyneuropathies
- Intrathecal injection/drugs.

Meticulous attention should focus on microbiology in suspected CNS infection. Close liaison between clinician and microbiologist is essential. Specific techniques (e.g. polymerase chain reaction to identify bacteria) are invaluable. Repeated CSF examination is often necessary in chronic infection such as tuberculosis. Post-LP headaches, worse on standing, are a common complaint for several days (or more). Prolonged headaches can be treated by an ‘autologous intrathecal blood patch’ – injection of 20 mL of the patient’s venous blood into the CSF.

## Biopsy

Interpretation of brain, tonsillar, muscle and nerve histology requires specialist neuropathology services.

### Brain and meninges

Brain biopsy (e.g. of a non-dominant frontal lobe) is sometimes used to diagnose inflammatory and degenerative brain diseases. CT and MR stereotactic biopsies of intracranial lesions are standard procedures.

### Tonsillar biopsy

This is used in the diagnosis of variant Creutzfeldt-Jakob disease.

### Muscle

Biopsy, with light and electron microscopy and biochemical analysis, elucidates diagnosis of inflammatory, metabolic and dystrophic disorders (p. 1152).

**Practical Box 22.3**

**Lumbar puncture**

The procedure should be explained to the patient, and consent obtained. LP should not be performed in the presence of raised intracranial pressure or when an intracranial mass lesion is possible.

**Technique**

- The patient is placed on the edge of the bed in the left lateral position with knees and chin as close together as possible.
- The third and fourth lumbar spines are marked. The fourth lumbar spine usually lies on a line joining the iliac crests.
- Using sterile precautions, 2% lidocaine is injected into the dermis by raising a bleb in either the third or fourth lumbar interspace.
- The LP needle is pushed through the skin in the midline, steadily forwards and slightly towards the head, with the head and spine bolstered horizontally with pillows.
- When the needle is felt to penetrate the dura, the stylet is withdrawn and a few drops of CSF allowed to escape.
- The CSF pressure can then be measured with a manometer connected to the needle. The patient’s head must be on the same level as the sacrum. Normal CSF pressure is 60–150 mm of CSF. The level rises and falls with respiration and heart beat, and rises on coughing.
- CSF specimens are collected in three sterile bottles and a sample for CSF glucose, together with a simultaneous blood glucose sample.
- Record CSF naked-eye appearance: clear, cloudy, yellow (xanthochromic), red.
- The patient is asked to lie flat after the procedure to avoid subsequent headaches, but this manoeuvre is probably of little value.
- Analgesics may be required for post-LP headaches.

**Contraindications**

- Suspicion of a mass lesion in the brain or cord. Caudal herniation of the cerebellar tonsils (coning) may occur if an intracranial mass is present and the pressure below is reduced by removal of CSF.
- Any cause of raised intracranial pressure.
- Local infection near the LP site.
- Congenital lesions in the lumbosacral region (e.g. meningomyelocele).
- Platelet count <40×10⁹/L and other clotting abnormalities, including anticoagulant drugs.
- Unconscious patients and those with papilloedema must have a CT scan before lumbar puncture.

**Notes**

- Contraindications are relative; there are circumstances when LP is carried out despite them.
- Composition of normal CSF is shown in Table 22.8.

**Peripheral nerve**

Biopsy, usually of a sural nerve (ankle) or superficial branch of a radial nerve, aids diagnosis in polyneuropathies.

**Psychometric assessment**

Psychometric testing assesses cognitive function. Preservation of verbal IQ (a measure of past attainments) with deterioration of performance IQ (a measure of present abilities) indicates decline of cognitive function, seen for example following brain injury or in dementia. Low subtest scores (e.g. block design, various aspects of memory, visual, speech and constructional skills) indicate impaired function of specific brain regions.

Depression and lack of attention also reduce scores – a substantial problem. Opinions sometimes vary between psychologists about interpretation of tests, particularly after brain injury, limiting the value of the tests.
Disturbed consciousness: definitions

Coma: a state of unrousable unresponsiveness. Level of consciousness represents a continuum between being alert and deeply comatose. It may be quantified using the Glasgow Coma Scale (GCS) with a score between 3 and 15 (Table 22.10). Coma may be conveniently defined as a GCS of 8 or lower. Terms such as stupor and obtundation have been superseded by the GCS score and are no longer used.

Delirium: The term used to describe a confusional state in which reduced attention is a cardinal feature, usually with altered behaviour, cognition, orientation and a fluctuating level of consciousness (from agitation to hypoarousal) (see p. 1187).

Mechanisms and causes of coma (Box 22.11)

Altered consciousness is produced by four mechanisms affecting the ARAS in the brainstem or thalamus, and/or widespread impairment of cortical function (Fig. 22.18).

Brainstem lesion. A discrete brainstem or thalamic lesion, e.g. stroke may damage the ARAS.

Brainstem compression. A supratentorial mass lesion within the brain compresses the brainstem, inhibiting the ARAS, e.g. ‘coning’ from a brain tumour or...
Unconsciousness and coma

Mass lesions within the posterior fossa are particularly prone to cause brainstem compression and hydrocephalus.

**Diffuse brain dysfunction.** Generalized severe metabolic or toxic disorders (e.g. alcohol, sedatives, uraemia, hypercapnia) depress cortical and ARAS function.

**Massive cortical damage.** Unlike brainstem lesions, extensive damage of the cerebral cortex and cortical connections is required to cause coma, e.g. meningitis or hypoxic-ischaemic damage after cardiac arrest (see Fig. 22.19).

A single focal hemisphere (or cerebellar) lesion does not produce coma unless it compresses the brainstem. Cerebral oedema frequently surrounds masses, increasing their pressure effects.

The commonest causes of coma are:

- Metabolic disorders – 35%
- Drugs and toxins – 25%
- Mass lesions – 20%
- Other – including trauma, stroke and CNS infections.

**The unconscious patient**

**Immediate assessment and management**

- Check the airway, breathing and circulation.
- Stix for blood glucose; if hypoglycaemic give glucose (25 mL 50%).

**Obtain as much history as possible**

Limited history is one of the problems faced in assessing the unconscious patient. What were the circumstances? Ask paramedics, police, and witnesses. Contact the patient’s relatives, friends and GP and obtain past hospital notes. Look for drug details/bottles and identification data.

**General and neurological examination**

**General examination** (Fig. 22.20)

- Measure the patient’s temperature (with a low reading rectal thermometer if hypothermic). Check for meningism.
- Sniff the patient’s breath for ketones, alcohol and hepatic fetor.
- Survey the skin for signs of trauma or spinal injury, rash (meningococcal sepsis), jaundice or stigmata of chronic liver disease, cyanosis, injection marks.
- Respiratory pattern; e.g. Cheyne–Stokes (alternating hyperpnoea and periods of apnoea indicating bilateral cerebral or upper brainstem dysfunction) or acidotic (Kussmaul) respiration (deep, sighing hyperventilation seen in diabetic ketoacidosis and uraemia).

**Neurological examination**

Neurological examination aims to determine:

- Depth of coma (GCS)
- Brainstem function
- Lateralization of pathology.

**Glasgow Coma Scale**

Assessment of the GCS score is repeated regularly to determine whether the patient’s level of consciousness is progressively declining. Use painful stimulus (e.g. nail bed pressure) to each limb and central area (sternal rub or pressure over supraorbital nerve) and record best response. Shout commands.

---

**Figure 22.18 Anatomy of vegetative state, locked-in syndrome and brainstem death.** (Adapted from Bates D. Coma and brainstem death. Medicine 2004; 32, with permission of Elsevier.)

**Figure 22.19 MRI showing extensive cortical damage following meningitis** resulting in a permanent vegetative state.

**Figure 22.20 Assessing level of consciousness.**

- Treat seizures with buccal midazolam and if not terminated, intravenous phenytoin.
- If there is fever and meningism, give intravenous antibiotics.
- Intravenous naloxone or flumazenil (overdose) and thiamine (Wernicke’s encephalopathy) in people who use excess alcohol.

---

**Immediate assessment and management**

- Check the airway, breathing and circulation.
- Stix for blood glucose; if hypoglycaemic give glucose (25 mL 50%).
Neurological disease

The weak limbs (the PPRF in the pons controls lateral gaze to the ipsilateral side – page 1075) (Fig. 22.24).

Vestibulo-ocular reflex. Passive head turning produces conjugate ocular deviation away from the direction of rotation (doll’s head reflex). This reflex disappears in deep coma, in brainstem lesions and in brain death (Fig. 22.25).

Fundus
Look for papilloedema and subhyaloid retinal haemorrhage (seen in SAH).

Brainstem function

Pupils
Record their size and reaction to light (Fig. 22.21):
- **Dilatation of one pupil** that then becomes fixed to light indicates compression of the IIIrd nerve. This is a potential neurosurgical emergency (Fig. 22.22).
- **Bilateral mid-point reactive pupils** (i.e. normal pupils) are characteristic of metabolic comas and follow coma due to sedative drugs except opiates.
- **Bilateral light-fixed, dilated pupils** are one cardinal sign of brain death. They can occur in deep coma of any cause, but particularly in barbiturate intoxication and hypothermia.
- **Bilateral pinpoint, light-fixed pupils** occur with pontine lesions (e.g. haemorrhage) and with opiates.
- Mydriatic drugs and previous pupillary surgery can cause diagnostic difficulty.

Eye movements and position
- Dysconjugate eyes (divergent ocular axes) indicate a brainstem lesion, e.g. skew deviation (one eye up, one eye down; Fig. 22.23).
- Conjugate gaze deviation – towards the lesion in the frontal lobe and the normal limbs (unopposed activity of the intact frontal eye fields drives eyes to the opposite side); away from the lesion in the brainstem and towards the weak limbs (the PPRF in the pons controls lateral gaze to the ipsilateral side – page 1075) (Fig. 22.24).
In light coma, slow, side-to-side eye movements are seen (‘windscreen wiper’ eyes Fig. 22.26). Also seen with extensive cortical damage in deep coma.

Other brainstem reflexes
- Corneal reflex
- Gag/cough reflex (via ET tube if intubated)
- Respiratory drive (p. 794).

Lateralizing signs
Coma makes it difficult to recognize lateralizing signs. These are helpful:
- Asymmetry of response to visual threat in a stuporose patient: suggests hemianopia
- Asymmetry of face. Drooping or dribbling on one side, blowing in and out of mouth when the paralysed cheek does not move
- Asymmetry of tone. Unilateral flaccidity or spasticity may be the only sign of hemiparesis
- Asymmetry of decerebrate and decorticate posturing
- Asymmetrical response to painful stimuli
- Asymmetry of tendon reflexes and plantar responses. Both plantars are often extensor in deep coma.

Figure 22.26 ‘Windscreen wiper’ eyes (‘ping pong’ eyes). Slow side-to-side movements demonstrate diffuse cortical dysfunction. This is common in light coma and implies normal brainstem function. In deep coma it indicates extensive cortical damage.

Coma ‘look-alikes’
- Psychogenic coma.
- ‘Locked-in’ syndrome – complete paralysis except vertical eye movements/blinking in ventral pontine infarction. Patients have a functioning cerebral cortex and are fully aware but unable to communicate except through eye movements (Table 22.11).
- Severe paralysis, e.g. myasthenic crisis or severe Guillain–Barré syndrome.

Diagnosis and investigations in coma
Often, the cause is evident (e.g. head injury, metabolic disorder, overdose). Where lateralizing signs or brainstem pathology are found on examination, a mass lesion or infarction/haemorrhage is likely (note hypoglycaemia may also cause focal signs). If no cause is evident after clinical assessment, further investigations are essential.

Blood and urine
- Drugs screen – blood alcohol and salicylates, urine toxicology including screening for benzodiazepines, narcotics, amphetamines
- Biochemistry (urea, electrolytes, glucose, calcium, liver biochemistry)
- Metabolic and endocrine studies (TSH, cortisol)
- Arterial blood gases – for acidosis or high CO₂ levels
- Other, e.g. cerebral malaria (request thick blood film) and porphyria (p. 1043).

Brain imaging
CT brain imaging is the most readily available and safest modality in the unconscious patient (MRI is useful where CT is normal but presents greater monitoring challenges in the unconscious patient). CT is quick and effective in demonstrating all types of brain haemorrhage and most mass lesions; infarcts may be missed in the early stages and where only the brainstem is affected.

EEG, electroencephalography; PET, positron emission tomography; VS, vegetative state.
EEG and PET are not required to confirm brain death.
Stroke is the third most common cause of death (11% of all deaths in the UK) and the leading cause of adult disability worldwide. Although data are difficult to obtain, approximately two-thirds of the global burden of strokes is in middle- and low-income countries. Stroke risk increases with age but one-quarter of all strokes occur before the age of 65. The death rate following stroke is 20–25%.

Definitions

- **Stroke.** To the public, stroke means weakness, usually permanent on one side, often with loss of speech. Stroke is **defined** as a syndrome of rapid onset of cerebral deficit (usually focal) lasting >24 h or leading to death, with no cause apparent other than a vascular one. Hemiplegia following middle cerebral arterial thromboembolism is the typical example.

- **Transient ischaemic attack** (TIA) means a brief episode of neurological dysfunction due to temporary focal cerebral or retinal ischaemia without infarction, e.g. a weak limb, aphasia or loss of vision, usually lasting seconds or minutes with complete recovery. TIAs may herald a stroke. The arbitrary time of <24 hours is no longer used. Avoid the vague term ‘cerebrovascular accident’.

Pathophysiology

The underlying pathology responsible for stroke is either infarction or haemorrhage. Stroke mechanism and pathophysiology depends on the population studied but is broadly as follows (Fig. 22.27):

- **Ischaemic stroke**/infarction (80%)
  - Thrombotic
  - Large artery stenosis
  - Small vessel disease
  - Cardio-embolic
  - Hypoperfusion

- **Haemorrhagic stroke** (17%) (see p. 1104)
  - Intracerebral haemorrhage (12%) (see p. 1104)
  - Subarachnoid haemorrhage (5%) (see p. 1105)

- Other (3%), e.g. arterial dissection, venous sinus thrombosis, vasculitis (see p. 1108).

Ischaemic stroke

Arterial disease and atherosclerosis is the main pathological process causing stroke. Arterial branch points such as the origin of the great vessels arising from the aorta, the proximal internal carotid artery and its distal intracranial branches are particularly affected (Fig. 22.28). Non-Caucasian populations tend to have more intracranial narrowing and white populations more extracranial disease (which is strongly correlated with co-morbid coronary artery and peripheral vascular disease).

**Thrombosis** at the site of ruptured mural plaque leads to artery to artery embolism or vessel occlusion.

**Large artery stenosis** usually causes stroke by acting as an embolic source rather than by occlusion of the vessel (which may not in itself cause stroke if it occurs gradually and collateral circulation is adequate).
Cardio-embolic stroke. The heart is a common source of embolic material. Atrial fibrillation (and other arrhythmias) causing thrombosis in a dilated left atrium is the commonest cause. Cardiac valve disease, including congenital valve disorders, infective vegetations, rheumatic and degenerative calcific changes may cause embolization. Mural thrombosis may occur in a damaged or akinetic segment of the ventricle. A patent foramen ovale (PFO), which is a common variant, may occasionally allow passage of fragments of thrombus (e.g. from a lower limb DVT) from the right atrium to the left when Valsalva causes shunting of blood across the PFO. Pulmonary arteriovenous fistulas may also act as a conduit for paradoxical embolization. Rarer causes include fat emboli after long bone fracture, atrial myxomas and iatrogenic causes such as cardiac bypass and air embolism.

Simultaneous infarcts in different vascular territories are very suggestive of a proximal source of emboli in the heart or aorta.

Hypoperfusion. Severe hypotension, e.g. in cardiac arrest, may lead to borderzone infarction in the watershed areas between vascular territories, particularly if there is severe stenosis of proximal carotid vessels. The parieto-occipital area between the middle and posterior cerebral artery territories is particularly vulnerable.

Carotid and vertebral artery dissection
Dissection accounts for around 1 in 5 strokes below age 40 and is sometimes a sequel of trivial neck trauma or hyperextension, e.g. after whiplash, osteopathic manipulation, hairwashing in a salon, or exercise. It is now thought that subtle collagen disorders, e.g. partial forms of Marfan’s syndrome, may be a predisposing factor.

Most dissections are in large extracranial neck vessels. Blood penetrates the subintimal vessel wall forming a false lumen, but it is thrombosis within the true lumen due to tissue thromboplastin release that leads to embolization from the site of dissection and stroke, sometimes days after the initial event.

Pain in the neck or face is often the clue leading to diagnosis. Horner’s syndrome or lower cranial nerve palsies may occur with carotid dissection, as these structures are intimately associated with the carotid artery in the neck.

Venous stroke
Only 1% of strokes are venous. Thrombosis within intracranial venous sinuses, such as the superior sagittal sinus, or in cortical veins may occur in pregnancy, hypercoagulable states and thrombotic disorders or with dehydration or malignancy. Cortical infarction, seizures and raised intracranial pressure result.

For haemorrhagic stroke, see page 1104.

Transient ischaemic attacks
TIAs are usually the result of microemboli, but different mechanisms produce similar clinical events. For example, TIAs may be caused by a fall in cerebral perfusion (e.g. a cardiac dysrhythmia, postural hypotension or decreased flow through atheromatous arteries). Infarction is usually averted by autoregulation. Rarely, tumours and subdural haematomas cause episodes indistinguishable from thromboembolic TIAs. Principal sources of emboli to the brain are cardiac thrombus and atheromatous plaques/thrombus within the aortic arch, carotid and vertebral systems. Cardiac thrombus often results from atrial fibrillation or myocardial infarction. Cardiac valve disease may be a source of emboli, e.g. calcific material
Knowledge of normal arterial anatomy and likely sites of atheromatous plaques and stenoses helps understanding of the main stroke syndromes. The circle of Willis is supplied by the two internal carotid arteries (the anterior cerebral circulation) and by the vertebro-basilar posterior cerebral circulation. The distribution of the anterior, middle and posterior cerebral arteries that supply the cerebrum is shown in Figures 22.28–22.30.

Clinical syndromes

Transient ischaemic attacks (TIAs)

Features

TIAs cause sudden loss of function, and usually last minutes or hours (by classical definition <24 h, but this is not used now). The site is often suggested by the type of attack. Clinical features of the principal forms of TIA are given in Box 22.12. Hemiparesis and aphasia are the commonest.

Amaurosis fugax

This is a sudden transient loss of vision in one eye. When due to the passage of emboli through the retinal arteries, arterial obstruction is sometimes visible through an
An underlying condition may be evident:
- Atheroma
- Hypertension
- Postural hypotension
- Bradycardia or low cardiac output
- Diabetes mellitus
- Rarely, arteritis, polycythaemia, neurosyphilis, HIV
- Antiphospholipid syndrome (p. 538).

Differential diagnosis
TIAs can be distinguished, usually on clinical grounds, from other transient episodes (p. 1116). Occasionally, events identical to TIAs are produced by mass lesions. Focal epilepsy is usually recognized by its positive features (e.g. limb jerking and loss of consciousness) and progression over minutes. In a TIA, involuntary limb movements do occur occasionally; deficit is usually instantaneous. A focal prodrome in migraine sometimes causes diagnostic difficulty. Headache, common but not invariable in migraine, is rare in TIA. Typical migrainous visual disturbances are not seen in TIA.

Prognosis
Prospective studies show that 5 years after a single thromboembolic TIA:
- 30% have had a stroke, a third of these in the first year
- 15% have suffered a myocardial infarct.

TIAs in the anterior cerebral circulation carry a more serious prognosis than those in the posterior circulation (see Table 22.12).

The ABCD² score can help to stratify stroke risk in the first 2 days:
- Age >60 years 1 point
- BP >140 mmHg systolic and/or diastolic >90 mmHg 1 point
- Clinical features
  - unilateral weakness 2
  - isolated speech disturbance 1
  - other 0
- Duration of symptoms (minutes)
  - >60 2
  - 10–59 1
  - <10 0
- Diabetes
  - present 1
  - absent 0

A score of <4 is associated with a minimal risk whereas >6 is high risk for a stroke within 7 days of a TIA.

If patients are considered to have had a high risk TIA, i.e. ABCD² score >4, or have had two recent TIAs, especially within the same vascular territory, then the patient should ideally be admitted for investigation and commencement of secondary prevention. ALL patients should be referred to a TIA Clinic and ideally seen within 24 h. Investigation and treatment should be regarded as urgent and completed within 2 weeks.

In TIA, involuntary limb movements do occur occasionally; deficit is usually instantaneous. A focal prodrome in migraine sometimes causes diagnostic difficulty. Headache, common but not invariable in migraine, is rare in TIA. Typical migrainous visual disturbances are not seen in TIA.

Clinical findings in TIA
Diagnosis of TIA is often based solely upon its description. It is unusual to witness an attack as they are so brief. Consciousness is usually preserved in TIA. There may be clinical evidence of a source of embolus, e.g.:
- Carotid arterial bruit (stenosis)
- Atrial fibrillation or other dysrhythmia
- Valvular heart disease/endocarditis
- Recent myocardial infarction.

Cerebral infarction
Major thromboembolic cerebral infarction usually causes an obvious stroke. The clinical picture is thus very variable,
dependent on the infarct site and extent. While the general site can be deduced from physical patterns (e.g. cortex, internal capsule, brainstem), clinical estimations of precise vascular territories are often inaccurate, when compared to imaging.

Following vessel occlusion brain ischaemia occurs, followed by infarction. The infarcted region is surrounded by a swollen area which does not function but is structurally intact. This is the ischaemic penumbra, which is detected on MRI and can regain function with neurological recovery.

Within the ischaemic area, hypoxia leads to neuronal damage. There is a fall in ATP with release of glutamate, which opens calcium channels with release of free radicals. These alterations lead to inflammatory damage, necrosis and apoptotic cell death.

**Clinical features**

Stroke most typically seen is caused by infarction in the internal capsule following thromboembolism in a middle cerebral artery branch (Fig. 22.31). A similar picture is caused by internal carotid occlusion (see Fig. 22.28). Limb weakness on the opposite side to the infarct develops over seconds, minutes or hours (occasionally longer). There is a contralateral hemiplegia or hemiparesis with facial weakness. Aphasia is usual when the dominant hemisphere is affected. Weak limbs are at first flaccid and areflexic. Headache is unusual. Consciousness is usually preserved. Exceptionally, an epileptic seizure occurs at the onset. After a variable interval, usually several days, reflexes return, becoming exaggerated. An extensor plantar response appears. Weakness is maximal at first; recovery occurs gradually over days, weeks or many months.

**Brainstem infarction**

This causes complex signs depending on the relationship of the infarct to cranial nerve nuclei, long tracts and brainstem connections (Table 22.13).

- **The lateral medullary syndrome** (posterior inferior cerebellar artery (PICA) thrombosis and Wallenberg’s syndrome) is a common example of brainstem infarction presenting as acute vertigo with cerebellar and other signs (Table 22.14 and Fig. 22.32). It follows thromboembolism in the PICA or its branches, vertebral artery thromboembolism or dissection. Features depend on the precise structures damaged.

- **Coma** follows damage to the brainstem reticular activating system.

- **The locked-in syndrome** is caused by upper brainstem infarction (p. 1095).

- **Pseudobulbar palsy** (p. 1080) can follow lower brainstem infarction.

**Other patterns of infarction**

**Lacunar infarction**

Lacunes are small (<1.5 cm³) infarcts seen on MRI or at autopsy. Hypertension is commonly present. Minor strokes (e.g. pure motor stroke, pure sensory stroke, sudden unilateral ataxia and sudden dysarthria with a clumsy hand)

</tbody>
</table>
are syndromes caused typically by single lacunar infarcts. Lacunar infarction is often symptomless.

**Hypertensive encephalopathy (p. 778)**
This is due to cerebral oedema, causing severe headaches, nausea and vomiting. Agitation, confusion, fits and coma occur if the hypertension is not treated. Papilloedema develops, either due to ischaemic optic neuropathy or following the brain swelling due to multiple acute infarcts. MRI shows oedematous white matter in the parieto-occipital regions.

**Multi-infarct dementia (vascular dementia)**
Multiple lacunes or larger infarcts cause generalized intellectual loss seen with advanced cerebrovascular disease. In the late stages, there is dementia, pseudobulbar palsy and a shuffling gait — the *marche à petits pas* (small steps), sometimes called atherosclerotic Parkinsonism. *Binswanger’s disease* is a term for widespread low attenuation in cerebral white matter, usually with dementia, TIAs and stroke episodes in hypertensive patients (the changes being seen on imaging/autopsy).

**Visual cortex infarction**
Posterior cerebral artery infarction or infarction of the middle cerebral artery macular branch causes combinations of hemianopic visual loss and cortical blindness (Anton’s syndrome, Fig. 22.30 and p. 1073).

**Weber’s syndrome**
Ipsilateral IIIrd nerve palsy with contralateral hemiplegia is due to a unilateral infarct in the midbrain. Paralysis of upward gaze is usually present.

**Watershed (borderzone) infarction**
Cortical infarcts, often multiple, follow prolonged periods of low perfusion (e.g. hypotension after massive myocardial infarction or cardiac bypass surgery). Infarcts occur in the borderzones, between areas supplied by the anterior, middle and posterior cerebral arteries. Cortical visual loss, memory loss and intellectual impairment are typical. In some cases, a vegetative state or minimal conscious state follows (p. 1096).

**Acute stroke: immediate care and thrombolysis**
(See also Box 22.14)
Paramedics and members of the public are encouraged to make the diagnosis of stroke on a simple history and examination – **FAST:**

- **Face** – sudden weakness of the face
- **Arm** – sudden weakness of one or both arms

---

**Further investigations**
- Routine bloods (for ESR, polycythaemia, infection, vasculitis, thrombophilia, syphilitic serology, clotting studies, autoantibodies, lipids)
- Chest X-ray
- ECG
- Carotid Doppler studies
- MR angiography, if appropriate

**Further management**
- Drugs for hypertension, heart disease, diabetes, other medical conditions
- Antiplatelet agents, e.g. aspirin and elopidogrel
- Question of endarterectomy
- Question of anticoagulation – Table 22.15
- Speech therapy, dysphagia care, physiotherapy, occupational therapy
- Specific issues, e.g. epilepsy, pain, incontinence
- Preparations for future care

**Speech** – difficulty speaking, slurred speech

**Time** – the sooner treatment can be started, the better.

Dedicated units with multidisciplinary, organized teams deliver higher standards of care than a general hospital ward, reducing stroke mortality and long-term disability. Evidence-based guidelines have contributed to clear protocols. Admission to hospital should proceed without delay, for imaging, care and investigation.

Following a stroke, immediate, continued and meticulous attention to the airway and to swallowing is essential. Management of unconscious or stuporose patients is outlined on page 1096.

In cerebral infarction, the issue is thrombolysis. Practical Box 22.4 outlines the current proposals for stroke thrombolysis. Alteplase is commonly used although tenecteplase is also effective. The benefit of thrombolysis is shown on CT perfusion scans (Fig. 22.33) and decreases with time, even within the time window of 4.5 h. **Every minute counts.** If thrombolysis is not given, aspirin 300 mg daily should be given as soon as a diagnosis of ischaemic stroke or thromboembolic TIA is confirmed, reducing to 75 mg after several days. Following thrombolysis aspirin should not be started until 24–48 h later.

**Investigations**
The purpose of investigations in stroke is:

- to confirm the clinical diagnosis and distinguish between haemorrhage and thromboembolic infarction;
- to look for underlying causes and to direct therapy;
- to exclude other causes, e.g. tumour.

Sources of embolus should be sought (e.g. carotid bruit, atrial fibrillation, valve lesion, evidence of endocarditis, previous emboli or TIA) and hypertension/postural hypotension assessed. Brachial BP should be measured on each side; >20 mmHg difference is suggestive of subclavian artery stenosis.

Routine investigations in thromboembolic stroke and TIA are listed in Box 22.13.

**Imaging in acute stroke**
**CT and MRI:**

- **Non-contrast CT** will demonstrate haemorrhage immediately but cerebral infarction is often not detected or only subtle changes are seen initially (Fig. 22.34a).
Practical Box 22.4

Thrombolysis in acute ischaemic stroke

Eligibility
- Age ≥18 years
- Clinical diagnosis of acute ischaemic stroke
- Assessed by experienced team
- Measurable neurological deficit
- Blood tests: results available
- CT or MRI consistent with acute ischaemic stroke
- Timing of onset well established
- Thrombolysis should commence as soon as possible and up to 4.5 hours after acute stroke

Exclusion criteria

Historical
- Stroke or head trauma within the prior 3 months
- Any prior history of intracranial haemorrhage
- Major surgery within 14 days
- Gastrointestinal or genitourinary bleeding within the previous 21 days
- Myocardial infarction in the prior 3 months
- Arterial puncture at a non-compressible site within 7 days
- Lumbar puncture within 7 days

Clinical
- Rapidly improving stroke syndrome
- Minor and isolated neurological signs
- Seizure at the onset of stroke if the residual impairments are due to postictal phenomena
- Symptoms suggestive of subarachnoid haemorrhage, even if the CT is normal
- Acute MI or post-MI pericarditis
- Persistent systolic BP >185, diastolic BP >110 mmHg, or requiring aggressive therapy to control BP
- Pregnancy or lactation
- Active bleeding or acute trauma (fracture)

Laboratory
- Platelets <100 000/mm³
- Serum glucose <2.8 mmol/L or >21.2 mmol/L
- INR >1.7 if on warfarin
- Elevated partial thromboplastin time if on heparin

Dose of i.v. alteplase (tissue plasminogen activator)
- Total dose 0.9 mg/kg (max. 90 mg)
- 10% of total dose by initial i.v. bolus over 1 minute
- Remainder infused i.v. over 60 minutes

Figure 22.33 CT perfusion scans: (a) pre-thrombolysis; (b) post-thrombolysis showing reperfusion of the ischaemic site. (Courtesy of Professor Adrian Dixon, Cambridge Radiology Department, UK.)

- MRI shows changes early in infarction (Fig. 22.35a) and a later MRI shows the full extent of the damaged area or penumbra (Fig. 22.35b).
- Diffusion-weighted MRI (DWI) can detect cerebral infarction immediately (see Fig. 22.34b) but is as accurate as CT for the detection of haemorrhage.

Figure 22.34 Middle cerebral artery infarction. (a) CT performed initially shows only very subtle low density changes in right MCA territory. (b) Diffusion-weighted MRI done at the same time shows full extent of the area of ischaemia. (Courtesy of Dr Paul Jarman.)

CT is still more widely available than MRI and should be performed if MRI is unavailable so that there is no delay in giving thrombolysis for cerebral infarction.

More detailed studies involving perfusion-weighted images and diffusion-weighted MRI will differentiate the infarct core and the penumbral area which is potentially recoverable.

Treatment of acute stroke

This is shown in Box 22.14. Thrombolysis has been shown to improve outcome and should be used immediately if
there are no contraindications. In a massive middle cerebral artery infarct, hemispheric swelling occurs with oedema (Fig. 22.36). Decompressive hemicraniectomy reduces the intracranial pressure and the mortality but extensive neurological deficits remain.

Later investigations
MR angiography (MRA) or CT angiography is valuable in anterior circulation TIAs to confirm surgically accessible arterial stenoses, mainly internal carotid stenosis (Fig. 22.35c). If ultrasound suggests carotid stenosis, normotensive patients with TIA or stroke in the anterior circulation should have vascular imaging.

Carotid Doppler and duplex scanning. These screen for carotid (and vertebral) stenosis and occlusion: in skilled hands they demonstrate accurately the degree of internal carotid stenosis.

Long-term management
Medical therapy
Risk factors (Table 22.12) should be identified and addressed.

Antihypertensive therapy
Recognition and good control of high blood pressure is the major factor in primary and secondary stroke prevention. Transient hypertension, often seen following stroke, usually does not require treatment provided diastolic pressure does not rise >100 mmHg. Sustained severe hypertension needs treatment (p. 781); BP should be lowered slowly to avoid any sudden fall in perfusion.

Antiplatelet therapy (see also p. 425)
Long-term soluble aspirin (75 mg daily) reduces substantially the incidence of further infarction following thromboembolic TIA or stroke. Aspirin inhibits cyclo-oxygenase, which converts arachidonic acid to prostaglandins and thromboxanes; predominant therapeutic effects are reduction of platelet aggregation. Clopidogrel and dipyridamole are also used (p. 425). Combined aspirin 75 mg daily and clopidogrel 75 mg daily provide optimal prophylaxis against further thromboembolic stroke or TIA. Dipyridamole 200 mg twice daily is used if clopidogrel is contraindicated.

Anticoagulants
Heparin and warfarin should be given when there is atrial fibrillation, other paroxysmal dysrhythmias or when there are cardiac valve lesions (uninfected) or cardiomyopathies. Brain haemorrhage must be excluded by CT/MRI. Patients must be aware of the small risk of cerebral (and other) haemorrhage. Anticoagulants are potentially dangerous in the two weeks following infarction because of the risk of provoking cerebral haemorrhage; there are wide differences in clinical practice. Antithrombins are now being used. Table 22.15 outlines the issues in secondary stroke prevention.

Other measures
Polycythaemia and any clotting abnormalities should be treated (p. 402). Statin therapy should be given for all.
Surgical approaches

*Internal carotid endarterectomy*

Surgery is usually recommended in TIA or stroke patients with internal carotid artery stenosis >70% (see ABCD² above). Successful surgery reduces the risk of further TIA/stroke by around 75%. Endarterectomy has a mortality around 3%, and a similar risk of stroke. Percutaneous transluminal angioplasty (stenting) is an alternative. The value of surgery for asymptomatic carotid stenosis is debatable.

**Stroke in the elderly**

While in the elderly the yield of investigation in stroke diminishes, age is no barrier to recovery; elderly patients benefit the most from good rehabilitation. Consider social isolation, pre-existing cognitive impairment, nutrition, skin and sphincter care, and reassess swallowing. Carotid endarterectomy over 75 years carries little more risk than in younger cases. Fibrinolysis is not contraindicated.

**Rehabilitation: multidisciplinary approach**

Physiotherapy has particular value in the first few weeks after stroke to relieve spasticity, prevent contractures and teach patients to use walking aids. The benefits of physiotherapy for longer-term outcome are still inadequately researched. Baclofen and/or botulinum toxin are sometimes helpful in the management of severe spasticity.

Speech and language therapists have a vital understanding of aphasic patients’ problems and frustration. Return of speech is hastened by conversation generally. If swallowing is unsafe because of the risk of aspiration, either nasogastric feeding or percutaneous gastrostomy will be needed. Video-fluoroscopy while attempting to swallow is helpful.

Physiotherapy, occupational and speech therapy have a vital role in assessing and facilitating the future care pathway. Stroke is frequently devastating and, particularly during working life, alters radically the patient’s remaining years. Many become unemployed, lose independence and are financially embarrassed. Loss of self-esteem makes depression common.

At home, aids and alterations may be needed: stair and bath rails, portable lavatories, hoists, sliding boards, wheelchairs, tripods, stair lifts, electric blinds and modified sleeping arrangements, kitchen, steps, flooring and doorways. Liaison between hospital-based and community care teams, and primary care physician is essential.

**Prognosis**

About 25% of patients die within 2 years of a stroke, nearly 10% within the 1st month. This early mortality is higher following intracranial haemorrhage than thromboembolic infarction. Poor outcome is likely when there is coma, a defect in conjugate gaze and hemiplegia. Many complications, particularly in the elderly, are preventable, e.g. aspiration. Coordinated care reduces deaths.

Recurrent strokes are, however, common (10% in the 1st year) and many patients die subsequently from myocardial infarction. Of initial stroke survivors, some 30–40% remain alive at 3 years.

Gradual improvement usually follows stroke, although late residual deficits are typically substantial. One-third of survivors return to independent mobility and one-third have disability requiring institutional care.

The outlook for recovery of language varies: in general, if language is intelligible at all at 3 weeks, prognosis for fluent speech is good, but many are left with word-finding difficulties.

**Intracranial haemorrhage**

This comprises:

- intracerebral and cerebellar haemorrhage
- subarachnoid haemorrhage
- subdural and extradural haemorrhage/haematoma.

**Intracerebral haemorrhage**

**Aetiology**

Intracerebral haemorrhage causes approximately 15% of strokes. Rupture of microaneurysms (Charcot–Bouchard aneurysms, 0.8–1.0 mm diameter) and degeneration of small deep penetrating arteries are the principal pathology. Such haemorrhage is usually massive, often fatal, and occurs in chronic hypertension and at well-defined sites – basal ganglia, pons, cerebellum and subcortical white matter.

In normotensive patients, particularly over 60 years, *lobar* intracerebral haemorrhage occurs in the frontal, temporal, parietal or occipital cortex. Cerebral amyloid angiopathy (rare) is the cause in some of these haemorrhages, and the tendency to rebleed is associated with particular apolipoprotein E genotypes.

**Recognition**

At the bedside, there is no entirely reliable way of distinguishing between haemorrhage and thromboembolic infarction. Both produce stroke. Intracerebral haemorrhage tends to be dramatic with severe headache. It is more likely to lead to coma than thromboembolism.

Brain haemorrhage is seen on CT imaging immediately (cf. infarction, p. 1091) as intraparenchymal, intraventricular or subarachnoid blood. Routine MRI may not identify an acute small haemorrhage correctly in the first few hours but MRI diffusion-weighted (MRI-DW) is as good as CT.

**Management: haemorrhagic stroke**

The principles are those for cerebral infarction. The immediate prognosis is less good. Antiplaetelet drugs and, of course, anticoagulants are contraindicated. Control of hypertension is vital. Urgent neurosurgical clot evacuation is occasionally necessary when there is deepening coma and coning (particularly in cerebellar haemorrhage).

**Cerebellar haemorrhage** (Fig. 22.37)

There is headache, often followed by stupor/coma and signs of cerebellar/brainstem origin (e.g. nystagmus, ocular palsies). Gaze deviates towards the haemorrhage. Skew deviation (p. 1094) may develop. Cerebellar haemorrhage sometimes causes acute hydrocephalus, a potential surgical emergency.
Subarachnoid haemorrhage (SAH)
SAH means spontaneous arterial bleeding into the subarachnoid space, and is usually clearly recognizable clinically from its dramatic onset. SAH accounts for some 5% of strokes and has an annual incidence of 6 per 100 000.

Causes
The causes of SAH are shown in Table 22.16; it is unusual to find any contributing disease.

Saccular (berry) aneurysms (Fig. 22.38)
Saccular aneurysms develop within the circle of Willis and adjacent arteries. Common sites are at arterial junctions:
- Between posterior communicating and internal carotid artery – posterior communicating artery aneurysm
- Between anterior communicating and anterior cerebral artery – anterior communicating and anterior cerebral artery aneurysm
- At the trifurcation or a bifurcation of the middle cerebral artery – middle cerebral artery aneurysm

Other aneurysm sites are on the basilar, posterior inferior cerebellar, intracavernous internal carotid and ophthalmic arteries. Saccular aneurysms are an incidental finding in 1% of autopsies and can be multiple.

Aneurysms cause symptoms either by spontaneous rupture, when there is usually no preceding history, or by direct pressure on surrounding structures; for example, an enlarging unruptured posterior communicating artery aneurysm is the commonest cause of a painful IIIrd nerve palsy (p. 1081).

Arteriovenous malformation (AVM)
AVMs are vascular developmental malformations, often with a fistula between arterial and venous systems causing high flow through the AVM and high pressure arterialization of draining veins. An AVM may also cause epilepsy, often focal. The risk of a first haemorrhage (20% fatal and 30% resulting in permanent disability) is approximately 2–3% per year. Once an AVM has caused a haemorrhage, the risk of rebleeds is increased– to approximately 10% per year. AVMs may be ablated with endovascular treatment (catheter injection of glue into the nidus usually), surgery or stereotactic radiotherapy. A multidisciplinary team approach with neurologist, interventional neuro-radiologist and neurosurgeon is required in deciding on treatment options.

Cavernous haemangiomas (cavernomas) are common (0.1–0.5% prevalence) and consist of a tangle of low pressure dilated vessels without a major feeding artery; they are frequently symptomless (Fig. 22.39) and seen incidentally on imaging. Multiple cavernomas often have a genetic basis, with linkage to two loci on chromosome 7q. Cavernomas may cause seizures. Small haemorrhages may occur but are usually low pressure bleeds and rarely cause severe deficits. Surgical resection is rarely needed except where the cavernoma is gradually enlarging or causing significant neurological symptoms.

Clinical features of subarachnoid haemorrhage
There is a sudden very severe headache, often occipital (mean time to peak headache 3 min). Headache is usually followed by vomiting and often by coma and death. Survivors of SAH may remain comatose or drowsy for hours, days, or longer. SAH is a possible diagnosis in any sudden headache.

Following major SAH there is neck stiffness and a positive Kernig’s sign. Papilloedema is sometimes present, with retinal and/or subhyaloid haemorrhage (tracking beneath the retinal hyaloid membrane). Minor bleeds cause few signs, but almost invariably headache (approximately 17% of patients have small ‘sentinel bleeds’ in the weeks before presenting with SAH).

Investigations
CT imaging is the immediate investigation (Fig. 22.40). Subarachnoid and/or intraventricular blood is usually seen (sensitivity of CT to detect subarachnoid blood is 95% within 24 h of onset but much lower over subsequent days). Lumbar puncture is not necessary if SAH is confirmed by CT, but should be performed if doubt remains. CSF becomes yellow (xanthochromic) within 12 h of SAH and remains detectable for 2 weeks. Visual inspection of supernatant CSF is usually...
sufficiently reliable for diagnosis. Spectrophotometry to estimate bilirubin in the CSF released from lysed cells is used to define SAH with certainty. CT angiography or catheter angiography to identify the aneurysm or other source of bleeding is performed in patients potentially fit for surgery. In some, no aneurysm or source of bleeding is found, despite a definite SAH.

**Differential diagnosis**

SAH must be differentiated from migraine. This is sometimes difficult – a short time to maximal headache intensity and the presence of neck stiffness usually indicate SAH. Thunderclap headache is used (confusingly) to describe either SAH or a sudden (benign) headache for which no cause is ever found. The syndrome of reversible cerebral vasospasm (Call–Fleming syndrome) presents with thunderclap headache. Acute bacterial meningitis occasionally causes a very abrupt headache, when a meningeal microabscess ruptures; SAH also occasionally occurs at the onset of acute bacterial meningitis. Cervical arterial dissection can present with a sudden headache.

**Complications**

Blood in the subarachnoid space can lead to obstructive hydrocephalus, seen on CT. Hydrocephalus can be asymptomatic but may cause deteriorating consciousness following SAH. Shunting may be necessary. Arterial spasm (visible on angiography and a cause of coma or hemiparesis) is a serious complication of SAH and a poor prognostic feature.

**Management**

Immediate treatment of SAH is bed rest and supportive measures. Hypertension should be controlled. Nimodipine, a calcium-channel blocker given for 3 weeks, reduces mortality.

All SAH cases should be discussed urgently with a neurosurgical centre. Nearly half of SAH cases are either dead or moribund before reaching hospital. Of the remainder, a further 10–20% rebleed and die within weeks. Failure to diagnose SAH, e.g. mistaking SAH for migraine, contributes to this mortality.

Where angiography demonstrates an aneurysm (the cause of the vast majority of SAH), endovascular treatment by placing platinum coils via a catheter in the aneurysm sac to promote thrombosis and ablation of the aneurysm, is now the first line treatment. Endovascular coiling has a lower complication rate than surgery but direct surgical clipping of the aneurysm neck is still required in some selected cases.

For asymptomatic (unruptured) aneurysms over 8 mm in diameter the risk of treatment is less than the risk of haemorrhage if not treated. Patients who remain comatose or who have persistent severe deficits after SAH have a poor outlook.

**Subdural and extradural bleeding**

These conditions can cause death following head injuries unless treated promptly.

**Subdural haematoma (SDH)**

SDH means accumulation of blood in the subdural space following rupture of a vein. This usually follows a head injury, sometimes trivial. The interval between injury and symptoms can be days, or extend to weeks or months. Chronic, apparently spontaneous SDH is common in the elderly, and also occurs with anticoagulants.

Headache, drowsiness and confusion are common; symptoms are indolent and can fluctuate. Focal deficits, e.g. hemiparesis or sensory loss, develop. Epilepsy occasionally occurs. Stupor, coma and coning may follow.

**Extradural haemorrhage (EDH)**

EDH typically follows a linear skull vault fracture tearing a branch of the middle meningeal artery. Extradural blood accumulates rapidly over minutes or hours. A characteristic picture is of a head injury with a brief duration of unconsciousness, followed by improvement (the lucid interval). The patient then becomes stuporous, with an ipsilateral dilated pupil and contralateral hemiparesis, with rapid transtentorial coning. Bilateral fixed dilated pupils, tetraplegia and respiratory arrest follow. An acute progressive SDH presents similarly.

**Management**

Possible extradural or subdural bleeding needs immediate imaging. CT (Fig. 22.41a) is the most widely used investigation because of its immediate availability. MRI is more sensitive for the detection of small haematomas. T₁-weighted MRI (Fig. 22.41b) shows bright images due to the presence of methaemoglobin.

EDHs require urgent neurosurgery: if it is performed early, the outlook is excellent. When far from a neurosurgeon, e.g. in wartime or at sea, drainage through skull burr-holes has been lifesaving when an EDH has been diagnosed clinically.

Subdural bleeding usually needs less immediate attention but close neurosurgical liaison is necessary. Even large
collections can resolve spontaneously without drainage. Serial imaging is needed to assess progress.

**Cortical venous thrombosis and dural venous sinus thrombosis**

Intracranial venous thromboses are usually (>50%) associated with a pro-thrombotic risk factor, e.g. oral contraceptives, pregnancy, genetic or acquired pro-thrombotic states and dehydration. Head injury is also a cause. Infection, e.g. from a paranasal sinus, may be present. Venous thromboses can also arise spontaneously.

**Cortical venous thrombosis**
The venous infarct leads to headache, focal signs (e.g. hemiparesis) and/or epilepsy, often with fever.

**Dural venous sinus thromboses**
Cavernous sinuses, dural sinuses and CSF may be involved in migraine. Venous sinuses may be occluded by thrombosis, often with intracranial pressure with headache, fever, papilloedema and often epilepsy.

**Management**
MRI, MRA and MR venography (MRV) show occluded sinuses and/or veins. Treatment is with heparin initially, though its value is questioned, followed by warfarin for 6 months. Anti-convulsants are given if necessary.

**HEADACHE, MIGRAINE AND FACIAL PAIN**

Headache is an almost universal experience and one of the most common symptoms in medical practice. It varies from an infrequent and trivial nuisance to a pointer to serious disease. Headache symptoms are unpleasant, disabling, common worldwide and have a substantial economic impact because of time lost from work.

**Mechanisms**
Pain receptors are located at the base of the brain in arteries and veins and throughout meninges, extracranial vessels, scalp, neck and facial muscles, paranasal sinuses, eyes and teeth. Curiously, brain substance is almost devoid of pain receptors. Head pain is mediated by the Vth and IXth cranial nerves and upper cervical sensory roots.

**A general approach to assessing headache symptoms**
In assessing patients with headache the aim should be to make a confident diagnosis based on the history. Examination is helpful in excluding underlying medical disorders as a cause of headache but will not distinguish between different types of primary headache.

There is an internationally agreed classification for headaches that defines all headache patterns. Headache is divided into primary headache disorders such as migraine, and secondary headaches due to underlying pathology such as raised intracranial pressure or meningitis (Box 22.15). It is also useful to distinguish between episodic (recurrent) headache, single first headache episodes and patients with chronic headache. In an outpatient clinic setting most headaches will be benign. Fewer than 1% of outpatients with non-acute headache have a serious underlying cause but in the Emergency Department there will be a much higher prevalence of serious underlying pathology presenting with headache. New onset severe headache in those without a previous headache history, especially in older patients (>50), requires exclusion of underlying pathology causing secondary headache.

There are some widely believed ‘headache myths’. Headaches are not caused by hypertension except rarely with malignant hypertension (p. 778). Eyestrain from refractive error does not cause headache and sinusitis is rarely the explanation for recurrent or chronic headache.

**Taking a headache history**
Ask about:
- Headache location (e.g. hemicranial), severity and character (e.g. throbbing vs non-throbbing)
- Associated symptoms, e.g. nausea, photophobia, phonophobia and motion sensitivity
- Presence of autonomic symptoms, e.g. tearing or ptosis
- Relieving or exacerbating features, e.g. effect of posture
- Headache pattern. Is headache episodic and part of a pattern of previous similar headaches? Age at onset and headache frequency
- Duration of headache episodes (helpful in distinguishing between different primary headache types)
- Triggers
- Pattern of analgesic use
- Family history of headache
- ‘Red flag’ symptoms – fever (meningitis, sinusitis)
- Sudden onset in less than 1 minute (SAH)
- Features of raised intracranial pressure
- Jaw claudication (giant cell arteritis).

**Examination**
Examination should include fundoscopy to look for papilloedema. In older patients, temporal arteries should be palpated for loss of pulsatility and tenderness that may be features of giant cell arteritis (GCA). Fever and neck stiffness suggest meningitis. Examination is generally normal in patients with primary headache disorders.

**Investigations**
Investigations, including brain imaging, do not contribute to the diagnosis of primary headache disorders. Neuroimaging is indicated only where history or examination suggests an underlying secondary cause. Older patients with new onset headache and those with ‘red flag’ symptoms should have brain CT. In patients over 50 with new headache ESR should be checked to exclude GCA.

**Primary headache disorders**

**Migraine**
Migraine is the commonest cause of episodic headache (15–20% of women and 5–10% of men); in 90%, onset is...
before 40 years of age. Episodes of headache are associated with sensory sensitivity such as to light, sound or movement, and sometimes with nausea and vomiting. There is a spectrum of severity between individuals and from one attack to another. Migraine is usually high impact, with inability to function normally during episodes. Headache frequency in migraine varies from an occasional inconvenience to frequent headaches severely impacting quality of life, and may transform into chronic daily headache.

**Mechanisms**

Genetic factors play a part in causing the neuronal hyperexcitability that is probably the biological basis of migraine. Migraine is polygenic but a rare form of familial migraine is associated with mutations in the \( \alpha-1 \) subunit of the P/Q-type voltage-gated calcium channel or neuronal sodium channel (SCN1A), and a dominant loss of function mutation in a potassium channel gene (TRESK) has recently been identified in some patients with migraine with aura.

The pathophysiology of migraine is now thought to have a primarily neurogenic rather than vascular basis. Spreading cortical depression—a wave of neuronal depolarization followed by depressed activity spreading slowly anteriorly across the cerebral cortex from the occipital region—is thought to be the basis of the migraine aura. Activation of trigeminal pain neurones is the basis of the headache. The innervation of the large intracranial vessels and dura by trigeminal pain neurones is the basis of the headache. The scalp may be tender to touch during episodes (allodynia) and the preference is to be still in a dark, quiet environment.

**Clinical features**

**Migraine without aura**

Migraine typically starts around puberty with increasing prevalence into the 4th decade. There is a spectrum of severity and associated features, but attacks have recognizable core features (Box 22.16). Most migraine attacks are usually of sufficient severity to prevent sufferers continuing with normal activities and sleep usually helps, with a washed out feeling following the attack. The scalp may be tender to touch during episodes (allodynia) and the preference is to be still in a dark, quiet environment.

Some patients recognize changes in routine as trigger factors:
- Sleep (too little or too much)
- Stress (including let down after a period of stress)
- Hormonal factors for women—changes in oestrogen levels, e.g. menstrual migraine (usually just before menses) and worsening with the OC pill and menopause
- Eating—skipping meals and alcohol. Contrary to popular belief, individual foods are rarely a trigger
- Other—sensory stimuli such as bright lights or loud sounds. Physical exertion. Changes in weather patterns, e.g. stormy weather. Minor head injuries may trigger a worsening of migraine frequency and severity.

**Migraine with aura**

Approximately 25% of migraine sufferers experience focal neurological symptoms immediately preceding the headache phase in some or all attacks—termed migraine aura. Most never experience aura and presence of aura is therefore not required for a diagnosis of migraine. Aura usually evolves over 5–20 minutes with symptoms changing as the wave of spreading neuronal depression moves across the surface of the cortex. It rarely lasts longer than 60 minutes and is followed immediately by the headache phase.

Visual aura is the commonest type, with positive visual symptoms such as shimmering, teichopsia (zig-zag lines also called fortification spectra) and fragmentation of the image (like looking through a pane of broken glass) often accompanied by patches of loss of vision which may move across the visual field (scotomas) and even evolve into hemianopia or tunnel vision. Positive sensory symptoms (mainly tingling), dysphasia and rarely loss of motor function may also occur and may occur successively within the same epidose of aura following the visual symptoms.

Migraine aura usually presents no diagnostic difficulty, but problems with diagnosis may sometimes arise in men over the age of 50 who develop migraine aura for the first time without subsequent headache (sometimes referred to as afebrile migrainous aura). This is frequently misdiagnosed as a transient ischaemic attack (see p. 1098). Distinguishing the two conditions is often difficult and relies on the characteristic evolution of symptoms over minutes and presence of positive symptoms in aura in contrast to TIA where symptom onset is acute and negative symptoms (visual loss as opposed to visual distortion and teichopsia) the norm. There may also be a history of previous typical migraine aura in early adult life to help distinguish the conditions.

**Migraine-related dizziness**

Vertigo is now recognized as being a migrainous symptom in some individuals with attacks lasting for hours in the context of migraine attacks. There is an overlap with what is sometimes described as basilar migraine, a poorly defined migraine subtype associated with brainstem aura type symptoms before or during attacks, including perioral paraesthesiae, diplopia, unsteadiness and rarely reduced level of consciousness.

**Hemiplegic migraine**

This rare autosomal dominant disorder causes a hemiparesis and/or coma and headache, with recovery within 24 hours. Some patients have permanent cerebellar signs as it is allelic with episodic ataxia. It is distinct from commoner forms of migraine.
Management

General measures include:

- Explanation
- Avoidance of trigger factors and lifestyle modification where possible.

Acute treatment of attacks

Analgesics such as high-dose dispersible aspirin (900 mg), paracetamol 1g or a non-steroidal anti-inflammatory (e.g. naproxen 250–500 mg), are often effective, with an antiemetic such as metoclopramide if necessary. Acute treatment should be taken as soon as possible after onset of headache. Patients should be aware that repeated use of analgesics leads to further headaches (see medication overuse; headache p. 1110).

Triptans (5-HT1B/1D agonists) are specific for migraine and may be effective where simple analgesics are insufficient. Sumatriptan was the first marketed; almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan and zolmitriptan are now available, with various routes of administration. Subcutaneous sumatriptan injection may be effective where vomiting prevents absorption of oral medication (note: nasal triptan spays rely on gastrointestinal rather than nasal absorption). Triptans should be avoided if there is a co-present viral disease, and like analgesics, not overused. CGRP antagonists, e.g. telcagepant, are proving to be very effective for acute treatment of migraine.

Migraine suppression medication

Where migraine episodes are frequent, e.g. >1–2 per month, and impacting on quality of life, migraine suppression medication should be offered. The key principles are that a period of 3–6 months treatment is usually sufficient to reduce headache frequency and severity by approximately 50%, with the effect of ‘resetting’ migraine frequency beyond the treatment period. However, these medications will not be effective where ongoing analgesic overuse is an issue. Treatment options include:

- Anticonvulsants. Valproate (800 mg) used off licence or topiramate (100–200 mg daily) are generally the most effective options
- Beta-blockers, e.g. propranolol slow release 80–160 mg daily
- Tricyclics, e.g. amitriptyline 10 mg increasing weekly in 10 mg steps to 50–60 mg
- Botulinum toxin was recently recommended as a treatment for chronic migraine (see p. 1110). The technique involves 31 injections over the scalp and neck repeated every 3 months
- Pizotifen is rarely used. Flunarizine (a calcium antagonist) and methysergide are used in refractory patients.

Tension-type headache (TTH)

The exact pathogenesis of this headache type remains unclear. There is overlap with migraine and many headaches traditionally subsumed under this category probably in fact represent mild migraine. Since there are no diagnostic tests to separate TTH from mild migraine it is difficult to know if the conditions are biologically distinct. In contrast to migraine, pain is usually mild to moderate severity, bilateral and relatively featureless, with tight band sensations, pressure behind the eyes, and bursting sensations being described.

Depression is also a frequent co-morbid feature. TTH is often attributed to cervical spondylosis, refractive errors or high blood pressure: evidence for such associations is poor. Simple analgesics are often effective but overuse should be avoided. Physical treatments such as massage, ice packs, and relaxation are often recommended. Frequent or chronic TTH may respond to migraine suppression medications as above, with tricyclics often being used first-line.

Trigeminal autonomic cephalgias

The trigeminal autonomic cephalalgias are a group of primary headache disorders characterized by unilateral trigeminal distribution pain (usually in the ophthalmic division of the nerve) and prominent ipsilateral autonomic features.

Cluster headache

Cluster headache is distinct from migraine and much rarer (1 per 1000). It affects adults, mostly males aged between 20 and 40. Patients describe recurrent bouts (clusters) of excruciating unilateral retro-orbital pain with parasympathetic autonomic activation in the same eye causing redness or tearing of the eye, nasal congestion or even a transient Horner’s syndrome. The pain is reputed to be the worst known to man and patients often contemplate, and sometimes commit, suicide, such is the severity of the pain. Unlike migraine attacks patients prefer to move about or rock rather than remain still.

Attacks are shorter than migraine, usually 30–90 minutes, and may occur several times per day, especially during sleep. Clusters last one to two months with attacks most nights before stopping completely and typically recurring a year or more later, often at the same time of year. Although the cause is not known, hypothalamic activation is seen on functional imaging studies during an attack.

Management. Analgesics are unhelpful. Subcutaneous sumatriptan is the drug of choice for acute treatment as no other drug works quickly enough. High flow oxygen is also used. Most prophylactic migraine drugs are unhelpful. Verapamil, lithium and/or a short course of steroids help terminate a bout of cluster headaches.

Paroxysmal hemicrania and SUNCT

Paroxysmal hemicrania is a rare condition with similarities to cluster headache, differing mainly in that attacks are briefer (10–30 min) and more frequent (>5 per day, at any time of day) and do not occur in clusters. Women are more often affected than men. There is a rapid and complete response to indometacin.

SUNCT (short-lasting unilateral neuralgiform headache with conjunctival injection and tearing) is very rare. Attacks are short, 5 seconds to 2 minutes, and very frequently occurring in bouts. Distinguishing from trigeminal neuralgia can be difficult.

Other primary headache disorders

- **Primary stabbing headache (‘ice pick headache’).** Momentary jabs or stabs of localized pain occurring either in the same spot or moving about the head. Symptoms wax and wane and are more common in patients with other primary headache disorders, particularly migraine. Treatment is usually not needed but it responds well to indometacin.
- **Primary cough headache** is a sudden sharp head pain on coughing. No underlying cause is found but intracranial pathology should be excluded. The problem often resolves spontaneously. Indometacin is the
treatment of choice; lumbar puncture with removal of CSF can help.

- **Primary sex headache** is characterized by explosive headache at or before orgasm. It often resolves spontaneously after several attacks. Investigation to exclude subarachnoid haemorrhage is required after the first episode.

- **Other varieties** of primary headache include hemicrania continua, primary exertional headache, hypnic headache (headache triggered by sleep), and primary thunderclap headache.

**Chronic daily headache**

Defined as headache on ≥15 days per month for at least 3 months. Up to 4% of the population are affected by daily or near daily headache. Although there are many possible causes, including secondary headache disorders, in practice primary headache disorders, particularly migraine, are responsible for the majority. Where migraine is the cause, the term chronic migraine is now preferred.

Overuse of analgesic medication or triptans (termed medication overuse headache) is often a major factor leading to and maintaining chronicity, particularly in those with migrainous biology. Use of ≥10 doses per month of any analgesic or triptan, particularly codeine or opiate-containing drugs such as co-codamol, or numerous over-the-counter analgesics, may eventually lead to transformation of episodic headache into chronic daily headache.

Explanation that medication overuse is part of the problem is essential to help patients withdraw from or substantially reduce analgesic intake. This is a difficult process for many patients, especially as there may be a period of transient rebound worsening of headache after withdrawal. Concurrent introduction of migraine suppression medication (see above) may help withdrawal but will not be effective if patients cannot withdraw from frequent analgesic use. Occasionally hospital admission for analgesic withdrawal with parenteral administration of dihydroergotamine is required.

**Secondary headache disorders**

**Raised intracranial pressure headache**

Any headache present on waking and made worse by coughing, straining or sneezing may be due to raised intracranial pressure (ICP) caused by a mass lesion. Vomiting often accompanies pressure headaches. Visual obscurations (momentary bilateral visual loss with bending or coughing) are characteristic and seen in the presence of papilloedema. Occasionally, where ICP rises quickly, papilloedema may not be present.

Neuroimaging is mandatory where raised ICP is suspected. Where no mass lesion, venous sinus thrombosis or hydrocephalus is detected on imaging in the presence of papilloedema, idiopathic intracranial hypertension (IIH) may be the cause and lumbar puncture is performed to measure CSF opening pressure.

**Idiopathic intracranial hypertension (IIH)**

IIH probably results from reduced CSF resorption. IIH typically develops in younger overweight female patients, many of whom have polycystic ovaries. Headaches and transient visual obscurations due to the florid papilloedema are the presenting features. A Vth nerve palsy may develop – a false localizing sign (p. 1076). CSF pressure is very elevated, with normal constituents. Brain imaging is normal although ventricles may be small and appear ‘slit-like’.

Various drugs, e.g. tetracyclines, and vitamin A supplements have been implicated. Other causes of papilloedema should be excluded. Sagittal sinus thrombosis can cause a similar picture and should always be looked for on MR venography.

It is usually self-limiting. However, optic nerve damage can result from longstanding severe papilloedema with progressive loss of peripheral visual fields. Regular monitoring of visual fields with perimetry is essential. Repeated lumbar puncture, acetazolamide, and thiazide diuretics are used to reduce CSF production. Weight reduction is helpful. Ventriculoperitoneal shunt insertion is sometimes necessary or optic nerve sheath fenestration to protect vision.

**Low CSF volume (low pressure) headache**

Although seen most often following lumbar puncture, CSF leaks may occur spontaneously leading to postural headache, worse on standing or sitting and relieved completely by lying flat. The patient may give a history of vigorous Valsalva, straining or coughing just prior to onset. Leptomeningeal enhancement may be seen on MRI but is not reliably present. Lumbar puncture is generally avoided for obvious reasons, but may reveal low opening pressure. The site of the leak is usually within the spine, thus treatment consists of injection of autologous blood into the spinal epidural space to seal the leak (a ‘blood patch’), or occasionally surgical repair of the dural tear. Intravenous caffeine infusion and bed rest are sometimes effective.

**Post-traumatic headache**

Pre-existing migraine may worsen following head injury. De novo headache sometimes follows a minor head injury but post-traumatic headache is an ill defined entity. Improvement over a few weeks is the norm but where litigation is ongoing symptoms can persist for long periods. Subdural haematoma and low pressure headache need to be considered as a possible cause.

**Facial pain**

The face has many pain-sensitive structures: teeth, gums, sinuses, temporomandibular joints, jaw and eyes. Dental causes are common and should always be considered. Facial pain is also caused by specific neurological conditions.

**Trigeminal neuralgia**

Trigeminal neuralgia typically starts in the 6th and 7th decades; hypertension is the main risk factor. Compression of the trigeminal nerve at or near the pons by an ectatic vascular loop is the usual cause. High resolution MRI studies may demonstrate the vascular loop in contact with the nerve in a high proportion of cases. Younger patients are more likely to have multiple sclerosis or cerebellopontine angle tumours (acoustic schwannomas, meningiomas, epidermoid) as the cause.

**Clinical features**

Paroxysms of knife-like or electric shock-like pain, lasting seconds, occur in the distribution of the Vth nerve. Pain tends to commence in the mandibular division (V3) but may spread over time to involve the maxillary (V2) and occasionally the ophthalmic divisions (V1). Bilateral TN is rare (3%) and usually
due to intrinsic brainstem pathology such as demyelination. Episodes occur many times a day with a refractory period after each. They may be brought on by stimulation of one or more trigger zones in the face. Washing, shaving, a cold wind or chewing are examples of trivial stimuli that provoke pain. The face may be screwed up in agony. Spontaneous remissions last months or years before (almost invariable) recurrence. There are no signs of Vth nerve dysfunction on examination.

**Treatment**
Carbamazepine (600–1200 mg daily) reduces severity of attacks in the majority. Oxcarbazepine, lamotrigine and gabapentin are also used. If drugs fail or are not tolerated, a number of surgical options are available which in general are more effective than medical treatments. Percutaneous radiofrequency selective ablation of the trigeminal ganglion are more effective than medical treatments. Percutaneous microvascular decompression is established immediately by superficial temporal artery biopsy because of the risk of blindness. Immediate high doses of steroids (prednisolone, initially 1 mg/kg) should be started in a patient with typical features, even before biopsy. Since the risk of visual loss persists, long-term treatment is recommended, for a year at least.

**Atypical facial pain**
Facial pain differs from trigeminal neuralgia in quality and distribution and trigger points are absent. The condition is probably heterogeneous in aetiology but is believed by some (on little evidence) to be a somatic manifestation of depression. Tricyclic antidepressants and drugs used in neuropathic pain are sometimes helpful.

**Other causes of facial pain**
Facial pain occurs in the trigeminal autonomic cephalgias (see above), occasionally in migraine and in carotid dissection.

**Giant cell arteritis (temporal arteritis)**
A granulomatous large vessel arteritis seen almost exclusively in people over 50 (p. 1108).

**Clinical features**
- **Headache** is almost invariable in giant cell arteritis (GCA). Pain develops over inflamed superficial temporal and/or occipital arteries. Touching the skin over an inflamed vessel (e.g. combing hair) causes pain. Arterial pulsation is soon lost; the artery becomes hard, tortuous and thickened. The scalp over inflamed vessels may become red. Rarely, gangrenous patches appear.
- **Facial pain.** Pain in the face, jaw and mouth is caused by inflammation of facial, maxillary and lingual branches of the external carotid artery in GCA. Pain is characteristically worse on eating (jaw claudication). Mouth opening and protruding the tongue become difficult. A painful, ischaemic tongue occurs rarely.
- **Visual problems.** Visual loss from arterial inflammation and occlusion occurs in 25% of untreated cases. Posterior ciliary artery occlusion causes anterior ischaemic optic neuropathy in three-quarters of these. Other mechanisms are central retinal artery occlusion, cilioretinal artery occlusion and posterior ischaemic optic neuropathy. There is sudden monocular visual loss (partial or complete), usually painless. Amaurosis fugax (p. 1098) may precede permanent blindness.
  
  When the posterior ciliary vessels are affected, ischaemic optic neuropathy causes the disc to become swollen and pale; retinal branch vessels usually remain normal. When the central retinal artery is occluded, there is sudden permanent unilateral blindness, disc pallor and visible retinal ischaemia. Bilateral blindness may develop, with the second eye being affected 1–2 weeks after the first.

**Diagnosis and management**
The condition should always be suspected in older patients with new facial pain or headache. The usual screening test is checking the ESR, which is greatly elevated (>50); liver enzymes are usually also elevated. The diagnosis should be established immediately by superficial temporal artery biopsy because of the risk of blindness. Immediate high doses of steroids (prednisolone, initially 1 mg/kg) should be started in a patient with typical features, even before biopsy. Since the risk of visual loss persists, long-term treatment is recommended, for a year at least.

**EPILEPSY AND LOSS OF CONSCIOUSNESS**

**Epilepsy**
An epileptic seizure can be defined as: a sudden synchronous discharge of cerebral neurones causing symptoms or signs that are apparent either to the patient or an observer. For example a limited discharge affecting only part of the cortex may cause a subjective aura apparent only to the patient, or a generalized seizure may cause a convulsion witnessed by an observer that the patient may be unaware of. This definition excludes disorders such as migrainous aura that are more gradual in onset and usually more prolonged, and EEG discharges that do not have a clinical correlate. Epilepsy is an ongoing liability to recurrent epileptic seizures.

**Epidemiology**
Epilepsy is common. Its population prevalence is 0.7–0.8% (higher in developing countries). Approximately 440 000 people in the UK have epilepsy. The incidence of epilepsy is 0.5% per 100 000; liver enzymes are usually also elevated. The diagnosis should be established immediately by superficial temporal artery biopsy because of the risk of blindness. Immediate high doses of steroids (prednisolone, initially 1 mg/kg) should be started in a patient with typical features, even before biopsy. Since the risk of visual loss persists, long-term treatment is recommended, for a year at least.

**Different types of epileptic seizure**
Seizures are divided by clinical pattern into two main groups (Box 22.17, Fig. 22.42) – partial seizures and generalized seizures.
- **A partial (focal) seizure** is caused by electrical discharge restricted to a limited part of the cortex of one cerebral hemisphere. Partial seizures are further sub-divided according to whether or not there is loss of awareness:
  - simple partial seizures – without loss of awareness, e.g. one limb jerking (a Jacksonian seizure),
  - complex partial seizures – with loss of awareness, e.g. a temporal lobe seizure.
- **In generalized seizures,** there is simultaneous involvement of both hemispheres, always associated with loss of consciousness or awareness. Partial seizures with electrical activity confined to one part of the brain may spread after a few seconds, due to failure
of inhibitory mechanisms, to involve the whole of both hemispheres causing a secondary generalized seizure. The patient may remember the initial partial seizure before losing consciousness, in which case this is called an aura; but sometimes the spread of electrical activity is so rapid that the patient does not experience any warning before a secondary generalized seizure.

Generalized seizure types

Typical absence seizures (petit mal)

This generalized epilepsy almost invariably begins in childhood. Each attack is accompanied by 3 Hz spike-and-wave EEG activity (Fig. 22.16, p. 1090). There is loss of awareness and a vacant expression for <10 seconds before returning abruptly to normal and continuing as though nothing had happened. Apart from slight fluttering of the eyelids there are no motor manifestations. Patients often do not realize they have had an attack but may have many per day. Typical absence attacks are never due to acquired lesions such as tumours – they are a manifestation of primary generalized epilepsy. Children with absence seizures may go on to develop generalized convulsive seizures. Absence seizures are often confused with the complex partial seizures of temporal lobe epilepsy.

Generalized tonic–clonic seizures (GTCS, grand mal seizures)

Prodrome. There is often no warning or there may be an aura prior to a secondary generalized seizure.

Tonic-clonic phase. An initial tonic stiffening is followed by the clonic phase with synchronous jerking of the limbs, reducing in frequency over about 2 minutes until the convulsion stops. The patient may utter an initial cry and falls, sometimes suffering serious injury. The eyes remain open and the tongue is often bitten. There may be incontinence of urine or faeces.

Post-ictal phase. A period of flaccid unresponsiveness is followed by gradual return of awareness with confusion and drowsiness lasting 15 minutes to an hour or longer. Headache is common after a GTCS.

Myoclonic, tonic and atonic seizures

Myoclonic seizures or ‘jerks’ take the form of momentary brief contractions of a muscle or muscle groups, e.g. causing a sudden involuntary twitch of a finger or hand. They are common in primary generalized epilepsies. Tonic seizures consist of stiffening of the body, not followed by jerking. Atonic seizure. A sudden collapse with loss of muscle tone and consciousness.

Partial seizure types

Simple partial seizures

One example is a focal motor seizure (Jacksonian). These simple partial seizures originate within the motor cortex. Jerking typically begins on one side of the mouth or in one hand, sometimes spreading to involve the entire side. This visible spread of activity is called the march of a seizure. Local temporary paralysis of the limbs affected sometimes follows – Todd’s paralysis. With some frontal seizures, conjugate gaze (p. 1075) deviates away from the epileptic focus and the head turns; this is known as an adverse seizure.

Complex partial seizures (temporal lobe seizures)

These usually arise from the temporal lobe (60%) or the frontal lobe. The preceding aura (in effect a simple partial seizure) often includes a rising epigastric sensation and nausea with a wide variety of possible psychic phenomena (often hard for the patient to describe) or hallucinations including:

- Déjà vu or jamais vu
- Olfactory hallucinations
- Formed visual hallucinations or misperceptions, e.g. micropsia or macropsia (objects appear small or large, respectively)
- Fear (may be mistaken for panic attacks).

There follows a period of complete or partial loss of awareness of surroundings, lasting for 1–2 minutes on average (as opposed to 10 seconds in absence seizures) which the patient generally does not remember subsequently. This stage is accompanied by speech arrest and often by automatisms – semi-purposeful stereotyped motions such as lip smacking or dystonic limb posturing, or more complex motor behaviours such as walking in a circle or undressing. The attacks may be followed by a short period of post-ictal confusion or may develop into a secondary generalized convulsive seizure.
Epilepsy syndromes and causes of epilepsy (Box 22.18)
The range of causes of epilepsy is different at different ages and in different countries.

- **Children and teenagers** – genetic, perinatal and congenital disorders predominate
- **Younger adults** – trauma, drugs and alcohol are common
- **Older ages (over 60 years)** – cerebrovascular disease and mass lesions such as neoplasms

**Primary generalized epilepsies (PGE)**
Presenting in childhood and early adult life, these account for up to 20% of all patients with epilepsy. The cause is thought to be polygenic with complex inheritance. The brain is structurally normal but abnormalities of ion channels influencing neuronal firing, abnormalities of neurotransmitter release and synaptic connections are probably the underlying molecular pathological substrates. They include:

- **Childhood absence epilepsy**: absence seizures. Spontaneous remission by age 18 is usual.
- **Juvenile myoclonic epilepsy** (JME, see Box 22.19); this accounts for 10% of all epilepsy patients. Typically myoclonic jerks start in teenage years (usually ignored by the patient – ask about jerks when taking an epilepsy history – see Box 22.19), followed by generalized tonic-clonic seizures that bring the patient to medical attention. One-third of patients also have absences. Seizures and jerks often occur in the morning after waking. Lack of sleep, alcohol and strobe lighting are seizure triggers in JME. JME usually responds well to treatment, is usually associated with EEG abnormalities and requires life-long treatment.
- **Monogenic disorders**. Research has identified a number of single gene epilepsy disorders, e.g. autosomal dominant nocturnal frontal lobe epilepsy (caused by mutations in the nicotinic acetylcholine receptor gene). These are rarities.

**Symptomatic and localization-related epilepsy (LRE)**
Almost any process disrupting the cortical grey matter can cause epilepsy. This is usually localization-related epilepsy with partial seizures arising from the affected area of cortex, with or without secondary generalized seizures (these may obscure the focal onset). In general, the response to treatment is less good than with PGE.

Box 22.19 Juvenile myoclonic epilepsy (JME)

- 10% of all epilepsy patients
- Starts in teenage years
- Clinical features:
  - Myoclonic jerks
  - Generalised Tonic Clonic Seizures (GTCS)
  - Absence in one-third
  - Triggers: sleep deprivation, alcohol, strobe lighting
- Abnormal EEG
- Good response to treatment
- Requires life-long treatment

**Hippocampal sclerosis**
This is a major cause of epilepsy. Hippocampal sclerosis (damage with scarring and atrophy of the hippocampus and surrounding cortex) is the main pathological substrate causing temporal lobe epilepsy and the leading cause of localization-related epilepsy. Childhood febrile convulsions are the main risk factor. Hippocampal sclerosis is usually visible on MRI. It is one of the commoner causes of refractory epilepsy, in which case it may be amenable to surgical resection of the damaged temporal lobe.

**Genetic and developmental disorders**
Over 200 genetic disorders include epilepsy among their features, e.g. tuberous sclerosis. These account for fewer than 2% of epilepsy cases. Neuronal migration defects during brain development, dysplastic areas of cerebral cortex and hamartomas contribute to seizures both in infancy and adult life.

**Trauma, hypoxia and neurosurgery**
**Traumatic brain injury** may cause epilepsy, sometimes years after the event. The risk is not increased after mild injury (loss of consciousness or post-traumatic amnesia <30 min). Depressed skull fracture, penetrating injury and intracranial hemorrhage increase risk significantly.

**Perinatal brain injury and cerebral palsy**, Periventricular leukomalacia and brain haemorrhage associated with prematurity and fetal hypoxia may cause early onset epilepsy. One-third of children with cerebral palsy have epilepsy.

**Brain surgery** is followed by seizures in up to 17% of cases. Prophylactic anticonvulsant use after surgery is not recommended.

**Brain tumours and other mass lesions**
Mass lesions involving the cortex cause epilepsy. Seizures are one of the commonest presenting features of brain tumours. 6% of cases of adult onset epilepsy are caused by brain tumours.

**Vascular disorders**
**Stroke and small vessel cerebrovascular disease** – is the commonest cause of epilepsy after the age of 60.

**Cortical venous thrombosis or venous sinus thrombosis**
**Arteriovenous malformations** commonly cause epilepsy.

**Neurodegenerative disorders**
Neurodegenerative disorders involving the cerebral cortex such as Alzheimer’s disease are associated with an increased risk of epilepsy.
Encephalitis and inflammatory conditions
Seizures are often the presenting feature of encephalitis, cerebral abscesses, and tuberculomas. They also occur in chronic meningitis (e.g. TB) and may rarely be the first sign of acute bacterial meningitis. Neurocysticercosis is a major cause of seizures in countries where the pork tapeworm is endemic, e.g. India and South America.

Alcohol and drugs
Chronic alcohol use is a common cause of seizures. These occur either while drinking heavily or during periods of withdrawal. Alcohol-induced hypoglycaemia and head injury also cause seizures.

Several drugs including antipsychotic drugs, tricyclic antidepressants, SSRIs, lithium, class Ib anti-arrhythmics such as lidocaine, cisclosporin and mefloquine sometimes provoke fits, either in overdose or at therapeutic doses in individuals with a low seizure threshold. Stimulant drugs such as cocaine also cause seizures.

Withdrawal of antiepileptic drugs (especially barbiturates) and benzodiazepines may provoke seizures.

Metabolic abnormalities
Seizures can be caused by:
- Hypocalcaemia, hypoglycaemia, hyponatraemia
- Acute hypoxia
- Uraemia, hepatic encephalopathy
- Porphyria.

The first fit

Diagnosis
The diagnosis of a seizure is essentially a clinical one based on taking a history from the patient and any witnesses (Boxes 22.20, 22.21).
Investigations have a limited role in distinguishing between a seizure and other causes of a blackout or attack (p. 1116).
The majority of patients referred to a first fit clinic have not had a seizure. The commonest error is to misdiagnose a syncopal blackout for a seizure.

Which investigations are needed?
Blood tests including serum calcium, and an ECG (rhythm, conduction abnormalities, QT interval) are necessary in most patients following an episode of loss of consciousness (Box 22.22).

Electroencephalography
EEG is most useful to categorize epilepsy and understand its cause, rather than as a means of confirming a doubtful diagnosis of epilepsy. EEG has a high false negative rate in epilepsy (over 20% even with awake and sleep recordings) and a low false positive rate (1% of people without epilepsy have epileptiform changes on EEG).

- EEG abnormalities in epilepsy: focal cortical spikes (e.g. over a temporal lobe) or generalized spike-and-wave activity (in PGE). Epileptic activity is continuous in status epilepticus.
- Sleep recordings or 24 h ambulatory EEG increase sensitivity when routine EEG is normal.
- Inpatient EEG videotelemetry helpful for diagnosis in attacks of uncertain cause.

Brain imaging
MRI is indicated in most patients after a first seizure, particularly with partial onset seizures and in older patients where the chance of a focal brain lesion is greatest. In patients below the age of 30 with a definite electro-clinical diagnosis of primary generalized epilepsy brain imaging is not essential.

Recurrence risk after a first fit
Some 70–80% of people will have a second seizure, the risk being highest in the first 6 months after the initial seizure. The vast majority of those who have a second seizure will have further seizures if not started on treatment. The risk of seizure recurrence is significantly increased by features of PGE on...
EEG, partial seizures and the presence of structural brain lesions.

**Treatment**

**Emergency measures**

Most seizures last only minutes and end spontaneously. A prolonged seizure (>5 min) or repeated seizures may be terminated with rectal diazepam, i.v. lorazepam or buccal midazolam. Give oxygen and monitor airway in post-ictal phase.

**Status epilepticus**

This medical emergency (Practical Box 22.5) means continuous seizures for 30 minutes or longer (or two or more seizures without recovery of consciousness between them over a similar period). Status epilepticus has a mortality of 10–15%. The longer the duration of status, the greater the risk of permanent cerebral damage. Rhabdomyolysis may lead to acute kidney injury in convulsive status epilepticus.

Over 50% of cases occur without a previous history of epilepsy. Some 25% with apparent refractory status have pseudostatus (non-epileptic attack disorder).

Not all status is convulsive. In absence status, for example, status is non-convulsive – the patient is in a continuous, distant, stuporous state. Focal status also occurs. Epilepsia partialis continua is continuous seizure activity in one part of the body, such as a finger or a limb, without loss of consciousness. This is often due to a cortical neoplasm or, in the elderly, a cortical infarct.

**Antiepileptic drugs (AEDs)** (Table 22.17)

AEDs are indicated when there is a firm clinical diagnosis of epilepsy and a substantial risk of recurrent seizures. Some general principles apply:

- Introduce AEDs at low dose and slowly titrate upwards until the seizures are controlled or side effects become unacceptable.
- Aim for monotherapy – 70% of patients will have good seizure control with a single AED.
- If seizures not controlled with first AED, gradually introduce second agent and then slowly withdraw the first AED. If still not seizure free then combination therapy is required.
- Epilepsy is one of the few disorders where non-generic (‘brand name’) prescribing is justified to ensure consistent drug levels.
- Routine monitoring of AED levels is not needed and should be reserved for assessing compliance and toxicity. Measuring sodium valproate levels is rarely useful as levels fluctuate widely.
- There are interactions between AEDs (and with other medications), e.g. between sodium valproate and lamotrigine. New generation AEDs have fewer interactions.
- Phenytoin is no longer considered a first-line AED; it is now principally used in emergency control of seizures (see status epilepticus). Levetiracetam is increasingly used in most types of epilepsy.

**Practical Box 22.5**

**Status epilepticus – management**

**Early status (up to 30 min):**
- Administer oxygen, monitor ECG, BP, routine bloods (include sugar, calcium, drug screen, anticonvulsant levels urgently)
- Give lorazepam i.v. 4 mg bolus. Repeat once if necessary. Buccal midazolam is an alternative

**Established status (30–90 min):**
- Phenytoin: give 15 mg/kg i.v. diluted to 10 mg/mL in saline into a large vein at 50 mg/min (ECG monitoring required) or
- Fosphenytoin: this is a pro-drug of phenytoin and can be given faster than phenytoin. Doses are expressed in phenytoin equivalents (PE): fosphenytoin 1.5 mg = 1 mg phenytoin. Give 15 mg/kg (PE) fosphenytoin (15 mg \* 1.5 = 21.5 mg) diluted to 10 mg/mL in saline at 50–100 mg (PE)/min

**If ongoing seizures:**
- Phenobarbital 10 mg/kg i.v. diluted 1 in 10 in water for injection at <100 mg/min.
- Valproate i.v. (25 mg/kg) is an alternative

**Refractory status (over 90 min) – general anaesthesia**

- Only in intensive care setting, intubation and ventilation usually required
- Propofol bolus 2 mg/kg, repeat, followed by continuous infusion of 5–10 mg/kg per hour
- Thiopentone and midazolam infusions may also be used
- Continuous EEG monitoring used to assess efficacy of treatment – aim for EEG burst suppression pattern
- Reinstate previous AED medication via NG tube
- Establish diagnosis: CT or MRI may reveal an underlying cause
- Remember: 25% of apparent status turns out to be pseudostatus

</table>
Unwanted effects of drugs. Intoxication with most AEDs causes unsteadiness, nystagmus and drowsiness. Side-effects are commoner with multiple AEDs. Skin rashes are seen particularly with lamotrigine, carbamazepine and phenytoin. A wide variety of idiosyncratic drug reactions may occur, e.g. blood dyscrasias with carbamazepine.

Epilepsy in women

Birth defects. The overall risk of birth defects in babies of mothers who take one AED is around 7%, as compared with 3% in women without epilepsy. Counselling before conception is essential. The risk to the fetus of uncontrolled seizures is greater than the risks of continuing AED treatment. If drugs cannot be safely stopped, monotherapy is preferable at the minimum effective dose. Sodium valproate is associated with a higher rate of serious malformations (e.g. neural tube defects) and should be stopped or substituted if possible. Folic acid (5 mg/day) supplements should be taken before conception and throughout the first trimester. Vitamin K 20 mg orally should also be taken during the month before delivery to prevent neonatal haemorrhage. Antenatal screening is necessary.

Contraception. AEDs inducing hepatic enzymes (e.g. carbamazepine, phenytoin and phenobarbital) reduce efficacy of oral contraceptives. A combined contraceptive pill containing a higher dose of oestrogen or the progesterone only pill provides greater contraceptive security. An IUCD or barrier methods of contraception are often used in preference to oral contraceptives.

Breast-feeding. Mothers taking AEDs need not in general be discouraged from breast-feeding, though manufacturers are often hesitant in assureing that there is no risk to the baby.

Epilepsy and driving

Patients should be asked to stop driving after a seizure and to inform the regulatory authorities if they hold a driving licence. After a seizure, a temporary driving ban until seizure free is usual but regulations vary from country to country. Many driving regulatory bodies also suggest refraining from driving while withdrawing from AEDs.

Lifestyle and safety

People with epilepsy (the term ‘epileptic’ is no longer used) should be encouraged to lead lives as unrestricted as reasonably possible, though with simple, safety measures such as avoiding swimming and dangerous sports such as rock-climbing. Advice at home includes leaving bathroom and lavatory doors unlocked and taking showers rather than baths. Epilepsy triggers such as sleep deprivation, excess alcohol and drugs should be avoided, and strobe lighting where there is EEG evidence of a photo-paroxysmal response.

Drug withdrawal

Withdrawal of AEDs should be considered after a seizure-free period of at least 2–3 years. There is a 50% seizure recurrence rate after withdrawal so careful discussion and explanation are essential.

Refractory epilepsy

- Seizures may persist despite treatment, especially with temporal lobe partial epilepsy.
- Re-evaluate the diagnosis.
- Consider concordance (compliance).
- Combine AEDs and use maximum tolerated dose.
- Refer to a specialist unit for consideration of epilepsy surgery.

Other causes of blackouts (Box 22.23)

- Epilepsy
- Syncope
  - Neurocardiogenic syncope (vasovagal)
  - Cardiac syncope (Stokes–Adams attacks)
  - Micturition syncope
  - Cough syncope
  - Postural hypotension
  - Carotid sinus syncope
- Non-epileptic attacks (pseudoseizures)
- Panic attacks and hyperventilation
- Hypoglycaemia
- Drop attacks
- Hydrocephalic attacks
- Basilar migraine
- Severe vertigo
- Cataplexy, narcolepsy, sleep paralysis

Other non-pharmacological treatments such as vagal nerve stimulation and the ketogenic low carbohydrate diet may sometimes be useful.

Epilepsy surgery

Temporal lobectomy will result in seizure freedom in 50–70% of selected patients with uncontrolled seizures caused by hippocampal sclerosis (defined by imaging and confirmed by EEG).

The distinction between a fit (seizure), a faint (syncope) or another type of attack is primarily a clinical one, dependent on the history and an eyewitness account. Mistaking a syncopeal loss of consciousness for a seizure is the most frequent error made in differential diagnosis.

Syncope or faints

The simple faint that over half the population experiences at some time (particularly in childhood, in youth or in pregnancy) is due to sudden reflex bradycardia with vasodilatation of both peripheral and splanchnic vasculature (neurocardiogenic or vasovagal syncope).

- Precipitants: a common response to prolonged standing, fear, venesection or pain. Syncope almost never occurs in the recumbent posture.
- The blackout (p. 1068): Usually lie still but jerking and twitching movements can occur and are sometimes mistaken for a convulsion. Appearance is pale. Incontinence of urine or faeces can occur and is not a good discriminator between seizure and syncope.
- Recovery is rapid, usually seconds but may be followed by a feeling of general fatigue (as opposed to post-ictal drowsiness and confusion following a seizure).

Other types of syncope

Cardiac syncope (Stokes–Adams attacks) are potentially serious and often treatable. Typically, there is little or no warning. Cardiac arrhythmias, e.g. due to heart block, or left ventricular outflow tract obstruction may be the cause. Syncope during exercise is often cardiac in origin.

Micturition syncope occurs during micturition in men, particularly at night.

Cough syncope occurs when venous return to the heart is obstructed by bouts of severe coughing. Also occasionally seen with laughter.
Movement disorders

**Postural hypotension** (p. 676) can cause syncope and occurs in the elderly, in autonomic neuropathy, with some drugs, e.g. antihypertensives.

**Carotid sinus syncope** (p. 676) due to a vagal response caused by pressure over the carotid sinus baroreceptors in the neck, e.g. due to a tight collar.

**Convulsive syncope**, collapsing in a propped up position following a syncope results in a delayed restoration of cerebral blood flow and may result in a secondary anoxic seizure following syncope.

**Syncope: investigation**

A 12-lead ECG should always be performed after a syncope to identify heart block, pre-excitation or long QT syndrome. Cardiac ECG holter monitoring and echocardiography are required where cardiac syncope is suspected. An implantable loop recorder is occasionally needed for infrequent events with a possible cardiac origin. Tilt table testing (p. 684) is sometimes diagnostic, but has low sensitivity.

**Other conditions**

**Non-epileptic attack disorder (pseudoseizures)** regularly cause difficulty in diagnosis. Attacks may look like grand mal fits. Usually there are bizarre thrashing, non-synchronous limb movements, but there can be extreme difficulty in separating these attacks from seizures. EEG videotelemetry is valuable. Apparent status epilepticus can occur. The serum prolactin level is of some value: this rises during a grand mal seizure but not during a pseudoseizure (or a partial seizure).

**Panic attacks** (see p. 1178) trigger sudden sympathetic activation and often hyperventilation leading to respiratory alkalosis. They cause some or all of the following symptoms: dizziness, chest pains or tightness, a feeling of choking or shortness of breath, tingling in face and extremities, palpitations, trembling and a feeling of dissociation or of impending doom. Consciousness is usually preserved and attacks easily recognized.

**Hypoglycaemia** (p. 1015) causes confusion followed by loss of consciousness, sometimes with a convulsion, dysphasia or hemiparesis. There is often warning, with hunger, malaise, shaking and sweating. Prompt recovery occurs with i.v. (or oral) glucose. Prolonged hypoglycaemia causes widespread cerebral damage. Hypoglycaemic attacks unrelated to diabetes are rare (p. 1030). Feeling faint after fasting does not indicate anything serious.

**Vertigo**. When acute, vertigo can be sufficiently severe as to cause prostration: a few seconds’ unresponsiveness sometimes follows.

**Migraine**. Severe basilar migraine and familial hemiplegic migraine may occasionally lead to loss of consciousness.

**Drop attacks** are instant, unexpected episodes of lower limb weakness with falling, largely in women over 60 years. Awareness is preserved. They are due to sudden change in lower limb tone, presumably of brainstem origin. Sudden attacks of leg weakness also occur in hydrocephalus.

**Transient ischaemic attacks** are almost never a cause of loss of consciousness.

**Movement disorders**

Sleep disorders

Sleep architecture and insomnia are discussed on page 1167. Myoclonic jerks when falling asleep are a normal phenomenon (p. 1121). Seizures may occur predominantly or solely during sleep.

**Narcolepsy and cataplexy**

Narcolepsy is caused by abnormalities of the brain neurotransmitter hypocretin (orexin) which is a regulator of sleep. CSF levels are usually low, thought in most cases to be due to autoimmune damage to the hypothalamic cells secreting the neurotransmitter. Narcolepsy is strongly associated with HLA-DR2 and HLA-DQBl*0602 antigens. The prevalence is estimated at 30–50/100000.

There are four main clinical features but not all patients have the full tetrad:

- **Excessive daytime sleepiness (EDS)**. This is the usual presenting symptom and the main cause of disability. Patients have frequent irresistible sleep attacks during the day, often in inappropriate circumstances, e.g. during meals or conversations or while driving. EDS may be quantified with the Epworth Sleepiness Scale. Nighttime sleep may be disrupted and paradoxically insomnia may occur.

- **Cataplexy** is sudden loss of muscle tone leading to head drop or even falling with intact awareness. Attacks are often set off by sudden surprise or emotion, e.g. laughter.

- **Hypnagogic/hypnopompic hallucinations**. Dream-like hallucinations occurring while falling asleep or waking from sleep. Often frightening.

- **Sleep paralysis**. A brief paralysis on waking or while falling asleep due to intrusion of REM atonia into wakefulness. This occasionally occurs in people without narcolepsy.

**Diagnosis and treatment**

Multiple Sleep Latency Testing demonstrating rapid transition from wakefulness to sleep and short time to onset of REM sleep confirms the diagnosis. HLA testing may also be useful.

Good sleep hygiene advice is necessary. Modafinil dexamfetamine and methylphenidate are used to treat EDS, often with only partial response. Tricyclic antidepressants, particularly clomipramine, or SSRIs can improve cataplexy. Sodium oxybate is also used.

**Parasomnias**

**Disruptive motor or verbal behaviours occurring during sleep**. They are divided into REM and non-REM parasomnias depending on which stage of sleep they arise in. They include sleepwalking, night terrors, confusional arousals and REM sleep behaviour disorder (which may be an early feature of Parkinson’s disease).

**Obstructive sleep apnoea** (see p. 818)

**FURTHER READING**

Parkinson’s disease is clinically and pathologically distinct from other parkinsonian syndromes.

The causes of idiopathic Parkinson’s disease (PD) is still not fully understood. The relatively uniform worldwide prevalence suggests that a single environmental agent is not responsible. There may be multiple interacting risk factors including genetic susceptibility;

**Age and gender.** Prevalence increases sharply with age, particularly over 70 years with prevalence of 1 in 200 over age 80. Ageing changes are likely to be an important factor in causation. Prevalence is higher in men (1.5:1 M:F)

**Environmental factors.** Epidemiological studies consistently show a small increased risk with rural living and drinking well water. Pesticide exposure has been implicated and pesticide-induced rodent models of PD exist, which increases biological plausibility of a link. The chemical compound MPTP, a potent mitochondrial toxin, causes severe Parkinsonism, leading to suggestions that oxidative stress may be a factor leading to neuronal cell death in idiopathic PD. Studies consistently show that non-smokers have a higher risk of PD than smokers (even after controlling for shorter life expectancy in smokers), an observation that is difficult to explain.

**Genetic factors.** Idiopathic PD is not usually familial, but twin studies show there is a significant genetic component in early onset PD (onset before 40). Several genetic loci for Mendelian inherited monogenic forms of PD have now been identified (Table 22.18), designated PARK 1–11. Most of these are rare but together they account for a large proportion of early onset and familial PD, and a small proportion (perhaps 1–2%), of sporadic late onset cases. The main significance of the PARK genes is that they provide insights into the pathophysiological mechanisms underlying PD that may be relevant to sporadic cases. Research is ongoing to determine whether polymorphisms in these and other genes may, in combination, constitute a susceptibility to PD which can be triggered by environmental factors or the ageing process.

**Pathology**

The pathological hallmarks of PD are the presence of neuronal inclusions called Lewy bodies and loss of the dopaminergic neurones from the pars compacta of the substantia nigra in the midbrain that project to the striatum of the basal ganglia (Fig 22.10). Lewy bodies contain tangles of α-synuclein and ubiquitin and become gradually more widespread as the condition progresses, spreading from the lower brainstem, to the midbrain and then into the cortex. Degeneration also occurs in other basal ganglia nuclei. The extent of nigrostriatal dopaminergic cell loss correlates with the degree of akinesia.

**Symptoms and signs**

PD almost always presents with the typical motor symptoms of tremor and slowness of movement but it is likely that the pathological process starts many years before these symptoms develop. By the time of first presentation, on average 70% of dopaminergic nigrostriatal cells have already been lost.

**Prodromal premotor symptoms**

Patients develop a variety of nonspecific non-motor symptoms during the approximately seven years, sometimes longer, before the motor symptoms become manifest. These include:

- Anosmia (present in 90%) – the olfactory bulb is one of the first structures to be affected
- Depression/anxiety (50%)
- Aches and pains
- REM sleep behaviour disorder
- Autonomic features – urinary urgency, hypotension
- Constipation
- Restless legs syndrome.

**Motor symptoms**

These develop slowly and insidiously and are often initially attributed to ‘old age’ by patients. The core motor features of PD are:

- Akinesia
- Tremor
- Rigidity
- Postural and gait disturbance.

Slowness causes difficulty rising from a chair or getting into or out of bed. Writing becomes small (micrographia) and spidery, tending to tail off. Relatives often notice other features – slowness and an impassive face. Idiopathic PD is almost always initially more prominent on one side. The diagnosis is usually evident from the overall appearance.

**Akinesia**

Poverty/Slowing of movement (also called bradykinesia) is the cardinal clinical feature of Parkinsonism and the main cause of disability. What distinguishes it from slowness of movement from other causes is a progressive fatiguing and decrement in amplitude of repetitive movements.

There is difficulty initiating movement. The upper limb is usually affected first and is almost always unilateral for the first years. Rapid dexterous movements are impaired causing difficulty writing (micrographia), and doing up buttons and zips for example. Facial immobility gives a mask-like semblance of depression. Frequency of spontaneous blinking diminishes, producing a serpentine stare.

Akinesia is tested for clinically by asking the patient to perform rapid alternating movements such as opening and closing the hand repetitively or pronating and supinating the arm, looking for progressive slowing and decrement in amplitude of movement.

**Tremor**

The presenting symptom in 70% of patients. Almost always starts in the fingers and hand and like akinesia, is unilateral initially, spreading later to the leg on the same side and then

</tbody>
</table>
...the opposite arm. The tremor is present at rest and reduces or stops completely when the hand is in motion. The frequency is 3–6 Hz and it is often described as *pill-rolling* because the patient appears to be rolling something between thumb and forefinger. As with most tremors it is made worse by emotion or stress.

**Rigidity**
A sign rather than a symptom usually. Stiffness on passive limb movement is described as ‘lead pipe’ as it is present throughout the range of movement and unlike spasticity, is not dependent on speed of movement. When stiffness occurs with tremor (not always visible), a ratchet-like jerkiness is felt, described as cogwheel rigidity.

**Postural and gait changes**
A stooped posture is characteristic. Gait gradually becomes shuffling with small stride length, slow turns, freezing and reduced arm swing. Postural stability eventually deteriorates, leading to falls, but this is a late stage feature which should arouse suspicion of an alternative diagnosis if present during the first 5 years.

**Speech and swallowing**
Speech becomes quiet, indistinct and flat. Drooling may be an embarrassing problem and swallowing difficulty is a late feature that may eventually lead to aspiration pneumonia as a terminal event.

**Cognitive and psychiatric changes**
Cognitive impairment is now recognized to be common in late stage PD (80%) and may develop into dementia. Visual hallucinations on treatment, and psychosis are not uncommon, and may herald evolving cognitive decline. Cholinesterase inhibitors (p. 1141) may be helpful.

Depression is common, probably due to involvement of serotonergic and adrenergic systems, and an important cause of reduced quality of life in PD. Anxiety is also co-morbid with PD.

**The clinical evolution of PD**
PD worsens slowly over the years as more neuronal cells become affected by the pathological process. Initial symptoms may be trivial, especially if affecting the non-dominant hand, but worsening akinesia and tremor eventually cause significant disability if untreated. Symptoms which are initially unilateral eventually spread to the opposite side, and axial symptoms such as walking difficulty and postural instability develop.

Most patients respond well to treatment and there is generally a period of several years in which symptoms are well controlled with relatively little disability. Response to dopaminergic drugs is never lost but treatment-related fluctuations may develop (see below) which can be limiting, especially for patients with early age at onset. Eventually, usually by mid-70s, late stage, treatment-unresponsive, features such as cognitive impairment, swallowing difficulty, loss of postural stability and falls start to emerge.

The rate of progression is very variable, with a benign form running over several decades. Usually the course is over 10–20 years, with death resulting from bronchopneumonia and immobility.

**Diagnosis**
There is no laboratory test; diagnosis is made by recognizing physical signs and distinguishing idiopathic PD from other Parkinsonian syndromes. Patients with suspected PD should be referred to a specialist without initiation of treatment.

**MRI imaging** is normal and not necessary in typical cases. Dopamine transporter (DaT) imaging makes use of a radio-labelled ligand binding to dopaminergic terminals to assess the extent of nigrostriatal cell loss. It may occasionally be needed to distinguish PD from other causes of tremor, or drug-induced Parkinsonism, but it cannot discriminate between PD and other akinetic-rigid syndromes.

**Treatment**
Education about the condition is necessary and physical activity is beneficial and should be encouraged. Dopamine replacement with levodopa or a dopamine agonist (DA) improves motor symptoms and is the basis of pharmacological therapy. Treatment of non-motor symptoms such as depression, constipation, pain and sleep disorders is also necessary and significantly improves quality of life.

Dopamine replacement may not always be needed in early stage PD and is only started when symptoms start to cause disability. The mechanism of action of drugs in PD is shown in Figure 22.43.

**Levodopa**
Levodopa remains the most effective form of treatment and all patients with PD will eventually need it. It is combined with a dopa decarboxylase inhibitor – benserazide (co-beneldopa) or carbidopa (co-careldopa) – to reduce the peripheral adverse effects (e.g. nausea and hypotension); 50 mg of L-dopa (e.g. co-careldopa 62.5 mg) three times daily, increasing after 1 week to 100 mg three times daily is a typical starting dose. The response is often dramatic.

**Dopamine agonists**
Dopamine agonists (DA) may be used in combination with levodopa or as initial monotherapy in younger patients (below age 65–70) with mild to moderate impairment. Although less...
efficacious in symptom control than levodopa and generally less well tolerated, DAs are associated with fewer motor complications over a 5 year period. Non-ergot DAs (Pramipexole and ropinirole or rotigotine via transdermal patch) are used in preference to ergot-derived drugs, which may be associated with fibrotic reactions including cardiac valvular fibrosis. Domperidone is used as an antiemetic when initiating DA therapy (other antiemetics should not be used as they may worsen symptoms by blocking central dopamine receptors).

Other drugs used in PD

- **Selegiline** 5–10 mg once daily (a monoamine oxidase B inhibitor) reduces catabolism of dopamine in brain. Mild symptomatic effect. **Rasagiline** is another MAOB inhibitor.
- **Amantadine** has a modest anti-Parkinsonian effect but is mainly used to improve dyskinesias in advanced disease.
- **Anticholinergics** (e.g. trihexyphenidyl) may help tremor but are now rarely used in PD except in younger patients. High propensity to cause confusion in older patients.
- **Apomorphine** is a potent, short-acting, DA administered subcutaneously by an autoinjector pen as intermittent ‘rescue’ injection for off periods or by continuous infusion pump. Used in advanced PD.

Long-term response to treatment

As the disease progresses, medical therapy for PD becomes more difficult as higher doses of dopamine replacement therapy are required and response becomes more unpredictable with the development of motor fluctuations and dyskinesias, but response to dopaminergic drugs is never lost. Approximately 10% of patients per year develop motor complications in the form of ‘wearing off’ (the duration of effect of individual doses of LD becomes progressively shorter), dyskinesias (involuntary choreiform movements) and eventually, on/off phenomenon (sudden, unpredictable transitions from mobile to immobile). Eventually, patients may alternate between the on state with dopamine-induced dyskinesias and periods of complete immobility (off).

Management of motor complications of treatment represents one of the greatest challenges in the management of PD. Management strategies include:

- **Dose fractionation of levodopa** – increasing dose frequency

- **Addition of COMT (catecol-O-methyl transferase) inhibitor entacapone** (200 mg with each levodopa dose) to prolong duration of action. Also available as a combined preparation with levodopa and carbidopa

- **Slow release levodopa** – mostly used for overnight symptoms as absorption is erratic and difficult to predict, so limiting effectiveness in control of daytime symptoms

- **Avoiding protein-rich meals** (which impair levodopa absorption) and taking doses at least 40 minutes prior to meals

- **Apomorphine continuous subcutaneous infusion** (see above)

- **Deep brain stimulation** and L-dopa intestinal gel (see below).

Deep brain stimulation (DBS)

Stereotactic insertion of electrodes into the brain has proved to be a major therapeutic advance in selected patients (usually under age 70) with disabling dyskinesias and motor fluctuations not adequately controlled with medical therapy. Targets include:

- **Subthalamic nucleus** – response similar to levodopa with reduction in dyskinesia

- **Globus pallidus** – improves dyskinesia but levodopa still required for motor symptoms

- **Thalamic** – for tremor only.

L-dopa intestinal gel infusion

Continuous infusion of this gel into the small intestine via a jejunostomy using a patient-operated pump is effective for selected patients with severe motor complications. At present, it is used only where apomorphine or DBS are contraindicated, partly because of high costs.

Tissue transplantation

Transplantation of embryonic mesencephalic dopaminergic cells directly into the putamen has produced mixed results but is potentially promising with research ongoing to refine the technique. Stem cells and gene therapy approaches are in development.

Physiotherapy, OT and physical aids

Physiotherapy, occupational therapy and speech therapy all have a role to play in managing PD and reducing disability, speech and swallowing problems and falls. Walking aids are often a hindrance early on, but later a frame or a tripod may help. A variety of external cueing techniques may help with freezing.

Other akinetic-rigid syndromes

Drug-induced Parkinsonism

Dopamine blocking or depleting drugs, particularly neuroleptics (with the exception of clozapine), induce Parkinsonism or worsen symptoms in affected patients, and may precipitate symptoms in elderly patients in the presymptomatic phase.

Atypical Parkinsonism

A number of neurodegenerative disorders affect the basal ganglia causing prominent Parkinsonism as part of the clinical picture and may be mistaken for idiopathic PD in the early stages. These include:

- **Progressive supranuclear palsy** (Steele–Richardson–Olszewski syndrome). Causes Parkinsonism, postural instability with early falls, vertical supranuclear gaze palsy, pseudobulbar palsy and dementia. Tau deposition seen pathologically.

- **Multiple system atrophy**. Autonomic symptoms and ataxia occur in addition to Parkinsonism. Pathologically α-synuclein positive glial cytoplasmic inclusions occur.

- **Corticobasal degeneration**. Alien limb phenomena, myoclonus and dementia.

These disorders are relentlessly progressive, although they sometimes respond to levodopa, and usually cause death within a decade. ‘Red flag’ symptoms suggesting one of these disorders include:

- Symmetrical presentation and absence of tremor

- Levodopa unresponsiveness (or poor response)

- Early falls (within first year)

- Additional neurological features.
Dementia with Lewy bodies
See page 1140.

Wilson’s disease
This rare and treatable disorder of copper metabolism is inherited as an autosomal recessive. Copper deposition occurs in the basal ganglia, the cornea and liver (p. 341), where it can cause cirrhosis. All young patients (below age 50) with an akinetic-rigid syndrome or any hyperkinetic movement disorder, or with liver cirrhosis should be screened for Wilson’s disease (check serum copper and caeruloplasmin). Intellectual impairment develops. Neurological damage is reversible with early treatment. Diagnosis, and treatment with the chelating agent penicillamine is discussed on page 341.

Hyperkinetic movement disorders
There are five hyperkinetic movement disorders. These can sometimes be difficult to separate from one another and may occur in combination.
- Tremor – rhythmic sinusoidal oscillation of a body part
- Chorea – excessive, irregular movements flitting from one body part to another (‘dance-like’)
- Myoclonus – brief electric shock-like jerks
- Tics – stereotyped movements or vocalizations (may be temporarily suppressed)
- Dystonia – sustained muscle spasms causing twisting movements and abnormal postures.

Essential tremor
This common condition, often inherited as an autosomal dominant trait, causes a bilateral, fast, low amplitude tremor, mainly in the upper limbs. The head and voice are occasionally involved. Tremor is postural, such as when holding a glass or cutlery. Essential tremor occurs at any age but usually starts in early life. Tremor is slowly progressive but rarely produces severe disability. There may be a cerebellar-type action tremor component. Anxiety exacerbates the tremor.

Treatment is often unnecessary, and unsatisfactory. Many patients are reassured to find they do not have PD, with which essential tremor is often confused. Small amounts of alcohol, beta-blockers (propranolol), primidone or gabapentin may help. Sympathomimetics (e.g. salbutamol) make all tremors worse. Stereotactic thalamotomy and thalamic DBS are used in severe cases.

Chorea
There are a wide variety of possible causes of chorea. These include:
- Systemic disease – thyrotoxicosis, SLE, antiphospholipid syndrome, primary polycythaemia
- Genetic disorders – Huntington’s disease and genetic phenocopies, neuroacanthocytosis, benign hereditary chorea
- Structural and vascular disorders affecting the basal ganglia
- Drugs (e.g. levodopa and OC pill)
- Post-infectious (Sydenham’s chorea), following months after streptococcal infection or as part of acute rheumatic fever
- Pregnancy.

Treatment is of the underlying cause, but dopamine blocking drugs such as phenothiazines (e.g. sulpiride) and dopamine depleting drugs (tetrabenazine) reduce chorea (as the prototypical excessive movement condition the treatment is the opposite of PD).

Huntington’s disease (HD)
A cause of chorea, usually presenting in middle life, initially with subtle ‘fidgetiness’ followed by development of progressive psychiatric and cognitive symptoms.

Prevalence worldwide is about 5/100 000. HD is due to a CAG trinucleotide repeat expansion which forms the basis of the diagnostic test (p. 42). This results in translation of an expanded polyglutamine repeat sequence in huntingtin, the protein gene product, the function of which is unclear. The expansion is thought to be a toxic ‘gain of function’ mutation. Most adult onset patients have 36–55 repeats and there is an inverse relationship between repeat length and age at onset, with juvenile onset patients having over 60 repeats. Expansion of the unstable CAG repeat during meiosis, particularly spermatogenesis, is the molecular basis for the phenomenon of anticipation (a tendency for successive generations to have earlier onset and more severe disease) particularly when inherited from the father.

HD is inherited in an autosomal dominant manner with complete penetrance (all gene carriers will develop the disease eventually). Previous family history is often not known. There is no disease modifying treatment at present, although chorea can improve with treatment, but progressive neurodegeneration leads to dementia and ultimately death after 10–20 years. Patients with small or intermediate range expansions may present in old age with isolated chorea.

Absence of treatment results in a low take-up rate for presymptomatic testing in at-risk individuals. Test centres have protocols for counselling families and addressing ethical issues.

Hemiballismus
Hemiballismus (see Fig. 22.10) describes violent swinging movements of one side caused usually by infarction or haemorrhage in the contralateral subthalamic nucleus.

Acute chorea-hemiballismus also occurs after diabetic non-ketotic hyperglycaemia, with signal change seen in the basal ganglia on CT or MRI, thought to be due to osmotic shifts causing myelinolysis.

Myoclonus
Cortical myoclonus is usually distal (hands and fingers especially) and stimulus sensitive (spontaneous but also triggered by touch or loud noises) and caused by a wide variety of pathologies affecting the cerebral cortex; spinal and brainstem myoclonus are caused by localized lesions affecting these structures.

Primary myoclonus
Physiological myoclonus. Nocturnal myoclonus consisting of sudden jerks (often with a feeling of falling) on dropping off to sleep or waking – is common and not pathological. The startle response is also a form of brainstem myoclonus.

Myoclonic dystonia (DYT11). Myoclonic ‘lightning jerks’ often with dystonia, inherited as a rare autosomal dominant disorder due to mutations in the e-sarcoglycan gene. The condition is thought to be allelic with benign essential myoclonus (caused by disruption of the same gene).

Myoclonus in epilepsy
Myoclonic jerks occurs in several forms of epilepsy (p. 1112). An antiepileptic drug, e.g. valproate, may be helpful.
Progressive myoclonic epilepsy-ataxia syndromes
These rare conditions include genetic and metabolic disorders where myoclonus accompanies progressive epilepsy, cognitive decline and/or ataxia. Lafora body disease, neuronal ceroid lipofuscinosis and Unverricht-Lundborg disease are examples.

Secondary myoclonus
Myoclonus may be seen in a wide variety of metabolic disorders including hepatic and renal failure (asterixis), as part of several dementias and neurodegenerative disorders (e.g. Alzheimer’s disease) and encephalitis.

Post-anoxic myoclonus sometimes follows severe cerebral anoxia.

Tics
Tics are common (15% lifetime prevalence), brief stereotyped movements usually affecting the face or neck but which may affect any body part including vocal tics. Unlike other movement disorders they may be transiently suppressed, leading to a build-up of anxiety and overflow after release.

Simple transient tics (e.g. blinking, sniffing or facial grimacing) are common in childhood, but may persist. Adult onset tics are rare and usually due to a secondary cause. The borderland between normal and pathological is vague.

Tourette’s syndrome
The commonest cause of tics, characterized by multiple motor tics and at least one vocal tic, starting in childhood and persisting longer than a year. Boys are affected more often than girls in a 3:1 ratio. Behavioural problems including attention deficit hyperactivity disorder (ADHD) and obsessive–compulsive disorder (OCD) are common and may sometimes be the major cause of disability. There is sometimes explosive barking and grunting of obscenities (coprolalia) and gestures (copropraxia) or echolalia (copying what other people say). Many affected individuals never come to medical attention. The cause is not known but it may be a complex problem with histaminergic neurotransmission.

Dystonias (Box 22.24)
Dystonia is most usefully classified by aetiology, into:
- **Primary dystonias** – where dystonia is the only, or main, clinical manifestation (usually genetic)
- **Secondary dystonia** – due to brain injury, cerebral palsy or drugs for example

**Box 22.24 A classification of dystonias**
- Generalized dystonia
- Primary torsion dystonia (PTD)
- Dopamine-responsive dystonia (DRD)
- Drug-induced dystonia (e.g. metoclopramide)
- Symptomatic dystonia (e.g. after encephalitis lethargica or in Wilson’s disease)
- Paroxysmal dystonia (very rare, familial, with marked fluctuation)
- Facial dystonia
- Spasmodic torticollis
- Writer’s cramp
- Oromandibular dystonia
- Blepharospasm
- Hemiplegic dystonia, e.g. following stroke
- Multiple sclerosis – rare
- **Heredo-degenerative dystonia** – as part of a wider neurodegenerative disorder
- **Paroxysmal dystonias** – rare, mostly genetic, attacks of sudden involuntary movements with elements of dystonia and chorea.

Primary dystonias
Young onset. Mutations in the DYT1 gene locus, seen particularly in the Ashkenazi Jewish population, cause limb-onset dystonia (usually foot), before age 28. Most patients have a 3 base-pair GAG deletion in the torsinA endoplasmic reticulum ATPase protein encoded by the DYT1 gene. Penetrance is low (autosomal dominant) and phenotype very variable, but it often spreads over years to become generalized dystonia, and can result in severe disability. Cognitive function remains normal. The condition is rare and the definitive form of treatment for severe cases is now deep brain stimulation (electrodes inserted into globus pallidus).

Adult onset. Much the commonest type of primary dystonia. Onset is usually around 55 and dystonia is usually focal (restricted to one body part), particularly affecting the head and neck unlike DYT1 dystonia. Various patterns are recognized:

Torticollis
Dystonic spasms gradually develop in neck muscles causing the head to turn (torticollis) or to be drawn backwards (retrocollis). There may also be a jerky head tremor. A gentle touch with a finger tip at a specific site may relieve the spasm temporarily (sensory trick or ‘geste’).

Writer’s cramp and task-specific dystonias
A specific inability to perform a previously highly developed repetitive skilled movement, e.g. writing. The movement provokes dystonic posturing. Other functions of the hand remain normal. Overuse may lead to task-specific dystonias in certain occupations, e.g. musicians, typists and even golfers.

Blepharospasm and oromandibular dystonia
These consist of spasms of forced blinking or involuntary movement of the mouth and tongue (e.g. lip-smacking and protrusion of the tongue and jaw). Speech may be affected.

Dopa-responsive dystonia (DRD)
In this rare disorder dystonia is completely abolished by small doses of levodopa. Typically dystonic walking begins in childhood and may resemble a spastic paraparesis or even present as cerebral palsy. Dominantly inherited mutations in the GTP cyclohydrolase gene on chromosome 14q21.3 (necessary for synthesis of a co-factor – tetrahydrobiopterin – needed for dopamine synthesis) lead to brain dopamine deficiency. Patients with dystonic gait are sometimes given test doses of levodopa.

Neuroleptics and movement disorders
Neuroleptics (antipsychotic drugs used to treat schizophrenia) and related drugs used as antiemetics (e.g. metoclopramide) can cause a variety of movement disorders.
- **Akathisia.** This is a restless, repetitive and irresistible need to move
- **Parkinsonism.** Due to D1 and D2 dopamine receptor blockade – see above
- **Acute dystonic reactions.** Spasmodic torticollis, trismus and oculogyric crises (episodes of sustained
upward gaze) develop, dramatically and unpredictably, after single doses

- **Tardive dyskinesia.** These mouthing and lip-smacking grimaces occur after several years of neuroleptic use. They often become temporarily worse when the drug is stopped or the dose reduced. Even if treatment ceases, resolution seldom follows. Atypical neuroleptics are less prone to cause this complication.

**Treatment**

Targeted injection of botulinum toxin into affected muscles is now the principal form of treatment for all focal dystonias. Antimuscarinics (e.g. trihexyphenidyl) are sometimes helpful.

### MULTIPLE SCLEROSIS (MS)

MS is a chronic autoimmune T-cell mediated inflammatory disorder of the CNS. Multiple plaques of demyelination occur throughout the brain and spinal cord, occurring sporadically over years (dissemination in space and time which is crucial for diagnosis).

MS is a major cause of disability in young adults but recent therapeutic advances mean that it is no longer an ‘untreatable’ disease.

**Epidemiology**

*Prevalence:* MS is a common neurological disorder in the UK with prevalence of 1.2/1000. Approximately 80,000 people in the UK have MS.

*Gender:* women outnumber men by 2:1. There is evidence that this ratio is widening with an increasing proportion of women being affected.

*Age:* presentation is typically between 20 and 40 years of age. Presentation after age 60 is rare although diagnosis may sometimes be much delayed, occurring years after initial symptoms.

Prevalence varies widely in different geographic regions and ethnic groups. This probably reflects both genetic and environmental influences in pathogenesis. It is much commoner in white populations and with increasing distance from the equator. Even within the UK there is a north–south divide with prevalence being higher in Scotland than southern England. Migration studies show that children moving from a low risk to a high risk area (e.g. the UK) develop a higher risk of MS, similar to the population of the country to which they migrate, indicating that environmental factors are a factor in pathogenesis.

Other autoimmune disorders occur with increased frequency in patients with MS and their relatives, indicating a genetic predisposition to autoimmunity.

**Aetiology and pathogenesis**

MS is a T-cell mediated autoimmune disease causing an inflammatory process mainly within the white matter of the brain and spinal cord. The aetiology of MS is complex and not yet fully understood.

**Genetic susceptibility**

Multiple genes interact to confer increased risk of MS, giving a complex polygenic inheritance pattern. Genetic differences between different populations probably account for part of the observed variation in MS incidence around the world.

Family studies show that there is a much increased risk of MS in 1st-degree relatives of affected patients (approx. 3–5% lifetime risk of developing MS). Twin studies confirm a major genetic component to susceptibility with 30% of monozygotic twins being concordant for MS versus 5% of dizygotic twins.

Genes. Variations in some 60 different genes have been identified so far as conferring an increased risk of MS; 80% of these are genes relating to immune system function and regulation, including HLA and MHC polymorphisms.

**Environmental factors**

Migration studies (see above) and twin studies indicate that environmental factors play a role in the development of MS but these factors are still largely unknown. Viral infections can precipitate MS relapses and exposure to infectious agents at critical times in development may trigger MS in genetically susceptible individuals. There is evidence that exposure to EBV may be linked to MS; EBV seropositivity is higher in patients with MS than the general population. Human herpesvirus 6 (HHV-6) has also been implicated. Exposure to infectious agents in childhood may reduce risk of developing MS and other autoimmune disorders (the ‘Hygiene Hypothesis’). There is also some evidence that low levels of vitamin D and lack of sunlight exposure may be a risk factor for MS.

**Pathology** (Fig. 22.44)

Plaques of demyelination, 2–10 mm in size, are the cardinal features. Plaques occur anywhere in CNS white matter (and sometimes grey matter) but have a predilection for distinct CNS sites: optic nerves, the periventricular region, the corpus callosum, the brainstem and its cerebellar connections and the spinal cord (corticospinal tracts and posterior columns). MRI studies show that most inflammatory plaques are asymptomatic. Peripheral myelinated nerves are not directly affected in MS.

Acute relapses are caused by focal inflammation causing myelin damage and conduction block. Recovery follows as inflammation subsides and remyelination occurs. When damage is severe, secondary permanent axonal destruction occurs. Progressive axonal damage is the pathological basis of the progressive disability seen in progressive forms of MS. The exact relationship between the inflammatory lesions seen in early relapsing-remitting forms of MS and the progressive axonal loss of chronic forms of MS is disputed.

**Clinical features**

No single group of signs or symptoms is diagnostic. A wide variety of possible symptoms may occur depending on the...
anatomical site of lesions; MS has been described as the modern ‘great imitator’. The clinical time course of attacks and tempo of evolution of symptoms are as good as the symptoms themselves in making the diagnosis of MS.

**Types of MS**

There are three main clinical patterns (Fig. 22.45):

- Relapsing-remitting MS (RRMS) (85–90%). The commonest pattern of MS. Symptoms occur in attacks (relapses) with a characteristic time course: onset over days and typically recovery, either partial or complete, over weeks. On average patients have one relapse per year but occasionally many years may separate relapses (benign MS ~ 10% of patients). Patients may accumulate disability over time if relapses do not recover fully.

- Secondary progressive MS – this late stage of MS consists of gradually worsening disability progressing slowly over years. 75% of patients with relapsing-remitting MS will eventually evolve into a secondary progressive phase by 35 years after onset. Relapses may sometimes occur in this progressive phase (relapsing–progressive MS).

- Primary progressive MS (10–15%). The least common form of MS, characterized by gradually worsening disability without relapses or remissions. Typically presents later and is associated with fewer inflammatory changes on MRI.

**Clinical presentations**

Three characteristic common presentations of MS are optic neuritis (neuritis), brainstem demyelination and spinal cord lesions, described below.

**Optic neuritis (ON)**

See ‘Inflammatory optic neuropathy’, page 1073.

**Brainstem demyelination**

A relapse affecting the brainstem causes combinations of diplopia, vertigo, facial numbness/weakness, dysarthria or dysphagia. Pyramidal signs in the limbs occur when the corticospinal tracts are involved. A typical picture is sudden diplopia, and vertigo with nystagmus, but without tinnitus or deafness. Bilateral internuclear ophthalmoplegia (INO, in this chapter) is pathognomonic of MS.

**Spinal cord lesions**

Paraparesis developing over days or weeks (Box 22.27) is a typical result of a plaque in the cervical or thoracic cord, causing difficulty in walking and limb numbness with tingling, often asymmetric. Lhermitte’s sign may be present (p. 1087). Arms are sometimes also involved in high cervical cord lesions. A tight band sensation around the abdomen or chest is common with thoracic cord lesions.

**Common symptoms in MS**

Disability and neurological impairments accumulate gradually over the years. Several symptoms are common and many can be improved with symptomatic treatments.

- Visual changes (see p. 1073).
- Sensory symptoms – often unusual, e.g. sensation of water trickling down skin. The presenting feature in 40% of patients. Reduced vibration sensation and proprioception in the feet are among the commonest abnormalities on examination but examination may be normal despite significant sensory symptoms.
- Clumsy/useless hand or limb – due to loss of proprioception (often a dorsal column spinal plaque).
- Unsteadiness or ataxia.
- Urinary symptoms – bladder hyper-reflexia causing urinary urgency and frequency. Treat with antimuscarinics or intravesical botulinum toxin injections.
- Pain – neuropathic pain is common.
- Fatigue – a common and often debilitating symptom which can occur in patients with otherwise mild disease. This sometimes responds to amantadine or modafinil or a fatigue management programme.
- Spasticity – may require baclofen or other muscle relaxants. Occasionally botulinum toxin injections for focal spasticity.
- Depression.
- Sexual dysfunction.
- Temperature sensitivity – temporary worsening of pre-existing symptoms with increases in body temperature, e.g. after exercise or a hot bath, is known as Uhthoff’s phenomenon.

**Unusual presentations**

Epilepsy and trigeminal neuralgia (p. 1110) occur more commonly in MS patients than in the general population. Tonic spasms (frequent brief spasms of one limb) are rare but pathognomonic of MS.

**Late stage multiple sclerosis**

Late MS causes severe disability with spastic tetraparesis, ataxia, optic atrophy, nystagmus, brainstem signs (e.g. bilateral INO), pseudobulbar palsy and urinary incontinence. Cognitive impairment, often with frontal lobe features, may occur in late stage disease. In a proportion of patients, disability eventually becomes severe with median time to requiring walking aids of 15 years and time to wheelchair use 25 years from onset.

**Diagnosis of MS**

Few other neurological diseases have a similar relapsing and remitting course. The diagnosis of MS requires two or more attacks affecting different parts of the CNS, i.e. dissemination in time and space, and exclusion of other possible causes. History and support from investigations, particularly MR imaging, make the diagnosis. The McDonald criteria formalize the diagnostic criteria but are designed mainly for research purposes and rarely used in clinical practice.

When taking a history at the time of initial presentation it is essential to ask about previous episodes of neurological
symptoms, often years previously, that may represent episodes of unrecognized demyelination. For example a severe episode of vertigo lasting weeks or loss of vision in one eye that gradually recovered.

Investigations

The purpose of investigations is to provide supportive evidence of dissemination in time and space (i.e. to show scattered demyelinating lesions which evolve over time), to exclude other diseases and to provide evidence of immunological disturbance.

- MRI of brain and cord is the definitive investigation as it demonstrates areas of demyelination with high sensitivity.

Multiple scattered plaques are usually seen, demonstrating dissemination in space.

Typical lesions are oval in shape, up to 2 cm in diameter, and often orientated perpendicular to the lateral ventricles. Occasionally, large ‘tumefactive’ (swelling) lesions are seen. Acute lesions show gadolinium enhancement for 6–8 weeks.

Although a sensitive technique to demonstrate plaques (normal MRI in MS is possible but distinctly rare), it is limited by lower specificity. Over the age of 50, small ischaemic lesions may be difficult to distinguish from demyelination and in younger patients of other neuro-inflammatory disorders such as sarcoidosis, Behcet’s syndrome and vasculitis may produce similar imaging appearances.

The presence of spinal cord lesions is quite specific for inflammatory disorders such as MS rather than ischaemic lesions so cord imaging is often useful where there is diagnostic difficulty.

Plaques are rarely visible on CT.

- CSF examination is often unnecessary with suggestive MR imaging and a compatible clinical picture. CSF analysis shows oligoclonal IgG bands in over 90% of cases but these are not specific for MS. The CSF cell count may be raised (5–60 mononuclear cells/mm³).

Evoked responses, e.g. visual evoked responses in optic nerve lesions, may demonstrate clinically silent lesions. However since the advent of MRI they are less important in diagnosis.

Blood tests are used to exclude other inflammatory disorders such as sarcoidosis or SLE or other causes of paraparesis, e.g. adrenoleucodystrophy, HIV, HTLV-1 and B₁₂ deficiency.

The clinically isolated syndrome (CIS)

In patients presenting with a first ever episode of neurological symptoms suggestive of neuro-inflammation, termed a ‘clinically isolated syndrome’, a diagnosis of MS cannot be made by definition. In up to 70% of such patients MRI shows multiple clinically silent lesions. An abnormal brain MRI at presentation, with multiple inflammatory type lesions, confers an 85% chance of developing MS over subsequent years (50% if presenting with optic neuritis). Patients need to be made aware of this possibility.

A second clinical event indicative of a new lesion in a different anatomical location allows the diagnosis of MS to be confirmed. Alternatively, a repeat MRI brain scan at least 1 month later showing either a new lesion or a gadolinium enhancing lesion is sufficient to show dissemination in time and space and confirm the diagnosis even in the absence of new symptoms.

Treatment

There is no cure for MS but in recent years several immunomodulatory treatments for MS have been introduced that have dramatically altered the ability to modify the course of the inflammatory relapsing-remitting phase of MS. It is hoped that these will translate into reduced long-term disability but this has yet to be proven.

- General measures. Education, provision of appropriate written materials and support from a multidisciplinary team including an MS nurse specialist are essentials. Treatments are available for various symptoms, e.g. pain and urinary symptoms. Physiotherapy and occupational therapy are helpful where there is persisting impairment between relapses. Infections should be treated early as they may precipitate relapses or lead to worsening of existing symptoms. Immunizations are safe.

- Acute relapses. Short courses of steroids, such as i.v. methylprednisolone 1 g/day for 3 days or high-dose oral steroids, are used for severe relapses. They speed recovery but do not influence long-term outcome.

- Disease modifying drugs (DMDs) (Table 22.19). Immunomodulatory drugs such as β-interferon (both INF-β₁b and 1a) and glatiramer acetate reduce relapse rate by one-third and serious relapses by up to half in RRMS. They also significantly reduce development of new MRI lesions and may reduce accumulation of disability over the short term. They are self-administered by s.c. or i.m. injection and are generally well tolerated apart from flu-like side-effects and injection site irritation. From a health economics point of view cost is an issue as these drugs are very expensive.

Current recommendations in the UK are that DMDs are offered to ambulant patients with RRMS where there have been two or more significant relapses over a 2-year period or after one major disabling relapse. When used after CIS the conversion rate to definite MS is reduced from 50% to 30% over 3 years, but in the UK treatment with DMDs after CIS is rarely recommended. DMDs are not effective in primary progressive or secondary progressive MS.

- Treatment of aggressive RRMS. Immunomodulatory drugs and biological agents (monoclonal antibodies) such as natalizumab, alemtuzumab and oral fingolimod have shown high efficacy in preventing relapses and may reduce accumulation of disability significantly (Table 22.19). Their exact place in MS treatment is not yet established but they have the potential to cause serious adverse effects and are generally used only in very aggressive disease or where relapses are not reduced by β-interferon or glatiramer acetate. Recently, oral teriflunomide which reversibly inhibits dihydroorotate dehydrogenase (an enzyme involved in pyrimidine synthesis) has been shown in a phase III study to reduce relapses and MRI evidence of disease activity

Prognosis

The clinical course of MS is unpredictable: a high MR lesion load at initial presentation, high relapse rate, male gender and late presentation are poor prognostic features but not invariably so. There is wide variation in severity. Many patients continue to live independent, productive lives; a minority become severely disabled. Life expectancy is reduced by 7 years on average.
NERVOUS SYSTEM INFECTION AND INFLAMMATION

Meningitis

Meningitis usually implies serious infection of the meninges (Box 22.25). Bacterial meningitis is fatal unless treated. Microorganisms reach the meninges either by direct extension from the ears, nasopharynx, cranial injury or congenital meningeal defect, or by bloodstream spread. Immuno-compromised patients are at risk of infection by unusual organisms. Non-infective causes of meningeal inflammation include malignant meningitis, intrathecal drugs and blood following subarachnoid haemorrhage.

Pathology

In acute bacterial meningitis, the pia-arachnoid is congested with polymorphs. A layer of pus forms. This may organize to form adhesions, causing cranial nerve palsies and hydrocephalus.

In chronic infection (e.g. TB), the brain is covered in a viscous grey-green exudate with numerous meningeal tubercles. Adhesions are invariable. Cerebral oedema occurs in any bacterial meningitis.

In viral meningitis there is a predominantly lymphocytic inflammatory CSF reaction without pus formation, polymorphs or adhesions; there is little or no cerebral oedema unless encephalitis develops.

Clinical features

The meningitic syndrome

This is a simple triad: headache, neck stiffness and fever. Photophobia and vomiting are often present. In acute bacterial infection there is usually intense malaise, fever, rigors, severe headache, photophobia and vomiting, developing within hours or minutes. The patient is irritable and often prefers to lie still. Neck stiffness and positive Kernig’s sign usually appear within hours.

In less severe cases (e.g. many viral meningitides), there are less prominent meningitic signs. However, bacterial infection may also be indolent, with a deceptively mild onset.

In uncomplicated meningitis, consciousness remains intact, although anyone with high fever may be delirious. Progressive drowsiness, lateralizing signs and cranial nerve lesions indicate complications such as venous sinus thrombosis (p. 1107), severe cerebral oedema, hydrocephalus, or an alternative diagnosis such as cerebral abscess (p. 1130) or encephalitis (p. 1128).

Specific varieties of meningitis

Clinical clues point to the diagnosis (Table 22.20). If there is access to the subarachnoid space via skull fracture

Bacteria

- Neisseria meningitidis
- Streptococcus pneumoniae
- Staphylococcus aureus
- Streptococcus Group B
- Listeria monocytogenes
- Gram-negative bacilli, e.g. E. coli
- Mycobacterium tuberculosis
- Treponema pallidum

Viruses

- Enteroviruses:
  - ECHO
  - Coxsackie
- (Poliomyelitis – mainly eradicated worldwide)
- Mumps
- Herpes simplex
- HIV
- Epstein-Barr virus

Fungi

- Cryptococcus neoformans
- Candida albicans
- Coccidioides immitis, Histoplasma capsulatum, Blastomyces dermatitidis (USA)

*These organisms account for 70% of acute bacterial meningitis outside the neonatal period. A wide variety of infective agents are responsible for the remaining 30% of cases. Haemophilus influenzae b (Hib) has been eliminated as a cause in many countries by immunization. Malaria often presents with cerebral symptoms and a fever.

MCA, Monoclonal antibody; PML, Progressive multifocal leucoencephalopathy. ITP, immune thrombocytopenic purpura.
Acute bacterial meningitis

Onset is typically sudden, with rigors and high fever. Meningococcal meningitis is often heralded by a petechial rash, sometimes sparse (see Emergency Box 22.1). The meningitis may be part of a generalized meningococcal septicemia (p. 127). Acute septicemic shock may develop in any bacterial meningitis.

Viral meningitis

This is almost always a benign, self-limiting condition lasting 4–10 days. Headache may follow for some months. There are no serious sequelae, unless an encephalitis is present (p. 1128).

Chronic meningitis (see below)

For further discussion on chronic meningitis, see below.

Differential diagnosis

It may be difficult to distinguish between the sudden headache of subarachnoid haemorrhage, migraine and acute meningitis. Meningitis should be considered seriously in anyone with headache and fever and in any sudden headache. Neck stiffness should be looked for – it may not be obvious. Chronic meningitis sometimes resembles an intracranial mass lesion, with headache, epilepsy and focal signs. Cerebral malaria can mimic bacterial meningitis.

Management (Emergency Box 22.1)

Recognition and immediate treatment of acute bacterial meningitis is vital. Minutes save lives. Bacterial meningitis is lethal. Even with optimal care, mortality is around 15%. The following applies to adult patients; management is similar in children.

When meningococcal meningitis is diagnosed clinically by the petechial rash, immediate i.v. antibiotics should be given and blood cultures taken; lumbar puncture is unnecessary. In other causes of meningitis, a lumbar puncture is performed if there is no clinical suspicion of a mass lesion (p. 1091). If the latter is suspected an immediate CT scan must be performed because coning of the cerebellar tonsils may follow LP. Typical CSF changes are shown in Table 22.21. CSF pressure is characteristically elevated. If a presumptive diagnosis of the organism can be made (e.g. pneumococcus is likely with skull fracture or sinus infection), targeted treatment should be started immediately. Immediate antibiotic treatment in acute bacterial meningitis is shown in Table 22.22.

Blood should be taken for cultures, glucose and routine tests. Chest and skull films should be obtained if appropriate.

CSF stains demonstrate organisms (e.g. Gram-positive intracellular diplococci – pneumococcus; Gram-negative cocci-meningococcus). Ziehl–Neelsen stain demonstrates acid-fast bacilli (TB), though TB organisms are rarely numerous. Indian ink stains fungi.

Meticulous attention should focus on microbiological studies in suspected CNS infection with close liaison between clinician and microbiologist. Specific techniques (e.g. polymerase chain reaction for meningococci and other bacteria) are invaluable. Syphilitic serology should always be carried out.

Emergency Box 22.1

Meningococcal meningitis and meningococcaemia: emergency treatment

Suspicion of meningococcal infection is a medical emergency requiring treatment immediately.

Clinical features:

- Petechial or nonspecific blotchy red rash
- Fever, headache, neck stiffness.
  - All these features may not be present – and meningococcal infection may sometimes begin like any apparently non-serious infection.
- Immediate treatment for suspected meningococcal meningitis at first contact before transfer to hospital or investigation:
- Benzylpenicillin 1200 mg (adult dose) slow i.v. injection or intramuscularly
- Alternative if penicillin allergy – cefotaxime 1 g i.v.
  - On arrival in hospital:
    - Routine tests including blood cultures immediately
    - Watch out for septicemic shock.
    - For further management and prophylaxis, see text.
The clinical picture and CSF examination should thus yield a presumptive cause for acute meningitis within hours. Antibiotics, however, must be started before the actual organism is identified.

If bacterial meningitis is diagnosed, further discussion with the microbiologist should include antibiotics, drug resistance, recent infections in the locality, barrier nursing and prophylaxis.

In adults with pneumococcal meningitis, dexamethasone should be given first with the initial antibiotics. Intrathecal antibiotics are no longer used.

Local infection (e.g. paranasal sinus) should be treated surgically if necessary. Repair of a depressed skull fracture or meningeal tear may be required.

**Prophylaxis**

Meningococcal infection should be notified to public health authorities, and advice sought about immunization and prophylaxis of contacts, e.g. with rifampicin or ciprofloxacin. MenC, a meningococcal C conjugate vaccine, is part of many countries’ immunization programme and often given to case contacts. A combined A and C meningococcal vaccine is sometimes used prior to travel from the UK to endemic regions, e.g. Africa, Asia; and a quadrivalent ACWY vaccine for specific events, e.g. the Haj and Umrah in Mecca. There is no vaccine for Group B.

A polyvalent pneumococcal vaccine is used after recurrent meningitis, e.g. after a CSF leak following skull fracture. *Hib* (*Haemophilus influenzae*) vaccine is given routinely in the 1990s, West Nile virus caused an epidemic and focal neurological deficits, e.g. speech disturbance, often occur (especially in herpes simplex encephalitis).

**Chronic meningitis**

*Tuberculous meningitis* (TBM) and *cryptococcal meningitis* commence typically with vague headache, lassitude, anorexia and vomiting. Acute meningitis can occur but is unusual. Meningitic signs often take some weeks to develop. Drowsiness, focal signs (e.g. diplopia, papilloedema, hemiparesis) and seizures are common. Syphilis, sarcoidosis and Behçet’s also cause chronic meningitis. In some cases of chronic meningitis, an organism is never identified.

**Management of tuberculous meningitis**

TBM is a common and serious disease worldwide. Brain imaging, usually with MRI, may show meningeal enhancement, hydrocephalus and tuberculomas (in this chapter), although it may remain normal (see Table 22.21 for CSF changes). In many cases the sparse TB organisms cannot be seen on staining and PCR testing should be performed, although results may be negative. Repeated CSF examination is often necessary and it will be some weeks before cultures are confirmatory. Treatment with antituberculosis drugs (p. 842) – rifampicin, isoniazid and pyrazinamide – must commence on a presumptive basis and continue for at least 9 months. Ethambutol should be avoided because of its eye complications. Adjuvant corticosteroids, e.g. prednisolone 60 mg for 3 weeks, are now recommended (often tapered off). Relapses and complications (e.g. seizures, hydrocephalus) are common in TBM. The mortality remains over 60% even with early treatment.

**Malignant meningitis**

Malignant cells can cause a subacute or chronic non-infective meningitic process. A meningitic syndrome, cranial nerve lesions, paraparesis and root lesions are seen, often in confusing and fluctuating patterns. The CSF cell count is raised, with high protein and low glucose. Treatment with intrathecal cytotoxic agents is rarely helpful.

**Cells in a sterile CSF (pleocytosis)**

A raised CSF cell count is present without an evident infecting organism. CSF pleocytosis, i.e. a mixture of lymphocytes and polymorphs, is the usual situation (Box 22.26).

**Encephalitis**

Encephalitis means acute inflammation of brain parenchyma, usually viral. In viral encephalitis fever (90%) and meningism are usual, but in contrast to meningitis the clinical picture is dominated by brain parenchyma inflammation. Personality and behavioural change is a common early manifestation which progresses to a reduced level of consciousness and even coma. Seizures (focal and generalized) are very common and focal neurological deficits, e.g. speech disturbance, often occur (especially in herpes simplex encephalitis).

**Viral encephalitis**

The viruses isolated from adult UK cases are usually herpes simplex, VZV and other herpes group viruses, HHV-6, 7, enteroviruses and adenovirus. HSV encephalitis (HSVE) typically affects the temporal lobes initially, often asymmetric. Often, the virus is never identified. Outside the UK in endemic regions different pathogens cause encephalitis including Flaviviruses (Japanese encephalitis, West Nile virus, tick-borne encephalitis) and rabies.

Local epidemics can occur. For example, in New York in the 1990s, West Nile virus caused an epidemic and
Venezuelan equine virus was isolated from encephalitis cases in South America.

Investigations
- MR imaging shows areas of inflammation and swelling, generally in the temporal lobes in HSV encephalitis. Raised intracranial pressure and midline shift may occur leading to coning.
- EEG shows periodic sharp and slow wave complexes.
- CSF shows an elevated lymphocyte count (95%).
- Viral detection by CSF PCR is highly sensitive for several viruses such as HSV and VZV. However, a false negative result may occur within the first 48 h after symptom onset. Serology (blood and CSF) is also helpful.
- Brain biopsy is rarely required since the advent of MRI and PCR.

Treatment
Suspected HSV and VZV encephalitis is treated immediately with i.v. aciclovir (10 mg/kg 3 times a day for 14–21 days), even before investigation results are available. Early treatment significantly reduces both mortality and long-term neurological damage in survivors. Seizures are treated with anticonvulsants. Occasionally decompressive craniectomy is required to prevent coning but coma confers a poor prognosis.

Long-term complications are common including memory impairment, personality change and epilepsy.

Post-infectious encephalomyelitis
Acute disseminated encephalomyelitis (ADEM) follows many infections (e.g. measles, mycoplasma, mumps and rubella) and rarely follows immunization after 1–2 weeks. There is a monophasic illness with multifocal brain, brainstorm and often spinal cord inflammatory lesions in white matter, with demyelination. ADEM is caused by an immune mediated host response to infection and occurs principally in children and young adults. Mild cases recover completely. Survivors often have permanent brain damage. Treatment is supportive, with steroids and anticonvulsants.

Autoimmune encephalitis
This group of disorders have been described in recent years and are increasingly recognized. Autoantibodies directed against neuronal epitopes cause a subacute encephalitic illness – limbic encephalitis or panencephalitis. Limbic encephalitis presents over weeks or months with memory impairment, confusion, psychiatric disturbance, and seizures – usually temporal lobe seizures reflecting involvement of the hippocampus and mesial temporal lobes.

Paraneoplastic limbic encephalitis (PLE). Seen particularly with small cell lung cancer and testicular tumours and associated with a variety of antibodies including anti-Hu and anti-Ma2. Antibodies can be detected in 60% of cases. MRI usually shows a hippocampal high signal. PLE precedes the diagnosis of cancer in most cases and should prompt investigation to identify the tumour.

Voltage gated potassium channel (VGKC) limbic encephalitis. VGKC antibodies (which can be tested for) produce a variety of disorders including limbic encephalitis, characteristic faciobrachial dystonic seizures, neuromyotonia and peripheral nerve hyperexcitability syndromes. This usually occurs in patients older than 50 but is rarely associated with cancer (thymoma).

Anti NMDA receptor antibody panencephalitis. Presents as limbic encephalitis followed by coma and often status epilepticus. Orofacial dyskineties are characteristic. Usually younger patients, some have ovarian teratomas.

Patients may respond to immunotherapy – i.v. immunoglobulin or plasma exchange initially followed by steroids, rituximab or cyclophosphamide. PLE responds less well to treatment.

Herpes zoster (shingles)
This is caused by reactivation of varicella zoster virus (VZV), usually within dorsal root ganglia. Primary infection with VZV causes chickenpox following which the virus remains latent in sensory ganglia. Development of shingles may indicate a decline in cell mediated immunity, e.g. due to age or malignancy.

Clinical patterns and complications
Dermatomal shingles. Thoracic dermatomes are most commonly affected. Tingling or painful dysesthesias precede the vesicular rash by a few days (p. 81). Motor radiculopathy can occur (usually lumbar or cervical, as thoracic involvement is often clinically silent). It rarely occurs without the rash – zoster sin herpete. Antiviral drugs such as aciclovir, famciclovir or valaciclovir reduce the incidence of postherpetic neuralgia.

Postherpetic neuralgia. Defined as pain lasting more than 4 months after developing shingles; occurs in 10% of patients (often elderly). Burning, intractable pain responds poorly to analgesics. Response to treatment is unsatisfactory but there is a trend towards gradual recovery over 2 years. Amitriptyline or gabapentin are commonly used and topical lidocaine patches may help.

Crani al nerve involvement. Only cranial nerves with sensory fibres are affected, particularly the trigeminal and facial nerves. Ophthalmic herpes is due to involvement of V1. This can lead to corneal scarring and secondary panophthalmitis. Involvement of the geniculate ganglion of the facial nerve is also called Ramsay Hunt syndrome (p. 1098).

Myelitis may occur in the context of shingles when the inflammatory process spreads from the dorsal root ganglion to the adjacent spinal cord.

Immunization. The Centers for Disease Control and Prevention (CDC) in America have suggested that all adults over 60 years old should be vaccinated against herpes zoster (even those who have had shingles previously), as it reduces the incidence of shingles by about 50%.

Neurosyphilis
Many neurological symptoms occur, sometimes mixed (see also syphilis, p. 166).

Asymptomatic neurosyphilis
This means positive CSF serology without signs.

Meningovascular syphilis
This causes:
- Subacute meningitis with cranial nerve palsies and papilloedema
- A gumma – a chronic expanding intracranial mass
- Paraparesis – a spinal meningovasculitis.

Tabes dorsalis
Demyelination in dorsal roots causes a complex deafferentation syndrome. The elements of tabes:
Lightning pains (p. 1086)
Ataxia, stamping gait, reflex/sensory loss, wasting
Neuropathic (Charcot) joints
Argyll Robertson pupils (p. 1074)
Ptosis and optic atrophy.

General paralytic of the insane (GPI)
The grandiose title describes dementia and weakness. GPI dementia is typically similar to Alzheimer’s (p. 1138). Progressive cognitive decline, seizures, brisk reflexes, extensor plantar reflexes and tremor develop. Death follows within 3 years. Argyll Robertson pupils are usual. GPI and tabes are rarities in the UK.

Other forms of neurosyphilis
In congenital neurosyphilis (acquired in utero), features of combined tabs and GPI develop in childhood – taboparesis.

Secondary syphilis can be symptomless or cause a self-limiting subacute meningitis.

Treatment
Benzylpenicillin 1 g daily i.m. for 10 days in primary infection eliminates any risk of neurosyphilis. Allergic (Jarisch–Herrnheimer) reactions can occur; steroid cover is usually given with penicillin (p. 1129). Established neurological disease is arrested but not reversed by penicillin.

Neurocysticercosis
The pork tapeworm, Taenia solium, is endemic in Latin America, Africa, India and much of South-east Asia (p. 159). Epilepsy is the commonest clinical manifestation of neurocysticercosis and one of the commonest causes of epilepsy in endemic countries. Most infected people remain asymptomatic.

Brain CT and MRI show ring-enhancing lesions with surrounding oedema when the cyst dies and later calcification. Multiple cysts are often seen in both brain and skeletal muscle. Serological tests indicate infection but not activity. Biopsy of a lesion is rarely necessary. Management is primarily the control of seizures and the anthelminthic agent albendazole is often also given (usually with steroid cover).

HIV and neurology
HIV-infected individuals frequently present with or develop neurological conditions. The HIV virus itself is directly neuroinvasive and neurovirulent. Immunosuppression leads to indolent, atypical clinical patterns (p. 176). HIV patients also have a high incidence of stroke. The pattern of disease is changing where antiretroviral (ARV) therapy is available.

CNS and peripheral nerve disease in HIV

HIV seroconversion can cause meningitis, encephalitis, Guillain–Barré syndrome and Bell’s palsy (the commonest cause of Bell’s palsy in South Africa).

Chronic meningitis occurs with fungi (e.g. Cryptococcus neoformans or Aspergillus), TB, listeria, coliforms or other organisms. Raised CSF pressure is common in cryptococcal meningitis.

AIDS-dementia complex (ADC). A progressive, HIV-related dementia, sometimes with cerebellar signs, is still seen where antiretroviral therapy is unavailable.

Encephalitis and brain abscess. Toxoplasma, cytomegalovirus, herpes simplex and other organisms cause severe encephalitis. Multiple brain abscesses develop in HIV infection, usually due to toxoplasmomiasis.

CNS lymphoma. This is typically fatal (Chapter 9). Progressive multi-focal leucoencephalopathy (PML) is due to JC virus and occurs with very low CD4 counts (p. 191).

Spinal vacuolar myelopathy occurs in advanced disease.

Peripheral nerve disease. HIV related peripheral neuropathy is common (70%) and can be difficult to distinguish from the effects of ARV treatment which is also toxic to peripheral nerves.

Other infections
Many other infections involve the CNS and are discussed in Chapter 4, e.g. rabies, tetanus, botulism, Lyme disease and leprosy.

Other inflammatory conditions
Subacute sclerosing panencephalitis (SSPE)
Persistence of measles antigen in the CNS is associated with this rare late sequel of measles. Progressive mental deterioration, fits, myoclonus and pyramidal signs develop, typically in a child. Diagnosis is made by high measles antibody titre in blood and CSF. Measles immunization protects against SSPE, which has now been almost eliminated in the UK.

Progressive rubella encephalitis
Some 10 years after primary rubella infection, this causes progressive cognitive impairment, fits, optic atrophy, cerebellar and pyramidal signs. Antibody to rubella viral antigen is produced locally within the CNS. It is even rarer than SSPE.

Mollaret’s meningitis
This is recurrent self-limiting episodes of aseptic meningitis (i.e. no bacterial cause is found) over many years. Viral (possibly herpes simplex) infection is postulated.

Whipple’s disease
CNS Whipple’s disease, due to Tropheryma whipplei infection is characterized by myoclonus, dementia and supranuclear ophthalmoplegia (p. 268). Diagnosis of CNS involvement is made by CSF PCR (only 50% sensitivity) or brain biopsy.

Neurosarcoidosis
Neurosarcoid with or without systemic sarcoid causes chronic meningoencephalitis, cord lesions, cranial nerve palsies, particularly bilateral VIIIth nerve lesions, polyneuropathy and myopathy (p. 845).

Behçet’s syndrome (see also p. 544)
Behçet’s principal features are recurrent oral and/or genital ulceration, inflammatory ocular disease (uveitis, p. 1062) and neurological syndromes. Brainstem and cord lesions, aseptic meningitis, encephalitis and cerebral venous thrombosis occur.

Brain and spinal abscesses

Brain abscess
Focal bacterial infection behaves as any expanding mass. Typical bacteria found are Streptococcus anginosus and Bacteroides species (paranasal sinuses and teeth) and staphylococci (penetrating trauma). Mixed infections are common. Multiple abscesses develop, particularly in HIV infection. Fungi also cause brain abscesses. A parameningeal infective focus (e.g. ear, nose, paranasal sinus, skull fracture) or a distant source of infection (e.g. lung, heart,
Brain tumours

Primary intracranial tumours account for some 10% of neoplasms. The most common tumours are outlined in Table 22.23. Metastases are the commonest intracranial tumours (Fig. 22.47). Symptomless meningiomas (benign) are found quite commonly on imaging or at autopsy.

**Clinical features and management**

Headache, focal signs (e.g. hemiparesis, aphasia, hemianopia), epilepsy and raised intracranial pressure develop. Fever, leucocytosis and raised ESR are usual although not invariable.

Urgent imaging is essential. MRI shows a ring-enhancing mass, usually with considerable surrounding oedema. The search for a focus of infection should include a detailed examination of the skull, ears, paranasal sinuses and teeth, and distant sites such as heart and abdomen. Lumbar puncture is dangerous and should not be performed. Neurosurgical aspiration with stereotactic guidance allows the infective organism to be identified. Treatment is with high-dose antibiotics and sometimes surgical resection/decompression. Despite treatment, mortality remains high at approximately 25%. Epilepsy is common in survivors.

**Brain tuberculoma**

TB causes chronic caseating intracranial granulomatous masses – tuberculomas. These are the commonest intracranial masses in countries where TB is common, e.g. India. Brain tuberculomas either present as mass lesions de novo or develop during tuberculous meningitis; they are also found as symptomless intracranial calcification on imaging. Spinal cord tuberculomas also occur. Treatment is described on page 842.

**Subdural empyema and intracranial epidural abscess**

*Intracranial subdural empyema* is a collection of subdural pus, usually secondary to local skull or middle ear infection. Features are similar to those of a cerebral abscess. Imaging is diagnostic.

In *intracranial epidural abscess* a layer of pus, 1–3 mm thick, tracks along the epidural space causing sequential cranial nerve palsies. There is usually local infection, e.g. in the middle ear. MRI shows the collection; CT is typically normal. Drainage is required, and antibiotics.

**Spinal epidural abscess**

*Staphylococcus aureus* is the usual organism, reaching the spine via the bloodstream, e.g. from a boil. Fever and back pain are followed by paraparesis and/or root lesions.

Emergency imaging and antibiotics are essential and surgical decompression is often necessary.

**BRAIN TUMOURS**

These malignant tumours of neuroepithelial origin are usually seen within the hemispheres, but occasionally in the cerebellum, brainstem or cord. Their cause is unknown. Gliomas are occasionally associated with neurofibromatosis. They tend to spread by direct extension, virtually never metastasizing outside the CNS.

- Astrocytomas are gliomas that arise from astrocytes. They are classified histologically into grades I–IV. Grade I astrocytomas grow slowly over many years, while grade IV tumours (*glioblastoma multiforme*) cause death within several months. Cystic astrocytomas of childhood are relatively benign, and usually cerebellar.
- Oligodendrogliomas arise from oligodendrocytes. They grow slowly, usually over several decades. Calcification is common.
Neurological disease

Meningiomas

These benign tumours (Figs 22.49–22.51) arise from the arachnoid and may grow to a large size, usually over years. Those close to the skull erode bone or cause local hyperostosis. They often occur along the intracranial venous sinuses, which they may invade. They are unusual below the tentorium. Common sites are the parasagittal region, sphenoidal ridge, subfrontal region, pituitary fossa and skull base.

Neurofibromas (Schwannomas)

These solid benign tumours arise from Schwann cells and occur principally in the cerebellopontine angle, where they arise from the VIIIth nerve sheath (acoustic neuroma, p. 1070). They may be bilateral in neurofibromatosis type 2 (p. 1143).

Other neoplasms

Other less common neoplasms include cerebellar haemangioblastoma, ependymomas of the IVth ventricle, colloid cysts of the IIIrd ventricle, pinealomas, chordomas of the skull base, glomus tumours of the jugular bulb, medulloblastomas (a cerebellar childhood tumour), craniopharyngiomas (p. 937) and primary CNS lymphomas (p. 468). For pituitary tumours, see page 946.

Clinical features

Mass lesions within the brain produce symptoms and signs by three mechanisms:

- By direct effect – brain is infiltrated and local function impaired
- By secondary effects of raised intracranial pressure and shift of intracranial contents (e.g. papilloedema, vomiting, headache)
- By provoking generalized and/or partial seizures.

Although neoplasms, either secondary or primary, are the commonest mass lesions in the UK, cerebral abscess, tuberculoma, neurocysticercosis, subdural and intracranial haematoma can also produce features that are clinically similar.

Direct effects of mass lesions

The hallmark of a direct effect of a mass is local progressive deterioration of function. Tumours can occur anywhere within the brain. Three examples are given:

- A left frontal meningioma caused a frontal lobe syndrome over several years with vague disturbance of personality, apathy and impaired intellect. Expressive aphasia developed, followed by progressive right hemiparesis as the corticospinal pathways became involved. As the mass enlarged further, pressure headaches and papilloedema developed.

- A right parietal lobe glioma caused a left homonymous field defect (optic radiation). Cortical sensory loss in the left limbs and left hemiparesis followed over 3 months. Partial seizures (episodes of tingling of the left limbs) developed.

- A left VIIIth nerve sheath neurofibroma (an acoustic neuroma, Schwannoma) in the cerebellopontine angle caused, over 3 years, progressive deafness (VIII), left facial numbness (V) and weakness (VII), followed by cerebellar ataxia on the same side.

With a hemisphere tumour, epilepsy and the direct effects commonly draw attention to the problem. The rate of progression varies greatly, from a few days or weeks in a highly malignant glioma, to several years with a slowly enlarging mass such as a meningioma. Cerebral oedema surrounds mass lesions: its effect is difficult to distinguish from that of the tumour itself.

Raised intracranial pressure

Raised intracranial pressure causing headache, vomiting and papilloedema is a relatively unusual presentation of a mass lesion in the brain. These symptoms often imply hydrocephalus – obstruction to CSF pathways. Typically this is produced early by posterior fossa masses that obstruct the aqueduct and IVth ventricle but only later with lesions above the tentorium. Shift of the intracranial contents produces features that co-exist with the direct effects of any expanding mass:

FURTHER READING
Distortion of the upper brainstem, as midline structures are displaced either caudally or laterally by a hemisphere mass (Fig. 22.48). This causes impairment of consciousness progressing to coning and death as the medulla and cerebellar tonsils are forced into the foramen magnum.

False localizing signs – false only because they do not point directly to the site of the mass. Three examples of false localizing signs are:

- A VIth nerve lesion, first on the side of a mass and later bilaterally as the VIth nerve is compressed or stretched during its long intracranial course.
- A IIIrd nerve lesion develops as the temporal lobe uncus herniates caudally, compressing III against the petroclinoid ligament. The first sign is ipsilateral pupil dilatation as parasympathetic fibres are compressed.
- Hemiparesis on the same side as a hemisphere tumour, i.e. the side you might not expect, from compression of the contralateral cerebral peduncle on the edge of the tentorium.

Seizures
Seizures are a common presenting feature of malignant brain tumours. Partial seizures, simple or complex, that may evolve into generalized tonic-clonic seizures, are characteristic of many hemisphere masses, whether malignant or benign. The pattern of partial seizure is of localizing value (p. 1112).

Investigations

Imaging

Both CT and MRI are useful in detecting brain tumours; MRI is superior for posterior fossa lesions. Benign and malignant tumours, brain abscess, TB, neurocysticercosis and infarction have characteristic, but not entirely reliable, appearances and refined imaging techniques and biopsy are often necessary. MR angiography is used occasionally to define blood supply and MR spectroscopy to identify patterns typical of certain gliomas. PET is sometimes helpful to locate an occult primary tumour with brain metastases.

Routine tests

Since metastases are common, routine tests, e.g. chest X-ray, should be performed.

Lumbar puncture

This is contraindicated when there is any possibility of a mass lesion as withdrawing CSF may provoke immediate coning. CSF examination is rarely helpful and has been superseded by imaging.

Biopsy and tumour removal

Stereotactic biopsy via a skull burr-hole is carried out to ascertain the histology of most suspected malignancies. With a benign tumour, e.g. a symptomatic, accessible meningioma, craniotomy and removal is usual.

Management

Cerebral oedema surrounding a tumour responds rapidly to steroids: i.v. or oral dexamethasone. Epilepsy is treated with anticonvulsants.

While complete surgical removal of a tumour is an objective, it is often not possible, nor is surgery always necessary. Follow-up with serial imaging is sometimes preferable in low-grade gliomas. At exploration, some benign tumours can be entirely removed (e.g. acoustic neuromas, some parasagittal meningiomas). With a malignant tumour it is not possible to entirely remove an infiltrating mass. Biopsy and debulking are performed.

Within the posterior fossa, tumour removal is often necessary because of raised pressure and danger of coning. Overall mortality for posterior fossa exploration remains around 10%.

For gliomas and metastases, radiotherapy is usually given and improves survival, if only slightly. Solitary metastases can often be excised successfully. Chemotherapy has little real value in the majority of primary or secondary brain tumours. Vincristine, procarbazine and temozolomide (an oral alkylating agent) can be used. Most malignant gliomas have a poor prognosis despite advances in imaging, surgery, chemotherapy and radiotherapy – <50% survival for grade IV gliomas at 2 years. Surgical debulking and radiotherapy improve survival by 4–5 months.

Stereotactic radiotherapy (gamma knife)

Only available in selected centres, a collimated radiotherapy beam can deliver high doses of radiation to small targets up to 3 cm in diameter with precision. It may be used to target small metastases, and inaccessible skull base tumours such as meningiomas or schwannomas. It may also be used to treat intracerebral AVMs.

HYDROCEPHALUS

Hydrocephalus is an excessive accumulation of CSF within the head caused by a disturbance of formation, flow or absorption. High pressure and ventricular dilatation result (Fig. 22.52).

Infantile hydrocephalus

Head enlargement in infancy occurs in 1 in 2000 live births. There are several causes:

- Arnold–Chiari malformations. Cerebellar tonsils descend into the cervical canal. Associated spina bifida is common. Syringomyelia may develop (p. 1137).
- Stenosis of the aqueduct of Sylvius. Aqueduct stenosis is either congenital (genetic) or acquired following neonatal meningitis/haemorrhage.
- Dandy–Walker syndrome. There is cerebellar hypoplasia and obstruction to IVth ventricle outflow foramina.

Hydrocephalus in adults

Hydrocephalus is sometimes an unsuspected finding on imaging. Stable childhood hydrocephalus can become
apparent in adult life (‘arrested hydrocephalus’) but can suddenly decompensate. Combinations of headache, cognitive impairment, features of raised intracranial pressure, and ataxia develop depending on how high the CSF pressure rises and rapidity of onset. Elderly patients with more compliant brains may present with gradual onset gait apraxia and subtle cognitive slowing.

Hydrocephalus may be caused by:

- **Posterior fossa and brainstem tumours** obstructing the aqueduct or IVth ventricular outflow
- **Subarachnoid haemorrhage**, head injury or meningitis (particularly tuberculous), causing obstruction of CSF flow and reabsorption
- **A IIIrd ventricle colloid cyst** causing intermittent hydrocephalus – recurrent prostrating headaches with episodes of lower limb weakness
- **Choroid plexus papilloma** (rare) secretes CSF.

Frequently, the underlying cause for hydrocephalus remains obscure.

**Treatment**

Ventriculoperitoneal shunting is necessary when progressive hydrocephalus causes symptoms. Removal of tumours is carried out when appropriate. Endoscopic third ventriculostomy may be performed.

**Normal pressure hydrocephalus (NPH)**

NPH describes a syndrome of enlarged lateral ventricles in elderly patients with the clinical triad of:

- A gait disorder – gait apraxia
- Dementia
- Urinary incontinence.

The term is a misnomer, as it is a low-grade hydrocephalus with intermittently raised ICP. Ventriculoperitoneal shunting may be required. A trial of prolonged drainage of lumbar CSF over several days predicts response to shunt insertion.

**TRAUMATIC BRAIN INJURY**

In most western countries head injury accounts for about 250 hospital admissions per 100,000 population annually. Traumatic brain injury (TBI) describes injuries with potentially permanent consequences. For each 100,000 people, 10 die annually following TBI; 10–15 are transferred to a neurosurgical unit – the majority of these require rehabilitation for a prolonged period of 1–9 months. The prevalence of survivors with a major persisting handicap is around 100/100,000. Road traffic accidents and excessive alcohol use are the principal aetiological factors in this major cause of morbidity and mortality, in many countries.

**Skull fractures**

**Linear** skull fracture of the vault or base is one indication of the severity of a blow, but is itself not necessarily associated with any brain injury. Healing of linear fractures takes place spontaneously. **Depressed** skull fracture is followed by a high incidence of post-traumatic epilepsy. Surgical elevation and debridement are usually necessary.

Principal local complications of skull fracture are:

- **Meningeal artery rupture** – causing extradural haematoma
- **Dural vein tears** – causing subdural haematoma (p. 1106)
- **CSF rhinorrhoea/otorrhoea** and consequent meningitis.

**Mechanisms of brain damage**

Older classifications attempted to separate concussion, transient coma for hours followed by apparent complete clinical recovery, from brain contusion, i.e. bruising, with prolonged coma, focal signs and lasting damage. Pathological support for this division is poor. Mechanisms of TBI are complex and interrelated:

- Diffuse axonal injury – shearing and rotational stresses on decelerating brain, sometimes at the site opposite impact (the contrecoup effect)
- Neuronal and axonal damage from direct trauma
- Brain oedema and raised intracranial pressure
- Brain hypoxia
- Brain ischaemia.

**Clinical course**

In a mild TBI, a patient is stunned or dazed for a few seconds or minutes. Following this the patient remains alert without post-traumatic amnesia. Headache can follow; complete recovery is usual. In more serious injuries duration of unconsciousness and particularly of post-traumatic amnesia (PTA) helps grade severity. PTA of >24 hours defines severe TBI. The Glasgow Coma Scale (GCS, p. 1092) is used to record the degree of coma; this has prognostic value. A GCS below 5/15 at 24 hours implies a serious injury; 50% of such patients die or remain in a vegetative or minimal conscious state (p. 1096). However, prolonged coma of up to some weeks is occasionally followed by good recovery.

Recovery after severe TBI takes many weeks or months. During the first few weeks, patients are often intermittently restless or lethargic and have focal deficits such as hemiparesis or aphasia. Gradually they become more aware, though they may remain in post-traumatic amnesia, being unable to lay down any continuous memory despite being awake. This amnesia may last some weeks or more, and may not be obvious clinically. PTA is one predictor of outcome. PTA over a week implies that persistent organic cognitive deficit is almost inevitable, although return to unsupported paid work may be possible.

**Late sequelae**

Sequelae of TBI are major causes of morbidity and can have serious social and medicolegal consequences. They include:

- **Incomplete recovery**, e.g. cognitive impairment, hemiparesis
- **Post-traumatic epilepsy** (p. 1113)
- **The post-traumatic (post-concussional) syndrome**. This describes the vague complaints of headache, dizziness and malaise that follow even minor head injuries. Litigation is frequently an issue. Depression is prominent. Symptoms may be prolonged
- **Benign paroxysmal positional vertigo** (BPPV, Chapter 21)
- **Chronic subdural haematoma** (p. 1071)
- **Hydrocephalus** (p. 1133)
- **Chronic traumatic encephalopathy**. This follows repeated and often minor injuries. It is known as the ‘punch-drunk syndrome’ and consists of cognitive impairment, extrapyramidal and pyramidal signs, seen typically in professional boxers.

**Immediate management**

Attention to the airway is vital. If there is coma, depressed fracture or suspicion of intracranial haematoma, CT imaging and discussion with a neurosurgical unit are essential.
Indications for CT imaging vary from imaging all minor head injuries in some US centres to more stringent criteria elsewhere.

In many severe TBI cases, assisted ventilation will be needed. Intracranial pressure monitoring is valuable. Hypothermia lowers intracranial pressure when used early after a TBI; an effect on outcome has only been seen in specialized neurotrauma centres. Care of the unconscious patient is described on page 1096. Prophylactic antiepileptic drugs have been shown to be of no value in prevention of late post-traumatic epilepsy.

Rehabilitation

TBI cases require skilled, prolonged and energetic support. Survivors with severe physical and cognitive deficits require rehabilitation in specialized units. Rehabilitation includes care from a multidisciplinary team with physiotherapeutical, psychological and practical skills. Many survivors are left with cognitive problems (amnesia, neglect, disordered attention and motivation) and behavioural/emotional problems (temper dyscontrol, depression and grief reactions). Long-term support for both patients and families is necessary.

SPINAL CORD DISEASE

The cord extends from C1, the junction with the medulla, to the lower vertebral body of L1, where it becomes the conus medullaris. Blood supply is from the anterior spinal artery and a plexus on the posterior cord. This network is supplied by the vertebral arteries, and several branches from lumbar and intercostal vessels including the artery of Adamkiewicz.

Spinal cord compression

Principal features of chronic and subacute cord compression are spastic paraparesis or tetraparesis, radicular pain at the level of compression, and sensory loss below the compression (Box 22.27).

For example, in compression at T4 (Fig. 22.15) a band of pain radiates around the thorax, characteristically worse on coughing or straining. Spastic paraparesis develops over months, days or hours, depending upon underlying pathology. Numbness commencing in the feet rises to the level of compression. This is called the sensory level and is usually 2–3 dermatome levels below the level of anatomical compression. Retention of urine and constipation develop.

Causes

Disc and vertebral lesions. Central cervical disc and thoracic disc protrusion cause cord compression (p. 1148).

Chronic compression due to cervical spondylotic myelopathy is frequently seen in clinical practice and is the commonest cause of a spastic paraparesis in an elderly person.

Trauma. Stabilize the neck and back and move patient with extreme caution in trauma. Any trauma to the back is potentially serious and the patient should be immobilized until the extent of the injury can be determined.

Spinal cord tumours. Extramedullary tumours, e.g. meningiomas and neurofibromas, cause cord compression (Fig. 22.53 and Box 22.28) gradually over weeks to months, often with root pain and a sensory level (p. 1087). Vertebral body destruction by bony metastases, e.g. in prostate or breast cancer, is a common cause of spinal cord compression.

Intramedullary tumours (e.g. ependymomas) are less common and typically progress slowly, sometimes over many years. Sensory disturbances similar to syringomyelia may develop (p. 1137).

Tuberculosis. Spinal TB is the commonest cause of cord compression in countries where TB is common. There is destruction of vertebral bodies and disc spaces, with local spread of infection. Cord compression and paraparesis follow, culminating in paralysis – Pott’s paraplegia.

Spinal epidural abscess. This is described on page 1131.

Epidural haemorrhage and haematoma. These are rare sequelae of anticoagulant therapy, bleeding disorders or trauma and can follow lumbar puncture when clotting is abnormal. A rapidly progressive cord or cauda equina lesion develops.

Management

Acute spinal cord compression is a medical emergency. Early diagnosis and treatment is vital. MRI is the imaging technique of choice.

FURTHER READING

Routine tests (e.g. chest X-ray) may indicate a primary neoplasm or infection. Surgical exploration is frequently necessary; if decompression is not performed promptly, irreversible cord damage results. Results are excellent if benign tumours and haematomas are removed early. Radiotherapy is used to treat cord malignancies, or compression due to inoperable malignant vertebral body disease causing cord compression.

Other spinal cord disorders

**Inflammatory cord lesions (transverse myelitis)**

This is one of the commoner causes of a non-compressive spinal cord syndrome. MS is the commonest cause of a spastic paraparesis in a young adult. Typically 1 or 2 spinal segments are affected with part or all of the cord area at that level involved. Clinically a myelopathy evolves over days and recovery (often partial) follows over weeks or months. MR is sensitive and shows cord swelling and oedema with gadolinium enhancement at the affected level(s). CSF may be inflammatory with an excess of lymphocytes. Causes include:

- Parainfectious autoimmune inflammatory response is the commonest cause, e.g. after viral infection or immunization or in the context of MS (sometimes the presenting feature of MS)
- Systemic inflammatory disorders, e.g. SLE, Sjögren’s, sarcoidosis
- Infection: viruses including herpesviruses such as VZV or EBV, HIV, HTLV-1&2 (tropical spastic paraparesis), mycobacteria-TB, syphilis, Lyme or schistosomiasis
- Neuromyelitis optica (Devic’s disease) causes long cord lesions (≥3 segments) and optic nerve demyelination. Diagnosis is made by testing for aquaporin-4 antibodies.

Treatment is usually with high-dose steroids or other immunosuppression or antimicrobial therapy in the case of specific infections.

**Anterior spinal artery (ASA) occlusion**

There is acute paraplegia and loss of spinthalamic (pain and temperature) sensation, with infarction of the anterior two-thirds of the spinal cord. It may result from aortic atherosclerosis, dissection, trauma or cross-clamping in surgery. Vasculitis, emboli, haematological disorders causing thrombosis and severe hypotension are also causes. Occlusion of the artery of Adamkiewicz, which supplies the thoracic ASA, causes watershed infarction of the cord typically at the T8 level where perfusion is relatively poor.

**Arteriovenous malformations (AVMs) of the cord**

Although rare, spinal AVMs may be difficult to diagnose but are potentially curable. The two main types seen are dural AV fistulas (acquired) and true intramedullary AVMs (probably congenital but gradually enlarge). Dural AV fistulas occur mainly in middle aged men due to formation of a direct connection between an artery and vein in a dural nerve root sleeve. This causes arteriolealization of veins with venous hypertension and thus oedema and congestion of the spinal cord at and below the affected level. Presentation is with a gradually progressive myelopathy over months or a few years, often with thoracic back pain. MRI usually shows cord swelling and may show the enlarged arteriolealized veins over the surface of the cord. Spinal angiography demonstrates the fistula and allows endovascular ablation with glue, often with complete resolution of symptoms if permanent neuronal damage has not already occurred.

**Genetic disorders – hereditary spastic paraparesis (HSP)**

Several genetic disorders may present with a gradually evolving upper motor neurone syndrome resembling a myelopathy. Typically spasticity and stiffness dominate the clinical picture rather than weakness especially in HSP. Muscle relaxants such as baclofen improve gait. There are 28 known genes associated with HSP, some causing ‘pure’ spasticity and others with associated neurological features, e.g. thinning of the corpus callosum.

Other genetic disorders such as adrenoleucodystrophy may cause a slowly progressive spastic paraparesis (including in manifesting female carriers) as can the spinocerebellar ataxias (p. 1143) or presenilin-1 mutations (p. 1140).

**Vitamin B₁₂ deficiency**

Subacute combined degeneration of the cord resulting from vitamin B₁₂ deficiency (p. 382) is the most common example of metabolic disease causing spinal cord damage. Abuse of nitric oxide may precipitate functional B₁₂ deficiency with normal serum B₁₂ levels.

**Other causes of a spastic paraparesis**

Motor neurone disease may present initially with a spastic paraparesis before lower motor neurone features develop (p. 1141). Paraneoplastic disorders, radiotherapy, copper deficiency, liver failure and rare toxins (e.g. lathyrism) may cause spinal cord damage. Not all causes of paraparesis relate to spinal cord pathology – beware a parasagittal cerebral meningioma presenting with a paraparesis due to bilateral compression of the leg area of the motor cortex.

**Care of the patient with paraplegia**

Where patients are left with a severe paraplegia there are several issues in long-term care and specialist nursing is vital.

**Bladder management.** The bladder does not empty and urinary retention results. Patients self-catheterize, or develop reflex bladder emptying, helped by abdominal pressure. Early treatment of urine infections is essential. Chronic kidney disease is a common cause of death.

**Bowel function.** Constipation and impaction must be avoided. Following acute paraplegia, manual evacuation is necessary; reflex emptying develops later.

**Skin care.** Risks of pressure sores and their sequelae are serious. Meticulous attention must be paid to cleanliness and regular turning. The sacrum, iliac crests, greater trochanters, heels and malleoli should be inspected frequently (p. 1227). Pressure relieving mattresses are useful initially until patients can turn themselves. If pressure sores develop, plastic surgical repair may be required. Pressure palsies, e.g. of ulnar nerves, can occur.

**Lower limbs.** Passive physiotherapy helps to prevent contractures. Severe spasticity, with flexor or extensor spasms, may be helped by muscle relaxants such as baclofen or by botulinum toxin injections.

**Rehabilitation.** Many patients with traumatic paraplegia or tetraplegia return to self-sufficiency (especially if the level is at C7 or below). A specialist spinal rehabilitation unit is necessary. Lightweight, specially adapted wheelchairs provide independence. Tendon transfer operations may allow functional grip if hands are weak. Autonomic dysreflexia may be a problem. Patients with paraplegia have substantial practical, psychological and sexual needs.
These disorders are increasing in an ageing population. Understanding of the molecular pathogenesis of these disorders has advanced rapidly and common themes are emerging, including genetic causes, protein misfolding disorders and disorders of protein degradation by the proteosome system.

**Dementia**

Dementia is a clinical syndrome with multiple causes, defined by:

- An acquired loss of higher mental function, affecting two or more cognitive domains including:
  - Episodic memory – usually (but not always) involved
  - Language function
  - Frontal executive function
  - Visuospatial function
  - Apraxia or agnosia
- Of sufficient severity to significantly cause social or occupational impairment
- Occurring in clear consciousness (to distinguish it from delirium).

Although dementia is usually progressive it is not invariably so and may even be reversible in some cases. Dementia robs patients of their independence, is a serious burden on carers and a major socioeconomic challenge for society as a whole.

**Epidemiology**

Dementia is common and becoming commoner as a result of an ageing population and better case ascertainment. Age is the main risk factor followed by family history. Over age 65 there is a 6% prevalence and over age 85 the prevalence increases to 20%.

**Clinical assessment**

There are two main considerations:

- Does the patient have dementia?
- Is the pattern of cognitive deficits, tempo of progression, or associated features suggestive of a distinct cause?

Taking a history from a spouse or relative is essential. Patients may tend to downplay or deny symptoms (anosognosia) or constantly look to the relative for answers (the ‘head turning sign’). See Box 22.29 for key elements in taking a history.

**Examination**

Conversation with the patient during history taking may be as revealing as formal cognitive assessment but many patients hide deficits well behind an intact social façade.

**Bedside cognitive assessment**

The mini-mental state examination (MMSE) (see p. 1155) is commonly used to assess cognitive function but has its limitations, such as relative insensitivity to milder cognitive impairment and to frontal lobe dysfunction.

The Addenbrooke’s Cognitive Examination (ACE) is a tool developed to address the deficiencies of the MMSE but is short enough to use in clinical practice.

It is useful to ask patients to give an account of recent news events to assess episodic memory.

Individual cognitive domains can be tested separately in detail, e.g. clock drawing for parietal lobe function, naming and reading tasks for language function, verbal fluency, cognitive estimates and stop-go tasks for frontal lobe function (frontal assessment battery – FAB).

**NEURODEGENERATIVE DISEASES**

An umbrella term for disorders characterized by progressive neuronal cell loss with distinct patterns in different disorders.
Memory:
- Is (s)he repetitive, e.g. with questions?
- Is there a temporal gradient of amnesia – preservation of more distant memories with amnesia for recent events?
- Is there difficulty learning to use new devices, e.g. computer, mobile phone?

Functional ability
- Has work performance declined or ability to cook and do domestic tasks?
- Has responsibility for finances and admin. shifted to the spouse?
- Does (s)he get easily muddled?

Personality and frontal lobe function
- Has personality altered?
- More aggressive/apathetic/lacking initiative?
- Disinhibition?
- Change in food preference or religiosity?

Language
- Difficulty with word finding or remembering names?
- Visuospatial ability
- Does (s)he get lost in familiar places?
- Difficulty dressing, e.g. putting jacket on the wrong way round?

Psychiatric features
- Features of depression?
- Tempo of progression?
- Family history of dementia?
- Alcohol and drug use?
- Medication?
- Any other neurological problems, e.g. Parkinsonism, gait disorder, strokes?

Check for primitive reflexes (frontal release signs) such as grasp, palmo-mental and pout reflexes and perseveration or utilization behaviour with frontal lobe involvement

Test praxis – copying hand gestures and miming tasks – e.g. ‘show me how you brush your teeth’.

Complete neurological examination to look for evidence of, e.g. papilloedema, Parkinsonism, myoclonus, gait disorders is also necessary as is general examination and assessment of mental state.

Investigations (Box 22.30)
Investigations are aimed at identifying treatable causes and helping support a clinical diagnosis of dementia type. For most patients this should include:

Blood tests. FBC, B12, thyroid function, urea and electrolytes, liver function, glucose and ESR.

Brain imaging. CT is adequate to exclude structural lesions, e.g. tumours or hydrocephalus. The superior anatomical resolution of MRI may help identify patterns of regional brain atrophy and so distinguish between different types of degenerative dementia (e.g. hippocampal atrophy in AD vs temporal lobe and frontal atrophy in frontotemporal dementia). Imaging also allows assessment of brain ‘vascular load’.

Detailed neuropsychometric assessment. In some patients, this allows quantification of the relative involvement of different cognitive domains and may be helpful if performed serially over time to assess progression.

Younger patients (<65 years). More intensive investigation is usually necessary. In addition to the tests listed above, EEG, genetic tests (e.g. for Huntington’s, familial AD genes), HIV serology, metabolic tests, and occasionally brain biopsy, may be appropriate.

CSF examination is not routine. However, recently measurement of CSF protein biomarkers has been shown to be useful in distinguishing between different types of dementia, e.g. in AD, CSF and tau is raised and Aβ42 reduced. In CJD and other rapidly progressive dementias protein 14–3–3 is increased.

New imaging modalities. Radionuclide scans using radioactively labelled ligands such as 18F-FIB that bind directly to amyloid allowing amyloid deposition in the brain to be directly imaged have great potential for earlier and more accurate diagnosis of AD. PiB scans are likely to be a part of routine clinical practice in the near future.

Mild cognitive impairment (MCI)
MCI is an intermediate state between normal cognition and dementia. Often mild memory impairment, greater than expected for age but not sufficient to classify as dementia, is the only symptom (‘amnestic MCI’). MCI may be a pre-dementia state with 10–15% of patients per year developing overt Alzheimer’s dementia.

Causes of dementia (Box 22.31)
There are many causes of dementia, by far the commonest being Alzheimer’s disease. Cause varies according to age (Fig. 22.55).

Alzheimer’s disease (AD)
Although technically a definitive diagnosis can only be made by histopathology, in practice the clinical features are sufficiently characteristic that a diagnosis can usually be made with considerable accuracy in life, often supported by diagnostic investigations. The key clinical features are:

- Memory impairment. Episodic (autobiographical) memory is affected. There is progressive loss of ability to learn, retain and process new information. There is a characteristic temporal gradient with relative preservation of distant memory and amnesia for more recent events. This is not ‘short-term memory loss’ which technically refers to loss of working memory, e.g. digit span, which is preserved in AD.

- Language – usually becomes impaired as the disease advances. Difficulty with word finding is characteristic.

- Apraxia – impaired ability to carry out skilled motor activities (p. 1068).

- Agnosia – failure to recognize objects, e.g. clothing, places or people.

- Frontal executive function – impairment of organizing, planning and sequencing.
**Neurodegenerative diseases**

- **Parietal presentation** with visuospatial difficulties and difficulty with orientation in space and navigation may occur. Parietal lobe involvement is also seen as a later feature in more typical presentations.

- **Posterior cortical atrophy.** The least common presentation of AD with visual disorientation due to initial involvement of the occipital lobes and occipito-parietal regions. Patients have complex visual symptoms that may be difficult to describe; they often say that it is easier to see distant than close up objects. Memory is initially well preserved.

**Box 22.31 Causes of dementia**

- Degenerative
  - Alzheimer’s disease
  - Dementia with Lewy bodies
  - Frontotemporal dementia
  - Huntington’s disease
  - Parkinson’s disease
  - Prion diseases, e.g. Creutzfeldt–Jakob
- Vascular
  - Cerebral vasculitis (rare)
- Metabolic
  - Uraemia
  - Liver failure
- Toxic
  - Alcohol
  - Solvent abuse
  - Heavy metals
- Vitamin deficiency
  - B_12 and thiamine
- Traumatic
  - Severe or repeated brain injury
- Intracranial lesions
  - Intracranial haematoma
  - Tumours
  - Hydrocephalus
- Infections
  - HIV
  - Neurosyphilis
  - Whipple’s disease
  - Tuberculosis
- Endocrine
  - Hypothyroidism
  - Hypoparathyroidism
- Psychiatric
  - Pseudodementia

**Personality.** In contrast to other dementias such as FTD, basic personality and social behaviour remain intact until late AD.

- **Anosognosia.** Lack of insight by the patient into their difficulties is common and they may be reluctant to seek medical attention but be brought by a family member.

- **Tempo.** Onset is insidious and often not noticed by family members initially. Progression is gradual but inexorable over a decade or longer with eventual severe deficits in multiple cognitive domains.

- **Late non-cognitive features.** Myoclonus may develop, sometimes followed by seizures (the cortex is the main site of pathology). Sleep–wake cycle reversal and incontinence may place a great strain on carers. Motor function is usually striking preserved so patients are capable of wandering and getting lost. Swallowing may become impaired leading to aspiration pneumonia – often a terminal event.

**Molecular pathology and aetiology**

Although the cause of AD is still not known, a great deal is now understood about the molecular pathology of AD. The pathological hallmarks are the deposition of β-amyloid (Aβ) in amyloid plaques in the cortex and formation of tau-containing intracellular neurofibrillary tangles. These protein aggregates damage synapses and ultimately lead to neuronal death. Amyloid may also be laid down in cerebral blood vessels leading to amyloid angiopathy.

The amyloid precursor protein (APP) is processed by secretase enzymes to form pathogenic Aβ_{1–42} monomers which polymerize into amyloid plaques (Fig. 22.56). A basal forebrain cholinergic deficit occurs and may explain the therapeutic response to cholinesterase inhibitor drugs.

**Genetics of AD**

A 1st-degree relative with AD confers a doubled lifetime risk of AD. There are rare autosomal dominant monogenic early onset forms of familial AD with high penetrance caused by mutations in specific genes – taken together these only account for 1% of cases of AD.

**Amyloid precursor protein (APP).** Point mutations in the APP gene can cause AD and the presence of 3 copies of the APP gene on chromosome 21 in Down’s syndrome patients is responsible for the high incidence of AD in that condition.
**Neurological disease**

**Vascular dementia (multi-infarct dementia)**

This common cause of dementia is distinguished from AD by its clinical features and imaging but both may co-exist (mixed dementia). Dementia can be progressive and similar to AD. There is sometimes a history of TIAs or the dementia follows a succession of cerebrovascular events or has a stepwise course. Apraxic gait disorder, pyramidal signs and urinary incontinence are common additional features. Widespread small vessel disease seen on MRI is the typical finding and may produce a variety of cognitive deficits reflecting the site of ischaemic damage.

**Frontotemporal dementia (FTD)**

A group of neurodegenerative disorders characterized by frontal lobe and temporal lobe atrophy on MRI and at post-mortem. Onset is usually below the age of 65 and there is often a family history. There are three distinct presentations depending on which anatomical region is affected first.

**Frontal presentation:** personality change, emotional blunting, apathy, disinhibition, carelessness and behavioural change with striking preservation of memory.

**Temporal presentations:** characterized by progressive impairment of language function. Involvement of the left temporal lobe produces ‘semantic dementia’, with progressive loss of word-finding ability but fluent speech relatively lacking in meaningful content and difficulty with comprehension of language. The second temporal lobe presentation is progressive non-fluent aphasia due to peri-sylvian atrophy, with loss of verbal fluency and increasingly telegrammatic speech.

About 30% of cases are familial, associated with mutations in the tau or progranulin genes; 10% of patients have associated motor neurone disease. There is no cure or specific treatment at present.

**Prion diseases including Creutzfeldt–Jakob disease (CJD) (p. 113)**

Prion diseases are transmissible neurodegenerative disorders with a long incubation period caused by accumulation of misfolded native prion protein (PrP\(^\text{C}\)). Misfolding and conformational change in PrP\(^\text{C}\) is caused either by exposure to the abnormal misfolded isoform of the protein (PrP\(^\text{Sc}\)) or mutations in the PrP gene (PRNP), leading to toxic accumulation of PrP\(^\text{Sc}\) as amyloid in beta-pleated sheets. Neuronal cell damage and ‘spongiform’ change in the brain result (p. 113), the clinical correlate being a rapidly progressive dementia in most cases.

**Creutzfeldt–Jakob disease (CJD)** is the commonest prion disease in man, the animal equivalents being bovine spongiform encephalopathy (BSE) in cattle and scrapie in sheep. It may be sporadic, iatrogenic or familial.

**Sporadic CJD** is the commonest form, occurring over the age of 50, with an incidence of approximately 1 per million. It is thought to be due to spontaneous somatic mutations in the PRNP gene or stochastic conformational change in PrP\(^\text{C}\) to PrP\(^\text{Sc}\) with a subsequent ‘domino effect’ inducing misfolding in other PrP molecules. A rapidly progressive dementia leads to death within 6 months from onset. Rapidly progressive cognitive decline should always lead to suspicion of CJD. The presence of myoclonus is also a clinical clue (present in 90%). New forms of monoclonal antibody treatment are being studied.

**Iatrogenic CJD** is transmitted from neurosurgical instruments (prions are resistant to sterilization), transplant material (e.g. corneal grafts) and cadaveric pituitary derived growth hormone taken from patients with CJD or presymptomatic CJD. Iatrogenic CJD has a long incubation period of several years.

---

**Figure 22.56 Molecular pathogenesis of AD.** Processing of the APP molecule by secretase enzymes releases A\(_{\beta1-42}\) monomers which are the building block of amyloid plaques. A\(_{\beta}\) oligomers may damage synaptic membranes. Mutations in APP or \(\gamma\)-secretase (presenilin-1) cause genetic forms of AD. Disruption of the balance between formation and degradation of A\(_{\beta1-42}\) is thought to be important.

**Presenilin-1 and 2.** Mutations in these genes affect the \(\gamma\)-secretase enzyme function (Fig. 22.56). PS1 mutations account for 50% of monogenic forms of AD. The PS1/2 and APP genes may be sequenced for mutations in selected early onset cases with a family history.

**Other genes.** The E4 allele of the apolipoprotein E gene confers an increased risk of AD (\(<2–3\) lifetime risk), especially if two copies of the E4 allele are inherited (\(>6–8\) risk). Recently, several other candidate genes have been identified as risk factors for AD in large genome-wide association studies.

**Environmental risk factors**

Age is the main risk factor for AD as incidence increases exponentially with age. Head trauma and vascular risk factors also increase AD risk. Epidemiological studies show that taking anti-inflammatory drugs over a long period may confer some protection.

**Dementia with Lewy bodies (DBL) and Parkinson’s disease dementia (PDD)**

DLB is characterized by visual hallucinations, fluctuating cognition with variation in attention and alertness, sleep disorders (especially REM sleep behaviour disorder), dysautonomia and Parkinsonism. The visual hallucinations often take the form of people or animals or the sense of a presence (‘extracampine hallucinations’). Memory loss may not occur in the early stages. Delusions and transient loss of consciousness occur. Lewy bodies, inclusions containing aggregates of the protein \(\alpha\)-synuclein first described in Parkinson’s disease are found in the cortex.

In DLB the cognitive features dominate; Parkinsonism may evolve later and is typically mild. In PDD cognitive problems are a late feature, occurring at least 1 year after onset and usually after age 75. Both conditions may respond to cholinesterase inhibitors. Patients with DLB may be very sensitive to neuroleptic drugs with dramatic worsening.
Familial CJD (rare) is associated with PRNP gene mutations. Other clinical phenotypes such as familial fatal insomnias also occur.

Variant CJD (vCJD) was first seen in the UK in 1995. vCJD patients are younger than sporadic cases with a mean age of 29. Early symptoms are neuropsychiatric, followed by ataxia and dementia with myoclonus or chorea. The diagnosis can be confirmed by tonsillar biopsy but very recently a sensitive blood test has been developed. vCJD has a longer course than sporadic CJD – up to several years. vCJD and BSE are caused by the same prion strain, giving rise to speculation that transmission from animal to human food chain occurred, i.e. infection from BSE-infected cattle to humans (p. 113). Transmission via blood transfusion may also occur. Most patients with vCJD and sporadic CJD have a specific polymorphism at codon 129 of the PRNP gene that leads to susceptibility.

Other dementias

Other neurodegenerative disorders may include dementia as one of their clinical manifestations, e.g. corticobasal degeneration (CBD), progressive supranuclear palsy (PSP), and dementia may be a feature of a number of genetic and metabolic disorders, e.g. Huntington’s disease (p. 1121) and the leuкоdystrophies.

Treatment

It is rare that a treatable cause for dementia is found, for example hypothyroidism. Management is supportive, to preserve dignity and to provide care for as long as possible in the familiar home environment. The burden of illness falls frequently on relatives. Dementia clinical nurse specialists form a central part of the multidisciplinary team.

General measures. Some evidence suggests that participation in cognitively demanding activities in later life may protect against or delay the onset of dementia. High-dose B vitamins may possibly slow conversion from MCI to AD.

Cognitive enhancers. They have a modest symptomatic benefit in AD, equivalent to an increase in 1–2 points on the MMSE. They are not disease modifying, so do not slow or prevent progression. Whilst there is dispute about the place for these drugs – all are costly – they contribute in some cases to patients being able to prolong independence and remain at home for longer than might otherwise be the case.

Cholinesterase inhibitors (donepezil, rivastigmine and galantamine) increase brain acetylcholine levels by inhibiting CNS acetylcholinesterase. Cholinesterase inhibitors are also effective in DLB and Parkinson’s dementia but not in FTD or vascular dementia.

Memantine is an NMDA receptor antagonist. It is used in moderate or severe AD or where cholinesterase inhibitors are not tolerated. There is some evidence that combination of Memantine and cholinesterase inhibitors is better than either used alone.

Psychiatric and behavioural problems. Depression is common in dementia and may be difficult to distinguish from dementia symptoms such as apathy and worsening cognitive function. A trial of an antidepressant is appropriate where depression is suspected. Distinguishing depressive pseudodementia from organic dementia can be difficult but is crucial. Behavioural disturbance (e.g. due to agitation or delusions) and hallucinations may occur in late stage disease. Use of antipsychotic medications is associated with significantly increased stroke risk in patients with dementia and should only be used as a last resort.

Drugs in development. The greatest need is for disease modifying therapies that halt or slow progression in early stage disease. Potential treatments in development include anti-amyloid therapies such as monoclonal antibodies directed against Aβ and inhibitors of secretase enzymes that process APP into Aβ fragments.

Financial and legal issues. Patients may want to set up a Lasting Power of Attorney (if they retain mental capacity to do so in legal terms) to allow a spouse or relative to deal with their financial affairs on their behalf when they lose the capacity to do so. Patients and carers may be entitled to state financial benefits.

Driving. After a diagnosis of dementia patients in the UK have a duty to inform the DVLA licensing authority who may request a driving safety assessment.

Motor neurone disease (MND)

Motor neurone disease is a devastating condition causing progressive weakness and eventually death, usually as a result of respiratory failure or aspiration. It is relatively uncommon with an annual incidence of 2/100,000. Presentation is usually between ages 50 and 75. Below age 70 men are affected more often than women. ALS (amyotrophic lateral sclerosis) is the term more commonly used for MND in some countries.

Pathogenesis

MND predominantly affects upper and lower motor neurones in the spinal cord, cranial nerve motor nuclei and cortex. However, other neuronal systems may also be affected – 5% of patients also develop frontotemporal dementia (p. 1087) and up to 40% have some measurable frontal lobe cognitive impairment. MND is usually sporadic and of unknown cause with no known environmental risk factors. Ubiquinated cytoplasmic inclusions containing the RNA processing proteins TDP-43 and FUS are the pathological hallmarks found in axons, indicating that protein aggregation may be involved in pathogenesis as with other neurodegenerative disorders. Oxidative neuronal damage and glutamate mediated excitotoxicity have also been implicated in pathogenesis.

5–10% of cases of MND are familial and mutations in the free radical scavenging enzyme superoxide dismutase (SOD-1) and in a number of other genes including TDP-43 and FUS have been identified. A hexanucleotide GGGGCC repeat expansion in the C9ORF72 gene on chromosome 9 accounts for a significant proportion of familial cases of MND-FTD overlap.

Clinical features

Four main clinical patterns are seen. These different presentations usually merge as MND progresses. The sensory system is not involved so sensory symptoms such as numbness, tingling and pain do not occur.

Amyotrophic lateral sclerosis (ALS). The classic presentation with simultaneous involvement of upper and lower motor neurones, usually in one limb, spreading gradually to other limbs and trunk muscles. The typical picture is of progressive focal muscle weakness and wasting (e.g. in one hand) with muscle fasciculations due to spontaneous firing of abnormally large motor units formed by surviving axons branching to innervate muscle fibres that have lost their nerve supply. Cramps are a common but nonspecific symptom. Examination often reveals upper motor neurone signs such as brisk reflexes (a brisk reflex in a wasted muscle is a classic sign), extensor plantar responses and spasticity. Sometimes an asymmetric spastic paraparesis is the presenting feature with lower

FURTHER READING

motor neurone features developing months later. Relentless progression of signs and symptoms over months allows a diagnosis that may initially be suspected to be confirmed.

- Progressive muscular atrophy. A pure lower motor neurone presentation with weakness, muscle wasting and fasciculations, usually starting in one limb and gradually spreading to involve other adjacent spinal segments.

- Progressive bulbar and pseudobulbar palsy (20%). The lower cranial nerve nuclei and their supranuclear connections are initially involved. Dysarthria, dysphagia, nasal regurgitation of fluids and choking are the presenting symptoms. A fasciculating tongue with slow, stiff tongue movements is the classic finding in a mixed bulbar palsy. Emotional incontinence with pathological laughter and crying may occur in pseudobulbar palsy.

- Primary lateral sclerosis (rare 1–2%). The least common form of MND confined to upper motor neurones, causing a slowly progressive tetraparesis and pseudobulbar palsy.

Diagnosis
Diagnosis is largely clinical. There are no diagnostic tests but investigations may allow exclusion of other disorders and may confirm subclinical involvement of muscle groups, e.g. paraspinal muscles. Denervation of muscles due to degeneration of lower motor neurones is confirmed by EMG.

Cervical spondylosis causing radiculopathy with myelopathy (upper and lower motor neurone signs), can cause diagnostic difficulty. Motor neuropathies such as multifocal motor neuropathy can also appear like motor neurone disease (see p. 1146).

Prognosis and treatment
Survival for more than 3 years is unusual, although there are rare MND cases who survive for a decade or longer.

No treatment has been shown to influence outcome substantially. Riluzole, a sodium-channel blocker that inhibits glutamate release, slows progression slightly, increasing life expectancy by 3–4 months on average. Non-invasive ventilatory support and feeding via a gastrostomy help prolong survival. Patients should be supported by a specialist multidisciplinary team with access to palliative care and a clinical nurse specialist.

CONGENITAL DISORDERS
Cerebral palsy
Cerebral palsy (CP) is an umbrella term encompassing disparate disorders apparent at birth or in childhood characteristic by non-progressive motor deficits. It is the commonest form of physical disability in childhood and most affected children survive into adulthood. A variety of intrauterine and neonatal cerebral insults may cause CP including prematurity and its complications, hypoxia, intrauterine infections and kernicterus. In many cases, no specific cause can be identified.

Clinical features
Failure to achieve normal milestones is usually the earliest feature. Specific motor syndromes become apparent later in childhood or, rarely, in adult life.

- Spastic diplegia – lower limb spasticity, with scissoring of gait
- Athetoid cerebral palsy (p. 1121)
- Infantile hemiparesis. Hemiparesis may be noted at birth or later. One hemisphere is hypotrophic and the contralateral, hemiparetic limbs small (hemiatrophy)
- Ataxic and dystonic CP
- Co-morbidity – particularly epilepsy and learning difficulty are common and at least as disabling as the motor deficit.

Dysraphism
Failure of normal fusion of the fetal neural tube leads to a group of congenital anomalies. Folate deficiency during pregnancy is contributory: supplements should always be given (p. 211). Antiepileptic drugs, e.g. valproate, are also implicated (p. 1116). If there is access from the skin, e.g. a sinus connecting to the subarachnoid space, bacterial meningitis may follow.

- Meningoencephalocele. Brain and meninges extrude through a midline skull defect – protrusion can be minor or massive.
- Spina bifida is failure of lumbosacral neural tube fusion. Several varieties occur.
- Spina bifida occulta is isolated failure of vertebral arch fusion (usually lumbar), often seen incidentally on X-rays (3% of the population). A dimple or a tuft of hair may overlie the anomaly; clinical abnormalities are unusual.
- Meningomyelocele with spina bifida. Meningomyelocele consists of elements of spinal cord and lumbosacral roots within a meningeal sac. This herniates through a vertebral defect. In severe cases both lower limbs and sphincters are paralysed. Meningocele is a meningeal defect alone. The defect should be closed in the first 24 h after birth.

NEUROGENETIC DISORDERS
Of the 20–30,000 human genes approximately 80% are expressed in the brain. It is therefore not surprising that of the 5000 or so Mendelian disorders of man, a high proportion are neurological disorders. Several hundred neurological disease genes have been identified and molecular genetic testing in now part of the neurological diagnostic process. Many of these disorders are largely covered in individual disease sections of this chapter.

Neurocutaneous syndromes
Neurofibromatosis type 1 (von Recklinghausen’s disease, NF-1)
One of the commonest neurogenetic disorders with a prevalence 1 in 3000. Inheritance is autosomal dominant but 50% of cases are due to new mutations with no family history. The protein is called neurofibromin1. NF-1 is characterized by multiple skin neurofibromas and pigmentation (café-au-lait patches p. 1219, axillary freckling and iris Lisch nodules). The neurofibromas arise from the neurilemmal sheath.

Skin neurofibromas present as soft subcutaneous, sometimes pedunculated, lumps (p. 1219). They increase in number throughout life. Plexiform neurofibromas may develop on major nerves and proximal nerve roots, sometimes involving the spinal cord. Treatment is surgical removal if pressure
symptoms develop. Associated features include: learning difficulties, malignant transformation of neurofibromas, bone abnormalities including scoliosis and fibrous dysplasia.

**Neurofibromatosis type 2 (NF-2)**

NF-2 is much less common than NF-1. It is also autosomal dominant; the gene product Merlin or Schwannomin is a cytoskeletal protein. Many neural tumours occur:
- Acoustic neuromas (usually bilateral) in 90%
- Meningiomas
- Gliomas (including optic nerve glioma)
- Cutaneous neurofibromas (30%).

**Tuberous sclerosis (epiloia)**

Features of this rare multi-system autosomal dominant condition include adenoma sebaceum, renal tumours and glial overgrowth in the brain (cortical tubers and sub-ependymal nodules). Epilepsy (70%) and learning difficulties (50%) are common complications.

**Von Hippel-Lindau disease**

This rare condition is dominantly inherited. Cerebellar, spinal and retinal haemangioblastomas develop and can be surgically removed. Tumours – renal cell carcinoma and phaeochromocytomas – may also occur. Polycythaemia sometimes develops.

**Spinocerebellar ataxias (SCAs)**

A wide variety of genetic disorders cause cerebellar ataxia as the sole or predominant clinical feature. Many are due to trinucleotide repeat insertions.

**Early onset ataxia (< 20 years of age)**

Most early childhood onset inherited ataxias are autosomal recessive. Friedreich’s ataxia (FRDA) is by far the commonest, caused by a GAA trinucleotide repeat expansion in the frataxin gene (involved in mitochondrial iron metabolism). Onset is in early teens with progressive difficulty in walking due to cerebellar ataxia and sensory neuropathy. Associated features include: scoliosis, cardiomyopathy, optic atrophy, areflexia and diabetes.

Ataxia telangiectasia and ataxia with vitamin E deficiency are other rarer forms of autosomal recessive inherited ataxia.

**Late onset ataxia (>20 years of age)**

Adult onset inherited ataxias are usually dominantly inherited and there are some 30 different genetic forms, many caused by CAG trinucleotide repeats. There are three main categories of autosomal dominant cerebellar ataxia (ADCA):
- **ADCA-1**: progressive ataxia with variable additional features including peripheral neuropathy, pyramidal and extrapyramidal signs, and cognitive impairment. Caused by mutations in loci SCA1–3.
- **ADCA-2**: progressive ataxia with macular dystrophy. Rare. SCA7 gene.
- **ADCA-3**: late adult life onset ‘pure’ ataxia. SCA6 gene in 50%. Non-genetic phenocopies must be excluded.

**PARANEOPLEASTIC SYNDROMES**

Neurological disease may accompany malignancy in the absence of metastases. These paraneoplastic syndromes are associated with anti-neuronal antibodies, believed to be involved in generation of signs and symptoms. Numerous anti-neuronal antibodies have been described. Clinical pictures include:
- Sensorimotor neuropathy (p. 1146)
- Lambert–Eaton myasthenic-myopathic syndrome (LEMS, p. 1152) and myasthenia gravis with thymoma
- Motor neurone disease variants (p. 1152)
- Spastic paraparesis (p. 1136)
- Cerebellar syndrome (p. 1084)
- Limbic encephalitis (p. 1129)
- Paraneoplastic stiff person syndrome (see p. 1153).

The neurological syndrome usually precedes evidence of the neoplasm – often a small-cell bronchial carcinoma, breast or ovarian cancer. Diagnosis is based on the clinical pattern and antibody profile. Neuroimaging is typically normal. Treatment is often unsatisfactory.

**PERIPHERAL NERVE DISEASE**

**Mechanisms of damage to peripheral nerves**

Peripheral nerves consist of two principal cellular structures – the nerve nucleus with its axon and the myelin sheath, which is produced by Schwann cells between each node of Ranvier (Fig. 22.1). Blood supply is via vasa nervorum. Several mechanisms, some co-existing, cause nerve damage.

**Demyelination**

Schwann cell damage leads to myelin sheath disruption. This causes marked slowing of conduction, seen for example in Guillain–Barre syndrome and many genetic neuropathies.

**Axonal degeneration**

Axon damage leads to the nerve fibre dying back from the periphery. Conduction velocity initially remains normal (cf. demyelination) because axonal continuity is maintained in surviving fibres. Axonal degeneration occurs typically in toxic neuropathies. A wide range of toxic and metabolic disorders damage peripheral nerves as their long axons (requiring cellular transport of proteins from cell body to nerve terminals) make them uniquely vulnerable. This explains the concept of length dependent neuropathy with the longest, most vulnerable axons (to the toes) being affected first.

**Compression**

Focal demyelination at the point of compression causes disruption of conduction. This occurs typically in entrapment neuropathies, e.g. carpal tunnel syndrome (p. 1144).

**Infarction**

Microinfarction of vasa nervorum occurs in diabetes and arteritis, e.g. polyarteritis nodosa, Churg–Strauss syndrome (p. 847). Wallerian degeneration occurs distal to the infarct.

**Infarction**

Infiltration of peripheral nerves by inflammatory cells occurs in leprosy and granulomas, e.g. sarcoid, and by neoplastic cells.

**Nerve regeneration**

Regeneration occurs either by remyelination – Schwann cells produce new myelin sheaths around an axon – or...
by axonal growth down the nerve sheath with sprouting from the axonal stump. Axonal growth takes place at up to 1 mm/day.

**Types of peripheral nerve disease**

(Fig. 22.57)

- **Neuropathy** simply means a pathological process affecting a peripheral nerve or nerves.
- **Mononeuropathy** means a process affecting a single nerve.
- **Mononeuritis multiplex**, several individual nerves are affected.
- **Polyneuropathy** describes diffuse, symmetrical disease, usually commencing peripherally. The course may be acute, chronic, static, progressive, relapsing or towards recovery. Polyneuropathies are motor, sensory, sensorimotor and autonomic. They are classified broadly into demyelinating and axonal types, depending upon which principal pathological process predominates. It is often impossible to separate these clinically. Many systemic diseases cause neuropathies. Widespread loss of tendon reflexes is typical, with distal weakness and distal sensory loss.
- **Radiculopathy** means disease affecting nerve roots and **plexopathy**, the brachial or lumbosacral plexus.

Diagnosis is made by clinical pattern, nerve conduction/EMG, nerve biopsy, usually sural or radial, and identification of systemic or genetic disease.

### Mononeuropathies

**Peripheral nerve compression and entrapment** (Table 22.24)

Nerves are vulnerable to mechanical compression at a few key sites, e.g. the common peroneal nerve at the head of the fibula, or the ulnar nerve at the elbow. Entrapment develops in relatively tight anatomical passages, e.g. the carpal tunnel.

These neuropathies are recognized largely by clinical features. Diagnosis is confirmed by nerve conduction studies.

The commonest are mentioned here. All are seen more frequently in people with diabetes.

#### Carpal tunnel syndrome (CTS)

This common mononeuropathy, median nerve entrapment at the wrist, is usually known as carpal tunnel syndrome (CTS) (p. 502). CTS is typically not associated with any underlying disease. CTS is, however, seen in:

- Hypothyroidism
- Pregnancy (3rd trimester)

#### Ulnar nerve compression

The nerve is compressed in the cubital tunnel at the elbow. This follows prolonged or recurrent pressure and elbow fracture (‘tardy ulnar palsy’ as onset is very delayed).

There is clawing of the hand, wasting of interossei and hypothenar muscles, and weakness of interossei and medial two lumbricals – with sensory loss in the little finger and splitting the ring finger. Decompression and transposition of the nerve at the elbow is sometimes helpful but often disappointing.

The deep, solely motor branch of the ulnar nerve can be damaged in the palm by repeated trauma, e.g. from a crutch, screwdriver handle, or cycle handlebars.

#### Radial nerve compression

The radial nerve is compressed acutely against the humerus, e.g. when the arm is draped over a hard chair for several hours, known as Saturday night palsy. Wrist drop and weakness of brachioradialis and finger extension follow. Recovery is usual, though not invariably, within 1–3 months. Posterior interosseous nerve compression in the forearm also leads to wrist drop, without weakness of brachioradialis.

#### Lateral cutaneous nerve of the thigh compression

This is also known as meralgia paraesthetica and is described on page 506.

#### Common peroneal nerve palsy

The common peroneal nerve is compressed against the head of the fibula following prolonged squatting, yoga, pressure from a cast, prolonged bed rest or coma, or for no apparent reason. There is foot drop and weakness of ankle evasion. The ankle jerk (S1) is preserved. A patch of numbness develops on the anterolateral border of the dorsum of the foot and/or lateral calf. Confusion with an L5 motor radiculopathy may

- Amyloid including in dialysis patients.
occur. Recovery is usual, though not invariable, within several months.

**Hereditary neuropathy with pressure palsies (HNPP)**

The genetic converse of CMT 1A (p. 1148), this dominantly inherited disorder is due to deletion of the PMP-22 gene. Patients are susceptible to pressure palsies after minor compression episodes; even the brachial plexus may be involved. There is also a mild background neuropathy that gradually develops. Genetic testing can be performed.

**Mononeuritis multiplex**

This occurs in:
- Diabetes mellitus
- Leprosy
- Vasculitis including Churg–Strauss
- Amyloidosis
- Malignancy
- Neurofibromatosis
- HIV and hepatitis C infection
- Multifocal motor neuropathy with conduction block.

Several nerves become affected sequentially or simultaneously, e.g. ulnar, median, radial and lateral popliteal nerves. When multifocal neuropathy is symmetrical, there is difficulty distinguishing it from polyneuropathy.

**Polyneuropathies (peripheral neuropathy)**

Many diseases cause polyneuropathy. The diagnosis should not stop with identification of the polyneuropathy, but involve a full diagnostic work-up to identify the underlying cause (Box 22.32). However, despite thorough investigation the aetiology remains unknown in 50% of cases.

**Clinical features.** Duration, distribution and pattern of the different types of polyneuropathy vary considerably

**Neurophysiological features.** Nerve conduction studies allow separation into axonal and demyelinating forms.

**Diagnostic investigations** (in addition to neurophysiology). A stepped approach can be taken – Table 22.25.

**Immune-mediated neuropathies**

**Guillain–Barré syndrome (GBS)**

**Clinical features**

Also called acute inflammatory demyelinating polyradiculoneuropathy (AIDP). GBS is the most common acute polyneuropathy (3/100000 per year); it is usually demyelinating or occasionally axonal and has an immune-mediated, often post-infectious, basis. GBS is monophasic – it does not recur. The clinical spectrum of GBS extends to an acute motor axonal neuropathy (AMAN) and the Miller–Fisher syndrome – a rare proximal form causing ocular muscle palsies and ataxia.

Paralysis follows 1–3 weeks after an infection that is often trivial and seldom identified. *Campylobacter jejuni* and cytomegalovirus infections are well-recognized causes of severe GBS. Infecting organisms induce antibody responses against peripheral nerves. Molecular mimicry, i.e. sharing of homologous epitopes between microorganism liposaccharides and nerve gangliosides (e.g. GM1), is the possible mechanism.

The patient complains of weakness of distal limb muscles and/or distal numbness. Low back pain is a frequent early feature. The weakness and sensory loss progresses proximally, over several days to 6 weeks. Predominant proximal muscle involvement may occur and rarely pure sensory forms. Loss of tendon reflexes is almost invariable. In mild cases, there is mild disability before spontaneous recovery begins, but in some 20% respiratory and facial muscles become weak, sometimes progressing to complete paralysis. Autonomic features sometimes develop.

**Diagnosis**

This is established on clinical grounds and confirmed by nerve conduction studies; these show slowing of conduction in the common demyelinating form, prolonged distal motor latency and/or conduction block. CSF protein is often raised to 1–3 g/L; cell count and glucose level remain normal.

In the Miller–Fisher syndrome antibodies against GQ1b (ganglioside) have a sensitivity of 90%.

Differential diagnosis includes other acute paralytic illnesses, e.g. botulism, cord compression, muscle disease and myasthenia.

**Course and management**

Paralysis may progress rapidly (hours/days) to require ventilatory support. It is essential that ventilation (vital capacity) is monitored repeatedly to recognize emerging respiratory muscle weakness. LMW heparin (p. 429) and compression stockings should be used to reduce the risk of venous thrombosis.

**Box 22.32 Varieties of polyneuropathy**

- Guillain–Barré syndrome
- Chronic inflammatory demyelinating polyradiculoneuropathy
- Idiopathic sensorimotor neuropathy
- Metabolic, toxic and vitamin deficiency neuropathies (see Box 22.33)
Immunoglobulin given intravenously within the first 2 weeks reduces duration and severity of paralysis. Patients should be screened for IgA deficiency before immunoglobulin is given – severe allergic reactions due to IgG antibodies may occur when congenital IgA deficiency is present. Plasma exchange is an alternative. Prolonged ventilation may be necessary. Improvement towards independent mobility is gradual over many months or even years but may be incomplete. 5–8% either die and 30% are left disabled.

**Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)**
CIDP develops over months, causing progressive or relapsing proximal and distal limb weakness with sensory loss. Variants such as the sensory ataxic form and multifocal motor neuropathy occur. In some cases cranial nerves may be involved.

There is no single diagnostic test but CSF protein is raised and patchy demyelination is usually seen on nerve conduction studies. Some cases are associated with a serum paraprotein. Nerve biopsy is sometimes required. CIDP responds to long-term immunosuppression with steroids or to i.v. immunoglobulin in acute stages.

**Multifocal motor neuropathy with conduction block (MMNCB)**
A distal immune-mediated focal demyelinating motor neuropathy (often asymmetrical and predominantly in the hands) develops gradually over months with profuse fasciculation, hence confusion with motor neurone disease (in this chapter). Conduction block and denervation are seen electrically. Antibodies to the ganglioside GM1 are found in over 50% of cases; this is nonspecific – antibodies are sometimes seen in other neuropathies, e.g. Guillain–Barré syndrome.

Treatment is usually with regular intravenous immunoglobulin infusions that produce immediate improvement. Steroids may cause worsening and should be avoided.

**Paraproteinaemic neuropathies**
Up to 70% of patients with a serum paraprotein have a neuropathy and some 10% of patients with no other identifiable cause for their neuropathy have a paraprotein. Most are associated with MGUS (p. 471) but they are also seen in myeloma (see neuropathy in cancer, p. 1148). The antibody may be pathogenic for the neuropathy (e.g. anti-MAG) or coincidental in some cases.

**IgM paraproteins:** usually a demyelinating neuropathy.
Often directed against myelin associated glycoprotein (anti-MAG). The anti-MAG phenotype is a slowly progressive distal neuropathy with ataxia and prominent tremor.

**POEMS syndrome:** Polyneuropathy (demyelinating), Organomegaly (hepatomegaly 50%), Endocrinopathy (reduced testosterone usually), an M (paraprotein) band, and Skin changes. Probably caused by vascular endothelial growth factor (VEGF) release from a plasmacytoma. Treatment is of the plasmacytoma/plasma cell dyscrasia.

**Chronic sensorimotor neuropathy: no cause found**
This situation is common – progressive symmetrical numbness and tingling occurs in hands and feet, spreading proximally in a glove and stocking distribution. Distal weakness also ascends. Tendon reflexes are lost. Symptoms may progress, remain static or occasionally remit. Autonomic features are sometimes seen.

**Metabolic, toxic and vitamin deficiency neuropathies**

Other polyneuropathies:
- Neuropathy in cancer
- Neuropathies in systemic diseases
- Autonomic neuropathy
- HIV-associated neuropathy
- Critical illness neuropathy

Nerve conduction studies usually show axonal degeneration. Nerve biopsy helps to classify some cases, for example diagnosing CIDP, or unsuspected vasculitis.

**Metabolic neuropathies**
**Diabetes mellitus.** The commonest cause of neuropathy in developed countries; 50% of patients with diabetes have neuropathy after 25 years – good glycaemic control is protective from this microvascular complication of diabetes. Several varieties of neuropathy occur (p. 1026):

- **Distal symmetrical sensory neuropathy:** usually mild and asymptomatic. Related to diabetes duration and glycaemic control
- **Acute painful sensory neuropathy** (reversible with improved glycaemic control)
- **Mononeuropathy and multiple mononeuropathy** (mononeuritis multiplex):
  - cranial nerve lesions
  - individual mononeuropathies (e.g. carpal tunnel syndrome) or mononeuritis multiplex
- **Diabetic amyotrophy:** a reversible vasculitic plexopathy or femoral neuropathy
- **Autonomic neuropathy.**

**Uraemia.** Progressive sensorimotor neuropathy develops in chronic uraemia. Response to dialysis is variable; the neuropathy usually improves after transplantation.

**Thyroid disease.** A mild chronic sensorimotor neuropathy is sometimes seen in both hyperthyroidism and hypothyroidism. Myopathy also occurs in hypothyroidism (p. 964).
Porphyria. In acute intermittent porphyria (p. 1043) there are episodes of a severe, mainly proximal neuropathy in the limbs, sometimes with abdominal pain, confusion and coma. Alcohol, barbiturates and intercurrent infection can precipitate attacks.

Amyloidosis. Polyneuropathy or multifocal neuropathy develops (p. 1042).

Toxic neuropathies

Alcohol

Polyneuropathy, mainly in the lower limbs, occurs with chronic alcohol use. It is a common cause of neuropathy. A myopathy may accompany it. For other neurological consequences of alcohol, see Box 22.34.

Drugs and industrial toxins

Many drugs (Table 22.26) and a wide variety of industrial toxins cause polyneuropathy. Toxins include:
- Lead – motor neuropathy
- Acrylamide (plastics industry), trichlorethylene, hexane, fat-soluble hydrocarbons, e.g. glue-sniffing, page 1184
- Arsenic, thallium and heavy metals.

Vitamin deficiencies

Vitamin deficiencies cause nervous system damage that is potentially reversible if treated early, and progressive if not. Deficiencies, often of multiple vitamins, develop in malnutrition.

Thiamin (vitamin B₁)

Dietary deficiency causes beriberi (p. 209). Its principal features are polyneuropathy and cardiac failure. Thiamine deficiency also leads to Wernicke’s encephalopathy and Korsakoff psychosis. Alcohol is the commonest cause in western countries and, rarely, anorexia nervosa or vomiting of pregnancy.

Wernicke–Korsakoff syndrome. This thiamin-responsive encephalopathy is due to damage in the brainstem and its connections. It consists of:
- **Eye signs** – nyctagmus, bilateral lateral rectus palsies, conjugate gaze palsies
- **Ataxia** – broad-based gait, cerebellar signs and vestibular paralysis
- **Cognitive change** – acutely stupor and coma, later an amnestic syndrome with confabulation.

Wernicke-Korsakoff syndrome is underdiagnosed. Thiamine should be given parenterally if the diagnosis is a possibility. Untreated Wernicke-Korsakoff syndrome commonly leads to an irreversible amnestic state. Erythrocyte transketolase activity is reduced but the test is rarely available.

Pyridoxine (vitamin B₆)

Deficiency causes a mainly sensory neuropathy. In practical terms this is seen as limb numbness developing during anti-TB therapy in slow isoniazid acetylators (p. 913). Prophylactic pyridoxine 10 mg daily is given with isoniazid.

Vitamin B₁₂ (cobalamin)

Deficiency causes damage to the spinal cord, peripheral nerves and brain.

Subacute combined degeneration of the cord (SACD).

Combined cord and peripheral nerve damage is a sequel of Addisonian pernicious anaemia and rarely other causes of vitamin B₁₂ deficiency (p. 382). Initially there is numbness and tingling of fingers and toes, distal sensory loss, particularly posterior column, absent ankle jerks and, with cord involvement, exaggerated knee jerks and extensor plantars. Optic atrophy and retinal haemorrhage may occur. In later stages sphincter disturbance, severe generalized weakness and dementia develop. Exceptionally, dementia develops in the early stages.

Macrocytosis with megaloblastic marrow is usual though not invariable in SACD. Parenteral B₁₂ reverses nerve damage but has little effect on the cord and brain. Without treatment, SACD is fatal within 5 years. Copper deficiency is a very rare cause of a similar picture.

Genetic neuropathies

Inherited neuropathy may occur as ‘pure’ neuropathy disorders (e.g. CMT) or as part of a neurological multi-system disorder, e.g. SCAs (p. 1143).

Charcot–Marie–Tooth (CMT) disease

CMT disease is a complex group of heterogeneous motor and sensory neuropathies with multiple causative genes. Distal limb wasting and weakness typically progress slowly over many years, mostly in the legs, with variable loss of sensation and reflexes. In advanced disease severe foot drop results but patients usually remain ambulant. Mild
cases have pes cavus and toe clawing that can pass unnoticed.

- **HSMN Ia (CMT 1A)** – the commonest (70% of CMT; 1:2500 births), autosomal dominant demyelinating neuropathy caused by duplication (or point mutation) of a 1.5 megabase portion p11.2 of chromosome 17 encompassing the peripheral myelin protein 22 gene (PMP-22, 17p11.2).

- **HSMN Ib (CMT 1B)** – the second commonest, an autosomal dominant demyelinating neuropathy due to mutations in the myelin protein zero gene (MPZ) on chromosome 1 (1q22).

- **HSMN II (CMT 2)** – rare axonal polyneuropathies also caused by *MFN2* or *KIF1B* on chromosome 1p36 and other mutations. There is prominent sensory involvement with pain and paraesthesiaes.

- **Distal spinal muscular atrophy** – a rare cause of CMT phenotype.

- **CMT with optic atrophy**, deafness, retinitis pigmentosa and spastic paraparesis.

- **CMTX** is an X-linked dominant HSMN on chromosome Xq13.1. The gene product is a gap junction B1 protein (GJB1) or connexin 32 (p. 24).

### HSMN III

HSMN III is a rare childhood demyelinating sensory neuropathy (Déjérine–Sottas disease) leading to severe incapacity during adolescence. Nerve roots become hypertrophied. CSF protein is greatly elevated to \( \geq 10 \) g/L. Point mutations either of *PMP-22* gene or of *P0* can generate this phenotype.

### Other polyneuropathies

#### Neuropathy in cancer

Polyneuropathy is seen as a paraneoplastic syndrome (non-metastatic manifestation of malignancy). Polyneuropathy occurs in myeloma and other plasma cell dyscrasias via several mechanisms including: direct effects of paraproteins, amyloidosis and nerve infiltration, POEMS and effects of chemotherapy. Individual nerves may be infiltrated with malignant cells, e.g. lymphoma.

#### Neuropathies in systemic diseases

Vasculitic neuropathy occurs in SLE (p. 535), polyarteritis nodosa (p. 521), Churg–Strauss syndrome (p. 847), and rheumatoid disease (p. 543). Both multifocal neuropathy and symmetrical sensorimotor polyneuropathy occur.

#### Autonomic neuropathy

Autonomic neuropathy causes postural hypotension, urinary retention, erectile dysfunction, nocturnal diarrhoea, diminished sweating, impaired pupillary responses and cardiac arrhythmias. This can develop in diabetes and amyloidosis and may complicate Guillain–Barré syndrome and Parkinson’s disease. Many varieties of neuropathy cause autonomic problems in a mild form. Occasionally, e.g. with amyloidosis, a severe autonomic neuropathy may occur.

#### Neuromuscular weakness complicating critical illness (p. 896)

Some 50% of critically ill ITU patients with multiple organ failure and/or sepsis develop an axonal polyneuropathy. Typically distal weakness and absent reflexes are seen during recovery from critical illness. Resolution is usual.

---

**Plexus and nerve root lesions**

The common conditions that cause these are summarized in Box 22.35.

### Cervical and lumbar degeneration

Spondylosis (Tables 11.3, 11.6) describes vertebral and ligamentous degenerative changes occurring during ageing or following trauma. Several factors produce neurological signs and symptoms:

- **Osteophytes** – local overgrowth of bony spurs or bars
- **Thickening of spinal ligaments**
- **Congenital narrowing of the spinal canal**
- **Disc degeneration and protrusion** (posterior and lateral protrusion: cord and root compression)
- **Vertebral collapse** (osteoporosis, infection)
- **Rheumatoid synovitis** (p. 521)
- **Ischaemic changes within cord and nerve roots**.

Narrowing of disc spaces, osteophytes, narrowing of exit foramina, and narrowing of the spinal canal are also seen on X-rays and MRI in the symptomless population, commonly in the mid and lower cervical and lower lumbar region, and imaging must not be over interpreted.

#### Lateral cervical disc protrusion (Fig. 22.58)

The patient complains of pain in the arm. A C7 protrusion is the most common problem. There is root pain that radiates to the C7 myotome (triceps, deep to scapula and extensor aspect of forearm), with a sensory disturbance, tingling and numbness in the C7 dermatome.

---

**Box 22.35 Common root and plexus problems**

**Nerve root**

- **Cervical and lumbar spondylosis**
- **Trauma**
- **Herpes zoster**
- **Tumours, e.g. neurofibroma, metastases**
- **Meningeal inflammation, e.g. syphilis, arachnoiditis**

**Plexus**

- **Trauma**
- **Malignant infiltration**
- **Neuralgic amyotrophy**
- **Thoracic outlet syndrome (cervical rib)**

---

**Figure 22.58 Central and lateral disc protrusions.**

(a) Central disc protrusion compressing cord. (b) Lateral disc protrusion compressing nerve roots.
In an established C7 root lesion there is:
- Weakness/wasting – triceps, wrist and finger extensors
- Loss of the triceps jerk (C7 reflex arc)
- C7 dermatome sensory loss.

Although the initial pain can be very severe, most cases recover with rest and analgesics. It is usual to immobilize the neck. Disc protrusion with root compression is seen on MRI. Root decompression is sometimes helpful.

**Lateral lumbar disc protrusion**

The L5 and S1 roots are commonly compressed by lateral prolapse of L4–L5 and L5–S1 discs – the root number below a disc interspace is compressed. There is low back pain and sciatica, i.e. pain radiating from the back to buttock and leg. Onset is typically acute. This can follow lifting, bending or minor injury. When pain follows such an event, it is tempting to ascribe the disc protrusion to it. However, lateral lumbar disc protrusion is commonly apparently spontaneous – lifting or injury is usually only bringing forward an inevitable disc prolapse.

Straight-leg raising is limited. There is reflex loss, e.g. ankle jerk in an S1 root lesion, weakness of plantar flexion (S1) or great toe extension (L5). Sensory loss is found in the affected dermatome.

Most sciatica resolves with initial rest and analgesia followed by early mobilization. MRI is sometimes appropriate: surgery is indicated when a substantial persistent symptomatic disc lesion is shown.

**Acute low back pain**

Acute low back pain is extremely common. Often pain is of disc or facet joint origin. Significant nerve root compression is unusual. Maintaining activity and a trial of gentle manipulation is recommended (see also p. 504).

**Cervical spondylotic myelopathy**

This is a relatively common disorder of older adults. Posterior disc protrusion (Fig. 22.59), common at C4–5, C5–6 and C6–7 levels, causes spinal cord compression. Congenital spinal canal narrowing, osteophytic bars, ligamentous thickening and ischaemia are contributory. Usually there are no or few neck symptoms. The patient complains of slowly progressive difficulty walking as a spastic paraparesis develops. A reflex level in the upper limbs and evidence of cervical radiculopathy may co-exist. MRI demonstrates the level and extent of cord compression and T2 signal change is usually evident in the cervical cord at the point of maximal compression. Neck manipulation should be avoided.

Decompression by anterior cervical discectomy may be necessary when cord compression is severe or progressive. Complete recovery of the pyramidal signs may occur; progression is generally halted.

**Central thoracic disc protrusion**

Central protrusion of a thoracic disc is an unusual cause of paraparesis as the thoracic spine is relatively non-mobile and disc degeneration and protrusion, other than due to trauma, is rare.

**The cauda equina syndrome**

A central lumbosacral disc protrusion causes a cauda equina syndrome, i.e. bilateral flaccid (cf. spasticity in higher lesions) lower limb weakness, sacral numbness, retention of urine, erectile dysfunction and areflexia – usually with back pain.

Multiple lumbosacral nerve roots are involved. Onset is either acute – an acute flaccid paraparesis – or chronic, sometimes with intermittent claudication. A central lumbosacral protrusion should be suspected if a patient with back pain develops retention of urine or sacral numbness. Urgent imaging and surgical decompression is indicated for this emergency. Neoplasms in the lumbosacral region can present with similar features.

**Spinal stenosis**

A narrow spinal canal is developmental and frequently symptomless but a congenital narrowing of the cervical canal predisposes the cervical cord to damage from minor disc protrusion later.

In the lumbosacral region, further narrowing of the canal by disc protrusion causes root pain, and/or buttock and lower limb claudication. As the patient walks, nerve roots become hyperaemic and swell, producing buttock and lower limb pain with numbness. Surgical decompression is required.

**Neuralgic amyotrophy**

Severe pain in muscles around one shoulder is followed by wasting, usually of infraspinatus, supraspinatus, deltoid and serratus anterior. A demyelinating brachial plexopathy develops over several days. The cause is unknown; an allergic or viral basis is postulated. Rarely, a similar condition develops in distal upper limb muscles or in a lower limb. Recovery of wasted muscles is usual, but not invariably, over several months.

**Thoracic outlet syndrome**

A fibrous band or cervical rib extending from the tip of the C7 transverse process towards the first rib compresses the lower brachial plexus roots, C8 and T1. There is forearm pain (ulnar border), T1 sensory loss and thenar muscle wasting, principally abductor pollicis brevis. Horner’s syndrome may develop. The rib or band can be excised. Frequency of this diagnosis varies widely – thoracic outlet problems are sometimes invoked to explain ill-defined arm symptoms, typically on poor evidence.

A rib or band can also produce subclavian artery or venous occlusion. Neurological and vascular problems rarely occur together.

**Malignant infiltration and radiation plexopathy**

Metastatic disease of nerve roots, the brachial or lumbosacral plexus causes a painful radiculopathy and/or plexopathy.
An example is apical bronchial carcinoma (Pancoast’s tumour) causing a T1 and sympathetic outflow lesion – wasting of small hand muscles, pain and T1 sensory loss with ipsilateral Horner’s syndrome. This also occurs in apical TB. In the upper limb, radiotherapy following breast cancer can produce a plexopathy.

**Muscle fibres are affected by:**
- **Pathophysiology**
- **Definitions**
  - *Myopathy* means a disease of voluntary muscle.
  - *Myositis* indicates inflammation.
  - *Muscular dystrophies* are inherited disorders of muscle cells.
  - *Myotonia* is sustained contraction/slow relaxation.
  - *Channelopathies* are ion channel disorders of muscle cells.

  Weakness is the predominant feature of muscle disease. A selection of these conditions is mentioned in Box 22.36.

**Pathophysiology**

Muscle fibres are affected by:
- Acute inflammation and fibre necrosis (e.g. polymyositis, infection)
- Genetically determined metabolic failure (e.g. Duchenne muscular dystrophy)
- Infiltration by inflammatory tissue (e.g. sarcoidosis)
- Fibre hypertrophy and regeneration

**Box 22.36 Muscle disease: classification**

**Endocrine and toxic**

- Corticosteroids/Cushing’s
- Thyroid disease
- Calcium disorders
- Alcohol
- Drugs, e.g. statins

**Myasthenic**

- Myasthenia gravis
- Lambert–Eaton myasthenic-myopathic syndrome (LEMS)

**Genetic dystrophies**

- Duchenne
- Facioscapulohumeral
- Limb girdle, and others

**Myotonic**

- Myotonic dystrophy
- Myotonia congenita

**Channelopathies**

- Hypokalaemic periodic paralysis
- Hyperkalaemic periodic paralysis

**Metabolic**

- Myophosphorylase deficiency (McArdle’s syndrome)
- Other defects of glycogen and fatty acid metabolism

**Mitochondrial disease**

**Box 22.36**

- Mitochondrial diseases
- Immunological damage, e.g. myasthenia gravis and Lambert–Eaton myasthenic syndrome
- Ion channel disorders, e.g. chloride channel mutations in hereditary myotonias.

**Diagnosis**

Clinical features including the distribution of weakness, wasting or hypertrophy, and the tempo of progression and presence of family history help make a clinical diagnosis. Several investigations help make a definitive diagnosis:

**Serum muscle enzymes**

Serum creatine kinase (CK) is a marker of muscle fibre damage and is greatly elevated in many dystrophies, e.g. Duchenne, and in inflammatory muscle disorders, e.g. polymyositis.

**Neurogenetic tests**

These are essential in muscular dystrophies and mitochondrial disease.

**Electromyography**

Characteristic EMG patterns:
- **Myopathy**. Short-duration spiky polyphasic muscle action potentials are seen. Spontaneous fibrillation is occasionally recorded.
- **Myotonic discharges**. A characteristic high-frequency whine is heard.
- **Decrement and increment**. In myasthenia gravis, a characteristic decrement in evoked muscle action potential follows repetitive motor nerve stimulation. The reverse occurs, i.e. increment, following repetitive stimulation in LEMS, page 1152.
- In denervation, profuse fibrillation potentials are seen.

**Muscle biopsy**

Unlike neural tissue skeletal muscle can be easily biopsied to provide a definitive diagnosis using powerful molecular immunohistochemical techniques. Histology and muscle histochemistry of fibre types demonstrate denervation, inflammation and dystrophic changes. Electron microscopy is often valuable. In dystrophies immunohistochemistry in specialist labs allows identification of the abnormal muscle protein and a precise molecular diagnosis.

**Imaging**

MRI shows signal changes within muscles in some cases of myositis and fatty replacement of muscle in chronically damaged muscles.

**Inflammatory myopathies**

Inflammatory myopathies including polymyositis, dermatomyositis and inclusion body myositis are described on page 541. Granulomatous muscle infiltration and inflammation may occur in sarcoidosis and other disorders such as rheumatoid arthritis, causing a mild myopathy. Viral myositis may also occur and muscles may be involved in other infections such as neurocysticercosis (p. 1130).

**Metabolic and endocrine myopathies**

**Corticosteroids and Cushing’s syndrome**

Proximal weakness occurs with prolonged high-dose steroid therapy and in Cushing’s syndrome (p. 943). Selective type-2 fibre atrophy is seen on biopsy.
Thyroid disease
Several myopathies occur (see also p. 965). Thyrotoxicosis can be accompanied by severe proximal myopathy. There is also an association between thyrotoxicosis and myasthenia gravis, and between thyrotoxicosis and hypokalaemic periodic paralysis (p. 1153). Both associations are seen more frequently in South-east Asia. In ophthalmic Graves’ disease, there is swelling and lymphocytic infiltration of extracranial muscles (p. 967).

Hypothyroidism is sometimes associated with muscle pain and stiffness, resembling myotonia. A proximal myopathy also occurs.

Disorders of calcium and vitamin D metabolism
Proximal myopathy develops in hypocalcaemia, rickets and osteomalacia (p. 559.)

Hypokalaemia
Acute hypokalaemia (e.g. with diuretics) causes flaccid paralysis reversed by potassium, given slowly (p. 654). Chronic hypokalaemia leads to mild, mainly proximal, weakness. (See also periodic paralysis (p. 1080)).

Alcohol and drugs
Severe myopathy with muscle necrosis and myoglobinuria occurs in acute excess. A subacute proximal myopathy occurs with chronic alcohol use. A similar syndrome occurs in diphosphine and amphetamine addicts.

Drugs
Drug-induced muscle disorders include proximal myopathy (steroids), muscle weakness (lithium), painful muscles (fibrates), rhabdomyolysis (fibrate combined with a statin or interaction between statins and other drugs such as certain antibiotics) and malignant hyperpyrexia. Most respond to drug withdrawal.

Myophosphorylase deficiency (McArdle’s syndrome)
See page 1039.

Malignant hyperpyrexia
Widespread skeletal muscle rigidity with hyperpyrexia as a sequel of general anaesthesia or neuroleptic drugs, e.g. haloperidol, is due to a genetic defect in the sarcoplasmic reticulum calcium-release channel of the muscle ryanodine receptor, RyR1. Death during or following anaesthesia can occur in this rarity, sometimes inherited as an autosomal dominant. Dantrolene is of some help for rigidity.

Neuromuscular junction disorders

Myasthenia gravis (MG)
MG is an acquired and probably heterogeneous condition. It is characterized by weakness and fatiguability of proximal limb, bulbar and ocular muscles, the latter sometimes in isolation. The heart is not affected. The prevalence is about 4 in 100000. MG is twice as common in women as in men, with a peak age incidence around 30. The underlying cause is unknown.

Antibodies to acetylcholine receptor protein (anti-AChR antibodies) are commonly found. Immune complexes of anti-AChR IgG and complement are deposited at the postsynaptic membranes, causing interference with and later destruction of AChRs.

A second group of antibodies against muscle-specific receptor tyrosine kinase (anti-MuSK antibodies) have been identified in anti-AChR antibody negative cases. Ocular muscle MG is another subgroup.

Thymic hyperplasia is found in 70% of MG patients below the age of 40. In some 10%, a thymic tumour is found, the incidence increasing with age; antibodies to striated muscle can be demonstrated in some of these patients. Young patients without a thymoma have an increased association with HLA-B8 and DR3.

There is an association between MG and thyroid disease, rheumatoid disease, pernicious anaemia and SLE. Transient MG is sometimes caused by D-penicillamine treatment.

Clinical features
Fatiguability is typical. Limb muscles (proximal), extraocular, speech, facial expression and mastication muscles are commonly affected. Respiratory difficulties can be prominent. The clinical picture of fluctuating, fatiguable weakness is usually diagnostic. Muscle pain is typically absent. Early complaints of fatigue are frequently dismissed.

Complex extraocular palsies, ptosis and fluctuating proximal weakness are found. The reflexes are initially preserved but may be fatiguable, i.e. disappear following repetitive activity. Wasting is sometimes seen after many years.

Investigations

Serum anti-AChR and anti-MuSK antibodies.
Anti-AChR antibodies are present in some 80–90% of cases of generalized MG. These antibodies are not found in healthy controls but are seen rarely in other muscle disorders. In pure ocular MG, anti-AChR antibodies are detectable in less than 30% of cases.
Anti-MuSK antibodies define a subgroup of MG patients characterized by weakness predominantly in bulbar, facial and neck muscles.

Repetitive nerve stimulation. A characteristic decrement occurs in the evoked muscle action potential during repetitive stimulation. EMG is otherwise normal.

Tensilon (edrophonium) test. This is seldom required and the drug is not available worldwide. Edrophonium 10 mg is given intravenously following a 1–2 mg test dose from the 10 mg vial. When the test is positive, there is substantial improvement in weakness within seconds and this lasts for up to 5 minutes. Perform a control test using saline and have an observer. The sensitivity of the test is 80% but there are false negative and positive tests. Occasionally, edrophonium (an anticholinesterase) causes bronchospasm and syncope. Resuscitation facilities must be available.

Imaging and other tests. Mediastinal MR provides optimal structural imaging for thymoma. Routine blood studies are normal: the ESR is not raised, and CPK is normal. Antibodies to striated muscle suggest a thymoma; intrinsic factor and thyroid antibodies may be found. Rheumatoid factor and anti-nuclear antibody tests can be positive. Muscle biopsy is usually not performed, though ultrastructural neuromuscular junction abnormalities are well described.

Course and management
Myasthenia gravis fluctuates in severity; most cases have a protracted, lifelong course. Respiratory impairment, nasal regurgitation and dysphagia occur; emergency assisted ventilation may be required. Simple monitoring tests, such as the duration for which an arm can be held outstretched, and the vital capacity are useful.
Exacerbations are usually unpredictable and unprovoked but may be brought on by infections and by aminoglycosides. Magnesium sulphate enemas can provoke severe weakness.

**Treatment**

**Oral anticholinesterases**

Pyridostigmine (60 mg tablet) is widely used. The duration of action is 3–4 hours, the dose (usually 4–16 tablets daily) determined by response. Pyridostigmine prolongs acetylcholine action by inhibiting cholinesterase. Overdose of anticholinesterases causes severe weakness (cholinergic crisis). Muscarinic side-effects, e.g. colic and diarrhoea, are common; oral atropine (antimuscarinic) 0.5 mg helps to reduce this. Anticholinesterases help weakness but do not alter the natural history of myasthenia.

**Immunosuppressant drugs**

These drugs are used in patients who do not respond to pyridostigmine or who relapse on treatment. Steroids are often used. There is improvement in 70%, although this may be preceded by an initial relapse. Azathioprine, mycophenolate and other immunosuppressants are also used.

**Thymectomy**

Thymectomy improves prognosis, more so in women than men below 50 years with positive AchR antibodies, even in patients without a thymoma. Cases positive for anti-MuSK antibodies tend not to improve following thymectomy. When a thymoma is present, the potential for malignancy also makes surgery necessary.

**Plasmapheresis and intravenous immunoglobulin**

During exacerbations these interventions are of value.

**Other rare myasthenic syndromes** exist, e.g. congenital myasthenia.

**Lambert–Eaton myasthenic-myopathic syndrome (LEMS)**

This paraneoplastic manifestation of small-cell bronchial carcinoma is due to defective acetylcholine release at the neuromuscular junction. Proximal limb muscle weakness, sometimes with ocular/bulbar muscles develops, with some absent tendon reflexes, a cardinal sign. Weakness tends to improve after a few minutes of muscular contraction, and absent reflexes return (cf. myasthenia). Diagnosis is confirmed by EMG and repetitive stimulation (increment, see above). Antibodies to P/Q-type voltage-gated calcium channels are found in most cases (90%). 3,4-Diaminopyridine (DAP) is a reasonably safe and sometimes effective treatment.

**Muscular dystrophies**

These progressive genetically determined disorders of skeletal and sometimes cardiac muscle have a complex clinical and neurogenetic classification.

### Duchenne muscular dystrophy (DMD) and Becker’s muscular dystrophy

These are inherited as X-linked recessive disorders, though one-third of cases are spontaneous mutations. DMD occurs in 1 in 3000 male infants. There is absence of the gene product dystrophin, a rod-shaped cytoskeletal muscle protein in DMD. In Becker’s dystrophy dystrophin levels are present but low. DMD is usually obvious by the 4th year, and often causes death by the age of 20.

Dystrophin is essential for cell membrane stability. Deficiency leads to reduction in three glycoproteins (α-, β- and γ-sarcoglycans) in the dystrophin-associated protein complex (DAP-complex) that link dystrophin to laminin within cell membranes.

Becker’s muscular dystrophy is less severe than Duchenne and weakness only becomes apparent in young adults.

**Clinical features**

A boy with DMD is noticed to have difficulty running and rising to his feet – he uses his hands to climb up his legs (Gowers’ sign). There is initially a proximal limb weakness with calf pseudohypertrophy. The myocardium is affected. Severe disability is typical by the age of 10.

**Investigations**

The diagnosis is often suspected clinically. CK is grossly elevated (100–200 × normal). Biopsy shows variation in muscle fibre size, necrosis, regeneration and replacement by fat, and on immunochemical staining, absence of dystrophin.

**Management**

There is no curative treatment. Passive physiotherapy helps prevent contractures in the later stages. Portable respiratory support improves life expectancy.

**Carrier detection.** Females with an affected brother have a 50% chance of carrying the DMD gene. In carriers, 70% have a raised CK, usually EMG abnormalities and/or changes on biopsy. Carrier and prenatal diagnosis are available with genetic counselling.

**Limb-girdle and facioscapulohumeral dystrophy**

These less severe but disabling dystrophies are summarized in Table 22.27. There are many other varieties of dystrophy. Many are associated with a sarcoglycan deficiency. Genes for numerous limb-girdle muscular dystrophies (LGMD) have been identified.

**Myotonias**

Myotonias are characterized by continued, involuntary muscle contraction after cessation of voluntary effort, i.e. failure of muscle relaxation. EMG is characteristic (p. 1090). The two most common myotonias are described below. Patients with myotonia tolerate general anaesthetics poorly.

Myotonic dystrophy (MD)

This autosomal dominant condition is a genetic disorder with two different triple repeat mutations, most commonly an expanded CTG repeat in a protein-kinase (DMPK) gene (DM1). The less common variant (DM2) is caused by expanded CCTG repeat in a zinc finger protein gene. There is a correlation between disease severity, age at onset and approximate size of triple repeat mutations. There is progressive distal muscle weakness, with ptosis, weakness and thinning of the face and sternomastoids. Myotonia is typically present. Muscle disease is part of a syndrome comprising:

- Cataracts
- Frontal baldness
- Cognitive impairment (mild)
- Oesophageal dysfunction (and aspiration)
- Cardiomyopathy and conduction defects (sudden death can occur in type 1)
- Small pituitary fossa and hypogonadism
- Glucose intolerance
- Low serum IgG.

This gradually progressive condition usually becomes evident between 20 and 50 years. Phenytoin or procainamide sometimes helps the myotonia.

Myotonia congenita

Autosomal dominant myotonia, usually mild, becomes evident in childhood. The gene, CLCN1, codes for a muscle chloride channel. The myotonia, which persists, is accentuated by rest and by cold. Diffuse muscle hypertrophy occurs – the patient has bulky muscles.

Channelopathies

The common feature in these genetic disorders is malfunction of muscle membrane ion channels.

Hypokalaemic periodic paralysis

This disorder is characterized by generalized weakness, including bulbar muscles, that often starts after a heavy carbohydrate meal or following exertion. Attacks last for several hours. It often first comes to light in the teenage years and tends to remit after the age of 35. Serum potassium is usually below 3.0 mmol/L in an attack. The weakness responds to (slow) i.v. potassium chloride. It is usually an autosomal dominant trait caused by mutation in a muscle voltage-gated calcium channel gene (CACNL1A3). Other mutations in the sodium channels (SCN4A) and potassium channels (KCNE3) also occur. Acetazolamide sometimes helps prevent attacks. Weakness can be caused by diuretics. A similar condition can also occur with thyrotoxicosis.

Hyperkalaemic periodic paralysis

This condition, also autosomal dominant, is characterized by attacks of weakness, sometimes with exercise. Attacks start in childhood and tend to remit after the age of 20; they last about 30–120 min. Myotonia may occur. Serum potassium is elevated. An attack can be terminated by i.v. calcium gluconate or chloride. There are point mutations in a muscle voltage-gated sodium channel gene (SCN4A). Acetazolamide or a thiazide diuretic can be helpful.

A very rare normokalaemic, sodium-responsive periodic paralysis also occurs.

Stiff person syndrome

Stiff person syndrome (SPS) is a rare autoimmune disease, commoner in females, causing axial muscle stiffness with abnormal posture, spams and falls. Attacks of stiffness are sometimes provoked by noise or emotion, but sometimes occur spontaneously. Between attacks, which last from hours to days or even weeks, the patient may appear normal.

Widespread muscle stiffness is typical during an attack; there are no other neurological signs. SPS has been mistaken for Parkinson’s, dystonia and non-organic conditions. Anti-glutamic acid decarboxylase antibodies (anti-GAD) are found in very high titre in >50% of cases and are believed to be involved in the generation of muscle stiffness. Continuous motor activity in paraspinal muscles is seen on EMG.

Treatment with diazepam, other muscle relaxants and i.v. immunoglobulin can be helpful during attacks. A form of SPS is also seen occasionally as a paraneoplastic condition associated with antibodies to the synaptic protein amphiphysin (p. 437).

Mitochondrial diseases

These comprise a complex group of rare disorders involving muscle, peripheral nerves and CNS, characterized by morphological and biochemical abnormalities in mitochondria. Mitochondrial DNA is inherited maternally (p. 37). The spectrum is wide, ranging from optic atrophy (see Leber’s, p. 35) to myopathies, neuropathies and encephalopathy.

- MELAS (mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes) is one well-recognized form.
- Chronic progressive ophthalmoplegia (CPEO) is another.
- MERRF describes myoclonic epilepsy with abnormal muscle histology, the muscle appearance being described as ragged red fibres.

INTRODUCTION

Psychiatry is concerned with the study and management of disorders of mental function: primarily thoughts, perceptions, emotions and purposeful behaviours. Psychological medicine, or liaison psychiatry, is the discipline within psychiatry that is concerned with psychiatric and psychological disorders in patients who have physical complaints or conditions. This chapter will primarily concern itself with this particular branch of psychiatry.

The long-held belief that diseases are either physical or psychological has been replaced by the accumulated evidence that the brain is functionally or anatomically abnormal in most if not all psychiatric disorders. Physical, psychological and social factors, and their interactions must be looked into, in order to understand psychiatric conditions. This philosophical change of approach rejects the Cartesian dualistic approach of the mind/body biomedical model and replaces it with the more integrated biopsychosocial model.

Epidemiology (Box 23.1)

The prevalence of psychiatric disorders in the community in the UK is about 20%, mainly composed of depressive and anxiety disorders and substance misuse (mainly alcohol). The prevalence is about twice as high in patients attending the general hospital, with the highest rates in the accident and emergency department and medical wards.

Culture and ethnicity

These can alter either the presentation or the prevalence of psychiatric ill-health. Biological factors in mental illness are usually similar across cultural boundaries, whereas psychological and social factors will vary. For example, the prevalence and presentation of schizophrenia vary little between countries, suggesting that biological/genetic factors are operating independently of cultural factors. In contrast, disorders in which social factors play a greater role vary between cultures, so that anorexia nervosa is found more often in developed cultures. Culture can also influence the presentation of illnesses, such that physical symptoms are more common presentations of depressive illness in Asia than in Europe. Similarly culture will influence the healthcare sought for the same condition.

THE PSYCHIATRIC HISTORY

As in any medical specialty, the history is essential in making a diagnosis. It is similar to that used in all specialties but tailored to help to make a psychiatric diagnosis, determine possible aetiology, and estimate prognosis. Data may be taken from several sources, including interviewing the patient, a friend or relative (usually with the patient’s permission), or the patient’s general practitioner. The patient interview also enables a doctor to establish a therapeutic relationship with the patient. Box 23.2 gives essential guidance on how to safely conduct such an interview, although it is unlikely that a patient will physically harm a healthcare professional. When interviewing a patient for the first time, follow the guidance outlined in Chapter 1 (see pp. 10–12).

Components of the history are summarized in Table 23.1.

THE MENTAL STATE EXAMINATION (MSE)

The history will already have assessed several aspects of the MSE, but the interviewer will need to expand several areas...
as well as test specific areas, such as cognition. The MSE is typically followed by a physical examination and is concluded with an assessment of insight, risk and a formulation that takes into account a differential diagnosis and aetiology. Each domain of the MSE is given below; abnormalities that might be detected and the disorders in which they are found are summarized in Table 23.2. The major subheadings are listed below.

### Appearance and general behaviour

State and colour of clothes, facial appearance, eye contact, posture and movement provide information about a patient’s affect. Agitation and anxiety cause an easy startle response, sweating, tremor, restlessness, fidgeting, visual scanning (for danger) and even pacing up and down.

### Speech

The rate, rhythm, volume and content of the patient’s speech should be examined for abnormalities. Note that speech is the only way that one can examine thoughts and as such, disorders of thought are typically seen in this section of the examination. Thought content (literally the content of their thoughts) is dealt with separately (see below). Abnormalities that may reflect neurological lesions, such as dysarthria and dysphasia, should also be assessed.

### Mood and affect

The patient has an emotion or feeling, tells the doctor about their mood, and the doctor observes the patient’s affect. In psychiatric disorders, mood may be altered in three ways: a persistent change in mood, a fluctuating mood and an incongruous mood.

### Thoughts

In addition to those abnormalities looked at under ‘speech’ (see above), abnormalities of thought content and thought possession are discussed here. Delusions (Table 23.2) can be further categorized as primary or secondary. Depending on whether they arise de novo or in the context of other abnormalities in mental state.

Table 23.2 The mental state examination and the psychopathology it is used to detect

Continued
### Abnormal perceptions

The assessment of perceptions in the mental state involves observation of the patient as well as asking questions of them. For example, patients experiencing auditory hallucinations may appear startled by sounds or voices that you cannot hear or may interact with them, e.g. appearing to be engaged in conversation when nobody else is in the room.

Hallucinatory phenomena can affect any sensory modality and specific types of hallucination will be dealt with later in the chapter with the disorders in which they most commonly occur.

#### Cognitive state

Examination of the cognitive state is necessary to diagnose organic brain disorders, such as delirium and dementia. Poor concentration, confusion and memory problems are the most common subjective complaints. Clinical testing involves the screening of cognitive functions, which may suggest the need for more formal psychometry. A premorbid estimate of intelligence, necessary to judge changes in cognitive abilities, can be made from asking the patient the final year of education and the highest qualifications or skills achieved.

Testing can be divided into tests of diffuse and focal brain functions.

#### Diffuse functions

- **Orientation** in time, place and person. Consciousness can be defined as the awareness of the self and the environment. Clouding of consciousness is more accurately a fluctuating level of awareness and is commonly seen in delirium.
- **Attention** is tested by saying the months or days backwards.
- **Verbal memory.** Ask the patient to repeat a name and address with 10 or so items, noting how many times it takes to recall it 100% accurately (normal is 1 or 2) (immediate recall or registration).
- **Abstract thinking** involves thinking about the more general principles in a situation. Ask the patient to try to remember it and then ask it of them again after 5 min (0 or 1 error is normal) (short-term memory). Some psychiatric patients are unable to discriminate between what is real and what is imagined. They may have illusions, delusions or even hallucinations.

#### Focal functions

Frontal, temporal and parietal function tests are covered in chapter 22. Note any disinhibited behaviour not explained by another psychiatric illness. **Sequential tasks** are tested by asking the patient to alternate making a fist with one hand at the same time as a flat hand with the other. Ask the patient to tap a table once if you tap twice and vice-versa. Note any motor perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration whereby the patient cannot change the movement once established.

#### Assessing cognitive dysfunction

Questions on: orientation (e.g. time, date, place); registration (naming objects); attention and calculation (simple arithmetic); recall (previously mentioned objects); and language (understanding commands). This correlates well with more time-consuming intelligence quotient (IQ) tests, but it will not as easily pick up cognitive problems caused by focal brain lesions. Simple questioning will detect about 90% of people with cognitive impairments, with about 10% false positives.

#### Insight and illness beliefs

**Insight** is the degree to which a person recognizes that he or she is unwell, and is minimal in people with a psychosis. **Illness beliefs** are the patient’s own explanations of their illness.

Box 23.3 Main causes of disturbed behaviour

- Drug intoxication (especially alcohol)
- Delirium (acute confusional state)
- Acute psychosis
- Personality disorder

Health, including diagnosis and causes. These beliefs should be elicited because they can help to determine prognosis and adherence with treatment, whatever the diagnosis.

**Risk**

The assessment of risk may sound daunting but it is fundamental to clinical practice; for instance when determining whether a patient presenting with chest pain should be reviewed in the resuscitation room of the emergency department rather than a normal cubicle. Risk must be assessed in people with a psychiatric diagnosis, albeit that the nature of ‘risk’ is different.

Risk can be broken down into two parts: the risk that the patient poses to themselves and that which they pose to others (Table 23.3). You will have already made an appraisal of risk in your initial preparations for seeing the patient (Box 23.2) and in checking ‘forensic history’ (Table 23.1). It may be necessary to obtain additional information from family, friends or professionals who know the patient – this may save time and prove invaluable.

**Severe behavioural disturbance**

Patients who are aggressive or violent cause understandable apprehension in all staff, and are most commonly seen in the accident and emergency department. Information from anyone accompanying the patient, including police or carers, can help considerably. Box 23.3 gives the main causes of disturbed behaviour.

**Management of the severely disturbed patient**

The primary aims of management are control of dangerous behaviour and establishment of a provisional diagnosis. Three specific strategies may be necessary when dealing with the violent patient:

- Reassurance and explanation
- Medication.
- Physical restraint.

Remember that the behaviour exhibited is a reflection of an underlying disorder and as such portrays suffering and often fear. The approach to the agitated or even the violent patient therefore must take this into account and the steps used are with the intention of alleviating this suffering whilst maintaining the safety of the individual, the other patients and staff. Technically speaking, this management begins at the point of an initial assessment that takes into account prior episodes of disturbed behaviour and its precipitants. Armed with this knowledge it may be possible to prevent a recurrence.

**‘Verbal de-escalation’**. If a patient’s behaviour causes concern, the first step is to try and defuse the situation. Put more simply, this means talking to the patient. It may be something that is relatively simple to correct that has led to the disturbed behaviour such as staff explaining their intentions in approaching the patient.

**Medication** may be used but an effort should always be made to offer this on an oral basis. The protocol in the UK is to offer a short-acting benzodiazepine in the first instance, such as lorazepam (0.5–1 mg). Patients suffering from a psychotic disorder and who are already taking antipsychotics may be more appropriately treated with an antipsychotic but do not assume that this is the case and be wary of the ‘neuroleptic-naïve’ patient. In the delirious or elderly patient, benzodiazepines should be avoided, as they may worsen any underlying confusion and can cause paradoxical agitation. In this instance, low-dose haloperidol is appropriate (2.5–5 mg). More recently, antihistamines have been added to this protocol, such as promethazine. Medications should be given sequentially, rather than all at once, where possible and allowing between 30 min and 1 h for them to take effect.

**Physical restraint.** In the instance that the above measures do not resolve the situation, physical restraint may be necessary in order to maintain safety and to administer medications on an intramuscular basis (note that for haloperidol this will alter the maximum dose it is safe to use in a 24-hour period). This should not be the first step taken nor should it be performed by staff unless they have been adequately trained in approved methods of control and restraint. This will typically mean nursing staff on a psychiatric ward or security staff on a general medical or surgical ward. Although this may vary between countries, in the UK it is the case that doctors will never be involved in the restraint of the patient. Restraint is a potentially dangerous intervention, even more so when mixed with psychotropic medication, and deaths have occurred as a direct consequence.

**Monitoring.** If medications (oral or otherwise) are employed, with or without restraint, regular monitoring of physical parameters such as blood pressure, pulse, respiratory rate and oxygen saturation should be performed at a frequency dictated by the level of ongoing agitation and consciousness.

**Defence mechanisms**

Although not strictly part of the mental state examination, it is useful to be able to identify psychological defences in ourselves and our patients. Defence mechanisms are mental processes that are usually unconscious. Some of the most commonly used defence mechanisms are described in Table 23.4 and are useful in understanding many aspects of behaviour.

**The relevant physical examination**

This should be guided by the history and mental state examination. Particular attention should usually be paid to

THE CLASSIFICATION OF PSYCHIATRIC DISORDERS

The classification of psychiatric disorders into categories is mainly based on symptoms and behaviours, since there are currently few diagnostic tests for psychiatric disorders. There currently exists an unhelpful dualistic division of psychiatric disorders from neurological diseases, since the pathologies of at least the majority of each group of conditions are located in the brain, e.g. Alzheimer’s disease causing dementia and a pseudobulbar palsy causing emotional lability.

Psychiatric classifications have traditionally divided up disorders into neuroses and psychoses.

- **Neuroses** are illnesses in which symptoms vary only in severity from normal experiences, such as depressive illness.

- **Psychoses** are illnesses in which symptoms are qualitatively different from normal experience, with little insight into their nature, such as schizophrenia.

There are several problems with a neurotic-psychotic dichotomy. First, neuroses may be as severe in their effects as psychoses. Second, neuroses may cause symptoms that fulfill the definition of psychotic symptoms. For instance, someone with anorexia nervosa may be convinced that they are fat when they are thin, and this belief would meet all the criteria for a delusional belief. Yet we would traditionally classify the illness as a neurosis.

The ICD-10 Classification of Mental and Behavioural Disorders published by the World Health Organization has largely abandoned the traditional division between neurosis and psychosis, although the terms are still used. The disorders are now arranged in groups according to major common themes (e.g. mood disorders and delusional disorders). A classification of psychiatric disorders derived from ICD-10 is shown in Table 23.5, and this is the classification mainly used in this chapter (ICD-11 will be available in 2014).

The Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-IV-TR) is an alternative classification system (DSM-V in 2013).

### CAUSES OF A PSYCHIATRIC DISORDER

A psychiatric disorder may result from several causes which may interact. It is most helpful to divide causes into the three “Ps”: predisposing, precipitating and perpetuating factors.

- **Predisposing factors** often stem from early life and include genetic, pregnancy and delivery, previous emotional traumas and personality factors.

- **Precipitating (triggering) factors** may be physical, psychological or social in nature. Whether they produce a disorder depends on their nature, severity and the presence of predisposing factors. For instance a death of a close, rather than distant, family member is more likely to precipitate a pathological grief reaction in someone who has not come to terms with a previous bereavement.

- **Perpetuating (maintaining) factors** prolong the course of a disorder after it has occurred. Again they may be physical, psychological or social, and several are often active and interacting at the same time. For example, high levels of criticism at home combined with taking cannabis, as relief from the criticism, may help to maintain schizophrenia.

### PSYCHIATRIC ASPECTS OF PHYSICAL DISEASE

People with non-psychiatric, ‘physical’ diseases are more likely to suffer from psychiatric disorders than those who are well. The most common psychiatric disorders in physically unwell patients are mood or adjustment disorders and acute organic brain disorders (delirium). The relationship between psychological and physical symptoms may be understood in one of four ways:

- Psychological distress and disorders can precipitate physical diseases (e.g. the cardiac risk associated with depressive disorders or hypokalaemia causing arrhythmias in anorexia nervosa).
- Physical diseases and their treatments can cause psychological symptoms or ill-health (Table 23.6).
- Both the psychological and physical symptoms are caused by a common disease process (e.g. Huntington’s chorea).
- Physical and psychological symptoms and disorders may be independently co-morbid, particularly in the elderly.

Factors that increase the risk of a psychiatric disorder in someone with a physical disease are shown in Table 23.7.

### Differences in treatment

Although the basic principles are the same as in treating psychiatric illnesses in the physically healthy, there are some differences:

- **Uncertainty** regarding the physical diagnosis or prognosis, with its attendant tendency to imagine the worst, is often a triggering or maintaining factor, particularly in an adjustment or mood disorder. Good two-way communication between doctor and patient, with time taken to listen to the patient’s concerns, is often the most effective ‘antidepressant’ available.
- The history may reveal the role of a physical disease or treatment exacerbating the psychiatric condition, which should then be addressed (Table 23.6). For example, the dopamine agonist bromocriptine can precipitate a psychosis.
- When prescribing psychotropic drugs, the dose should be reduced in disorders affecting pharmacokinetics, e.g. fluoxetine in renal or hepatic failure.
- **Drug interactions** should be of particular concern, e.g. lithium and non-steroidal anti-inflammatory drugs.
- Sometimes a physical treatment may be planned that may exacerbate the psychiatric condition. An example would be high-dose steroids as part of chemotherapy in a patient with leukaemia and depressive illness.
- Always remember the risk of suicide in an inpatient with a mood disorder and take steps to reduce that risk; for example, moving the patient to a room on the ground floor and/or having a registered mental health nurse attend the patient while at risk.

### THE SICK ROLE AND ILLNESS BEHAVIOUR

The sick role describes behaviour usually adopted by ill people. Such people are not expected to fulfil their normal social obligations. They are treated with sympathy by others and are only obliged to see their doctor and take medical advice or treatments.

**Illness behaviour** is the way in which given symptoms may be differentially perceived, evaluated and acted (or not acted) upon by different kinds of persons. We all have illness behaviour when we choose what to do about a symptom. Going to see a doctor is generally more likely with more severe, distressing and numerous symptoms. It is also more likely in introspective individuals who focus on their health.

**Abnormal illness behaviour** occurs when there is a discrepancy between the objective pathology present and the patient’s response to it, in spite of adequate medical investigation and explanation.

---

- Irritable or functional bowel syndrome
- Irritable bladder

**FUNCTIONAL OR PSYCHOSOMATIC DISORDERS**

So-called functional (in contrast to ‘organic’) disorders are illnesses in which there is no obvious pathology or anatomical change in an organ and there is a presumed dysfunction of an organ or system. Examples are given in Table 23.8. The psychiatric classification of these disorders would be somatoform disorders, but they do not fit easily within either medical or psychiatric classification systems, since they occupy the borderland between them. This classification also implies a dualistic ‘mind or body’ dichotomy, which is not supported by neuroscience. Since current classifications still support this outmoded understanding, this chapter will address these conditions in this way.

The word psychosomatic has had several meanings, including psychogenic, ‘all in the mind’, imaginary and malinger. The modern meaning is that psychosomatic disorders are syndromes in which both physical and psychological factors are likely to be causative. So-called medically unexplained symptoms and syndromes are very common in both primary care and the general hospital (over half the outpatients in gastroenterology and neurology clinics have these syndromes). Because orthodox medicine has not been particularly effective in treating or understanding these disorders, many patients perceive their doctors as unsympathetic and seek out complementary or even alternative treatments of uncertain efficacy.

Because epidemiological studies suggest that having one of these syndromes significantly increases the risk of having another, some doctors believe that these syndromes represent different manifestations of a single ‘functional syndrome’, indicating a global somatization process. Functional disorders also have a significant association with depressive and anxiety disorders. Against this view is the evidence that the majority of primary care people with most of these disorders do not have either a mood or other functional disorder. It also seems that it requires a major stress or the development of a co-morbid psychiatric disorder in order for such sufferers to see their doctor, which might explain why doctors are so impressed with the associations between both stress and psychiatric disorders. Doctors have historically tended to diagnose ‘stress’ or ‘psychosomatic disorders’ in people with symptoms that they cannot explain. History is full of such disorders being reclassified as research clarifies the pathology. A famous example is writer’s cramp (p. 1122) which most neurologists now agree is a dystonia rather than a neurosis.

The likelihood is that these functional disorders will be reclassified as their causes and pathophysiology are revealed. Functional brain scans suggest enhancement of brain activity during interoception in more than one syndrome. Interoception is the perception of internal (visceral) phenomena, such as a rapid heartbeat.

**Chronic fatigue syndrome (CFS)**

There has probably been more controversy over the existence and cause of CFS than any other ‘functional’ syndrome in recent decades. This is reflected in its uncertain classification as neurasthenia in the psychiatric classification and myalgic encephalomyelitis (ME) under neurological diseases. There is now good evidence for the independent existence of this syndrome, although the diagnosis is made clinically and by exclusion of other fatiguing disorders. Its prevalence is 0.5–2.5% worldwide, mainly depending on how it is defined. It occurs most commonly in women between the ages of 20 and 50 years.

**Clinical features**

The cardinal symptom is chronic fatigue made worse by minimal exertion. The fatigue is usually both physical and mental, associated most commonly with:
- poor concentration
- impaired registration of memory
- alteration in sleep pattern (either insomnia or hypersomnia)
- muscular pain.

Mood disorders are present in a large minority of patients, and can cause problems in diagnosis because of the overlap in symptoms. These mood disorders may be secondary, independent (co-morbid), or primary (with a misdiagnosis of CFS).

**Aetiology**

Functional disorders often have some aetiological factors in common with each other (Table 23.9), as well as more specific aetiologies. In common, for instance, CFS can be triggered by certain infections, such as infectious mononucleosis and viral hepatitis. About 10% of patients who have infectious mononucleosis have CFS 6 months after the onset of infection, yet there is no evidence of persistent infection in these patients. Those fatigue states which clearly do follow a viral infection can also be classified as post-viral fatigue syndromes.

Other aetiological factors are uncertain. Immune and endocrine abnormalities noted in CFS may be secondary to the inactivity or sleep disturbance commonly seen. The role of stress is uncertain, with some indication that the influence of stress is mediated through consequent psychiatric disorders exacerbating fatigue, rather than any direct effect.

**Management**

The general principles of the management of functional disorders are given in Box 23.4. Specific management of CFS should include a mutually agreed and supervised programme of gradually increasing activity. However, only a quarter of patients recover after treatment. It is sometimes difficult to persuade a patient to accept what are inappropriately perceived as ‘psychological therapies’ for such a physically manifested condition. Antidepressants do not work in the absence of a mood disorder or insomnia.

**Prognosis**

Prognosis is poor without treatment, with less than 10% of hospital attenders recovered after 1 year. Outcomes are worse with greater severity, increasing age, co-morbid mood disorders, and the conviction that the illness is entirely physical. A large trial showed that about 60% improve with active rehabilitative treatments, such as graded exercise therapy and cognitive behaviour therapy when added to specialist medical care.
Apart from the general principles in Management, there are associations with depressive and anxiety disorders, other functional disorders, physical deconditioning and fatigue and sleep disturbance (see p. 1162). Different specialists have different views.

**Box 23.4 Management of functional somatic syndromes**

The first principle is the identification and treatment of maintaining factors (e.g. dysfunctional beliefs and behaviours, mood and sleep disorders).

- **Communication**
  - Explanation of ill-health, including diagnosis and causes
  - Education about management (including self-help leaflets)
- **Stopping drugs** (e.g. caffeine causing insomnia, analgesics causing dependence)
- **Rehabilitative therapies**
  - Cognitive behaviour therapy (to challenge unhelpful beliefs and change coping strategies)
  - Supervised and graded exercise therapy for approximately 3 months (to reduce inactivity and improve fitness)
- **Pharmacotherapies**
  - Specific antidepressants for mood disorders, analgesia and sleep disturbance (e.g. 10–50 mg of amitriptyline at night for sleep and pain)
  - Symptomatic medicines (e.g. appropriate analgesia, taken only when necessary)

**Other chronic pain syndromes**

A chronic pain syndrome is a condition of chronic disabling pain for which no medical cause can be found. The psychiatric classification would be a persistent somatoform pain disorder, but this is unsatisfactory since the criteria include the stipulation that emotional factors must be the main cause, and it is clinically difficult to be that certain.

The main sites of chronic pain syndromes are the head, face, neck, lower back, abdomen, genitalia or all over (CWP, fibromyalgia). “Functional” low back pain is the commonest ‘physical’ reason for being off sick long term in the UK (p. 503). Quite often, a minor abnormality will be found on investigation (such as mild cervical spondylosis on the neck X-ray), but this will not be severe enough to explain the severity of the pain and resultant disability. These pains are often unremitting and respond poorly to analgesics. Sleep disturbance is almost universal and co-morbid psychiatric disorders are commonly found.

**Aetiology**

The perception of pain involves sensory (nociceptive), emotional and cognitive processing in the brain. Functional brain scans suggest that the brain responds abnormally to pain in these conditions, with increased activation in response to chronic pain. This could be related to conditioned behavioural and physiological responses to the initial acute pain. The brain may then adapt to the prolonged stimulus of the pain by changing its central processing. The prefrontal cortex, thalamus and cingulate gyrus seem to be particularly affected and some of these areas are involved in the emotional appreciation of pain in general. Thus, it is possible to start to understand how beliefs, emotions and behaviours might influence the perception of chronic pain (Table 23.9).

**Management**

Management involves the same principles as used in other functional syndromes (Box 23.4). Since analgesics are rarely effective, and can cause long-term harm, patients should be encouraged to gradually reduce their use. It is often helpful to involve the patient’s immediate family or partner, to ensure...
that the partner is also supported and not unconsciously discouraging progress.

Specific drug treatments are few:

- **Nerve blocks** are not usually effective.
- **Anticonvulsants** such as carbamazepine, gabapentin and pregabalin may be given a therapeutic trial if the pain is thought to be neuropathic (see p. 1124).
- **Tricyclic antidepressants**: The antidepressant dosulepin is an effective treatment in half of the patients who have atypical facial pain, and this effect seems to be independent of dosulepin’s effect on mood. Another tricyclic antidepressant, amitriptyline, is helpful in tension headaches, which might be related to its independent analgesic effect. Amitriptyline has the added bonus of increasing slow wave sleep, which may be why it is more effective than NSAIDs in chronic widespread pain.

Tricyclic antidepressants that affect both serotonin and noradrenaline (norepinephrine) reuptake (e.g. p. 1172) seem to be more effective than more selective noradrenaline reuptake inhibitors, e.g. in neuropathic pain. There is some evidence that tricyclics are generally superior to SSRIs in chronic pain syndromes.

**Irritable bowel syndrome**

This is one of the commonest functional syndromes, affecting some 10–30% of the population worldwide. The clinical features and management of the syndrome and the related functional bowel disorders are described in more detail in chapter 6. Although the majority of sufferers with the irritable bowel syndrome (IBS) do not have a psychiatric disorder, depressive illness should be excluded in people with constipation and a poor appetite. Anxiety disorders should be excluded in people with nausea and diarrhoea. Persistent abdominal pain or a feeling of emptiness may occasionally be the presenting symptom of a severe depressive illness, particularly in the elderly, with a nihilistic delusion that the body is empty or dead inside (see p. 1168).

**Management**

This is dealt with in more detail in Box 23.4. Seeing a physician who provides specific education that particularly addresses individual illness beliefs and concerns can provide lasting benefit. Psychological therapies that help the more severely affected include:

- cognitive behaviour therapy
- biofeedback
- hypnotherapy
- brief interpersonal psychotherapy.

If indicated, the choice of antidepressant should be determined by the effects of these drugs on bowel transit times, with tricyclic antidepressants normally slowing and selective serotonin reuptake inhibitors (SSRIs) (p. 1172) normally speeding up transit times.

**Multiple chemical sensitivity, Candida hypersensitivity, and food allergies**

Some complementary health practitioners, doctors and patients themselves make diagnoses of multiple chemical sensitivities (MCS) (e.g. to foods, smoking, perfumes, petrol), Candida hypersensitivity and allergies (to food, tap-water and even electricity). Symptoms and syndromes attributed to these putative disorders are numerous and variable and include all the functional disorders, mood disorders and arthritis. Scientific support for the existence of these disorders is weak, particularly when double-blind methodologies have been used.

**Type 1 hypersensitivities** to foods such as nuts certainly exist, although they are fortunately uncommon (approximately 3/1000) (see pp. 68, 69). Direct specific food intolerances also occur (e.g. chocolate with migraine, caffeine with IBS).

**Candidiasis** can occur in the gastrointestinal tract in immunocompromised individuals, such as those with AIDS. Vaginal candidiasis can occur after antibiotic treatment in otherwise healthy women. A double-blind and controlled study of nystatin in women diagnosed as having candidiasis hypersensitivity syndrome showed that vaginitis was the only condition relieved more by nystatin than placebo. There is little evidence of *Candida* having a systemic role in other symptoms.

In spite of this evidence, the patient is often convinced of the legitimacy and usefulness of these diagnoses and their treatments.

**Aetiology**

Surveys of patients diagnosed with MCS or food allergies have shown high rates of current and previous mood and anxiety disorders (Table 23.9). Eating disorders (p. 1188) should be excluded in people with food intolerances. Some patients taking very low carbohydrate diets as putative treatments may develop reactive hypoglycaemia after a high carbohydrate meal, which they then interpret as a food allergy.

Classical conditioning can produce intolerance to foods and smells in healthy people and this may be a causative mechanism in some people with intolerance. This supports the existence of these intolerance conditions, but suggests they may be conditioned responses with attendant physiological consequences. This might explain why double-blinding sometimes abolishes the reaction to the stimulus.

**Management**

The general principles in Box 23.4 apply. If one assumes a phobic or conditioned response is responsible, graded exposure (systematic desensitization) to the conditioned stimulus may be worthwhile. Preliminary studies do suggest that this approach may successfully treat such intolerances, in the context of cognitive behaviour therapy.

**Premenstrual syndrome**

The premenstrual syndrome (PMS) consists of both physical and psychological symptoms that regularly occur during the premenstrual phase and substantially diminish or disappear soon after the period starts.

- Physical symptoms include headache, fatigue, breast tenderness, abdominal distension and fluid retention.
- Psychological symptoms can include irritability, emotional lability or low mood, and tension.

The premenstrual (late luteal) dysphoric disorder (PMDD) is a severe form of PMS with marked mood swings, irritability, depression and anxiety accompanying the physical symptoms. Women who generally suffer from mood disorders may be more prone to experience this disorder. The prevalence of PMS does not vary between cultures and is reported by the majority (75%) of women at some time in their lives. Severely disabling PMS (PMDD) occurs in about 3–8% of women.

The cause of the premenstrual syndrome remains unclear, although exacerbating factors include some of those outlined in Table 23.9. Research suggests that abnormalities of reproductive hormone receptors may play a role.
Management
The general principles in Box 23.4 apply. Treatments with vitamin B6 (p. 210), diuretics, progesterone, oral contraceptives, oil of evening primrose and oestrogen implants or patches (balanced by cyclical norethisterone) remain empirical. Psychotherapies aimed at enhancing the patient’s coping skills can reduce disability. Two trials suggest that graded exercise therapy improves symptoms. Several studies have demonstrated that SSRIs (p. 1172) are effective treatments for the premenstrual dysphoric disorder.

The menopause
The clinical features and management of the menopause are described on page 973. A prospective study has shown that there is no increased incidence of depressive disorders at this time. Such a significant bodily change, sometimes occurring at the same time as children leaving home, is naturally accompanied by an emotional adjustment that does not normally amount to a pathological state.

SOMATOFORM DISORDERS
As explained in the section on functional disorders (p. 1162), the classification of somatoform disorders is unsatisfactory because of the uncertain nature and aetiology of these disorders. However, there are certain disorders, beyond those described in ‘functional disorders’, that present frequently and coherently enough to be usefully recognized.

Somatization disorder
One in 10 patients presenting with a functional disorder will fulfil the criteria of a chronic somatization disorder. The condition is composed of multiple, recurrent, medically unexplained physical symptoms, usually starting early in adult life. Symptoms may be referred to almost any part or bodily system. The patient has often had multiple medical opinions and repeated negative investigations. Medical reassurance that the symptoms do not have a demonstrable physical cause fails to reassure the patient, who will continue to ‘doctor-shop’. The patient is usually reluctant to accept a psychological and/or social explanation for the symptoms. Abnormal illness behaviour is evident and patients can be attention-seeking and dependent on doctors. Yet they can complain about the medical care and attention they have previously received.

The aetiology is unknown, but both mood and personality disorders are often also present. It is often associated with dependence upon or misuse of prescribed medication, usually sedatives and analgesics. There is often a history of significant childhood traumas, or chronic ill-health in the child or parent, which may play an aetiological role or help to explain difficult therapeutic relationships (Table 23.9). The condition is probably the somatic presentation of psychological distress, although iatrogenic damage (from postoperative and drug-related problems) soon complicates the clinical picture. The course of the disorder is chronic and disabling, with long-standing family, marital and/or occupational problems.

Hypochondriasis
The conspicuous feature is a preoccupation with an assumed serious disease and its consequences. Patients commonly believe that they suffer from cancer or AIDS, or some other serious condition. Characteristically, such patients repeatedly request laboratory and other investigations to either prove they are ill or reassure themselves that they are well. Such reassurance rarely lasts long before another cycle of worry and requests begins. The symptom of hypochondriasis may be secondary to or associated with a variety of psychiatric disorders, particularly depressive and anxiety disorders. Occasionally the hypochondriasis is delusional, secondary to schizophrenia or a depressive psychosis. Hypochondriasis may co-exist with physical disease but the diagnostic point is that the patient’s concern is disproportionate and unjustified.

Management of somatoform disorders
The principles outlined in Box 23.4 apply to these disorders. Since they have a poor prognosis, the aim is to minimize disability. Furthermore, it is vital that all members of staff and close family members adopt the same approach to the patient’s problems. The patients often consciously or unconsciously split both medical staff and family members into ‘good’ and ‘bad’ (or caring and uncaring) people, as a way of projecting their distress.

Patients appreciate a discussion and explanation of their symptoms. The doctor should sensitively explore possible psychological and social difficulties, if possible by demonstrating links between symptoms and stresses. Such discussion usually gives information that can be used to formulate an agreed plan of management. A contract of mutually agreed care involving the appropriate professionals (general practitioner, and a choice of psychotherapist, health psychologist, complementary health professional, physician or psychiatrist), with agreed frequency of visits and a review date, can be helpful in managing the condition. Management also includes cessation of reassurance that no serious disease has been uncovered, since this simply reinforces dependence on the doctor. Repeated laboratory investigations should be discouraged.

Cognitive behaviour therapy has been shown to provide effective rehabilitation in significant numbers of patients suffering from a somatoform disorder.

Dissociative/conversion disorders

A dissociative disorder is a condition in which there is a profound loss of awareness or cognitive ability without medical explanation. The term dissociative indicates the disintegration of different mental activities, and covers such phenomena as amnesia, fugues and pseudoseizures (non-epileptic attacks).

Conversion disorder occurs when an unresolved conflict is converted into usually symbolic physical symptoms as a defence against it. Such symptoms commonly include paralysis, abnormal movements, sensory loss, aphony, disorders of gait and pseudocyesis (false pregnancy). The lifetime prevalence has been estimated at 3–6 per 1000 in women, with a lower prevalence in men. Most cases begin before the age of 35 years. Dissociation is unusual in the elderly.

Clinical features
The various symptoms are usually divided into dissociative and conversion categories (Table 23.10). Dissociative disorders have the following three characteristics that are necessary in order to make the diagnosis:

- They occur in the absence of physical pathology that would fully explain the symptoms.

Related reading
They are produced unconsciously.

Symptoms are not caused by overactivity of the sympathetic nervous system. Other characteristics include:

- Symptoms and signs often reflect a patient’s ideas about illness.
- There is usually abnormal illness behaviour, with exaggeration of disability.
- There may have been significant childhood traumas.
- **Primary gain** is the immediate relief from the emotional conflict.
- **Secondary gain** refers to the social advantage gained by the patient by being ill and disabled (sympathy of family and friends, being off work, disability pension).

Physical disease is not uncommonly also present (e.g. pseudoseizures are more common in someone with epilepsy).

**Dissociative amnesia** commences suddenly. Patients are unable to recall long periods of their lives and may even deny any knowledge of their previous life or personal identity. In a dissociative fugue, patients not only lose their memory but wander away from their usual surroundings, and, when found, deny all memory of their whereabouts during this wandering. The differential diagnosis of a fugue state includes post-epileptic automatism, depressive illness and alcohol misuse.

**Multiple personality disorder** is rare, but dramatic, and may be triggered by suggestion on the part of a psychotherapist. There are rapid alterations between two or more ‘personalities’ in the same person, each of which is repressed and dissociated from the other ‘personalities’. A differential diagnosis is rapid cycling manic depressive disorder which would explain sudden apparent changes in personality.

**Differential diagnosis**

Dissociation is usually a stable and reliable diagnosis over time, though high rates of co-morbid mood and personality disorders are found in chronic sufferers. Particular care should be taken to make the diagnosis on positive grounds, and not simply on the basis of an absence of a medical diagnosis. Care should also be taken to exclude or treat co-morbid psychiatric disorders.

**Aetiology**

Functional brain scans differ between healthy controls feigning a motor abnormality and people with a similar conversion motor symptom, which suggests that dissociation involves different areas of the brain from simulation (Fig. 23.1). Functional brain scanning of a patient with conversion paralysis has shown that recalling a past trauma not only activated the emotional areas, such as the amygdala, but also reduced motor cortex activity. This would suggest that conversion involves a disinhibition of voluntary will at an unconscious level, so that the patient can no longer will something to happen.

The psychoanalytical theory of dissociation is that it is the result of emotionally charged memories that are repressed into the unconscious at some point in the past. Symptoms are explained as the combined effects of repression and the symbolic conversion of this emotional energy into physical symptoms. This hypothesis is difficult to test, although there is some evidence that people with dissociative disorders are more likely to have suffered childhood abuse, particularly when the abuse was both sexual and physical and started early in childhood. Caution should be taken with such a history obtained by therapies that ‘recover’ childhood memories that were previously completely unknown to the patient.

People with dissociative disorders by definition adopt both the sick role and abnormal illness behaviour, with consequent secondary gains that help to maintain the illness.

**Management**

The treatment of dissociation is similar to the treatment of somatoform disorders in general, outlined above and in **Box 23.4**. The first task is to engage the patient and their family with an explanation of the illness that makes sense to them, is acceptable, and leads to the appropriate management. An invented example of a suitable explanation is given in **Box 23.5**. Such an explanation would be modified by mutual discussion until an agreed understanding was achieved, which would serve as a working model for the illness. Provision of a rehabilitation programme that addresses both the physical and psychological needs and problems of the patient would then be planned.

- A graded and mutually agreed plan for a return to normal function can usually be led by the appropriate therapist (e.g. speech therapist for dysphonia, physiotherapist for paralysis).
Sleep difficulties

At the same time, a psychotherapeutic assessment should be made in order to determine the appropriate form of psychotherapy. For instance, couple therapy will address a significant relationship difficulty; individual psychotherapy could ease an unresolved conflict from childhood.

Abreaction brought about by hypnosis or by intravenous injections of small amounts of midazolam may produce a dramatic, if sometimes short-lived, recovery. In the abreactive state, the patient is encouraged to relive the stressful events that provoked the disorder and to express the accompanying emotions, i.e. to abreact. Such an approach has been useful in the treatment of acute dissociative states in wartime, but appears to be of less value in civilian life. It should only be contemplated in the presence of an anaesthetist with suitable resuscitation equipment to hand.

Hypnotherapy is psychotherapy while the patient is in a hypnotic trance, the idea being that therapy is more possible because the patient is relaxed and not using repression. This may allow the therapist access to the previously unconscious emotional conflicts or memories. There are no published trials of this technique in dissociation, which Freud gave up as unsuccessful in order to found psychoanalysis, but some hypnotherapists claim good results. Care should be taken to avoid a catastrophic emotional reaction when the patient is suddenly faced with the previously repressed memories.

Prognosis

Most cases of recent onset recover quickly with treatment, which is why a positive diagnosis should be made early. Those cases that last longer than a year are likely to persist, and when under stress (Box 23.6). It can often be triggered by one of these factors, but then become a habit on its own, and when under stress or suffering from a mood disorder. Sleep disorders secondary to another medical diagnosis will not be discussed here.

Psychophysiological insomnia commonly occurs secondary to functional, mood and substance misuse disorders, and when under stress (Box 23.6). It can often be triggered by one of these factors, but then become a habit on its own, driven by anticipation of insomnia and day-time naps. Insomnia causes day-time sleepiness and fatigue, with consequences such as road traffic accidents. Assessment should pay particular attention to mood, life difficulties and drug intake (especially alcohol, nicotine and caffeine), and the timing of the insomnia should be ascertained.

Initial insomnia (trouble getting off to sleep) is common in mania, anxiety, depressive disorders and substance misuse.

■ Middle insomnia (waking up in the middle of the night) occurs with medical conditions such as sleep apnoea and prostatism.

■ Late insomnia (early morning waking) is caused by depressive illness and malnutrition (anorexia nervosa).

Habitual alcohol consumption should be carefully estimated since even a small excess can be a potent cause of insomnia, as well as recent withdrawal. Caffeine is perhaps the most commonly taken drug in the UK, and its effects are easily underestimated. Six cups of real coffee a day are likely to cause insomnia in the average healthy adult. Caffeine is not only found in tea and coffee, but is also found in chocolate, cola drinks and some analgesics. Prescription drugs that can either disturb sleep or cause vivid dreams include most appetite suppressants, glucocorticoids, dopamine agonists, lipid-soluble beta-blockers (e.g. propranolol) and certain psychotropic drugs (especially when first prescribed, e.g. fluoxetine, reboxetine, risperidone).

Hypersomnia is not uncommon in adolescents with depressive illness, occurs in narcolepsy, and may temporarily follow infections such as infectious mononucleosis.

Management of insomnia

This is determined by diagnosis. Where none is immediately apparent, it is worth educating the patient about sleep hygiene. In addition:

■ Simple measures such as decreasing alcohol intake, having supper earlier, exercising daily, having a hot bath prior to going to bed and establishing a routine of going to bed at the same time should all be tried.

■ Relaxation techniques and cognitive behaviour therapy have a role in those with intractable insomnia.

■ Short half-life benzodiazepines can be useful for acute insomnia, but should not be used for more than 2 weeks continuously to avoid dependence.

■ Non-benzodiazepine hypnotics (zaleplon, zopiclone, zolpidem) act at the benzodiazepine receptors and occasional dependence has been reported.

■ Certain antihistamines (e.g. diphenhydramine and promethazine) and antidepressants (e.g. amitriptyline, trimipramine, trazodone, mirtazapine) are not addictive and can be used as hypnotics in low dose, with the added advantage of improving slow wave sleep. The commonest side-effects are morning sedation and weight gain.

MOOD (AFFECTIVE) DISORDERS

Classification

The central feature of these disorders is an abnormality of mood. Mood is best described in terms of a continuum ranging from severe depression at one extreme to severe mania at the other, with the normal, stable mood in the middle. Mood disorders are divided into bipolar and unipolar affective disorders.

Bipolar affective disorder

Patients suffer bouts of both depression and mania. Although mania can rarely occur by itself without depressive mood swings (thus being ‘unipolar’), it is far more commonly found in association with depressive swings, even if sometimes it takes several years for the first depressive illness to appear.

Bipolar I disorder is defined as one or more manic or mixed (signs of mania and depression) episodes.

Bipolar II is defined as a depressive episode with at least one episode of hypomania (this is shorter lived than mania and is not accompanied by psychotic symptoms). Hypomania is noticeably abnormal but does not result in functional impairment or hospitalization.

Bipolar III disorder is less well established and describes depressive episodes, with hypomania occurring only when taking an antidepressant.

About 10% of patients who have depressive illness are eventually found to have a bipolar illness.

Unipolar affective disorders

Patients suffer from depressive episodes alone, although they are commonly recurrent.

Depressive disorders

Depressive disorders or ‘episodes’ are classified by the ICD-10 as mild, moderate or severe, with or without somatic symptoms. Severe depressive episodes are divided according to the presence or absence of psychotic symptoms.

Clinical features of depressive disorder

Whereas everyone will at some time or other feel ‘fed up’ or ‘down in the dumps’, it is when such symptoms become qualitatively different, pervasive or interfere with normal functioning that a depressive illness has occurred. Depressive disorder, clinical or ‘major’ depression, is characterized by disturbances of mood, speech, energy and ideas (Table 23.11). Patients often describe their symptoms in physical terms. Marked fatigue and headache are the two most common physical symptoms in depressive illness and may be the first symptoms to appear. Patients describe the world as looking grey, themselves as lacking a zest for living, being devoid of pleasure and interest in life (anhedonia). Anxiety and panic attacks are common; secondary obsessional and phobic symptoms may emerge. Symptoms should last for at least 2 weeks and should cause significant incapacity (e.g. trouble working or relating to others) in order to be dealt with as an illness.

Dysthymia is a mild or moderate depressive illness that lasts intermittently for 2 years or more and is characterized by tiredness and low mood, lack of pleasure, low self-esteem and a feeling of discouragement. The mood relapses and remits, with several weeks of feeling well, soon followed by longer periods of being unwell. It can be punctuated by depressive episodes of greater severity, so-called ‘double depression’.

Seasonal affective disorder
Seasonal affective disorder is characterized by recurrent episodes of depressive illness occurring during the winter months in the northern hemisphere. Symptoms are similar to those found with atypical depressive illness, in that patients complain of hypersomnia, increased appetite (with carbohydrate craving) and weight gain, with profound fatigue. Such patients have a higher prevalence of bipolar affective disorder, and some doctors are uncertain whether the condition is different from normal depressive illness, with the accentuation of mood that naturally occurs by season. However, there is evidence that seasonal depressive illness can be successfully treated with bright light therapy given in the early morning, which causes a phase advance in the circadian rhythm of melatonin. In contrast, the same treatment given in the early evening, with consequent phase delay of melatonin secretion, is less antidepressant. Selective serotonin reuptake inhibitors (SSRIs) are alternative treatments.

Puerperal affective disorders
Affective illnesses and distress are common in women soon after they have given birth. ‘Maternity blues’ describe the brief episodes of emotional lability, irritability and tearfulness that occur in about 50% of women 2–3 days postpartum and resolve spontaneously in a few days.

Postpartum psychosis occurs once in every 500–1000 births. Over 80% of cases are affective in type and the onset is usually within the first 2 weeks following delivery. In addition to the classical features of an affective psychosis, disorientation and confusion are often noted. Severely depressed patients may have delusional ideas that the child is deformed, evil or otherwise affected in some way, and such false ideas may lead to either attempts to kill the child or suicide. The response to speedy treatment is generally good. The recurrence rate for a psychosis in a subsequent puerperium is 20–30%.

Non-psychotic postnatal depressive disorders occur during the first postpartum year in 10% of mothers, especially in the first 3 months. Risk factors are first pregnancy, poor relationship with the partner, ambivalence about the pregnancy, and emotional personality traits. The Edinburgh Postnatal Depression Scale (EPDS) is a 10-item questionnaire and can be used as an effective screening tool. Depressive illness after childbirth is clinically similar to other depressive illnesses, but lack of emotional bonding with the baby is common.

Differential diagnosis
The differential diagnoses of depressive illness are shown in Table 23.12. Other psychiatric disorders are the most common misdiagnoses. Some 90% of patients presenting with a depressive illness while misusing alcohol will no longer be depressed 2 weeks after their last drink.

Pathological (abnormal) and normal grief are described on page 1180. Pathological grief is closely associated with depressive illness.

Investigations
A corroborative history can be valuable in helping to exclude differential diagnoses such as alcohol misuse and elucidating maintaining factors such as a poor relationship with a partner.
related neuropsychiatric disorders, including recurrent depression. The hippocampus is smaller in several stress-related neuropsychiatric disorders, including recurrent depression. The anterior cingulate cortex altered activation have all been implicated. Cognitive abnormalities seen in depression. Increased regions that are associated with both the emotional and cognitive abnormalities seen in depression. Increased brain ventricle volume, orbitofrontal, dorsolateral frontal and anterior cingulate cortex altered activation have all been implicated. The hippocampus is smaller in several stress-related neuropsychiatric disorders, including recurrent depression.

Neuroimaging changes

Neuroimaging studies have recently revealed a raised density of dopamine in monoamine oxidase A (MAO-A) receptors. It is proposed that depression is related to a chronic and ongoing depletion of these neurotransmitters as a result of this enzyme’s increased activity and its interaction with region-specific monoamine transporter densities. The relative transporter densities in particular regions and how they are affected by the global reduction in monoamine levels are then thought to determine the particular expression of the depressive illness and which symptoms predominate.

Neuroendocrine tests also suggest that the serotonin neurotransmitter system is downregulated. $5HT_{1A}$ and $5HT_{2}$ receptor subtypes are thought most likely to be involved. Receptor-labelled functional brain scans suggest that dopamine underactivity is related to psychomotor retardation.

Hypothalamo-pituitary-adrenal axis

The administration of exogenous steroids is associated with the onset of depressive symptoms and people with Cushing’s syndrome often demonstrate depressive episodes. Acute stress, whether physical or psychological, is associated with a rise in serum glucocorticoids. Severe depressive episodes have been associated with hypercortisolaemia (of note cortisol is low in ‘atypical’ depression with hyperphagia and hypersomnia). This cortisol dysregulation has been associated with impaired glucocorticoid negative feedback, adrenal hyper-responsiveness to ACTH and hypersecretion of CRH. Exposure to the high levels of cortisol is thought to directly affect neuronal plasticity and lower resistance to neuronal damage. The hippocampus seems especially susceptible to this, resulting in atrophic changes. This in turn has further deleterious effects on wider neuroendocrine function, resulting in a self-perpetuating dysregulation that may serve to maintain and/or worsen the illness. The interplay at this level becomes more complicated, with reduced central and peripheral glucocorticoid receptor sensitivity, hypothalamo-pituitary-adrenal (HPA) axis upregulation and the release of pro-inflammatory cytokines that may in turn explain changes in mood, fatigue, appetite, sensitivity to pain and libido (note that depression is a potentially dangerous side-effect of interferon treatment). Additionally at the cellular level, this affects monoamine transport, causes neuronal apoptosis and dysfunction of glial cells normally responsible for maintaining neuronal homeostasis.

Brain-derived neurotrophic factor

Healthy interactions between neurons and glial cells are maintained by brain-derived neurotrophic factor (BDNF), which is found in its greatest concentration in the hippocampus and cerebral cortex. It promotes cell growth and long-term potentiation (the enhancement of synchronous firing between two neurons). Pro-BDNF, its precursor, promotes the reduction of dendritic spines and apoptosis. BDNF is then involved in the growth and activity of neural networks.

Animal studies show it is reduced under stressful conditions.

Postmortem studies show reduced concentrations in suicide compared with non-suicide deaths.

Adult humans with untreated depressive illness have three times lower concentrations when compared with...
both healthy controls or those that have received antidepressant treatment.

- Low levels normalize with antidepressant treatment.

BDNF therefore has potential as an objective marker of depression and its response to treatment as well as being a potential target for treatment of the disorder itself.

### Sleep

A reduced time between onset of sleep and REM sleep (shortened REM latency) and reduced slow wave sleep both occur in depressive illness. These abnormalities persist in some patients when they are not depressed. Families with several sufferers of depressive illness can share these traits, suggesting that sleep patterns may be inherited and predispose to depression.

### Childhood traumas and personality

Physical, sexual and emotional abuse or neglect in childhood all predispose adults to depressive illness, but the effect is non-specific. Both ‘neurotic’ (emotional) and perfectionist personality traits are risks for depressive illness, and these may be determined as much by genetic factors as childhood environment.

### Social factors

Some 30% of women will develop a depressive illness after a severe life event or difficulty, such as a divorce, and this is compounded by low self-esteem and a lack of a confiding relationship. Unemployment is a significant risk factor in men.

### An integrated model of aetiology

Stress is more likely to trigger depressive illness in a person predisposed by lack of social support and/or certain personality traits. Stress in turn triggers various brain changes in both stress hormones (such as the release of corticotrophin-releasing hormone) and neurotransmitters (e.g. serotonin) that are both known to be altered in depressive illness. We can thus start to glimpse the model of an integrated biopsychosocial model of depressive illness. This model challenges dualistic ideas that depressive illnesses are either psychological or physical; depressive illnesses involve both the mind and the body, which are themselves indivisible.

### Treatment of depressive illness

The patient needs to know the diagnosis to provide understanding and rationalization of the overwhelming distress inherent in depressive illness. Knowing that self-loathing, guilt and suicidal thoughts are caused by the illness may have an ‘antinepressant’ effect. The further treatment of depressive disorders involves physical, psychological and social interventions (Box 23.8).

Patients who are actively suicidal, severely depressed (with or without psychotic symptoms) should be admitted to hospital. Admission is necessary for perhaps 1 in 1000 people with clinical depression in primary care. This provides the patient a break from self-care, and allows support, listening, observation, the close monitoring of treatments and the prevention of suicide. Avoid the pitfall of not treating a depressive illness just because it seems an ‘understandable’ reaction to serious illness or difficult circumstances. This is particularly likely to happen if the patient is elderly, severely or even terminally ill.

### Exercise

There is good evidence that regular exercise, particularly involving other people, can help relieve depressive illness of mild or moderate severity. The benefit is independent of a physical training effect.

### Drugs used in the treatment of clinical depression

Today’s antidepressants are designed to provide an acute increase in monoamine activity. They do this either through preventing reuptake or enzymatic degradation. Note that this occurs acutely and that although an equally rapid depletion of monoamines has an acute mood lowering effect, the mood elevating benefits of these drugs require weeks of continuous administration. The benefits are therefore unlikely to be due to this mechanism alone.

The effects of chronic administration of monoamine reuptake inhibitors are various. Examples include an increase in the synthesis of binding proteins necessary for serotonin receptor activity and increases in cyclic AMP activation which in turn increases BDNF synthesis, enhances glucocorticoid receptor sensitivity and inhibits cytokine signalling. These may be secondary to the acute restoration of monoamine levels but rely upon transcriptional and translational changes that alter neuronal plasticity. It is this protein synthesis-dependent process that is currently thought to be the final pathway responsible for the clinical effect of the drugs.

As the neurobiology for depressive illness becomes clearer, so too are novel approaches to its treatment; some of the novel targets under active investigation are listed in Box 23.9.

### Box 23.8 Management of depressive illness

**Physical**

- Stop depressing drugs (alcohol, steroids)
- Regular exercise (good for mild to moderate depression)
- Antidepressants (choice determined by side-effects, co-morbid illnesses and interactions)
- Adjunctive drugs (e.g. lithium; if no response to two different antidepressants)
- Electroconvulsive therapy (ECT) (if life-threatening or non-responsive)

**Psychological**

- Education and regular follow-up by same professional
- Cognitive behaviour therapy (CBT)
- Other indicated psychotherapies (couple, family, interpersonal)

**Social**

- Financial: eligible benefits, debt counselling
- Employment: acquire or change job or career
- Housing: adequate, secure tenancy, safe, social neighbours
- Young children: child-care support

**Treatments combined**

- The most effective treatment is a mixture of CBT and an antidepressant

### Box 23.9 Potential targets for novel antidepressant agents

| Brain-derived neurotrophic factor (BDNF) | Alpha-melanocyte stimulating hormone |
| Tumour necrosis factor-alpha (TNF-α) | Ghrelin |
| Interleukin-1 beta (IL-1β) | Leptin |
| Glucocorticoid receptors | Orexins |
| Corticotrophin-releasing hormone | Neuropeptide Y |
| Melanin concentrating hormone | Nesfatin-1 |

### Further reading

**General approach to drug treatment of depression**

- Recreational drugs such as alcohol should be stopped. Prescribed medicines suspected of exacerbating depression, such as corticosteroids, should be gradually stopped or reduced to a safe minimum.
- Treatment with antidepressants is more successful when accompanied by sufficient patient education and regular follow-up, particularly a week after starting treatment and throughout the following 6 weeks. Dysthymia responds less well to antidepressants than does a depressive episode.

  - The commonest two pharmacological types of antidepressants are selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs). All antidepressants have similar efficacy and speed of onset. Choice depends on their side-effects, which can be used to positive effect (sedating drugs given at night to enhance sleep), and their safety. A course of antidepressants should be given until 6 months after recovery from a first episode to prevent relapse. Stopping antidepressants immediately upon recovery leads to a 50% relapse rate within 6 months. The two greatest problems with these drugs are persuading the patient to take them and adherence, since 80% of the UK public wrongly believe that they are addictive.

**Drug choices in specific circumstances**

  - **Recurrent episodes:** maintenance treatment with the antidepressant at the dose that obtained remission should be continued for at least 2 years. Maintenance treatment beyond this point should be re-evaluated, taking into account age, co-morbidities and risk factors.
  - **Refractory depressive illness:** whilst 50% may show response, as few as 30% of individuals (outpatients) get a complete remission with the first choice of antidepressant agent. Strategies available at this point are switching drug classes or augmentation with other agents. This should be overseen by a specialist.
  - **Psychotic depression** needs either a combination of an antidepressant and an antipsychotic drug or electroconvulsive therapy.
  - **Bipolar depressive illness:** monotherapy with quetiapine has been proposed as the drug of choice. Other drugs include mood stabilizers or olanzapine, either alone or in combination with an antidepressant (see p. 1176).

**Selective serotonin reuptake inhibitors (SSRIs)**

SSRIs selectively inhibit the reuptake of the monoamine serotonin (5HT) within the synapse, and are thus termed ‘selective serotonin reuptake inhibitors’ or SSRIs. Citalopram and its laevo isomer escitalopram, fluvoxamine, fluoxetine, paroxetine, sertraline and venlafaxine (see p. 1176), a specific withdrawal syndrome, have also been reported with SSRIs. This is characterized by shivering, anxiety, dizziness, ‘electric shocks’, headache and nausea. Patients should be warned not to omit a dose and to gradually reduce SSRIs when stopping them. All antidepressants have the potential to cause a discontinuity syndrome if suddenly stopped.

**Tricyclic antidepressants (TCAs)**

These drugs potentiate the action of the monoamines, noradrenaline (norepinephrine) and serotonin, by inhibiting their reuptake into nerve terminals (Fig. 23.3). Other tricyclics in common use include nortriptyline, doxepin and clomipramine. Dosulepin, imipramine and amitriptyline are the three most commonly used in the UK, but many related compounds have been introduced, some having fewer autonomic and cardiotoxic effects (e.g. lofepramine).

TCAs have a number of side-effects (Table 23.13). In long-term treatment or prophylaxis, weight gain is most troublesome. Because of their toxicity in overdose, it is wisest not to prescribe them to outpatients who have suicidal thoughts without monitoring or giving the drugs to a reliable family member to look after.

**SNRIs and NRIs**

These antidepressants block a number of different neurotransmitter receptors both at the synapse and elsewhere. Their different receptor profiles cause different side-effects.

  - **SNRIs:** venlafaxine is a potent blocker of both serotonin and noradrenaline (norepinephrine) reuptake (SNRI); it has negligible affinity for other neurotransmitter receptor sites and so produces less sedation and fewer antimuscarinic effects. It can be given in slow-release
is suspected, it should be ruled out by ECG before starting treatment. Duloxetine works in a similar way to venlafaxine and has been found especially helpful with chronic pain.

- **NSSA**: mirtazapine is a 5HT₂ and 5HT₃ receptor antagonist and a potent α₂-adrenergic blocker. The consequent effect is to increase both noradrenaline (norepinephrine) and selective serotonin transmission: an NSSA. It can be given at night to aid sleep and rarely causes sexual side-effects. Mirtazapine can be sedating in low dose and can cause weight gain. An uncommon adverse effect is agranulocytosis.

**Monoamine oxidase inhibitors (MAOIs)**

These act by irreversibly inhibiting the intracellular enzymes monoamine oxidase A and B, leading to an increase of noradrenaline (norepinephrine), dopamine and 5HT in the brain (see Fig. 23.3). Because of their side-effects and restrictions while taking them, they are rarely used by non-psychiatrists. MAOIs also produce a dangerous hypertensive reaction with foods containing tyramine or dopamine and therefore a restricted diet is prescribed. Tyramine is present in cheese, pickled herring, yeast extracts, certain red wines, and any food, such as game, that has undergone partial decomposition. Dopamine is present in broad beans. MAOIs interact with drugs such as pethidine and can also occasionally cause liver damage.

**Reversible inhibitors of monoamine oxidase A (RIMAs)**

An example is moclobemide; usual dose 300 mg daily. These drugs appear to have fewer side-effects than the MAOIs (insomnia and headache, but some sexual problems) and constitute a low risk in overdose. Patients prescribed such antidepressants should be told that they can eat a normal diet, but should be careful to avoid excessive amounts of food rich in tyramine (see above).

**Antidepressant augmentation**

If two trials of antidepressants have failed, adding a second concomitant drug, e.g. lithium or tri-iodothyronine, can sometimes be helpful.

**Antidepressant use in general medicine**

- **Cardiac disease.** In people with cardiac disease, SSRIs, lofepramine and trazodone are preferred over more quinidine-like compounds.
- **Epilepsy.** MAOIs and mirtazapine do not affect epileptic thresholds.
- **Drug interactions.** SSRIs are metabolized by the cytochrome P450 system, unlike venlafaxine, mirtazapine and reboxetine; the latter therefore have fewer drug interactions.
- **Herbal medicine.** Care should be taken not to prescribe antidepressants while a patient is taking the herbal antidepressant St John’s wort, which interacts with serotonergic drugs in particular.
- **Elderly.** Doses of antidepressants should initially be halved in the elderly and in people with renal or hepatic failure.
- **Pregnancy.** Antidepressants should be avoided if possible in pregnancy and breast-feeding. If other treatments are ineffective, the risks of drug therapy should be balanced against taking no treatment, since depression can affect fetal progress and future mother-child bonding. Tricyclic antidepressants are generally

**Further reading**

believed to be safe in pregnancy, with no significant increase in congenital malformations in fetuses exposed to them. However, occasionally their antimuscarinic side-effects produce jitteriness, sucking problems and hyperexcitability in the newborn. Postpartum plasma levels of babies breast-fed by treated mothers are negligible. SSRIs do not seem to be teratogenic but manufacturers advise against their use in pregnancy until more data are available. Pulmonary hypertension in the newborn is a rare complication. MAOIs should be avoided during pregnancy because of the possibility of a hypertensive reaction in the mother.

Electroconvulsive therapy (ECT)
ECT is the treatment of choice in severe life-threatening depressive illness, particularly when psychotic symptoms are present. It is sometimes essential treatment when the patient is dangerously suicidal or refusing to eat and drink and when a rapid resolution is required such as in postpartum depressive illness, when returning baby to mother as soon as it is safe so to do forms part of the treatment.

The treatment is performed under general anaesthetic and involves the passage of an electric current across two electrodes applied to the anterior temporal areas of the scalp, in order to induce an epileptic fit. It was previously believed that the extent of the generalized seizure was proportional to its efficacy. We now know that the motonic seizure is less significant than its electrophysiological evidence (spike and wave activity on an EEG), without which benefit is unlikely to be seen. Treatments are normally given twice a week for 3–6 weeks.

ECT is a controversial treatment, yet it is free of serious side-effects. Most side-effects are due to the general anaesthetic; post-ictal confusion and headache are not uncommon, transient and short-term retrograde amnesia and a temporary defect in new learning can occur during the weeks of treatment, but these are typically short-lived effects. The frequency with which defects in autobiographical memory occur during the time of treatment should be noted. These are discrete and in most instances not recognized by the patient, unless the particular memory is actively sought. It is necessary to warn patients of its possibility beforehand.

Uncommonly used treatments
Transcranial magnetic stimulation (TMS) shows moderate efficacy, but is uncommonly used. Psychosurgery is very occasionally considered in people with severe intractable depressive illness, when all other treatments have failed (see p. 1181). A third improve remarkably, while a further third improve somewhat.

Vagal nerve and deep brain stimulation may represent major advances in the management of chronic and treatment-refractory depressive disorders, but definitive trials are not available.

Psychological treatments
Cognitive behaviour therapy (CBT)
Beck developed CBT to reverse the negative cognitive triad with which patients regarded themselves, their situation and their futures. It involves the identification of the negative automatic thoughts that maintain the negative perceptions that feed depression. They commonly include: catastrophizing (e.g. ‘I failed an exam; therefore I am a failure as a person.’); overgeneralizing (e.g. ‘I failed an exam; therefore I am a failure as a person.’); categorical (‘black or white’) thinking (e.g. ‘My work is either perfect or abysmal.’). CBT then involves identifying the links between these thoughts, consequent behaviour, and feeling low, and then testing their logic. This is done by looking at the evidence either in the therapy sessions (e.g. Q: ‘Did you pass the other exams you took?’; A: ‘Yes; I guess I did.’) or by behavioural ‘experiments’ (e.g. showing the ‘abysmal’ work to a colleague and asking their opinion).

There is good evidence that individual CBT is as effective as antidepressant drugs for mild and moderate depressive illness. CBT is also effective in preventing a relapse of clinical depression. Individual CBT is more effective than group delivered therapy, and there is preliminary evidence that computer delivered CBT programmes are also helpful, when used to supplement therapist involvement. Mindfulness-based CBT, based on the use of meditation, can play a helpful role in prevention of recurrence.

Interpersonal psychotherapy
This psychotherapy is probably as effective as both antidepressants and CBT in mild and moderate clinical depression. The therapist focuses on a patient’s interpersonal relationships involved in, or affected by, their illness (especially relationship changes or deficiencies), using problem-solving techniques to help the patient to find solutions.

Other psychotherapies
Couple therapy is particularly effective when a patient is in a problematic relationship that may be contributing to the perpetuation of the depressive illness; both the patient and partner attend therapy.

Family therapy is effective not only in a family with problems, but also as a way of helping the family to help the patient get better. It may involve understanding one family member’s ‘depression’ as a systemic ‘solution’ for a wider problem within the family.

Social treatments
Many people with clinical depression have associated social problems (Box 23.8). Assistance with social problems can make a significant contribution to clinical recovery. Other social interventions include the provision of group support, social clubs, occupational therapy and referral to a social worker. Educational programmes, self-help groups, and informed and supportive family members can help improve outcome.

Prognosis
Depression is one of the leading causes of disease burden worldwide. People with major depressive illness are between 1.5 and 2 times more likely to die than non-depressed people in the next 16 years, and the risks are not only suicide, but also cardiovascular. Depression produces greater disability than angina, arthritis, asthma and diabetes, which makes effective treatment and prevention imperative.

The majority of patients have recovered by 6 months in primary care and 12 months in secondary care. About a quarter of patients attending hospital with depressive illnesses will have a recurrence within 1 year, and three-quarters will have a recurrence within 10 years. People with recurrent depressive illnesses should be offered prevention. This may involve CBT that concentrates on relapse prevention, other forms of psychotherapy, antidepressant medication and advice on lifestyle activities such as regular exercise. Full-dose antidepressants are the most effective prophylaxis in recurrent depressive disorders.

Mania, hypomania and bipolar disorder
Mania and hypomania almost always occur as part of a bipolar disorder. The clinical features of mania include a
marked elevation of mood, characterized by euphoria, overactivity and disinhibition (Table 23.14). Hypomania is the mild form of mania. Hypomania lasts a shorter time and is less severe, with no psychotic features and less disability. Hypomania can be distinguished from normal happiness by its persistence, non-reactivity (not provoked by good news and not affected by bad news) and social disability. The social disability of mania can be severe, with disinhibited behaviour leading to significant debts (from overspending), lost relationships (from promiscuity or irritability), social ostracism and lost employment (from reckless or disinhibited behaviour).

Some patients have a rapid cycling illness, with frequent swings from one mood state to another. A mixed affective state occurs when features of mania and depressive illness are seen in the same episode. Cyclothymia is a personality trait with spontaneous swings in mood not sufficiently severe or persistent to warrant another diagnosis.

Differential diagnosis

Acute intoxication with recreational drugs such as amphetamines, amphetamine derivatives (MDMA: Ecstasy), and cocaine can mimic mania. Up to a quarter of people with Cushing’s syndrome develop mania. Similarly corticosteroids can induce mania less commonly than depressive illness. Dopamine agonists (e.g. bromocriptine) are also known to sometimes induce mania.

Epidemiology

The lifetime prevalence of bipolar affective disorder is 1% across the world. Unlike unipolar depressive illness, it is equally common in men and women, supporting its different aetiology. There is no variation by socioeconomic class or race. The mean age of onset is 21; earlier than unipolar depression. The higher prevalence found in divorced people is probably a consequence of the condition.

Aetiology

Genetic

There is strong evidence for a genetic aetiology in this disorder. There is a 60–80% concordance rate in monozygotic twins, compared to 15% in dizygotic twins, suggesting a high rate of heritability. Adoption studies show similar rates, so this high rate is probably genetic and not due to the family environment. Linkage studies have so far proved disappointing, with several polymorphism associations being found, and a recent large study finding similar polymorphisms to those associated with schizophrenia.

Biochemical

Brain monoamines, e.g. serotonin, seem to be increased in mania. Dexamethasone tends not to suppress cortisol levels in people with mania, suggesting a similar pattern of non-suppression to that seen in severe depressive illness.

Psychological

The effect of life events is much weaker in bipolar compared with unipolar illnesses; most effect being apparent at first onset. Similarly, personality does not seem to be a major influence, in contrast to unipolar depression, although there is some evidence of a link with the creativity and divergent thinking that is an advantage in the right occupation

Treatment

Acute mania or hypomania

This is summarized in Table 23.15.

- Acute mania is treated with an atypical antipsychotic (neuroleptic), sodium valproate or lithium. The atypical antipsychotics aripiprazole, olanzapine, quetiapine and risperidone are particularly recommended, especially with behavioural disturbance. Doses are similar to those used in schizophrenia. The behavioural excitement and overactivity are usually reduced within days, but elation, grandiosity and associated delusions often take longer to respond.
- Lithium may be used in instances where compliance is likely to be good; however, the screening necessary for lithium is

FURTHER READING

prior to its use (see below) may prohibit its use in these circumstances as a first-line agent.

- Valproic acid is also helpful in hypomania or in rapidly cycling illnesses (see below).

Prevention in bipolar disorders
Since bipolar illnesses tend to be relapsing and remitting, prevention of recurrence is the major therapeutic challenge in management. A patient who has experienced more than two episodes of affective disorder within a 5-year period is likely to benefit from preventive treatments. Recommendations include lithium, olanzapine, and valproic acid (so long as the patient is not a woman at risk of pregnancy).

Lithium
Lithium (carbonate or citrate) is one of the two main agents used for prophylaxis in people with repeated episodes of bipolar illness (the other being valproic acid). It is rapidly absorbed from the gastrointestinal tract and more than 95% is excreted by the kidneys; small amounts are found in the saliva, sweat and breast milk. Renal clearance of lithium correlates with renal creatinine clearance. Lithium is a mood-stabilizing drug that prevents mania more than depression. It reduces the frequency and severity of relapses by half and significantly reduces the likelihood of suicide. Its mode of action is unknown, but lithium is known to act on the serotonergic system. Poor response to lithium is associated with a negative family history, an unstable premorbid personality, and a rapid cycling illness. Recent pharmacogenetic work suggests that certain polymorphisms may predict response.

Plasma levels. These should be monitored weekly, with blood drawn 12 h after the last dose (a ‘trough’ level) until a steady state is reached and at 3-monthly intervals thereafter. The minimum level for prophylaxis is 0.4 mmol/L, with an optimum range of between 0.6 and 0.75 mmol. Levels higher than this may afford further protection against manic episodes but the relationship with depression is less clear. For this reason, the therapeutic range is typically quoted as 0.5–1.0 mmol/L. Fluctuations in plasma levels increase the risk of relapse.

Screening prior to starting lithium and at 6-monthly intervals thereafter includes:

- Thyroid function (free T₄, TSH and thyroid autoantibodies). Lithium interferes with thyroid function and can produce frank hypothyroidism. The presence of thyroid autoantibodies increases the risk.
- Parathyroid function. Serum calcium and parathyroid hormone levels higher in 10% of patients.
- Renal function (serum urea and creatinine, estimated glomerular filtration rate and 24-hour urinary volume). Long-term treatment with lithium causes two renal problems: nephrogenic diabetes insipidus (DI) and reduced glomerular function (see p. 566). The best screen for DI is to ask the patient about polyuria and polydipsia.

Toxicity. Patients should carry a lithium card with them at all times, be advised to avoid dehydration, and be warned of drug interactions, such as with NSAIDs and diuretics. As with all medications, it is vital to discuss side-effects and signs of toxicity (these are listed in Box 23.10).

Pregnancy. As a rule, lithium is not advised during pregnancy, particularly in the 1st trimester, because of an increased risk of fetal malformation (Eβstein’s anomaly). Between 25% and 30% of women with a history of bipolar disorder relapse within 2 weeks of delivery. Restarting lithium within 24 h of delivery (if the mother is prepared to forgo breast-feeding) markedly reduces the risk of relapse.

Other mood stabilizers
Valproic acid (as the semisodium salt) is recommended both in prophylaxis and treatment of maniac states. Second-line treatments include carbamazepine and lamotrigine. Some patients who do not respond to lithium may respond to these anticonvulsants or a combination of both. People with rapid cycling illnesses show a better response to anticonvulsants than to lithium. For antimanic treatment, dosage in the initial stage of treatment will be 200 mg twice daily of carbamazepine, increasing to a normal dose of 800–1000 mg. Other drugs which appear to exercise a prophylactic mood-stabilizing effect include olanzapine and risperidone.

Both carbamazepine and valproate can be teratogenic (neural tube defects) and should be avoided in pregnancy. Other side-effects of these drugs are given in Chapter 22.

Prognosis
The average duration of a manic episode is 2 months, with 95% making a full recovery in time. Recurrence is the rule in bipolar disorders, with up to 90% relapsing within 10 years.

**SUICIDE AND SELF-HARM**
(see also p. 909)

Suicide accounts for 2% of male and 1% of female deaths in England and Wales each year, equivalent to a rate of 8 per 100 000. The rate increases with age, peaking for women in their 60s and for men in their 70s. Suicide is the second most common cause of mortality in 15- to 34-year-olds. Approximately 15% of people who have suffered a severe depressive disorder (requiring admission) will eventually commit suicide, with 6% doing so in the 10 years after their first admission.

Suicide rates in schizophrenia sufferers are likewise high, being 20–50 times the rate in the general population; 20–40% of people with schizophrenia make suicide attempts, and 9–13% are successful.

The highest rates of suicide have been reported in rural southern India (148/100 000 in young women and 58/100 000 in young men) and in eastern Europe (30–40/100 000), while the lowest are those of Spain (3.9/100 000) and Greece (2.8/100 000), but such variations may reflect differences in reporting, which may be related to religion, as much as genuine differences. The provision of mental health care to suicidal individuals varies greatly around the world, with a recent WHO study suggesting that most receive no treatment at all. Factors that increase the risk of suicide are indicated in Table 23.16.

A distinction must be drawn between those who attempt suicide – self-harm (SH) – and those who succeed (suicides):
Anxiety disorders

Table 23.16 Factors that increase the risk of suicide

- Male sex
- Older age
- Living alone
- Immigrant status
- Recent bereavement, separation or divorce
- Recent loss of a job or retirement
- Living in a socially disorganized area
- Family history of affective disorder, suicide or alcohol misuse
- Previous history of affective disorder, alcohol or drug misuse
- Previous suicide attempt
- Addiction to alcohol or drugs
- Severe depression or early dementia
- Incapacitating painful physical illness

The majority of cases of SH occur in people under 35 years of age.

The majority of suicides occur in people aged over 60.

Suicides are more common in men, while SH is more common in women.

Suicides are more common in older men, although rates are falling. Rates in young men are rising fast throughout the UK and Europe.

Suicides in women are slowly falling in the UK.

Approximately 90% of cases of SH involve self-poisoning.

A formal psychiatric diagnosis usually can be made retrospectively in suicide, but is unusual in SH.

There is, however, an overlap between SH and suicide. Between 1% and 2% of people who attempt suicide will kill themselves in the year following SH. The risk of suicide stays elevated in those with SH, with 0.5% per annum committing suicide in the following 20 years. In the UK, there are 100,000 cases of SH each year, and the overwhelming majority of these are seen and treated within accident and emergency departments.

The guidelines (Box 23.11) for the assessment of such patients will help ensure that the risk factors relating to suicide are covered. Indications for referral to a psychiatrist before discharge from hospital are also given.

In general, it is worth trying to interview a family member or close friend and check these points with them. Requests for immediate re-prescription on discharge should be denied, except in cases of essential medication. In such cases, however, only 3 days’ supply of medication should be given, and the patient should be requested to report to their general practitioner or to their psychiatric outpatient clinic for further supplies. Occasionally, involuntary admission to hospital may be required (p. 1191).

Box 23.11 Guidelines for the assessment of patients who harm themselves

Questions to ask: of concern if positive answer
- Was there a clear precipitant/cause for the attempt?
- Was the act premeditated or impulsive?
- Did the patient leave a suicide note?
- Had the patient taken pains not to be discovered?
- Did the patient make the attempt in strange surroundings (i.e. away from home)?
- Would the patient do it again?

Other relevant factors
- Has the precipitant or crisis resolved?
- Is there continuing suicidal intent?
- Does the patient have any psychiatric symptoms?
- What is the patient’s social support system?
- Has the patient inflicted self-harm before?
- Has anyone in the family ever taken their life?
- Does the patient have a physical illness?

Indications for referral to a psychiatrist

Absolute indications include:
- Clinical depression
- Psychotic illness of any kind
- Clearly preplanned suicidal attempt which was not intended to be discovered
- Persistent suicidal intent (the more detailed the plans, the more serious the risk)
- A violent method used

Other common indications include:
- Alcohol and drug misuse
- Patients over 45 years, especially if male, and young adolescents
- Those with a family history of suicide in first-degree relatives
- Those with serious (especially incurable) physical disease
- Those living alone or otherwise unsupported
- Those in whom there is a major unresolved crisis
- Persistent suicide attempts
- Any patients who give you cause for concern

General anxiety disorder (GAD) and its related panic disorder are differential diagnoses for functional somatic syndromes, owing to the many physical symptoms that are caused by these conditions.

Clinical features

The physical and psychological symptoms are outlined in Table 23.18. The patient looks worried, has a tense posture, restless behaviour and a pale and sweaty skin. The patient takes time to go to sleep, and when asleep wakes intermittently with worry dreams. Associated conditions include the hyperventilation syndrome, which is even more common in panic disorder (Box 23.12). The patient will sigh deeply, particularly when talking about the stresses in their life.

Mixed anxiety and depressive disorder

This disorder is probably the commonest mood disorder in primary care, in which there are equal elements of both...
the conviction that they are about to die from a stroke or catastrophic illness beliefs during the panic attack, such as prevalence is 5%. People with panic disorder often have (palpitations, tremor, restlessness and sweating). The lifetime dilatation (severe physical symptoms, usually related to both hyperventilation). Panic disorder is diagnosed when the patient has repeated sudden attacks of overwhelming anxiety, accompanied by severe physical symptoms, usually related to both hyperventilation (Box 23.12) and sympathetic nervous system activity (palpitations, tremor, restlessness and sweating). The lifetime prevalence is 5%. People with panic disorder often have catastrophic illness beliefs during the panic attack, such as the conviction that they are about to die from a stroke or heart attack. The fear of a stroke is related to dizziness and headache. Fear of a heart attack accompanies chest pain (atypical chest pain). The occasional patient with long-standing attacks may deny feeling anxious and simply report the physical symptoms.

Aetiology
General anxiety and panic disorders occur four or more times as commonly in first-degree relatives of affected patients. Sympathetic nervous system overactivity, increased muscle tension and hyperventilation are the common pathophysiological mechanisms. Anxiety is the emotional response to the threat of a loss, whereas depression is the response to the loss itself. There is some evidence that being bullied, with the explicit threats involved, leads to anxiety disorders in adolescents.

Phobic (anxiety) disorders
Phobias are common conditions in which intense fear is triggered by a stimulus, or group of stimuli, that are predictable and normally cause no particular concern to others (e.g., agoraphobia, claustrophobia, social phobia). This leads to avoidance of the stimulus (Box 23.13). The patient knows that the fear is irrational, but cannot control it. The prevalence of all phobias is 8%, with many patients having more than one. Many phobias of ‘medical’ stimuli exist (e.g. of doctors, dentists, hospitals, vomit, blood and injections) which affect the patient’s ability to receive adequate healthcare.

Aetiology
Phobias may be caused by classical conditioning, in which a response (fear and avoidance) becomes conditioned to a previously benign stimulus (a lift), often after an initiating emotional shock (being stuck in a lift). In children, phobias can arise through imagined threats (e.g. stories of ghosts told in the playground). Women have twice the prevalence of phobias than men. Phobias aggregate in families, with increasing evidence of the importance of genetic factors being published.

Agoraphobia
Translated as ‘fear of the market place’, this common phobia (4% prevalence) presents as a fear of being away from home, with avoidance of travelling, walking down a road and supermarkets being common cues. This can be a very disabling condition, since the patient often avoids leaving home, particularly by themselves. It is often associated with claustrophobia, a fear of enclosed spaces.

Social phobia
This is the fear and avoidance of social situations: crowds, strangers, parties and meetings. Public speaking would be the sufferer’s worst nightmare. It is suffered by 2% of the population.

Simple phobias
The commonest is the phobia of spiders (arachnophobia), particularly in women. The prevalence of simple phobias is 7% in the general population. Other common phobias include anxiety and depression, showing how closely associated these two abnormal mood states are.

Panic disorder
Panic disorder is diagnosed when the patient has repeated sudden attacks of overwhelming anxiety, accompanied by severe physical symptoms, usually related to both hyperventilation (Box 23.12) and sympathetic nervous system activity (palpitations, tremor, restlessness and sweating). The lifetime prevalence is 5%. People with panic disorder often have catastrophic illness beliefs during the panic attack, such as the conviction that they are about to die from a stroke or
insects, moths, bats, dogs, snakes, heights, thunderstorms and the dark. Children are particularly phobic about the dark, ghosts and burglars, but the large majority grow out of these fears.

**Treatment of anxiety disorders**

**Psychological treatments**
For many people with brief episodes, discussion with a doctor concerning the nature of anxiety is usually sufficient.

- **Relaxation techniques** can be effective in mild/moderate anxiety. Relaxation can be achieved in many ways, including complementary techniques such as meditation and yoga. Conventional relaxation training involves slowing down the rate of breathing, muscle relaxation and mental imagery.

- **Anxiety management** training involves two stages. In the first stage, verbal cues and mental imagery are used to arouse anxiety to demonstrate the link with symptoms. In the second stage, the patient is trained to reduce this anxiety by relaxation, distraction and reassuring self-statements.

- **Biofeedback** is useful for showing patients that they are not relaxed, even when they fail to recognize it, having become so used to anxiety. Biofeedback involves feeding back to the patient a physiological measure that is abnormal in anxiety. These measures may include electrical resistance of the skin of the palm, heart rate, muscle electromyography or breathing pattern.

- **Behaviour therapies** are treatments that are intended to change behaviour and thus symptoms. The most common and successful behaviour therapy (with 80% success in some phobias) is graded exposure, otherwise known as systematic desensitization. First, the patient rates the phobia into a hierarchy or ‘ladder’ of worsening fears (e.g. in agoraphobia: walking to the front door with a coat on; walking out into the garden; walking to the end of the road). Second, the patient practices exposure to the least fearful stimulus until no fear is felt. The patient then moves ‘up the ladder’ of fears until they are cured.

- **Cognitive behaviour therapy** (CBT) (see p. 1174) is the treatment of choice for panic disorder and general anxiety disorder because the therapist and patient need to identify the mental cues (thoughts and memories) that may subtly provoke exacerbations of anxiety or panic attacks. CBT also allows identification and alteration of the patient’s ‘schema’, or way of looking at themselves and their situation, that feeds anxiety.

**Drug treatments**
Initial ‘drug’ treatment should involve advice to gradually cease taking anxiogenic recreational drugs such as caffeine and alcohol (which can cause a rebound anxiety and withdrawal). Prescribed drugs used in the treatment of anxiety can be divided into two groups: those that act primarily on the central nervous system, and those that block peripheral autonomic receptors.

- **Benzodiazepines** are centrally acting anxiolytic drugs. They are agonists of the inhibitory transmitter γ-aminobutyric acid (GABA). Diazepam (5 mg twice daily, up to 10 mg three times daily in severe cases), alprazolam (250–500 μg three times daily) and clonidiazepoxide have relatively long half-lives (20–40 h) and are used as anti-anxiety drugs in the short term. Side-effects include sedation and memory problems, and patients should be advised not to drive while on treatment. They can cause dependence and tolerance within 4–6 weeks, particularly in those with dependent personalities. A withdrawal syndrome (Table 23.19) can occur after just 3 weeks of continuous use and is particularly severe when high doses have been given for a longer time. Thus, if a benzodiazepine drug is prescribed for anxiety, it should be given in as low a dose as possible, preferably on an ‘as necessary’ basis, and for not more than 2–4 weeks. A withdrawal programme from chronic use includes changing the drug to the long-acting diazepam, followed by a very gradual reduction in dosage.

- **Most SSRIs** (e.g. fluoxetine, paroxetine, sertraline, escitalopram, citalopram) are useful symptomatic treatments for general anxiety and panic disorders, as well as some phobias (social phobia), although doses higher than those used in depression are often required. Duloxetine, mirtazapine, venlafaxine and pregabalin are alternative treatments for GAD with the added benefit of possibly preventing the subsequent development of depression. Treatment response is often delayed several weeks; a trial of treatment should last 3 months.

- **Antipsychotics** such as aripiprazole or olanzapine can be effective for more severe or refractory cases.

- **Beta-blockers** are effective in reducing peripheral symptoms: many of the symptoms of anxiety are due to an increased or sustained release of adrenaline (epinephrine) and noradrenaline (norepinephrine) from the adrenal medulla and sympathetic nerves. Beta-blockers such as propranolol (20–40 mg two or three times daily) are effective in reducing peripheral symptoms such as palpitations, tremor and tachycardia, but they do not help central symptoms such as anxiety.

**Acute stress reactions and adjustment disorders**

**Acute stress reaction**
This occurs in individuals in response to exceptional physical and/or psychological stress. While severe, such a reaction usually subsides within days. The stress may be an overwhelming traumatic experience (e.g. accident, battle, physical assault, rape) or a sudden change in the social circumstances of the individual, such as a bereavement. Individual vulnerability and coping capacity play a role in the occurrence and severity of an acute stress reaction, as evidenced by the fact that not all people exposed to exceptional stress develop symptoms. Symptoms usually include an initial state of feeling ‘dazed’ or numb, with inability to comprehend the situation. This may be followed either by further withdrawal from the situation or by anxiety and overactivity. No treatments beyond reassurance and support are normally necessary.

**Adjustment disorder**
This disorder can follow an acute stress reaction and is common in the general hospital. This is a prolonged
Normal grief

Normal grief immediately follows bereavement, is expressed openly, and allows a person to go through the social ceremonies and personal processes of bereavement. The three stages are, first, shock and disbelief, second, the emotional phase (anger, guilt and sadness) and, third, acceptance and resolution. This normal process of adjustment may take up to a year, with movement between all three stages occurring in a sometimes haphazard fashion.

Pathological (abnormal) grief

This is a particular kind of adjustment disorder. It can be characterized as excessive and/or prolonged grief, or even absent grieving with abnormal denial of the bereavement. Usually a relative will be stuck in grief, with insomnia and repeated dreams of the dead person, anger at doctors or even the patient for dying, consequent guilt in equal measure, and an inability to ‘say good-bye’ to the loved person by dealing with their effects. Guided mourning uses cognitive and behavioural techniques to allow the relative to stop grieving and move on in life.

Post-traumatic stress disorder (PTSD)

This is a protracted response to a stressful event or situation of an exceptionally threatening nature, likely to cause pervasive distress in almost anyone. Causes include natural or human disasters, war, serious accidents, witnessing the violent death of others, being the victim of sexual abuse, rape, torture, terrorism or hostage-taking. Predisposing factors such as personality, previously unresolved traumas, or a history of psychiatric illness may prolong the course of the syndrome. These factors are neither necessary nor sufficient to explain its occurrence, which is most related to the intensity of the trauma, the proximity of the patient to the traumatic event, and how prolonged or repeated it was. Functional brain scan research suggests a possible neurophysiological relationship with obsessive-compulsive disorder (p. 1181).

Clinical features

The typical symptoms of PTSD include:

- ‘Flashbacks’: repeated vivid reliving of the trauma in the form of intrusive memories, often triggered by a reminder of the trauma
- Insomnia, usually accompanied by nightmares, the nocturnal equivalent of flashbacks
- Emotional blunting, emptiness or ‘numbness’, alternating with
  - intense anxiety with exposure to events that resemble an aspect of the traumatic event, including anniversaries of the trauma
- Avoidance of activities and situations reminiscent of the trauma
- Emotional detachment from other people
- Hypervigilance with autonomic hyperarousal and an enhanced startle reaction.

This clinical picture represents the severe end of a spectrum of emotional reactions to trauma, which might alternatively take the form of an adjustment or mood disorder. The course is often fluctuating but recovery can be expected in two-thirds of cases at the end of the first year. Complications include depressive illness and alcohol misuse. In a small proportion of cases the condition may show a chronic course over many years and a transition to an enduring personality change.

Treatment and prevention

Compulsory psychological debriefing immediately after a trauma does not prevent PTSD and may be harmful. Prevention is better achieved by the support offered by others who were also involved. Trauma focused CBT is often effective. Eye movement desensitization and reprocessing (EMDR) is equally effective treatment and may require fewer sessions. SSRIs and venlafaxine have a place in the management of chronic PTSD, but drop-out from pharmacotherapy is common.

The adult consequences of childhood sexual and physical abuse

Estimates of the prevalence of childhood sexual abuse vary depending on definition but there is reasonable evidence that 20% of women and 10% of men suffered significant, coercive and inappropriate sexual activity in childhood. The abuser is usually a member of the family or known to the child. The likelihood of long-term consequences is determined by:

- an earlier age of onset
- the severity of the abuse
- the repeated nature and duration of the period of abuse
- the association with physical abuse.

Consequent adult psychiatric disorders include depressive illness, substance misuse, eating disorders, borderline personality disorder and deliberate self-harm. Other negative outcomes include a decline in socioeconomic status, sexual problems, prostitution and difficulties in forming adult relationships.

Repeated childhood physical and emotional abuse or neglect may also affect emotional and personality development, predisposing the adult to similar psychiatric disorders. Those with repeated abuse are more likely to have long-term physical stress related consequences, such as hypothalamic–pituitary–adrenal axis downregulation and smaller brain hippocampal sizes.

Psychodynamic psychotherapy

Psychodynamic psychotherapy is derived from psychoanalytic concepts and is based on a number of key analytical concepts. These include Freud’s ideas about psychosexual development, defence mechanisms, free association as the method of recall, and the therapeutic techniques of interpretation, including that of transference, defences and dreams. Such therapy usually involves once-weekly sessions, the length of treatment varying between 3 months and 2 years. The long-term aim of such therapy is twofold: symptom relief and personality change. Psychodynamic psychotherapy is classically indicated in the treatment of unresolved conflicts in early life, as might be found in non-psychotic and personality disorders, but there is no convincing evidence concerning its superiority over alternative forms of treatment.

Cognitive analytical therapy

Cognitive analytical therapy is an integration of cognitive behaviour therapy and psychodynamic therapy. It is a
short-term therapy that involves the patient and therapist recognizing the origins of a recurrent problem, reformulating how it continues to occur, and revising other ways of coping and internalizing it, using both the transference of the patient-therapist relationship and behavioural experiments.

### Obsessive-compulsive disorder

Obsessive-compulsive disorder (OCD) is characterized by obsessional ruminations and compulsive rituals. It is particularly associated with and/or secondary to both depressive illness and Gilles de la Tourette’s syndrome (p. 1122). The prevalence is between 1% and 2% in the general population, and patients often do not seek help. There is an equal distribution by gender, and the mean age of onset ranges from 20 to 40 years.

#### Clinical features

The obsessions and compulsions are time consuming and intrusive so that they affect functioning and cause considerable distress. Ruminations are often unpleasant repetitive thoughts, out of character, such as being dirty or violent. This can lead to a constant need to check that everything and everyone is alright and that things have been done correctly, and reassurance cannot remove the doubt that persists. Some rituals are derived from superstitions, such as actions repeated a fixed number of times, with the need to start again if interrupted. When severe and primary, OCD can last for many years and may be resistant to treatment. However, obsessional symptoms commonly occur in other disorders, most notably depressive illness and schizophrenia, and remit with the resolution of the primary disorder.

Minor degrees of obsessional symptoms and compulsive rituals or superstitions are common in people who are not ill or in need of treatment, particularly in times of stress. The mildest grade is that of obsessional personality traits such as over-conscientiousness, tidiness, punctuality and other attitudes and behaviours indicating a strong tendency towards conformity and inflexibility. Such individuals are perfectionists who are intolerant of shortcomings in themselves and others, and take pride in their high standards. When such traits are so marked that they dominate other aspects of the personality, in the absence of clear-cut OCD, the diagnosis is obsessional (anankastic) personality (see p. 1190).

#### Aetiology

##### Genetic

OCD is found in 5–7% of the first-degree relatives. Twin studies showed 80–90% concordance in monozygotic twins and about 50% in dizygotic twins. Genetic factors account for more of the variance in childhood onset cases than in those who develop it as an adult.

##### Biological model

Neuroimaging studies suggest dysfunction in the orbito-striatal area (including the caudate nucleus) and dorsolateral prefrontal cortex combined with abnormalities in serotonergic (underactive) and glutamatergic (overactive) neurotransmission. Further support for this model comes from an association with a number of neurological disorders involving dysfunction of the striatum, including Parkinson’s disease, Huntington’s and Sydenham’s chorea. The latter has also been associated with OCD and tic disorders in the paediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS). This is a rare condition in children following group A haemolytic streptococcal infection. OCD also can follow head trauma.

#### Cognitive-behavioural model

Most people have the occasional intrusive thoughts, but would ordinarily dismiss these as meaningless and not focus upon them further. These develop into an obsession when they assume great significance to the individual, causing greater anxiety. This anxiety motivates suppression of these thoughts and ritual behaviours are developed to further reduce anxiety.

#### Treatment

##### Psychological treatments

Cognitive behavioural therapy focusing on exposure and response prevention is reasonably effective. This involves confronting the anxiety provoking stimulus in a controlled environment and not performing the associated ritual. The aim is for the individual to habituate to the stimulus, thus reducing anxiety. Since it provokes anxiety, the drop-out rate is often high.

##### Physical treatment

**Tryptic antidepressants and serotonin reuptake inhibitors.** Clomipramine (a tricylic) and the SSRIs are the mainstay of drug treatment. Their efficacy is independent of their antidepressant action but the doses required are usually some 50–100% higher than those effective in depression. Although many sufferers respond, relapse rates on discontinuation are high. Three months’ treatment with maximum tolerated doses may be necessary for a positive response and in those who fail to respond, the addition of an antipsychotic significantly improves outcome, especially when tics occur co-morbidly. Positive correlations between reduced severity of OCD and decreased orbitofrontal and caudate metabolism following behavioural and SSRI treatments have been demonstrated in a number of studies.

**Anti-glutamatergic agents.** Recent studies have suggested that riluzole may be effective. A randomized, double-blind, placebo-controlled augmentation trial of D-cycloserine (an N-methyl-D-aspartic acid (NMDA) receptor agonist) administered in combination with CBT, prior to sessions, has suggested that this may speed treatment response time.

**Deep brain stimulation.** This is a non-ablative, and therefore potentially reversible, surgical technique that involves the electrical stimulation of the basal ganglia by implanted electrodes, creating a ‘functional lesion’. Although this has had success, often impressively so in intractable cases, issues still remain regarding subject selection and the optimum anatomical targets.

**Psychosurgery.** This is very occasionally recommended in cases of chronic and severe OCD that has not responded to other treatments. The development of stereotactic techniques has led to the replacement of the earlier, crude leucotomies with more precise surgical interventions such as subcaudate tractotomy and cingulotomy, with small yttrium radioactive implants, which induce lesions in the cingulate area or the ventromedial quadrant of the frontal lobe.

#### Prognosis

Two-thirds of cases improve within a year. The remainder run a fluctuating or persistent course. The prognosis is worse when the personality is obsessional or anankastic and the OCD is primary and severe.
ALCOHOL MISUSE AND DEPENDENCE

A wide range of physical, social and psychiatric problems are associated with excessive drinking. Alcohol misuse occurs when a patient is drinking in a way that regularly causes problems to the patient or others.

- **The problem drinker** is one who causes or experiences physical, psychological and/or social harm as a consequence of drinking alcohol. Many problem drinkers, while heavy drinkers, are not physically addicted to alcohol.

- **Heavy drinkers** are those who drink significantly more in terms of quantity and/or frequency than is safe to do in the long term.

- **Binge drinkers** are those who drink excessively in short bouts, usually 24–48 h long, separated by often quite lengthy periods of abstinence. Their overall monthly or weekly alcohol intake may be relatively modest.

- **Alcohol dependence** is defined by a physical dependence on or addiction to alcohol. The term ‘alcoholism’ is a confusing one with off-putting connotations of vagrancy, ‘meths’ drinking and social disintegration. It has been replaced by the term ‘alcohol dependence syndrome’.

**Epidemiology of alcohol misuse**

A total of 20% of men and 10% of women drink more than double the recommended limits of 3 units a day for alcohol for men, and 2 units for women in the UK. The amount of alcohol consumed in the UK has doubled over the last 50 years. Some 4% of men and 2% of women report alcohol withdrawal symptoms, suggesting dependence. Approximately one in five male admissions to acute medical wards is directly or indirectly due to alcohol. People with serious drinking problems have a two to three times increased risk of dying compared with members of the general population of the same age and sex.

Table 23.20 provides an approximate estimate of what can be expected in an average individual in the way of behavioural impairment resulting from a particular blood alcohol level. The amount of alcohol is measured for convenience in units which contain about 8 g of absolute alcohol and raises the blood alcohol concentration by about 15–20 mg/dL, the amount that is metabolized in 1 h. One unit of alcohol is found in half a pint of ordinary beer (3.5% alcohol by volume, ABV) and 125 ml of 9% wine. However, some beer and most lager is now 5% ABV; 3 units per pint. Wine is often 13% ABV and sold in 175 mL glasses; 2–3 units per glass.

**Detection**

Alcohol misuse should be suspected in any patient presenting with one or more physical problems commonly associated with excessive drinking (see p. 226). Alcohol misuse may also be associated with a number of psychiatric symptoms/disorders and social problems (Table 23.21).

**Guidelines**

The patient’s frequency of drinking and quantity drunk during a typical week should be established:

- Up to 21 units of alcohol a week for men and 14 units for women: this carries no long-term health risk
- 21–35 units a week for men and 14–24 units for women: there is unlikely to be any long-term health damage, provided the drinking is spread throughout the week
- Over 36 units a week for men and 24 for women: damage to health becomes increasingly likely
- Above 50 units a week for men and 35 for women: this is a definite health hazard.

**Diagnostic markers of alcohol misuse**

Laboratory parameters indicating alcohol misuse in recent weeks include elevated γ-glutamyl transpeptidase (γ-GT) and mean corpuscular volume (MCV). Blood or breath alcohol tests are useful in anyone suspected of very recent drinking.

**Alcohol dependence syndrome**

Dependence is a pattern of repeated self-administration that causes tolerance, withdrawal and compulsive drug-taking, the essential element of which is the continued use of the substance despite significant substance-related problems. Symptoms of alcohol dependence in a typical order of occurrence are shown in Table 23.22. Diagnostic criteria for alcohol withdrawal syndrome are shown in Table 23.23.

The course of the alcohol dependence syndrome

About 25% of all cases of alcohol misuse will lead to chronic alcohol dependence. This most commonly ends in social incapacity, death or abstinence. Alcohol dependence syndrome usually develops after 10 years of heavy drinking (3–4 years in women). In some individuals who use alcohol to alter consciousness, obliterate conscience and defy social mores, dependence and loss of control may appear in only a few months or years.

Delirium tremens (DTs)

Delirium tremens is the most serious withdrawal state and occurs 1–3 days after alcohol cessation, so is commonly seen 1–2 days after admission to hospital. Patients are disorientated, agitated, and have a marked tremor and visual hallucinations (e.g. insects or small animals coming menacingly towards them). Signs include sweating, tachycardia, tachypnoea and pyrexia. Complications include dehydration, infection, hepatic disease or the Wernicke–Korsakoff syndrome (p. 1147).

Causes of alcohol dependence

Genetic factors. Sons of alcohol-dependent people who are adopted by other families are four times more likely to develop drinking problems than are the adopted sons of non-alcohol misusers. Genetic markers include dopamine-2 receptor allele A1, alcohol dehydrogenase subtypes and monoamine oxidase B activity, but they are not specific.

Environmental factors. One in 10 boys who grow up in a household where neither parent misused alcohol subsequently become alcohol dependent, compared with one in four of those reared by alcohol-misusing mothers and one in three of those reared by alcohol-misusing fathers.

Biochemical factors. Several factors have been suggested, including abnormalities in alcohol dehydrogenase, neurotransmitter substances and brain amino acids, such as GABA. There is no conclusive evidence that these or other biochemical factors play a causal role.

Psychiatric illness. This is an uncommon cause of addictive drinking but it is a treatable one. Some depressed patients drink excessively in the hope of raising their mood. People with anxiety states or phobias are also at risk.

Excess consumption in society. The prevalence of alcohol dependence and problems correlates with the general level (per capita consumption) of alcohol use in a society. This, in turn, is determined by factors that may control overall consumption – including price, licensing laws, availability, and the societal norms concerning the use and misuse of alcohol.

Box 23.14 Management of delirium tremens (DTs)

General measures
- Admit the patient to a medical bed.
- Correct electrolyte abnormalities and dehydration.
- Treat any co-morbid disorder (e.g. infection).
- Give parenteral thiamine slowly (250 mg daily for 3–5 days in the absence of Wernicke–Korsakoff, W–K syndrome).
- Give parenteral thiamine slowly (500 mg daily for 3–5 days with W–K encephalopathy. Note: beware anaphylaxis).
- Give prophylactic phenytoin or carbamazepine, if previous history of withdrawal fits.

Specific drug treatment
- Give one of the following orally:
  - Diazepam 10–20 mg
  - Chlordiazepoxide 30–60 mg
- Repeat 1 h after last dose depending on response.

Fixed-schedule regimens
- Diazepam 10 mg every 6 h for 4 doses, then 5 mg 6-hourly for 8 doses OR
- Chlordiazepoxide 30 mg every 6 h for 4 doses, then 15 mg 6-hourly for 8 doses.

Provide additional benzodiazepine when symptoms and signs are not controlled.

Treatment

Psychological treatment of problem drinking
Successful identification at an early stage can be a helpful intervention in its own right. It should lead to:
- The provision of information concerning safe drinking levels
- A recommendation to cut down where indicated
- Simple support and advice concerning associated problems.

Such a brief intervention is effective in its own right. Successful alcohol misuse treatment involves motivational enhancement (motivational therapy), feedback, education about adverse effects of alcohol, and agreeing drinking goals. A motivational approach is based on five stages of change: precontemplation, contemplation, determination, action and maintenance. The therapist uses motivational interviewing and reflective listening to allow the patient to persuade himself along the five stages to change.

This technique, cognitive behaviour therapy and 12-step facilitation (as used by Alcoholics Anonymous, AA) have all been shown to reduce harmful drinking. With addictive drinking, self-help group therapy, which involves the long-term support by fellow members of the group (e.g. AA), is helpful in maintaining abstinence. Family and marital therapy involving both the alcohol misuser and spouse may also be helpful. Families of drinkers find meeting others in a similar situation helpful (Al-Anon).

Drug treatments of problem drinking

Alcohol withdrawal and DTs
Addicted drinkers often experience considerable difficulty when they attempt to reduce or stop their drinking. Withdrawal symptoms are a particular problem and delirium tremens needs urgent treatment (Box 23.14). In the absence of DTs, alcohol withdrawal can be treated on an outpatient basis, using one of the fixed schedules in Box 23.14, so long as the patient attends daily for medication and monitoring, and has good social support. Outpatient schedules are
Drugs for prevention of alcohol dependence

Naltrexone, the opioid antagonist (50 mg per day), reduces the risk of relapse into heavy drinking and the frequency of drinking. Acamprosate (1–2 g/day) acts on several receptors including those for GABA, noradrenaline (norepinephrine) and serotonin. There is reasonable evidence that it reduces drinking frequency. Neither drug seems particularly helpful in maintaining abstinence. Both drug effects are enhanced by combining them with counseling, but their moderate efficacy precludes regular use.

Drugs such as disulfiram react with alcohol to cause unpleasant acetaldehyde intoxication and histamine release. A daily maintenance dose means that the patient must wait until the disulfiram is eliminated from the body before drinking safely. There is mixed evidence of efficacy.

Oral thiamine (300 mg/day) can prevent Wernicke–Korsakoff syndrome (p. 1147) in heavy drinkers.

Outcome

Research suggests that 30–50% of alcohol-dependent drinkers are abstinent or drinking very much less up to 2 years following traditional intervention. It is too early to be certain of the long-term outcome of patients treated with the latest psychological and pharmacological therapies.

Once regular drug-taking is established, pharmacological factors determine dependence.

Solvents

Of the adolescents in the UK, 1% sniff solvents for their intoxicating effects. Tolerance develops over weeks or months. Intoxication is characterized by euphoria, excitement, a floating sensation, dizziness, slurred speech and ataxia. Acute intoxication can cause amnesia and visual hallucinations. In 2004, there were 47 deaths recorded in the UK from solvent misuse; 13 of these were among under 18-year-olds.

Amfetamines and related substances

These have temporary stimulant and euphoriant effects that are followed by fatigue and depression, with the latter sometimes prolonged for weeks. Psychological rather than true physical dependence occurs with amfetamine sulphate (‘speed’). Methyl amfetamine, also known as ‘methamfetamine’ or ‘crystal meth’, is another amfetamine psychostimulant. The particularly high potential for abuse is associated with the activation of neural reward mechanisms involving nucleus accumbens dopamine release.

In addition to a manic-like presentation, amfetamines can produce a paranoid psychosis indistinguishable from schizophrenia.

‘Ecstasy’ (also known as: E, white burger, white dove), is the street name for 3,4-methylenedioxy-methamfetamine (MDMA), a psychoactive phenylisopropylamine, synthesized as an amfetamine derivative. It is a psychedelic drug, which is often used as a ‘dance drug’. It has a brief duration of action (4–6 h). Deaths have been reported from malignant hyperpyrexia and dehydration. Acute renal and liver failure can occur.

Cocaine

Cocaine is a central nervous system stimulant (with similar effects to amfetamines) derived from *Erythroxylon coca* trees grown in the Andes. In purified form it may be taken by mouth, snorted or injected. If cocaine hydrochloride is converted to its base (‘crack’), it can be smoked. This causes an intense stimulating effect, and ‘free-basing’ is common. Compulsive use and dependence occur more frequently among users who are free-basing. Dependent users take large doses and alternate between withdrawal phenomena of depression, tremor and muscle pains, and the hyperarousal produced by increasing doses. Prolonged use of high doses produces irritability, restlessness, paranoid ideation and occasionally convulsions. Persistent sniffing of the drug can cause perforation of the nasal septum. Overdoses cause death through myocardial infarction, cerebrovascular disease, hyperthermia and arrhythmias (p. 917).

Hallucinogenic drugs

Hallucinogenic drugs, such as lysergic acid diethylamide (LSD) and mescaline, produce distortions and intensifications of sensory perceptions, as well as frank hallucinations in acute intoxication. Psychosis is a long-term complication.

Cannabis

Cannabis (also known as: grass, pot, skunk, spliff, marijuana) is a drug widely used in some subcultures. It is derived from the dried leaves and flowers of the plant *Cannabis sativa*. It

</table>
can cause tolerance and dependence. Hashish is the dried resin from the flower tops, whilst marijuana refers to any part of the plant. The drug, when smoked, seems to exaggerate the pre-existing mood, be it depression, euphoria or anxiety. It has specific analgesic properties. Cannabis use has increased in the UK recently, especially use of more potent ‘skunk’. An amotivational syndrome with apathy and memory problems has been reported with chronic daily use. Cannabis may of itself sometimes cause psychosis in the right circumstances (see below).

**Tranquillizers**

Drugs causing dependence include barbiturates and benzodiazepines. Benzodiazepine dependence is common and may be iatrogenic, when the drugs are prescribed and not discontinued. Discontinuing treatment with benzodiazepines may cause withdrawal symptoms (Table 23.19). For this reason, withdrawal should be supervised and gradual.

**Opiates**

Physical dependence occurs with morphine, heroin and codeine as well as with synthetic and semisynthetic opiates such as methadone, pethidine and fentanyl. These substances display cross-tolerance — the withdrawal effects of one are reduced by administration of another. The psychological effects of opiates are a calm, slightly euphoric mood associated with freedom from physical discomfort and a flattening of emotional response. This is believed to be due to the attachment of morphine and its analogues to endorphin receptors in the CNS. Tolerance to this group of drugs is rapidly developed and marked, but is rapidly lost following abstinence. The opiate withdrawal syndrome consists of a constellation of signs and symptoms (Table 23.25) that reaches peak intensity on the 2nd or 3rd day after the last dose of the opiate. These rapidly subside over the next 7 days. Withdrawal is dangerous in people with heart disease or other chronic debilitating conditions.

Opiate addicts have a relatively high mortality rate, owing to both the ease of accidental overdose and the blood-borne infections associated with shared needles. Heart disease (including infective endocarditis), tuberculosis and AIDS are common causes of death, while the complications of hepatitis B and C are also common.

**Treatment of chronic misuse**

Blood and urine screening for drugs is required in circumstances where drug misuse is suspected (Table 23.24). When a patient with an opiate addiction is admitted to hospital for another health problem, advice should be sought from a psychiatrist or drug misuse clinic regarding management of their addiction while an inpatient.

The treatment of chronic dependence is directed towards helping the patient either to live without drugs or to prevent secondary ill-health. Patients need help and advice in order to avoid a withdrawal syndrome. Some people with opiate addiction who cannot manage abstinence may be maintained on oral methadone. In the UK, only specially licensed doctors may legally prescribe heroin and cocaine to an addict for maintenance treatment of addiction. An overdose should be treated immediately with the opioid antagonist naloxone. Recently, injectable diacetylmorphine, the active ingredient in heroin, has been proposed as a more effective alternative to methadone but adverse effects (accidental overdose and seizures) remain a potential concern.

**Drug-induced psychosis**

Drug-induced psychosis has been reported with amphetamine and its derivatives, and cocaine and hallucinogens. It can occur acutely after drug use, but is more usually associated with chronic misuse. Psychoses are characterized by vivid hallucinations (usually auditory, but often in more than one sensory modality), misidentifications, delusions and/or ideas of reference (often of a persecutory nature), psychomotor disturbances (excitement or stupor) and an abnormal affect. ICD-10 requires that the condition occurs within 2 weeks and usually within 48 h of drug use and that it should persist for more than 48 h but not more than 6 months.

Cannabis use can result in anxiety, depression or hallucinations. Manic-like psychoses occurring after long-term cannabis use have been described, but seem more likely to be related to the toxic effects of heavy ingestion. However, a meta-analysis suggests that ever taking cannabis increases the risk of psychosis by 40%, daily cannabis use doubles the risk of psychosis, and that 14% of schizophrenia in the UK would be prevented if cannabis use ceased. The risk is higher in people taking cannabis early in their lives and with a heavy consumption.

**Schizophrenia**

The group of illnesses conventionally referred to as ‘schizophrenia’ is diverse in nature and covers a broad range of perceptual, cognitive and behavioural disturbances. The point prevalence of the condition is 0.5% throughout the world, with equal gender distribution. A physician primarily needs to know how to recognize schizophrenia, what problems it might present with in the general hospital, and how it is treated.

**Causes**

No single cause has been identified. Schizophrenia is likely to be a disease of neurodevelopmental disconnection caused by an interaction of genetic and multiple environmental factors that affect brain development. It is likely that daily cannabis use is a risk factor. The genetic aetiology is likely to be polygenic and non-mendelian. Schizophrenia has a heritability of about 60%. Functional neuroimaging studies and histology point towards alterations in prefrontal and less consistently temporal lobe function, with enlarged lateral ventricles and disorganized cytoarchitecture in the hippocampus, supporting the neurodevelopmental theory of aetiology. Dopamine excess (D2) is the oldest and most widely
accepted neurochemical hypothesis, although this may only explain one group of symptoms (the positive ones). The cognitive impairments in schizophrenia may be related to dopamine D₄ abnormalities. The interaction between serotonergic and dopaminergic systems is likely to play a role, although direct evidence is currently lacking. Additional hypotheses involving glutamate (NMDA) and GABA systems are currently also under scrutiny.

Clinical features
The illness can begin at any age but is rare before puberty. The peak age of onset is the early 20s. The symptoms that are diagnostic of the condition have been termed first rank symptoms and were described by the German psychiatrist Kurt Schneider. They consist of:
- Auditory hallucinations in the third person, and/or voices commenting on their behaviour
- Thought withdrawal, insertion and broadcast
- Primary delusion (arising out of nothing)
- Delusional perception
- Somatic passivity and feelings – patients believe that thoughts, feelings or acts are controlled by others.

The more of these symptoms a patient has, the more likely the diagnosis is schizophrenia, but these symptoms may also occur in other psychoses. Other symptoms of acute schizophrenia include behavioural disturbances, other hallucinations, secondary (usually persecutory) delusions and blunting of mood. Schizophrenia is sometimes divided into ‘positive’ (type 1) and ‘negative’ (type 2) types.

Positive schizophreniaн is characterized by acute onset, prominent delusions and hallucinations, normal brain structure, a biochemical disorder involving dopaminergic transmission, a good response to neuroleptics, and a better outcome.

Negative schizophreniaн is characterized by a slow, insidious onset, a relative absence of acute symptoms, the presence of apathy, social withdrawal, lack of motivation, underlying brain structure abnormalities and poor neuroleptic response.

Chronic schizophrenia
This is characterized by long duration and ‘negative’ symptoms of underactivity, lack of drive, social withdrawal and emotional emptiness.

Differential diagnosis
Schizophrenia should be distinguished from:
- Organic mental disorders (e.g. partial complex epilepsy)
- Mood (affective) disorders (e.g. mania)
- Drug psychoses (e.g. amfetamine psychosis)
- Personality disorders (schizotypal).

In older patients, any acute or chronic brain syndrome can present in a schizophrenia-like manner. A helpful diagnostic point is that altered consciousness and disturbances of memory do not occur in schizophrenia, and visual hallucinations are unusual.

A schizaffective psychosis describes a clinical presentation in which clear-cut affective and schizophrenic symptoms co-exist in the same episode.

Prognosis
The prognosis of schizophrenia is variable: 15–25% of people with schizophrenia recover completely, about 70% will have relapses and may develop mild to moderate negative symptoms, and about 10% will remain seriously disabled.

Treatment
The best results are obtained by combining drug and social treatments.

Antipsychotic (neuroleptic) drugs
These act by blocking the D₁ and D₂ groups of dopamine receptors. Such drugs are most effective against acute, positive symptoms and are least effective in the management of chronic, negative symptoms. Complete control of positive symptoms can take up to 3 months, and premature discontinuation of treatment can result in relapse.

As antipsychotic drugs block both D₁ and D₂ dopamine receptors, they usually produce extrapyramidal side-effects. This limits their use in maintenance therapy of many patients. They also block adrenergic and muscarinic receptors and thereby cause a number of unwanted effects (Table 23.26).

The neuroleptic malignant syndrome is an infrequent but potentially dangerous unwanted effect. This is a medical emergency and should be managed on a medical ward. It occurs in 0.2% of patients on neuroleptic drugs, particularly the potent dopaminergic antagonists, e.g. haloperidol. Symptoms occur a few days to a few weeks after starting treatment and consist of hyperthermia, muscle rigidity, autonomic instability (tachycardia, labile blood pressure, pallor) and a fluctuating level of consciousness. Investigations show a raised creatine kinase, raised white cell count and abnormal liver biochemistry. The more severe consequences include renal failure, pulmonary embolus and death. Treatment consists of stopping the drug and general resuscitation, e.g. temperature reduction. Bromocriptine enhances dopaminergic activity and dantrolene will reduce muscle tone but no treatment has proven benefit.

Pregnancy. Data on the potential teratogenicity of antipsychotic (neuroleptic) medications are still limited. The disadvantages of not treating during pregnancy have to be balanced against possible developmental risks to the fetus. The butyrophenones (e.g. haloperidol) are probably safer than the phenothiazines. Subsequent management decisions on dosage will depend primarily on the ability to avoid side-effects, since the antiparkinsonian agents are still believed to be teratogenic and should be avoided.

Table 23.26 Unwanted effects of antipsychotic drugs
Typical or first generation antipsychotics

Phenothiazines were the first group of antipsychotics to be developed but are used less frequently now. Chlorpromazine (100–1000 mg daily) is the drug of choice when a more sedating drug is required. Trifluoperazine is used when sedation is undesirable. Fluphenazine decanoate is used as a long-term prophylactic to prevent relapse, as a depot injection (25–100 mg every 1–4 weeks).

Butyrophenones (e.g. haloperidol 2–30 mg daily) are also powerful antipsychotics, used in the treatment of acute schizophrenia and mania. They are likely to cause a dystonia and/or extrapyramidal side-effects, but are much less sedating than the phenothiazines.

Atypical antipsychotics or serotonin dopamine antagonists (SDAs)

These drugs, also referred to as the ‘second generation antipsychotics’, are ‘atypical’ in that they block D2 receptors less than D1 and thus cause fewer extrapyramidal side-effects and less tardive dyskinesia. They are now recommended as first-line drugs for newly diagnosed schizophrenia and for patients taking typical antipsychotics but with significant adverse effects.

Risperidone is a benzisoxazole derivative with combined dopamine D2 receptor and 5HT2A receptor blocking properties. Dosage ranges from 6 to 10 mg/day. The drug is not markedly sedative and the overall incidence and severity of extrapyramidal side-effects is lower than with more conventional antipsychotics. Hyperprolactinaemia can be problematic and prolactin levels should be monitored. Paliperidone is an active metabolite of risperidone, available in oral and depot (4 weekly) preparations.

Olanzapine has affinity for 5HT2, D1, D2, D4, and muscarinic receptor sites. Clinical studies indicate it to have a lower incidence of extrapyramidal side-effects. The apparent better compliance with the drug may be related to its lower side-effect profile and its once-daily dosage of 5–15 mg. Weight gain is a problem with long-term treatment and there is an increased risk of type 2 diabetes mellitus with this and other atypicals.

Neither risperidone nor olanzapine seems as specific a treatment for intractable chronic schizophrenia as clozapine. Other atypical antipsychotics include amisulpride, lurasidone, sulpiride, zotepine, ziprasidone andquetiapine, the latter causing less hyperprolactinaemia. Those taking atypical antipsychotics should have regular monitoring of their body mass index, cholesterol levels, blood sugar and QT interval on ECG. No more than one antipsychotic should be prescribed routinely.

Clozapine is used in patients who have intractable schizophrenia who have failed to respond to at least two conventional antipsychotic drugs or as first-line therapy. This drug is a dibenzodiazepine with a high affinity for D2 dopamine receptors, as compared with D1, D3, D4 and D5, in addition to muscarinic and α-adrenergic receptors. It additionally acts as a partial agonist at 5HT1A receptors, which may be of benefit in treating ‘negative’ symptoms of psychosis. Functional brain scans have shown that clozapine selectively blocks limbic dopamine receptors more than striatal ones, which is probably why it causes considerably fewer extrapyramidal side-effects. Clozapine exercises a dramatic therapeutic effect on both intractable positive and negative symptoms. However, it is expensive and produces severe agranulocytosis in 1–2% of patients. Therefore, in the UK for example, it can only be presribed to registered patients by doctors and pharmacists registered with a patient-monitoring service. The starting dose is 25 mg per day with a maintenance dose of 150–300 mg daily. White cell counts should be monitored weekly for 18 weeks and then 2-weekly for the length of treatment. In addition to its antipsychotic actions, clozapine may also help reduce aggressive and hostile behaviour and the risk of suicide. It can cause considerable weight gain and sialorrhoea. There is an increased risk of diabetes mellitus and gastrointestinal hypomotility resulting in a functional obstruction has also been reported.

Psychological treatment

This consists of reassurance, support and a good doctor–patient relationship. Psychotherapy of an intensive or exploratory kind is contraindicated. In contrast, individual cognitive behaviour therapy can help reduce the intensity of delusions.

Social treatment

Social treatment involves attention being paid to the patient’s environment and social functioning. Family education can help relatives and partners to provide the optimal amount of emotional and social stimulation, so that not too much emotion is expressed (a risk for relapse). Sheltered employment is usually necessary for the majority of sufferers if they are to work. Assertive outreach mental health teams will follow up those poorly adhering to treatment.

Medical presentations related to treatment

The motor side-effects of neuroleptics are the commonest reason for a patient with schizophrenia to present to a physician, followed by self-harm. Acute dystonia normally arises in patients newly started on neuroleptics, causing torticollis. Extrapyramidal side-effects are common and present in the same way as Parkinson’s disease. They remit on stopping the drug and with antimuscarnic drugs, e.g. procyclidine. Akathisia is a motor restlessness, most commonly affecting the legs. It is similar to the restless legs syndrome, but apparent during the day. Amenorrhoea and galactorrhoea can be caused by dopamine antagonists. Postural hypotension can affect the elderly, and neuroleptics can be the cause of delirium in the elderly, if their antimuscarnic effects are prominent.

Long-term benefits outweigh the risks in most cases and long-term treatment is associated with a lower mortality rate when compared with no treatment. In this respect, the atypical antipsychotics are preferable to the typical antipsychotics and clozapine is the class leader in this regard.

Organic mental disorders

Organic brain disorders result from structural pathology, as in dementia, or from disturbed central nervous system (CNS) function, as in fever-induced delirium. They do not include mental and behavioural disorders due to alcohol and misuse of drugs, which are classified separately.

Delirium

Delirium, also termed toxic confusional state and acute organic psychosis, is an acute or subacute brain failure in which impairment of attention is accompanied by abnormalities of perception and mood. It is the most common psychosis seen in the general hospital setting, where it occurs in 14–24% of patients. This rises in specialist populations such as intensive care (70–87%). Confusion is usually worse at night, with consequent sleep reversal, so that the patient is asleep in the day and awake all night. During the acute phase, thought and speech are incoherent, memory is
impairment of consciousness, impaired awareness, and abnormal perception. The main clinical criteria for diagnosis are:

- Disturbance of consciousness:
  - ↓ clarity of awareness of environment
  - ↓ ability to focus, sustain or shift attention
- Change in cognition:
  - memory deficit, disorientation, language disturbance, perceptual disturbance
- Disturbance develops over a short period (hours or days)
- Fluctuation over the course of a day

All current drug therapy should be reviewed and, where possible, stopped. Psychoactive drugs should be avoided if possible (because of their own risk of exacerbating delirium). In severe delirium, haloperidol is an effective choice, the daily dose usually ranging between 1.5 mg (in the elderly) and 30 mg per day. Benzodiazepines should not be used as first-line medication and may prolong confusion. If necessary, the first dose can be administered intramuscularly. Olanzapine is an effective alternative, especially if given at night for insomnia.

**Prognosis of delirium**

Delirium usually clears within a week or two, but brain recovery usually lags behind the recovery from the causative physical illness. The prognosis depends not only on the successful treatment of the causative disease, but also on the underlying state of the brain. Some 25% of the elderly with delirium will have an underlying dementia; 15% of patients do not survive their underlying illness; 40% are in institutional care at 6 months.

**EATING DISORDERS**

**Obesity**

This is the commonest eating disorder (see p. 195) and has become epidemic in some developed countries. It is usually caused by a combination of constitutional and social factors, but a binge eating disorder and psychological determinants of “comfort eating” should be excluded.

**Anorexia nervosa**

The main clinical criteria for diagnosis are:

- A body weight more than 15% below the standard weight, or a body mass index (BMI) below 17.5 (ICD-10)
- Weight loss is self-induced by avoidance of fattening foods, vomiting, purging, exercise, or appetite suppressants
- A distortion of body image so that the patient regards her/himself as fat when she/he is thin
- A morbid fear of fatness
- Amenorrhoea in women.

Clinical features include:

- Onset usually in adolescence
- A previous history of faddish eating
- The patient generally eats little, yet is obsessed by food
- Excessive exercising.

The physical consequences of anorexia include sensitivity to cold, constipation, hypotension and bradycardia. In most cases, amenorrhoea is secondary to the weight loss. In those who also binge and vomit or abuse purgatives, there may be hypokalaemia and alkalosis.
Prevalence
Case register data suggest an incidence rate of 19/100000 females aged between 15 and 34 years. Surveys have suggested a prevalence rate of approximately 1% among schoolgirls and university students. However, many more young women have amenorrhoea accompanied by less weight loss than the 15% required for the diagnosis. The condition is much less common among men (ratio of 1:10).

Aetiology
Biological factors
Genetic. Some 6–10% of siblings of affected women suffer from anorexia nervosa. There is an increased concordance amongst monozygotic twins, suggesting a genetic predisposition.
Hormonal. The reductions in sex hormones and down-regulation of the hypothalamic-pituitary-adrenal axis are secondary to malnutrition and usually reversed by refeeding.

Psychological factors
Individual. Anorexia nervosa has often been seen as an escape from the emotional problems of adolescence and a regression into childhood. Patients will often have had dietary problems in early life. Perfectionism and low self-esteem are common antecedents. Studies suggest that survivors of childhood sexual or other abuse are at greater risk of developing an eating disorder, usually anorexia nervosa, in adolescence.
Family. Family problems are most commonly secondary to the stress of coping with a family member with the illness.

Social and cultural factors
There is a higher prevalence in higher social classes, westernized families and in certain occupational groups (e.g. ballet dancers and nurses) and in societies where cultural value is placed on thinness.

Prognosis
The condition runs a fluctuating course, with exacerbations and partial remissions. Long-term follow-up suggests that about two-thirds of patients maintain normal weight and that the remaining one-third are split between those who are moderately underweight and those who are seriously underweight. Indicators of a poor outcome include:
- A long initial illness
- Severe weight loss
- Older age at onset
- Bingeing and purging
- Personality difficulties
- Difficulties in relationships.

Suicide has been reported in 2–5% of people with chronic anorexia nervosa. The mortality rate per year is 0.5% from all causes. The illness can quickly cause osteopenia, and later osteoporosis. More than one-third have recurrent affective illness, and various family, genetic and endocrine studies have found associations between eating disorders and depression.

Treatment
Treatment can be conducted on an outpatient basis unless the weight loss is severe and accompanied by marked cardiovascular signs and/or electrolyte and vitamin disturbances. Hospital admission may then be unavoidable and may need to be on a medical ward initially. Uncommonly, the patient’s weight loss may be so severe as to be life-threatening. If the patient cannot be persuaded to enter hospital, compulsory admission may have to be used. Inpatient treatment goals include:
- Establishing a therapeutic relationship with both the patient and her family
- Restoring the weight to a level between the ideal body weight and the patient’s ideal weight
- The provision of a balanced diet, aimed at gaining 0.5–1 kg weight per week
- The elimination of purgative and/or laxative use and vomiting.

Outpatient treatment should include cognitive behavioural or interpersonal psychotherapies. Setting up a therapeutic alliance is vital. Family therapy is more effective than individual psychotherapy in adolescents and those still at home, and less effective in those who have left home. Motivational enhancement techniques are being used with some success.

Drug treatment has met with limited success, and those drugs that increase the QTc interval should be avoided. Vitamins and minerals may need replacement.

Bulimia nervosa
This refers to episodes of uncontrolled excessive eating, which are also termed ‘binges’, accompanied by means to lose weight. There is a preoccupation with food and habitual behaviours to avoid the fattening effects of periodic binges. These behaviours include:
- Self-induced vomiting
- Misuse of drugs – laxatives, diuretics, thyroid extract or anorectics.

Additional clinical features include:
- Physical complications of vomiting:
  a. cardiac arrhythmias
  b. renal impairment
  c. muscular paralysis
  d. tetany – from hypokalaemic alkalosis
  e. swollen salivary glands – from vomiting
  f. eroded dental enamel
- Associated psychiatric disorders:
  a. depressive illness
  b. alcohol misuse
- Fluctuations in body weight within normal limits
- Menstrual function – periods irregular but amenorrhoea rare
- Personality – perfectionism and/or low self-esteem present premorbidly.

The prevalence of bulimia in community studies is high; it affects between 5% and 30% of girls attending high schools, colleges or universities in the USA. Bulimia is sometimes associated with anorexia nervosa. A premorbid history of dieting is common. The prognosis for bulimia nervosa is better than for anorexia nervosa.

Treatment
Individual cognitive behaviour therapy is more effective than both interpersonal psychotherapy and drug treatments. SSRIs (e.g. fluoxetine) are also an effective treatment, even in the absence of a depressive illness, but may require high doses.

Atypical eating disorders
These include eating disorders that do not conform clinically to the diagnostic criteria for anorexia nervosa or bulimia.
nervosa. Binge eating disorders consist of bulimia without the vomiting and other weight-reducing strategies.

**SEXUAL DISORDERS**

Sexual disorders can be divided into sexual dysfunctions and deviations and gender role disorders (Table 23.29).

**Sexual dysfunction**

Sexual dysfunction in men refers to repeated inability to achieve normal sexual intercourse, whereas in women it refers to a repeatedly unsatisfactory quality of sexual satisfaction. Problems of sexual dysfunction can usefully be classified into those affecting sexual desire, arousal and orgasm. Among men presenting for treatment of sexual dysfunction, erectile dysfunction is the most frequent complaint. The prevalence of premature ejaculation is low, except in young men, while ejaculatory failure is rare.

Sexual drive is affected by constitutional factors, ignorance of sexual technique, anxiety about sexual performance, medical and psychiatric conditions and certain drugs (Tables 23.30, 23.31).

The treatment of sexual dysfunction involves careful assessment of both physical and psychosocial factors, the participation (where appropriate) of the patient’s partner, sex education, and specific therapeutic techniques, including relaxation, behavioural therapy and couple therapy. The introduction of phosphodiesterase type 5 inhibitors (e.g. sildenafil) has provided an effective therapy for the treatment of erectile dysfunction (see p. 977).

**Sexual deviation**

Sexual deviations are regarded as unusual forms of behaviour rather than as an illness. Doctors are only likely to be involved when the behaviour involves breaking the law (e.g. paedophilia) and when there is a question of an associated mental or physical disorder. Men are more likely than women to have sexual deviations.

**Gender role disorders**

Transsexualism involves a disturbance in gender identity in which the patient is convinced that their body is the wrong gender. A person’s gender identity refers to the individual’s sense of masculinity or femininity as distinct from sex. There is increasing evidence that transsexualism is biologically determined, perhaps by prenatal endocrine influences, and functional brain imaging shows specific differences from normal controls.

For males, treatment includes oestrogen administration and, if surgery is to be recommended, a period of living as a woman as a trial beforehand. In the case of female transsexuals, treatment involves surgery and the use of methyltestosterone.

**PERSONALITY DISORDERS**

These disorders comprise enduring patterns of behaviour which manifest themselves as inflexible responses to a broad range of personal and social situations. Personality disorders are developmental conditions that appear in childhood or adolescence and continue into adult life. Their prevalence is about 15% in the population. They are not secondary to another psychiatric disorder or brain disease, although they may precede or co-exist with other disorders. In contrast, personality change is acquired, usually in adult life, following severe or prolonged stress, extreme environmental deprivation, serious psychiatric disorder or brain injury or disease.

Personality disorders are usually subdivided according to clusters of traits that correspond to the most frequent or obvious behavioural manifestations, but many will show the characteristics of more than one category. The main categories of personality disorder are described in Table 23.32.
### Table 23.32 The main categories of personality disorder

<table>

*Chronic internal emptiness*  
*Frequent self-harm*  
*Transient 'pseudo' psychotic features*  
*Strong family history of mood disorders* |
| Paranoid                  | *Extreme sensitivity*  
*Suspicious*  
*Litigious*  
*Self-important*  
*Preoccupation with conspiracy theories* |
| Schizoid                  | *Emotionally cold and detached*  
*Limited capacity to express emotions*  
*Indifference to praise or criticism*  
*Preference for solitary activities*  
*Lack of close friendships*  
*Marked insensitivity to social norms* |
| Antisocial                | *Callous unconcern for the feelings of others*  
*Incapacity to maintain enduring relationships*  
*Very low tolerance of frustration*  
*Incapacity to experience guilt and to learn from experience*  
*Tendency to blame others* |
| Histrionic                | *Self-dramatization, theatricality, suggestibility*  
*Shallow and labile emotions*  
*Continual seeking for excitement and appreciation*  
*Inappropriately seductive appearance and behaviour* |
| Narcissistic              | *Inflated sense of self-importance*  
*Need to be admired*  
*Self-referential*  
*Arogant* |
| Anankastic (obsessional)  | *Feelings of excessive doubt and caution*  
*Preoccupation with details, rules and order*  
*Perfectionism*  
*Excessive conscientiousness, scrupulousness, pedantry and rigidity* |
| Dependent                 | *Encourage others to make their personal decisions*  
*Subordinate their needs to others*  
*Unwilling to make demands on others*  
*Feel unable to care for themselves*  
*Preoccupied with fears of being abandoned* |

#### IN VOLUNTARY DETENTION OR COMMITMENT

Involuntary detention in hospital is typically used as a last resort and treatment on an outpatient basis is preferable in most cases. This describes the practice of *admitting or keeping a patient in hospital against their will*. This is done in compliance with the mental health legislation relevant to the particular country. Application for such a course of action may be made by a doctor (typically but not always a psychiatrist), social worker, psychologist or in some instances, a police officer.

Mental health laws differ between countries and in the case of the USA, also between states. However, in broad terms, the principles remain the same and are summarized in Box 23.16.

The potential for the abuse of such ‘powers’ is a constant focal point for the review of such legislation. Although this is thankfully uncommon, the detention of individuals as a means to suppress dissent against regimes is well known.

#### MENTAL CAPACITY ACT

Mental capacity is the ability to make decisions about all aspects of one’s life, including but not exclusively healthcare. All doctors need to be able to assess mental capacity. In England and Wales, a new ACT was passed in 2005, which, for the first time, formally protects patients who lack capacity (see Ch. 1, Box 1.4). Some 3% of people in the UK are thought to lack capacity due to conditions affecting brain function, such as dementia. However, the assessment of capacity is specific to an individual decision, so it is possible to have capacity to make one decision but not another. The assessment of capacity is outlined in Box 23.17. Capacity is assumed unless there is evidence to the contrary. In the absence of capacity, the doctor should act in the best interests of the patient and provide the least restrictive management, after consulting an independent advocate.

#### Box 23.17 Assessment of mental capacity to make a decision

The patient has a demonstrated impairment or disturbance of their mind/brain and a demonstrated inability to do any of the following:
- Understand relevant information
- Retain that information for sufficient time to make the decision
- Use or weigh that information
- Communicate their decision.

Introduction

Skin diseases have a high prevalence throughout the world. In developing countries infectious diseases such as tuberculosis, leprosy and onchocerciasis are common, whereas in developed countries inflammatory disorders such as eczema and acne are common. Skin disorders can be inherited, e.g. Ehlers–Danlos syndrome, a part of normal development, e.g. acne vulgaris, or may present as part of a systemic disorder, e.g. systemic lupus erythematosus (SLE). Approximately 25% of the UK population will develop a skin problem and skin disease accounts for 10% of the workload of family doctors. The common reasons that people with a rash present, are itching or pain, disturbed sleep, anxiety, depression, lack of self-confidence (if rash is obviously visible); and interfering with work (such as allergic hand eczema in a chef, builder or hairdresser).

Rarely, skin disease can be fatal. Examples are malignant melanoma, toxic epidermal necrolysis and pemphigus.

STRUCTURE AND FUNCTION OF THE SKIN

The skin consists of four distinct layers:
1. The epidermis
2. The basement membrane zone

The functions of the skin are summarized in Box 24.1.

The epidermis

The epidermis is a stratified epithelium of ectodermal origin that arises from dividing basal keratinocytes. The downward projections of the epidermis into the dermis are called the ‘rete ridges’. The lower epidermal cells (basal layer) produce a variety of keratin filaments and desmosomal proteins (e.g. desmoglein and desmoplakin), which make up the ‘cytoskeleton’. This confers strength to the epidermis preventing it shedding. Higher up in the granular layer, complex lipids are secreted by the keratinocytes and these form into intercellular lipid bilayers, which act as a semipermeable skin barrier. The upper cells (stratum corneum) lose their nuclei and become surrounded by a tough impermeable ‘envelope’ of various proteins (loricrin, involucrin, filaggrin and keratin). Changes in lipid metabolism and protein expression in the outer layers allow normal shedding of keratinocytes.

Keratinocytes can secrete a variety of cytokines (e.g. interleukins, gamma-interferon, tumour necrosis factor alpha) in response to tissue injury or in certain skin diseases. These play a role in specific immune function, cutaneous inflammation and tissue repair. There is a further layer of protection against microbial invasion – the innate immune system of...
Merkel cells are also found in the basal layer and originate either from neural crest or epidermal keratinocytes. They are numerous on finger tips and in the oral cavity and play a role in sensation.

Langerhans’ cells are dendritic cells found in the supra-basal layer. They derive from the bone marrow and express the cytokine CCR6. They are guided to normal skin, which contains a CCR6 agonist called macrophage inflammatory protein 3α. Langerhans’ cells endocytose extracellular antigens in the skin and then migrate to local lymph nodes for T cell presentation and thus act as antigen-presenting cells.

Basement membrane zone

The basement membrane zone (see Fig. 24.27) is a complex proteinaceous structure consisting of type IV, VII and XVII collagen, hemidesmosomal proteins, integrins and laminin. Collectively, they hold the skin together, keeping the epidermis firmly attached to the dermis. Inherited or autoimmune-induced deficiencies of these proteins can cause skin fragility and a variety of blistering diseases (see p. 1221).

The dermis

The dermis is of mesodermal origin and contains blood and lymphatic vessels, nerves, muscle, appendages (e.g. sweat glands).
The sweat glands

Eccrine sweat glands are found throughout the skin except the mucosal surfaces.

Apocrine sweat glands are found in the axillae, anogenital area and scalp and do not function until puberty.

The sweat glands and vasculature are involved in temperature control.

The sebaceous glands

These are inactive until puberty. They are responsible for secreting sebum or grease onto the skin surface (via the hair follicle) and are found in high numbers on the face and scalp.

Nerves

The skin is richly innervated. Nerve fibres enable sensation of touch, pain, itch, vibration and change in temperature.

Hair

Hairs arise from a downgrowth of epidermal keratinocytes into the dermis. The hair shaft has an inner and outer root sheath, a cortex and sometimes a medulla. The lower portion of the hair follicle consists of an expanded bulb (which also contains melanocytes) surrounding a richly innervated and vascularized dermal papilla. The hair regrows from the bulb after shedding. There are three types of hair:

- **Terminal**: medullated coarse hair, e.g. scalp, beard, pubic
- **Vellus**: non-medullated fine downy hairs seen on the face of women and in prepubertal children
- **Lanugo**: non-medullated soft hair on newborns (most marked in premature babies) and occasionally in people with anorexia nervosa.

All hair follicles follow a growth cycle: anagen (growth phase), catagen (involution phase), telogen (shedding phase). At any one time, most hairs (>90%) will be in the anagen phase, which is typically 3–5 years for scalp hair.

Grey hair is due to decreased tyrosinase activity in the hair bulb melanocytes. White hair is due to total loss of these melanocytes.

Nails

Nails are tough plates of hardened keratin, which arise from the nail matrix (just visible as the moon-shaped lunula) under the nail fold. It takes 6 months for a finger-nail to grow out fully and 1 year for a toe-nail.

The subcutaneous layer

The subcutaneous layer consists predominantly of adipose tissue as well as blood vessels and nerves. This layer provides insulation and acts as a lipid store.

**APPRAOCH TO THE PATIENT**

The history should aim to elicit the following points:

- Time course of rash
- Distribution of lesions
- Symptoms (e.g. itch or pain)
- Family history (especially of atopy and psoriasis)
- Drug/allergy history
- Past medical history

**INFECTIONS**

**Bacterial infections (see also p. 114)**

The skin’s normal bacterial flora prevents colonization by pathogenic organisms. A break in epithelial integrity by trauma, leg ulcers, fungal infections (e.g. athlete’s foot) or abnormal scaling of the skin (e.g. in eczema) can allow infection. Nasal carriage of bacteria can be a source of reinfection.

**Impetigo**

Impetigo is a highly infectious skin disease most common in children (Fig. 24.2). It presents as weeping, exudative areas with a typical honey-coloured crust on the surface. It is spread by direct contact. The term ‘scrum pox’ refers to impetigo spread between rugby players. Staphylococci or group A β-haemolytic streptococci are the causative agents: skin swabs should be taken.

**Prevention**

Prevention is by good personal hygiene, particularly hand washing with soap.

**Treatment**

Impetigo is usually treated with oral antibiotics for 7–10 days (flucloxacinill 500 mg four times daily for *Staphylococcus*; pheoxymethyl/penicillin 500 mg four times daily for *Streptococcus*). Other close contacts should be examined and children should avoid school for 1 week after starting therapy. If impetigo appears resistant to treatment or recurrent, take nasal swabs and check other family members. Nasal mupirocin (three times daily for 1 week) is useful to eradicate nasal carriage, especially in hospital staff. Community-acquired MRSA (in chapter 4) is increasingly recognized as a cause of superficial skin infections and treatment should be governed by bacterial sensitivities.

**Bullous impetigo/staphylococcal scalded skin syndrome**

Rarely *Staphylococcus* releases an exfoliating toxin which acts high up in the epidermis: toxin A causes blistering at the site of infection (bullous impetigo), toxin B spreads through the body causing more widespread blistering (staphylococcal scalded skin syndrome, SSSS). The latter is more common in childhood with very low mortality rates. In adults it is often associated with renal disease or immunosuppression, and mortality rates increase to 50%. Both these toxins cleave desmoglein 1 (a desmosomal protein) so that skin cells separate from one another.

**Family history** (especially of atopy and psoriasis)

**Symptoms** (e.g. itch or pain)

**Distribution of lesions**

**Provoking factors** (e.g. sunlight or diet)

**Previous skin treatments.**

**Examination** entails looking and feeling a rash (for terminology, see Table 24.1). It should include an assessment of nails, hair and mucosal surfaces even if these are recorded as unaffected. The following terms are used to describe distribution: flexural, extensor, acral (hands and feet), symmetrical, localized, widespread, facial, unilateral, linear, centripetal (trunk more than limbs), annular and reticulate (lacey network or mesh like).

**Investigation.** With regard to investigation, clinical acumen remains the most useful tool in dermatology but a variety of tests are useful in confirming a diagnosis (Table 24.2).

**Approach to the patient**

Infections

**Structure and function of the skin**

*Further reading*

mucosal involvement does not occur (this is analogous to pemphigus foliaceous which has the same target antigen, p. 1222).

SSSS can mimic toxic epidermal necrolysis (TEN, see p. 1231). It can be differentiated in two ways: mucosal involvement only occurs in TEN, and skin biopsy shows a more superficial split in SSSS (intraepidermal) than in TEN (subepidermal). Both bullous impetigo and SSSS are treated with anti-staphylococcal antibiotics (e.g. flucloxacillin) and supportive care.

**Cellulitis**

Cellulitis presents as a hot, sometimes tender area of confluent erythema of the skin due to infection of the deep subcutaneous layer. It often affects the lower leg, causing an upward-spread, hot erythema, and occasionally will blister, especially if oedema is prominent. It may also be seen affecting one side of the face. Patients are often unwell with a high temperature. It is usually caused by a β-haemolytic streptococcus, rarely a staphylococcus, and sometimes...
Infections

Post-cellulitic oedema is common and predisposes to further episodes of cellulitis.

Ecthyma

Ecthyma is also an infection due to *Streptococcus* or *Staphylococcus aureus* or occasionally both. It presents as chronic well-demarcated, deeply ulcerative lesions sometimes with an exudative crust. It is commoner in developing countries, being associated with poor nutrition and hygiene. It is rare in the UK but is seen more commonly in intravenous drug users and people with HIV infection.

Treatment is with phenoxymethylpenicillin and flucloxacillin (both 500 mg four times daily) for 10–14 days.

Erythrasma

Erythrasma is caused by *Corynebacterium minutissimum*. It usually presents as an orange-brown flexural rash, and is often seen in the axillae or toe web spaces (Fig. 24.3). It is frequently misdiagnosed as a fungal infection. The rash shows a dramatic coral pink fluorescence under Wood’s (ultraviolet) light.

Treatment is with oral erythromycin 500 mg four times daily for 7–10 days.

FURTHER READING

Folliculitis

Folliculitis is an inflammation of the hair follicle. It presents as itchy or tender papules and pustules. Staphylococcus aureus is frequently implicated. It is common in humid climates and when occlusive clothes are worn. A variant occurs in the beard area (called ‘sycosis barbae’), which is common in black Africans. This is probably caused by the ability of shaved hair to grow back into the skin, especially if the hair is naturally curly. Extensive, itchy folliculitis of the upper trunk and limbs should alert one to the possibility of underlying HIV infection. Folliculitis following use of hot tubs is due to Pseudomonas ovale.

**Treatment** is with topical antiseptics, topical antibiotics (e.g. sodium fusidate) or oral antibiotics (e.g. flucloxacillin 500 mg or erythromycin 500 mg both four times daily for 2–4 weeks).

Boils (furuncles)

Boils are a rather more deep-seated infection of the skin, often caused by Staphylococcus. These can cause painful red swellings. They are commoner in teenagers and often recurrent. Recurrent boils may rarely occur in diabetes mellitus or in immunosuppression. Large boils are sometimes called ‘carbuncles’. Swabs should be taken to check antibiotic sensitivity as community-acquired MRSA is an increasingly common cause.

**Treatment** is with oral antibiotics (e.g. erythromycin 500 mg four times daily for 10–14 days) and occasionally by incision and drainage.

Antiseptics such as chlorhexidine (as soap) can be useful in prophylaxis.

Hidradenitis suppurativa

This condition is characterized by a painful, discharging, chronic inflammation of the skin at sites rich in apocrine glands (axillae, groins, natal cleft). The cause is unknown but it is commoner in females and within some families. It appears to be inherited in an autosomal dominant fashion. The initial lesion is occlusion of the hair follicle producing an inflammatory reaction that spreads to the apocrine glands. Clinically it presents after puberty with papules, nodules and abscesses which often progress to cysts and sinus formation. With time, scarring arises. The condition follows a chronic relapsing/remitting course and is worse in obese individuals.

**Treatment** is difficult but weight loss, ‘prophylactic’ antibiotics, oral retinoids, zinc and co-cyprindiol (2 mg cyproterone acetate + 35 μg ethinylestradiol in females only) have been tried. They should be used as for acne vulgaris (p. 1212). Severe recalcitrant cases have been treated with intralesional corticosteroids or intralesional neomycin. Retinoids can also be used locally. Topical antibiotics are not very effective.

Pitted keratolysis

This is a superficial infection of the horny layer of the skin caused by a corynebacterium. It frequently involves the soles of the foot and appears as numerous small punched-out circular lesions of a rather macerated skin (e.g. as seen after prolonged immersion). There may be an associated hyperhidrosis of the feet and a prominent odour.

**Treatment**. Topical antibiotics (e.g. sodium fusidate or clindamycin, applied three times daily for 2–4 weeks) and topical anti-sweating lotions are effective therapies.

Mycobacterial infections

**Leprosy (Hansen’s disease)** (p. 130)

Leprosy usually involves the skin, and the clinical features depend on the body’s immune response to the organism *Mycobacterium leprae*.

**Indeterminate leprosy** is the commonest clinical type, especially in children. This presents as small, hypopigmented or erythematous circular macules with occasional mild anaesthesia and scaling. This may resolve spontaneously or progress to one of the other types. Biopsy reveals a perineural granulomatous infiltrate and scant acid-fast bacilli.

**Tuberculoid leprosy** presents with a few larger, hypopigmented (see Fig. 4.28) or erythematous plaques with an active inflammatory reaction. Lesions are usually markedly anaesthetic, dry and hairless, reflecting the nerve damage.

**Lepromatous leprosy** presents with multiple inflammatory papules, plaques and nodules. Loss of the eyebrows (‘madarosis’) and nasal stuffiness are common. Skin thickening and severe disfigurement may follow. Anaesthesia is much less prominent. Biopsy shows numerous acid-fast bacilli.

Diagnosis and treatment are discussed on page 131.

Skin manifestations of tuberculosis

Tuberculosis can occasionally cause skin manifestations:

- **Lupus vulgaris** usually arises as a post-primary infection. It usually presents on the head or neck with red-brown nodules that look like apple jelly when pressed with a glass slide (‘diascopy’). They heal with scarring and new lesions slowly spread out to form a chronic solitary erythematous plaque. Chronic lesions are at high risk of developing squamous cell carcinoma.

- **Tuberculosis verrucosa cutis** arises in people who are partially immune to tuberculosis but who suffer a further direct inoculation in the skin. It presents as warty lesions on a ‘cold’ erythematous base.

- **Scrofuloderma** arises when an infected lymph node spreads to the skin causing ulceration, scarring and discharge.

- **The tuberculides** are a group of rashes caused by an immune manifestation of tuberculosis rather than direct infection. Erythema nodosum is the commonest and is discussed on page 1216. Erythema induratum (‘Bazin’s disease’) produces similar deep red nodules but these are usually found on the calves rather than the shins and they often ulcerate.

Viral infections

**Viral exanthem**

This is the commonest type of virus-induced rash and presents clinically as a widespread nonspecific erythematous maculopapular rash. It probably arises due to circulating immune complexes of antibody and viral antigen localizing to dermal blood vessels. The rash can be caused by many different viruses (e.g. echovirus, erythrovirus, human herpes virus-6, Epstein–Barr virus; see chapter 4) and so is rarely diagnostic. The rash will resolve spontaneously in 7–10 days.

**Slapped cheek syndrome** *(erythema infectiosum, fifth disease)*

See page 101.
**Herpes simplex virus** (see also p. 97)

Herpes simplex virus (HSV) occurs as two genomic subtypes. Most people are affected in early childhood with HSV type 1 but the infection is usually subclinical. Occasionally it can present with either clusters of painful blisters on the face or a painful gingivostomatitis. In some individuals cell-mediated immunity is poor and they get recurrent attacks of HSV, often manifest as cold sores. Immunosuppression can also cause a recrudescence of HSV. HSV can also autoinoculate into sites of trauma and present as painful blisters/pustules which may be seen for example on the fingers of healthcare workers (“herpetic whitlow”).

HSV type 2 infections are discussed on page 97. Other rare complications of HSV infection include corneal ulceration, eczema herpeticum, chronic perianal ulceration in AIDS patients and erythema multiforme.

**Treatment**

Oral valaciclovir (500 mg twice daily for 5 days) is used for primary HSV and painful genital HSV. Cold sores are treated with aciclovir cream but this must be used early to be effective in shortening an attack; recurrent sores are treated with oral therapy. Attacks of herpes become less frequent with time. Intravenous aciclovir must be used in immunosuppressed patients.

**Varicella zoster virus**

Varicella zoster virus (VZV) causes the common childhood infection called chickenpox. It is discussed on page 98. It also causes herpes zoster.

**Herpes zoster (shingles)**

‘Shingles’ results from a reactivation of VZV. It may be preceded by a prodromal phase of tingling or pain, which is then followed by a painful and tender blistering eruption in a dermatomal distribution (Fig. 24.4 and Fig. 4.15, p. 98). The blisters occur in crops, may become pustular and then crust over. The rash lasts 2–4 weeks and is usually more severe in the elderly. Occasionally more than one dermatome is involved.

Complications of shingles include severe, persistent pain (post-herpetic neuralgia), ocular disease (if the ophthalmic nerve is involved) and rarely motor neuropathy.

**Treatment**

Herpes zoster requires adequate analgesia and antibiotics (if secondary bacterial infection is present). Valaciclovir 1 g or famciclovir 250 mg three times daily for 7 days is used, or oral aciclovir 800 mg, five times daily for 7 days helps shorten the attack if given early in the illness. Brivudine 125 mg is also available. High-dose intravenous aciclovir is used in immunosuppressed patients. It remains unclear how useful aciclovir therapy is in preventing prolonged post-herpetic neuralgia.

**Human papilloma virus**

Human papilloma virus (HPV) is responsible for the common cutaneous infection of ‘viral warts’.

**Common warts** are papular lesions with a coarse roughened surface, often seen on the hands and feet, but also on other sites. Small black dots (bleeding points) are often seen within the lesion (Fig. 24.5). If they occur on the face they are often elongated (“filiform”) Children and adolescents are usually affected. Spread is by direct contact and is also associated with trauma.

**Plantar warts** (verrucae) is the term used for lesions on the soles of the feet. They often appear flat (“inward growing”) although they have the same papillomatous surface change and black dots are often revealed if the skin is pared down (unlike callusities). Warts may be painful or tender if they are over pressure points or around nail folds.

**Plane warts** are much less common and are caused by certain HPV subtypes. They are clinically different and appear as very small, flesh-coloured or pigmented, flat-topped lesions (best seen with side-on lighting) with little in the way of surface change and no black dots within them. They are usually multiple and are frequently found on the face or the backs of the hands.

**Anogenital warts** are usually seen in adults and are normally transmitted by sexual contact. They are rare in childhood and, whilst child sexual abuse should always be considered, it should be remembered they may well have been transmitted through non-sexual contact. HPV subtypes 16 and 18 are potentially oncogenic and are associated with cervical and anal carcinomas.

**Treatment**

Common warts on the skin are surprisingly difficult to treat effectively but they almost always resolve spontaneously after months to years (with no scarring), presumably due to cell-mediated immune recognition. When they do resolve, they tend to do so rapidly within a few days.

Regular use of a topical keratolytic agent (e.g. 2–10% salicylic acid) over many months with weekly paring of the lesion helps speed up resolution in some patients and remains the mainstay of treatment. A course of cryotherapy (freezing) can also help. Cautery, surgery, carbon dioxide laser, alpha-interferon injection and bleomycin injection have all been used with variable success but are not recommended, as treatments may be very painful and can cause permanent scarring.

---

**Figure 24.4** Herpes zoster in an African male (courtesy of Dr P Matondo, Lusaka, Zambia).

**Figure 24.5** Viral wart.
Genital warts are usually treated with cryotherapy, trichloroacetic acid, 5% imiquimod cream or topical podophyllin. People with genital warts (and their sexual partners) must be screened for other sexually transmitted diseases.

HPV vaccines against the high-risk oncogenic subtypes (6, 11, 16 and 18) are now available; they should help protect against cervical neoplasia but will have no impact on common warts.

**Molluscum contagiosum**

*Molluscum contagiosum* is a common cutaneous infection of childhood caused by the pox virus. Clinically, lesions are multiple small (1–3 mm) translucent papules which often look like fluid-filled vesicles but are in fact solid. Individual lesions may have a central depression called a punctum. They exhibit the Köbner phenomenon (p. 1208). They can occur at any body site including the genitalia. Transmission is by direct contact. Occasionally lesions may be up to 1 cm in diameter (‘giant molluscum’).

They usually continue to occur in crops over 6–12 months and rarely require treatment as they spontaneously resolve. Any form of localized trauma, including scratching, helps speed up resolution, and cryotherapy is used in older children. One per cent stabilized hydrogen peroxide cream or 5% imiquimod cream is used in younger children. Molluscum in an adult, especially if giant, should raise the underlying possibility of immunosuppression, especially HIV infection.

**Orf**

Orf is a disease of sheep (and occasionally goats) due to a pox virus infection. It causes a vesicular and pustular rash around the mouths of young lambs. People who come into contact with the affected fluid may develop lesions on the hands. Clinically these appear as 1–2 cm reddish papules with a surrounding erythema which usually become pustular. The lesion(s) resolves spontaneously after 4–6 weeks and immunity is lifelong. Occasionally, orf is complicated by erythema multiforme.

**Fungal infections**

Fungal skin disease (mycosis) has a high prevalence in humans with ‘thrush’ and ‘athlete’s foot’ being two of the commonest examples. In the immunosuppressed, mycoses can be widespread and life-threatening. There are three groups of pathogenic fungi that commonly affect the outer layer of skin or keratinizing epithelium: dermatophytes, *Candida albicans* and pityrosporum.

**Dermatophyte infection**

By definition, dermatophytes cause a ‘ringworm’ type of rash. The three main genera responsible are *Trichophyton*, *Microsporum* and *Epidermophyton*. These organisms are identified by microscopy and culture of skin, hair or nail samples. The clinical appearance depends in part on the organism involved, the site affected and the host reaction. All are spread by direct contact from other humans or from infected animals.

**Tinea corporis**

Ringworm of the body usually presents with asymmetrical, scaly patches which show central clearing and an advancing, scaly, raised edge. Occasionally, vesicles or pustules may be seen in the edge. Central clearing is not a universal feature and it is recommended that all asymmetrical scaly lesions should be scraped for fungus. Ringworm of the face (tinea faciei) often arises after the use of topical steroids. It tends to be more erythematous and less scaly than trunk lesions and it may become itchy after sun exposure.

**Tinea cruris**

Ringworm of the groin is extremely common worldwide. Early on, the lesions appear as well-demarcated red plaques with an arc-like border extending down the upper thigh (Fig. 24.6). Central clearing may appear and a few pustules or vesicles may be seen if inflammation is intense. Satellite lesions, suggestive of *Candida*, are not present.

**Tinea pedis**

Athlete’s foot may be confined to the toe clefts where the skin looks white, macerated and fissured. It may also be more diffuse, usually causing a diffuse scaly erythema of the soles spreading on to the sides of the foot. Annular lesions are rarely present. There may be an associated hyperhidrosis and fungal involvement of one or more toe-nails. In severe infection a strong inflammatory reaction can occur causing pustules or blistering and this often leads to a misdiagnosis of pompholyx-type eczema.

**Tinea manuum**

Ringworm of the hands also presents with a diffuse erythematous scaling of the palms with variable skin peeling and skin thickening. Annular lesions are rare at this site.

**Tinea capitis**

Scalp ringworm infections are common. Fungus may confine itself to within the hair shaft (endothrix) or spread out over the hair surface (ectothrix). The latter can cause fluorescence under a Wood’s lamp (ultraviolet light). Scalp ringworm is spread by close contact (especially in schools and households) and may also be spread indirectly by hairdressers. Increase in travel and immigration has allowed the spread of different pathogenic fungi (e.g. *Trichophyton tonsurans* from Central America, *Trichophyton violaceum* from India and Pakistan) into new countries where there is overcrowding and poor social conditions. The majority of UK cases are due to *T. tonsurans* (which does not show fluorescence).

*Tinea capitis* is much commoner in children, especially those of black African origin whose scalp and hair seems more susceptible to fungal invasion. The clinical appearance of scalp ringworm is highly variable from a mild diffuse scaling with no hair loss (similar to dandruff) to the more typical appearance of circular scaly patches in the scalp with associated alopecia and broken hairs. As the host’s
Infections

Candida albicans

Candida albicans (see also p. 170) is a yeast that is sometimes found as part of the body’s flora, especially in the gastrointestinal tract. It acts as an opportunist, taking hold in the skin when there is a suitable warm moist environment such as in nappy rash (p. 1234) or intertrigo in obese individuals (Fig. 24.8).

The flexural areas affected are red with a rather ragged peeling edge that may contain a few small pustules. Small circular areas of erythema or small papules and pustules may be seen in front of the advancing edge (satellite lesions).

Candida may also affect the moist interdigital clefts of the toes and mimic tinea pedis. In people who have their hands immersed frequently in water (e.g. cleaners, nurses) Candida may cause infection in the macerated skin of the finger web spaces or the damaged skin around the nail folds (‘chronic paronychia’). Nail infection may mimic tinea unguium. Candida can infect mucosal surfaces of the mouth or genital tract. This tends to occur in patients taking broad-spectrum antibiotics (due to suppression of protective bacterial flora) or in immunosuppressed patients. Clinically, superficial white or creamy pseudomembranous plaques appear which can be scraped off leaving raw areas underneath.

Treatment

Treatment is aimed at removing any underlying predisposing factor and applying topical antifungal creams, e.g. clotrimazole or miconazole (or the equivalent as mouth lozenges/ pessaries). Candida nail infections require systemic antifungal therapy with an imidazole such as itraconazole (100 mg daily for 3–6 months). Recurrent candidiasis is relatively common, especially in women. Diabetes mellitus should always be excluded. Repeated topical treatment or an oral imidazole may be needed.

Tinea unguium

Ringworm of the nails is increasingly common with age and frequently ignored as it is often asymptomatic. Clinically this presents as asymmetrical whitening (or yellowish black discoloration) of one or more nails which usually starts at the distal or lateral edge before spreading throughout the nail (Fig. 24.7). The nail plate appears thickened. Crumbly white material appears under the nail plate and this is the best fungal infections specimen to obtain for mycology sampling. The nail plate may become destroyed with advanced disease.

‘Tinea incognito’

This is the term used to describe a fungal skin infection that has been modified by therapy with a topical steroid. The clinical appearance is variable but may show a nonspecific erythema with little in the way of scaling or a few reddish nodules. The history of the rash improving with treatment (owing to the suppression of inflammation) but worsening and spreading every time it is stopped is typical. Skin scrapings for mycology or even a biopsy should confirm the diagnosis.

Treatment

Localized ringworm of the body or flexures is treated with topical antifungal creams (clotrimazole, miconazole, terbinafine or amorolfin applied three times daily for 1–2 weeks). More widespread infection, tinea pedis, tinea manuum and tinea capitis require oral antifungal therapy. Itraconazole (100 mg daily) and terbinafine (250 mg daily) are the most effective drugs used for periods of 1–2 months. High-dose griseofulvin is still used in children for scalp ringworm (15–20 mg/kg per day for 8 weeks).

Tinea unguium of the toe-nails is the most resistant to treatment. Itraconazole (100 mg daily or 200 mg twice daily for 1 week per month ‘pulsed therapy’) or terbinafine (250 mg daily) given for 3–6 months will cure up to about 80% of cases.

Pityrosporum

This yeast occurs as part of the normal flora of human skin. Colonization is prominent in the scalp, flexures and upper trunk. There are two morphological variants, Pityrosporum ovale and Pityrosporum orbiculare, and the mycelial form of this yeast is called Malassezia furfur. Pityrosporum can immune response increases a few pustules may appear and an exudate may be present. At worst, a full-blown ‘kerion’ develops; a boggy swollen mass with copious quantities of discharging pus and exudate accompanied by severe alopecia. This is still poorly recognized and inappropriately treated with antibiotics and attempted surgical drainage.

Extensive infection is occasionally accompanied by a widespread papulopustular rash on the trunk. This is a so-called ‘id reaction’ and probably relates to the host immune response to the fungus. It resolves when the fungal infection is treated.

Figure 24.7 Dermatophyte infection of the nail showing white crumbling dystrophy.

Figure 24.8 Intertrigo with satellite lesions typical of candidiasis.
overgrow in some individuals and has been implicated in three dermatoses:
- Pityriasis versicolor
- Seborrhoeic eczema (p. 1206)
- Pityrosporum folliculitis.

Pityriasis versicolor
This is a relatively common condition of young adults caused by infection with Pityrosporum. In white people, it presents most commonly on the trunk with reddish brown macules, which are asymptomatic. In black-skinned individuals (or in whites who are sun-tanned) it more commonly presents as macular areas of hypopigmentation. Inappropriate use of topical steroids tends to spread the rash.

Differential diagnosis
Pityriasis versicolor can be confused with other conditions such as seborrhoeic dermatitis, psoriasis, and pityriasis rosea. The diagnosis is usually made on clinical grounds, and biopsy may be necessary in doubtful cases.

Treatment
Treatment is with topical emollients and possibly oral antifungal medication. Topical antifungal agents such as ketoconazole shampoo or cream may be effective. Systemic antifungal therapy may be necessary in severe cases.

Scabies
Scabies is an intensely itchy rash caused by the mite Sarcoptes scabiei. It can affect all races and people of any social class. It is most common in children and young adults but can affect any age group. There are 300 million cases of scabies in the world each year. It is commoner in poorer countries with social overcrowding.

Scabies is spread by prolonged close contact such as within households or institutions, and by sexual contact. It presents clinically with itchy papules and pustules which can occur anywhere in the skin but are found most commonly on the web spaces of the hand, around the wrists, fingers and toes, on the palms and soles, around the nipples and umbilicus. The distribution of lesions is often suggestive of the diagnosis (Fig. 24.9). Sites of predilection are the web spaces of the fingers and toes, the axillae, the groin, behind the knees and around the genitalia.

The pathognomonic sign is of linear or curved skin burrows but these are not always present. The pruritus is normally worse at night. Excoriations and secondary bacterial infection may complicate the rash. Scabies can be confirmed by taking skin scrapings of a lesion and examining potassium hydroxide preparation for the mite and/or its eggs by microscopy.

Suppression of the mite population in the environment
All close contacts should be treated at the same time even if asymptomatic.

The application should be repeated after 1 week.
Malathion can be used if permethrin is unavailable; benzyl benzoate is used occasionally but is very irritant and should not be used in children. Lindane is a cheap therapy but there are concerns about resistance to this drug and neurotoxicity. Oral ivermectin 200 μg/kg, as 2 doses 2 weeks apart, is as effective as topical therapy and is easy to use.

Crusted scabies
Crusted scabies is a clinical variant that occurs in immunosuppressed individuals where huge numbers of mites are carried in the skin. Patients are not always itchy but they are extremely infectious after relatively minimal contact, which is unfortunate as the diagnosis is often delayed. Clinically, the condition presents as hyperkeratotic crusted lesions, especially on the hands and feet. Lesions may progress such that the patient has a widespread erythema with irregular crusted plaques. It can therefore mimic infected eczema or psoriasis.

Treatment is with careful barrier nursing, repeated applications of a scabicide and oral ivermectin (200 μg/kg – at least 2 doses 1 week apart).

Lice infection
Lice are blood-sucking ectoparasites that can affect man in three ways.
Head lice (pediculosis capitis)

Head lice is a common infection worldwide affecting predominantly children and being commoner in females. Spread is by direct contact and encouraged by overcrowding. It usually presents with itch, scalp excoriations and popules on the neck.

Diagnosis can be confirmed by the presence of eggs (‘nits’) stuck to the hair shaft. Adult lice are seen rarely in heavy infection.

Treatment. Eradication is difficult because of non-compliance as well as resistance patterns. Malathion, carbaryl and fenothrin (two applications 7 days apart with a contact time of 12 hours) are the most commonly used agents. If one treatment fails, a different insecticide is used for the next course in an individual. Treatment is usually repeated after 7 days and metal nit combs may help remove the eggs. In resistant cases high-dose oral ivermectin (400 μg/kg as 2 doses 1 week apart) is used.

Body lice (pediculosis corporis)

Infestation with body lice is a disease of poverty and neglect. It is rarely seen in developed countries except in homeless individuals and vagrants. It is spread by direct contact or sharing infested clothing. The lice and eggs are rarely seen on the patient but are commonly found on the clothing. It presents with itch, excoriations and sometimes post-inflammatory hyperpigmentation of the skin.

Treatment consists of malathion or permethrin for the patient and high-temperature washing and drying of clothing.

Pubic lice (crabs, phthiriasis pubis) (p. 160)

Pubic lice are transmitted by direct contact, usually sexual. Infestation presents with itching, especially at night. Lice can be seen near the base of the hair with eggs somewhat further up the shaft. Occasionally eyebrows, eyelashes and the beard area are affected.

Treatment is as for head lice but all sexual contacts should be treated and other sexually transmitted diseases should be screened for. Pubic lice of the eyelashes is treated with white soft paraffin three times daily for 1–2 weeks.

Arthropod-borne diseases (‘insect bites’ or papular urticaria)

These depend on contact with an animal (e.g. dog, cat, bird) that is infested with fleas (Cheyletiella) or on bites from flying insects (e.g. midges, mosquitoes). In the case of flea bites the animal itself may be itchy with scaly and thickened skin. These fleas can also live in soft furnishings (e.g. carpets and beds) even after the animal has been removed. Bites present as itchy urticated lesions, which are often grouped in clusters. The legs are most commonly affected. It is not unusual for an individual to react badly to bites when other family members seem unaffected. Anti-flea treatment of the animal and furnishings is required. Insect repellents and appropriate clothing help lessen bites from flying insects.

Infestations with bed bugs have increased enormously in the past decade in the developed world. They can be seen as small brown/black lentil-sized insects at nighttime as they are attracted to warmth and carbon dioxide of sleeping humans. Infestations require professional insecticide treatments of properties. Advice can be obtained from the National Pest Technicians Association (www.npta.org.uk).

**PAPULO-SQUAMOUS/INFLAMMATORY RASHES**

**Eczema**

**Introduction**

Eczema is synonymous with the term dermatitis and the two words are interchangeable. In the developed world, eczema accounts for a large proportion of skin disease. It is estimated that 10% of people have some form of eczema at any one time, and up to 40% of the population will have an episode of eczema during their lifetime.

All eczemas (Table 24.3) have some features in common and there is a spectrum of clinical presentation from acute through to chronic. Vesicles or bullae may appear in the acute stage if inflammation is intense. In subacute eczema the skin can be erythematous, dry and flaky, oedematous and crusted (especially if secondarily infected). Chronic persistent eczema is characterized by thickened or lichenified skin. Eczema is nearly always itchy. Histologically ‘eczematous change’ refers to a collection of fluid in the epidermis between the keratinocytes (‘spongiosis’) and an upper dermal perivascular infiltrate of lymphohistiocytic cells. In more chronic disease there is marked thickening of the epidermis (‘acanthosis’).

**Atopic eczema**

This type of eczema (‘endogenous eczema’) occurs in individuals who are ‘atopic’ (p. 823). It is common, occurring in up to 5% of the UK population. It is commoner in early life, occurring at some stage during childhood in up to 10–20% of all children.

**Aetiology**

The exact pathophysiology is not fully understood but there is an initial selective activation of Th2-type CD4 lymphocytes in the skin which drives the inflammatory process. This precedes the chronic phase when Th0 and Th1 cells predominate. In at least 80% of cases there is a raised serum total IgE level. Atopic eczema is a genetically complex, familial disease with a strong maternal influence. A positive family history of atopic disease is often present: there is a 90% concordance in monozygotic twins but only 20% in dizygotic twins. If one parent has atopic disease, the risk for a child of developing eczema is about 20–30%. If both parents have atopic eczema the risk is greater than 50%.

Studies have shown abnormal skin-homing T cells in eczema compared to controls. Genetic research points towards a primary problem of skin barrier function, suggesting the above immunological changes are secondary. Loss-of-function mutations in the epidermal barrier protein filaggrin cause ichthyosis vulgaris but can predispose to atopic eczema in Caucasian individuals. Different mutations in the same gene have been found in Japanese people with...
eczema. *Filaggrin* is coded by *FLG* gene in the epidermal differentiation complex on chromosome 1q21. Very strong linkage to this region would suggest that other genes in this area are also involved in the development of atopic eczema (e.g. loricrin, involucrin, S100 calcium-binding proteins). Linkage is also found to 3q21, 3p22–24, 17q25, 20p. Other candidate genes include *SPINK 5* (a serine protease inhibitor), mast cell chymotryptase and peptidoglycan recognition proteins.

### Exacerbating factors

Infection either in the skin or systematically can lead to an exacerbation, possibly by a superantigen effect. Paradoxically, lack of infection (in infancy) may cause the immune system to follow a Th2 pathway and allow eczema to develop (the so-called ‘hygiene hypothesis’). Strong detergents, chemicals and even woolen clothes can be irritant and exacerbate eczema. Teething is another factor in young children. Severe anxiety or stress appears to exacerbate eczema in some individuals. Cat and dog fur can certainly make eczema worse, possibly by both allergic and irritant mechanisms. The role of house dust mites and diet is less clear cut. There is some evidence that food allergens may play a role in triggering atopic eczema and that dairy products or eggs cause exacerbation of eczema in a few infants under 12 months of age.

### Clinical features

Atopic eczema can present as a number of distinct morphological variants. The commonest presentation is of itchy erythematous scaly patches, especially in the flexures such as in front of the elbows and ankles, behind the knees (Fig. 24.10) and around the neck. In infants eczema often starts on the face before spreading to the body. Very acute lesions may weep or exude and can show small vesicles. Scratching can produce excoriations, and repeated rubbing produces skin thickening (lichenification) with exaggerated skin markings.

In people with pigmented skin, eczema often shows a reverse pattern of extensor involvement. Also the eczema may be papular or follicular in nature, and lichenification is common. A final problem in pigmented skin is of post-inflammatory hyper- or hypopigmentation which is often very slow to fade after control of the eczema.

### Associated features

In some atopic individuals, the skin of the upper arms and thighs may feel roughened due to follicular hyperkeratosis (‘keratosis pilaris’). The palms may show very prominent skin creases (‘hyperlinear palms’). There may be an associated dry ‘fish-like’ scaling of the skin which is non-inflammatory and often prominent on the lower legs (‘ichthyosis vulgaris’).

### Complications

Broken skin commonly becomes secondarily infected by bacteria, usually *Staphylococcus aureus*, although streptococci can colonize eczema, especially in macerated flexural areas such as the neck and groin. Clinically, this infection may appear as crusted, weeping impetigo-like lesions, Cutaneous viral infections (e.g. viral warts and molluscum) are often widespread in atopic eczema and are probably spread by scratching. HSV can cause a widespread eruption called eczema herpeticum (Kaposi’s varicelliform eruption. This can occasionally be a very severe infection and rarely can be fatal. It appears as multiple small blisters or punched-out crusted lesions associated with malaise and pyrexia, and needs rapid treatment with oral (or intravenous if severe) aciclovir. Ocular complications of atopic eczema include conjunctival irritation and less commonly keratoconjunctivitis and cataract. Retarded growth may be seen in children with chronic severe eczema; it is due to the disease itself and not the use of topical steroids.

### Investigations

The diagnosis of atopic eczema is clinical. However atopy is characterized by high serum IgE levels or high specific IgE levels to certain ingested or inhaled antigens and a blood eosinophilia in about 80% of cases.

### Prognosis

The majority (80–90%) of children with early-onset atopic eczema will spontaneously improve and ‘clear’ before the teenage years, 50% being clear by the age of 6. A few will get a recurrence as adults, even if just as hand eczema. However, if the onset of eczema is late in childhood or in adulthood, the disorder follows a more chronic remitting/relapsing course.

### Treatment (Box 24.2)

#### General measures

These include avoiding known irritants (especially soaps or furry animals), wearing cotton clothes, and not getting too hot. Manipulating the diet (e.g. dairy-free diet) is rarely beneficial except in a few children, especially those under 12 months of age where cows milk and egg allergy are common. Any change in diet should be made under supervision, especially with growing children who may need supplements such as calcium.

#### Topical therapies

Topical therapies (p. 1235) are sufficient to control atopic eczema in most people. The ‘triple’ combination of topical steroid, frequent emollients (see Table 24.18) and bath oil and soap substitute (e.g. aqueous cream) helps.

### Box 24.2 Management of atopic eczema

- Education and explanation
- Avoidance of irritants/allergens
- Emollients
- Bath oils/soap substitutes
- Topical therapies:
  - steroids
  - immunomodulators
- Adjunct therapies:
  - oral antibiotics
  - sedating antihistamines
  - bandaging
- Phototherapy
- Systemic therapy, e.g. oral prednisolone, ciclosporin

---

**Figure 24.10** Atopic eczema behind the knees.

---

**FURTHER READING**

Ciclosporin is a selective immunosuppressant that inhibits interleukin-2 production by T lymphocytes. A large number of other drugs interact with ciclosporin (e.g., erythromycin, NSAIDs) and should be avoided. Renal damage and hypertension are the two most serious side-effects so blood pressure, serum creatinine and estimated glomerular filtration rate (eGFR) should be measured every 6–12 weeks. Renal damage becomes increasingly common with time and tends to be dose-dependent but is mostly reversible. Hypertrichosis, paraesthesia and nausea are less serious side-effects. Pregnancy should be avoided.

Topical immunomodulators
Tacrolimus ointment (0.1% and 0.03%) and the less potent pimecrolimus cream can be used for atopic eczema in patients over 2 years old. They have the advantage over potent steroids of not causing skin atrophy and are thus very useful for treating sensitive areas such as the face and eyelids. They can be irritant when first used (although this settles with continued use) and 9% of patients develop flushing after alcohol. The long-term side-effects remain unknown but there have been no major problems. They do not work so well on lichenified eczema, probably due to poor absorption. Current advice is to avoid vaccinations and sun exposure when using these agents. The milder potency steroid creams are still first-line therapy but tacrolimus is a useful alternative to excessive use of potent steroids. Tacrolimus ointment is also used twice weekly to prevent eczema flares.

Antibiotics
These are needed for bacterial infection and are usually given orally for 7–10 days. Flucloxacillin (500 mg four times daily) acts against Staphylococcus and phenoxymethylpenicillin (500 mg four times daily) is effective against Staphylococcus and phenoxymethylpenicillin. Erythromycin (500 mg four times daily) is useful if there is allergy to penicillin. Topical antiseptics are used in cases of recurrent infection but they can be irritant. They are usually added to the bath water rather than applied directly to the skin.

Sedating antihistamines
These (e.g., oral hydroxyzine hydrochloride 10–25 mg) are useful at night-time.

Bandaging
Paste bandaging can be useful for resistant or lichenified eczema of the limbs. It helps absorption of treatment and acts as a barrier to prevent scratching. Wet tubular gauze bandages are used for inpatient therapy but are difficult and time-consuming to use at home.

Second-line agents
These are used in severe non-responsive cases, especially if the eczema is significantly interfering with an individual’s life (e.g., growth, sleeping, schoolwork or job). Ultraviolet phototherapy (see p. 1215), prednisolone (initial doses up to 30 mg daily), ciclosporin (3–5 mg/kg daily) and azathioprine (1–3 mg/kg daily) (in chapter 6) can all be effective treatments. However they all have side-effects and the risk/benefit ratio must be openly discussed with the patient before they are used.

Use of ciclosporin. Ciclosporin is a selective immunosuppressant that inhibits interleukin-2 production by T lymphocytes. A large number of other drugs interact with ciclosporin (e.g., erythromycin, NSAIDs) and should be avoided. Renal damage and hypertension are the two most serious side-effects so blood pressure, serum creatinine and estimated glomerular filtration rate (eGFR) should be measured every 6–12 weeks. Renal damage becomes increasingly common with time and tends to be dose-dependent but is mostly reversible. Hypertrichosis, paraesthesia and nausea are less serious side-effects. Pregnancy should be avoided.

Discoid eczema (nummular eczema)
Discoid eczema is a morphological variant of eczema characterized by well-demarcated scaly patches, especially on the limbs, and this can be confused sometimes with psoriasis. It is commoner in adults and can occur in both atopic and non-atopic individuals. It tends to follow an acute/subacute course rather than a chronic pattern. There is often an infective component (Staphylococcus aureus).

Hand eczema
Eczema may be confined to the hands (and feet). It can present with:

- itchy vesicles or blisters on the palm and along the sides of the fingers (also called ‘pompholyx’) (Fig. 24.11)
- a diffuse erythematous scaling and hyperkeratosis of the palms
- a scaling and peeling, most marked at the finger tips.

Hand eczema is not unusual in atopics but more frequently occurs in non-atopic individuals, and a cause is not always found. A history of contact with irritants (e.g., detergents, chemicals) and an occupational history should be sought, especially in finger-tip eczema. Patch testing for specific allergic or contact eczema should always be performed as up to 10% of individuals with hand eczema will show a positive test. Finally, look for evidence of fungal infection as this

Seborrhoeic eczema

Aetiology

Overgrowth of *Pityrosporum ovale* (also called *Malassezia furfur* in its hyphal form) together with a strong cutaneous immune response to this yeast produces the characteristic inflammation and scaling of seborrhoeic eczema. The condition is more common in Parkinsonism as well as in HIV disease.

Clinical features

Seborrhoeic eczema affects body sites rich in sebaceous glands, although these do not appear to be causal. Three age groups are affected:

- **In neonates** it is common and presents as yellowish thick crusts on the scalp (cradle cap). A more widespread erythematous, scaly rash can be seen over the trunk, especially affecting the nappy area. Unlike with atopic eczema, the child is normally unbothered as there is little associated pruritus. The rash normally improves spontaneously after a few weeks.

- **In young adults** (especially males) it occurs in 1–3% of the population. The rash is more persistent and presents as an erythematous scaling along the sides of the nose (Fig. 24.12), in the eyebrows, around the eyes and extending into the scalp (which shows marked dandruff). It may affect the skin over the sternum, axillae and groins, and the glans penis. A blepharitis may also be present.

- **In elderly people** seborrhoeic eczema can be more severe and progress to involve large areas of the body and even cause erythroderma.

Treatment

This is suppressive rather than curative. A combination of a mild steroid ointment (e.g. 1% hydrocortisone applied twice daily) and a topical antifungal cream (e.g. miconazole cream applied twice daily) will help to control the eruption. Topical 0.1% tacrolimus ointment or pimecrolimus cream can also be used.

Ketoconazole shampoo and arachis oil are useful for the scalp. Emollients and a soap substitute are useful adjuncts.

Venous eczema (varicose eczema, gravitational eczema)

This type of eczema occurs on the lower legs due to chronic venous hypertension (usually of more than 2 years’ duration) (see p. 1226).

Clinical features

Venous eczema tends to occur in older people, especially women. It usually appears on the lower legs around the ankles. There may be a past history of venous thrombosis or previous surgery for varicose veins. Brownish pigmentation (haemosiderin) may be seen in the skin and a venous leg ulcer or varicose veins may be present.

Superimposed contact eczema is common in venous eczema patients, especially when there have been chronic venous leg ulcers. This is usually due to an allergic reaction to topical therapies or skin dressings. Patch testing should always be done in treatment-resistant cases.

Treatment

This should include emollients and a moderately potent topical steroid. Support stockings or compression bandages, together with leg elevation, help decrease the underlying venous hypertension (p. 1226).

Asteatotic eczema (winter eczema, eczema craquelé, senile eczema)

This is a dry plate-like cracking of the skin with a red, eczematous component, which occurs in elderly people. It occurs predominantly on the lower legs and the backs of the hands, especially in winter. The exact cause is unknown but the repeated use of soaps in the elderly with the loss of the stratum corneum lipids with age is probably involved. Rarely asteatotic eczema can be the presenting sign of hypothyroidism or can follow the commencement of diuretic therapy.

Treatment

Avoidance of soaps, and the regular use of emollients and bath oils should be encouraged. If the skin is very inflamed, a mild topical steroid can be used.

Allergic contact and irritant contact eczema

If the eczema is in an unusual or localized distribution (Fig. 24.13), especially if there is no personal or family history of atopic disease, one of a variety of environmental agents (exogenous eczema) is the likely cause. A history of an exacerbation of eczema at the workplace is also suggestive.
Papulo-squamous/inflammatory rashes

significant surface damage from scratching. This is a chronic unremitting condition, which is often resistant to treatment. These two conditions overlap, with some patients showing mixed features. Atopic individuals seem predisposed to develop these conditions (in the absence of obviously active eczema). However, they can occur in non-atopics. Emotional stress appears to be a contributory factor in many of these patients (hence the name neurodermatitis).

The diagnosis is made by exclusion of other pathologies and may require a skin biopsy. General medical causes of pruritus should be excluded including HIV infection (p. 154 and p. 177). In the elderly, nodular prurigo may be an early sign of bullous pemphigoid, before the more typical blistering phase has appeared.

Treatment

Treatment is often difficult as symptoms can be intractable. Very potent topical steroids (e.g. 0.05% clobetasol propionate) with occlusive tar bandaging may sometimes help. Intralesional steroids can also be useful but there is a risk of atrophy. For resistant cases (especially of prurigo lesions) topical doxepin, phototherapy (p. 1215), low-dose oral amitriptyline (50 mg nightly) and ciclosporin (3–5 mg/kg per day) are used.

Psoriasis

Psoriasis is a common papulo-squamous disorder affecting 2% of the population and is characterized by well-demarcated, red scaly plaques. The skin becomes inflamed and hyperproliferates at about ten times the normal rate. It affects males and females equally and can affect all races. The age of onset occurs in two peaks. Early onset (age 16–22) is commoner and is often associated with a positive family history. Late-onset disease peaks at age 55–60 years.

Aetiology

The condition appears to be polygenic but is also dependent on certain environmental triggers. Twin studies show 73% concordance in monozygotic twins compared with 20% in dizygotic pairs. Nine genetic psoriasis susceptibility loci have been identified (PSORS 1–9). Some loci seem shared with other diseases: atopic eczema (1q21, 3q21, 17q25, 20p), rheumatoid arthritis (3q21, 17q24–25) and Crohn’s disease (16). The most studied locus, PSORS1 (which accounts for 35–50% of the heritable component), lies in the MHC region of chromosome 6 (HLA Cw6).

The exact aetiology is unknown but evidence suggests that psoriasis is a T-lymphocyte-driven disorder to an

1207
unidentified antigen(s). Figure 24.15 shows the trigger factors that activate the antigen-presenting cell (dendritic/Langerhans). This activation results in upregulation of Th1-type T cell cytokines, e.g. interferon-γ, interleukins (IL-1, -2, -8), growth factors (TGF-α and TNF-α) and adhesion molecules (ICAM-1). The pro-inflammatory cytokine TNF-α is also produced by keratinocytes and this may be involved in both initiation and maintenance of psoriatic lesions. TNF-α blocking drugs have proved highly effective in treatment (Fig. 24.15). IL-17 and IL-22 are thought to work together to produce clinical psoriasis (see p. 1210).

**Pathology**

Skin biopsy shows epidermal acanthosis and parakeratosis, reflecting the increase in skin turnover, and the granular layer is often absent. Polymorphonuclear abscesses may be seen in the upper epidermis. The epidermal rete ridges appear elongated and clubbed as they fold down into the dermis. Dermal changes include capillary dilation surrounded by a mixed neutrophilic and lymphohistiocytic perivascular infiltrate.

**Clinical features**

Psoriasis can present in different clinical patterns but there is overlap between the different forms. Certain drugs can make psoriasis worse, notably lithium, antimalarials and rarely beta-blockers.

**Chronic plaque psoriasis**

This is the ‘common’ type of psoriasis. It is characterized by pinkish red scaly plaques, with a silver scale seen, especially on extensor surfaces such as knees (Fig. 24.16a) and elbows. The lower back, ears and scalp are also commonly involved. New plaques of psoriasis occur at sites of skin trauma – the so-called ‘Köbner phenomenon’. The lesions can become itchy or sore.

![Pathogenesis of psoriasis](image-url)
Flexural psoriasis
This tends to occur in later life. It is characterized by well-demarcated, red glazed plaques confined to flexures such as the groin, natal cleft and sub-mammary region. As these sites are apposed, there is rarely any scaling. In the absence of psoriasis elsewhere the rash is often misdiagnosed as candida intertrigo but the latter will normally show satellite lesions.

Guttate psoriasis
‘Raindrop-like’ psoriasis is a variant most commonly seen in children and young adults (Fig. 24.17). An explosive eruption of very small circular or oval plaques appears over the trunk about 2 weeks after a streptococcal sore throat.

Erythrodermic and pustular psoriasis
These are the most severe types of psoriasis reflecting a widespread intense inflammation of the skin. They can occur together (‘Von Zumbusch’ psoriasis) and may be associated with malaise, pyrexia and circulatory disturbance. This form can be life-threatening. The pustules are not infected but are sterile collections of inflammatory cells. There is also a more localized variant of pustular psoriasis that confines itself to the hands and feet (palmo-plantar psoriasis) but is not associated with severe systemic symptoms. This latter type is more common in heavy cigarette smokers.

Associated features
Nails. Up to 50% of individuals with psoriasis develop nail changes (Fig. 24.17) and rarely these can precede the onset of skin disease. There are five types of nail change: (a) pitting of the nail plate; (b) distal separation of the nail plate (onycholysis); (c) yellow-brown discoloration; (d) subungual hyperkeratosis; (e) rarely a damaged nail matrix and lost nail plate. Treatment of nail dystrophy is very difficult.

Arthritis. Some 5–10% of individuals develop psoriatic arthritis and most of these will have nail changes (p. 602).

Treatment
This is concerned with control rather than cure and should be tailored to the patient’s wishes (Box 24.3). Severe cases may require hospitalization.

Chronic plaque psoriasis: emollients should always be used to hydrate the skin. Mild to moderate topical steroids, synthetic vitamin D3 analogues (e.g. calcipotriol, calcitriol, tacalcitol), 0.05% tazarotene (a retinoid) and purified coal tar are the most popular therapies. Salicylic acid can be a useful adjunct. All should be applied once to twice daily to palpable lesions. Once lesions have flattened, therapy can be discontinued. Tazarotene and calcipotriol can be very irritant (calcitriol somewhat less so) so they are often used in combination with steroid creams. Vitamin D analogues should be used with caution in extensive psoriasis because there is a risk of hypercalcaemia if greater than 100 g is used per week.

Dithranol causes staining of the skin and clothing and is more difficult to use at home on a regular basis. It is normally applied for 20–60 min and then washed off. It must be applied carefully to the lesions as it causes irritation to normal skin. Dithranol is more likely to induce remission than other therapies but is being recommended less because of poor compliance.

Topical therapies are sometimes used in combination with UVB or PUVA. The ‘Goeckerman regimen’ consists of tar and UVB; the ‘Ingram regimen’ consists of dithranol and UVB. The latter has similar results to oral PUVA in terms of clearance rates and lengths of remission – approximately 75% in 6 weeks.

Flexural psoriasis is usually treated with mild steroid and/or tar topical creams. Calcitriol and 0.1% tacrolimus ointment are also useful for treating flexural (facial and genital) psoriasis where irritation can be a problem.

Guttate psoriasis is usually treated with topical therapies and/or UVB phototherapy.

Palmo-plantar psoriasis is treated with very potent topical steroids, coal tar paste or local hand and foot PUVA.

Systemic therapy. Agents such as methotrexate, acitretin, mycophenolate, ciclosporin or hydroxycarbamide (hydroxyurea) are used for resistant cases.

Erythrodermic psoriasis also requires systemic therapy (but not phototherapy) as well as general supportive measures (p. 1215).

All systemic treatments must be monitored for toxicity.

Use of methotrexate. Methotrexate is normally given once weekly. Some patients experience severe nausea on the day they take it which can be lessened by folic acid therapy. Both men and women should avoid conception during and for 3 months after therapy. Some patients are allergic to methotrexate and develop a pyrexia and mouth ulceration. Regular blood tests need to be done to monitor for bone marrow suppression and liver damage. Alcohol must be avoided as this increases the risk of hepatotoxicity. NSAIDs should also be avoided as these inhibit excretion.

Lower doses should be used in the elderly. Long-term use causes hepatic fibrosis, and regular monitoring of patients’ serum procollagen III peptide level or elastography (p. 327) is being used to assess fibrosis development. People with concomitant psoriatic arthritis are more likely to develop pulmonary fibrosis.
Cytokine modulators (see Fig. 24.15)

Cytokine modulators are at present only used in patients who have severe disease who have failed (or cannot tolerate due to toxicity) conventional systemic treatments.

- Etanercept, infliximab and adalimumab (TNF-α blockers) are highly effective and tend to be used first-line in the UK as they have the longest safety data.

- Ustekinumab (a human interleukin-12/23 monoclonal antibody) is highly effective. Its safety data is limited so it is most commonly used in those patients that fail a TNF-α blocker.

- Alefacept (a dimeric fusion protein that blocks LFA-3/CD2 interaction on T cells) is somewhat less effective and has been licensed for use in North America and Australia but not Europe. CD4 counts must be checked during therapy.

- Brikunab, a monoclonal antibody against the p40 molecule shared by IL-12 and IL-23, is effective in moderate and severe psoriasis.

- Brodalumab (an anti-IL-17 receptor antibody) and ixekizumab (an anti-IL-17 monoclonal antibody) have recently been shown to be effective in psoriasis.

All these agents are given by injection and are very expensive. Long-term side-effects of these new agents are unknown. TNF-α blockers’ side-effects are discussed on page 524. One biologic drug (efalizumab) has been withdrawn due to the risk of prion brain disease.

Prognosis

Most individuals who develop chronic plaque psoriasis will have the condition lifelong but 80% will get a remission at times. It fluctuates in severity and there are no available tests to predict outcome. Guttate psoriasis resolves spontaneously and in up to a third of individuals does not recur. However, two-thirds will go on to get recurrent guttate attacks or will progress to chronic plaque psoriasis.

Urticaria and angio-oedema

Urticaria (hives, ‘nettles rash’) is a common skin condition characterized by the acute development of itchy weals or swellings in the skin due to leaky dermal vessels (Fig. 24.18).

Angio-oedema is a similar condition but involves sub-dermal vessels.

Aetiology

The final event in pathogenesis involves degranulation of cutaneous mast cells which releases a number of inflammatory mediators (including histamine) which in turn make the dermal and sub-dermal capillaries leaky. In most cases the underlying cause is autoimmune (patients develop autoantibodies against the high-affinity IgE receptor α-subunit of the mast cell). Occasionally urticaria is secondary to viral or parasitic infection, drug reactions (e.g. NSAIDs, penicillin, ACE inhibitors, opiates), food allergy (e.g. to strawberries, food colourings or seafood), or rarely systemic lupus erythematosus. Urticaria/angio-oedema is commoner in atopi individuals and usually presents in children and young adults.

In hereditary angio-oedema and ACE inhibitor induced angio-oedema, bradykinin (a potent vasodilator) is one of the key mediators (not histamine) and this observation has led to some new drug developments.

Clinical features

Urticaria produces cutaneous swellings or weals developing acutely over a few minutes. They can occur anywhere on the skin and last between minutes and hours before resolving spontaneously. Lesions are intensely itchy and show no surface change or scaling. They are normally erythematous but if very acutely swollen, they may appear flesh-coloured or whitish and people often mistake them for blisters.

Angio-oedema with subcutaneous involvement presents as soft tissue swelling (oedema) especially around the eyes, the lips and the hands but this is rarely itchy. This can be very alarming to the patient. It can also be dangerous if mucosal areas such as the mouth and larynx are involved but fortunately this is very rare.

Physical urticarias

Occasionally, urticaria can be caused by physical stimuli such as cold (cold urticaria), deep pressure (delayed pressure urticaria), stress or heat (cholinergic urticaria), sunlight (solar urticaria – p. 1215), water (aquagenic urticaria) or chemicals such as latex (contact urticaria).

Cholinergic urticaria is one of the commonest physical urticarias and has rather different clinical lesions from the other forms. Small itchy papules rather than weals appear on the upper trunk and arms after exercise or anxiety.

Pressure can cause two types of urticaria. More superficial pressure can cause dermographism which is relatively common. This presents as urticated weals occurring a few minutes after application of light pressure. Even scratching or rubbing will bring up linear weals in demographic individuals. Delayed pressure urticaria is rare and occurs as deep swellings some hours after pressure is removed (e.g. on the soles of the feet or under a tight belt).

Investigations

The history is the most useful factor in diagnosing urticaria. Routine investigation is probably not justified unless the history suggests one of the underlying causes listed above. The physical urticarias should be reproducible by applying the relevant stimulus.

Treatment

Any identifiable underlying cause should be treated appropriately. Patients should avoid salicylates and opiates as they can degranulate mast cells. Oral antihistamines (H1 blockers) are the most useful in treating the idiopathic cases. Therapy should be started with regular use of a non-sedating antihistamine (e.g. cetirizine 10 mg daily or loratadine 10 mg daily). If control proves difficult, addition of a sedating antihistamine, an H2 blocker or dapsone may be helpful. Angio-oedema of the mouth and throat may require urgent treatment with intramuscular adrenaline (epinephrine) and intravenous steroids (see Emergency Box 3.1).
Prognosis
Most cases of ‘idiopathic’ urticaria last a few weeks to months before disappearing spontaneously. The majority of these will be controlled with an antihistamine. A small percentage of people go on to develop chronic urticaria which can last for several months or years. The physical urticarias (especially cholinergic urticaria) are more persistent, often lasting for years, and they are often resistant to therapy.

Urticarial vasculitis
This is a variant of urticaria and should be suspected if individual urticarial lesions last longer than 24 hours and leave bruising behind after resolution. There is often an associated arthralgia or myalgia, and a small proportion may go on to develop an autoimmune rheumatic disease. The diagnosis is confirmed by skin biopsy. A full vasculitis screen should be carried out for an underlying cause (p. 537).

Treatment is with antihistamines, oral dapsone (50–100 mg daily) or immunosuppressants.

Hereditary angio-oedema
This is a rare autosomal dominant condition due to an inherited deficiency of C1 esterase inhibitor (C1-INH) which causes massive activation of the complement system, increased bradykinin levels and thus angio-oedema. The defect may be due to either reduced function (type I – 85%) or reduced levels (type II – 15%) and both these are due to mutations in the Serping-1 gene. A low serum C4 level is a good screening test (Table 24.5). Rarely this condition is acquired (due to autoantibody production against C1-INH) and associated with lymphoma or SLE and it presents at a later age. These types show low C1-INH but also low C1q levels.

A very rare X-linked dominant form exists in which C1-INH levels and function are normal (type III) and this is due to factor XII gene mutation. This type is much more common in females and is made worse by high oestrogen levels such as in pregnancy.

Clinical features
Hereditary angio-oedema presents with attacks of non-itchy cutaneous angio-oedema (but not urticaria), which may last up to 72 hours. It may also present with recurrent abdominal pain (due to intestinal oedema) and there may be a family history of sudden death (due to laryngeal involvement). It presents before the age of 15 in 75% of cases. A nonspecific erythematous rash (or erythema marginatum) may precede an attack of angio-oedema but urticaria itself is not a feature.

Treatment
In the acute setting treatment is with C1 esterase inhibitor concentrates and fresh frozen plasma. Adrenaline (epinephrine) and steroids are often ineffective. Two new therapies, icatibant (a bradykinin B2 receptor antagonist) and ecallantide (a plasma kallikrein inhibitor), are both being used for severe acute attacks.

Maintenance treatment with the anabolic steroid stanozolo (or danazol) stimulates an increase in hepatic synthesis of C1 esterase inhibitor but this should not be used in children. Family members should be screened.

Pityriasis rosea
Pityriasis rosea is a self-limiting rash seen in adolescents and young adults. The cause is unknown but it is thought to be a viral or post-viral rash. There is an increased incidence in spring and autumn and outbreaks may occur in institutions.

Clinical features
The rash consists of circular or oval pink macules with a collarette of scale and is more prominent on the trunk than the limbs. The long axis of the oval lesions tends to run along dermatomal lines giving a ‘Christmas tree’ pattern on the back. The rash may be preceded by a large solitary patch with peripheral scaling (‘herald patch’) and this is most commonly found on the trunk. The rash is usually asymptomatic and spontaneously resolves over 4–8 weeks.

Treatment
Treatment is not normally required but a weak steroid cream may help relieve any itch. In persistent cases UVB (p. 1215) may be helpful.

Lichen planus
Lichen planus is a pruritic inflammatory dermatosis that is commonly associated with mucosal involvement and rarely with nail dystrophy and scarring alopecia.

The cause is unknown but is possibly a T-cell-driven immune mechanism as an almost identical rash can be caused by certain drugs (e.g. beta-blockers, gold, levamisole, ACE inhibitors or antimalarials) or by graft-versus-host disease and in chronic HBV, HCV liver disease.

Pathology
Hyperkeratosis with thickening of the granular cell layer is seen in the epidermis. A dense T cell infiltrate is seen at the dermoepidermal junction, which becomes ragged and saw-toothed. The basal layer shows liquefactive degeneration with colloid (apoptotic) bodies in the upper dermis.

Clinical features
The rash is characterized by small, purple flat-topped, polygonal papules that are intensely pruritic (Fig. 24.19). It is common on the flexors of the wrists and the lower legs but can occur anywhere. There may be a fine lacy white pattern on the surface of lesions (Wickham’s striae). Lesions can fuse into plaques, especially on the lower legs and in black Africans. Hyperpigmentation is common after resolution of lesions, especially in people with pigmented skin. Atrophic, hypertrophic and annular variants can occur. Lichen planus

| Table 24.5 Hereditary angio-oedema |
| --- | --- | --- |
| Subtype | Gene (inheritance) | Biochemistry |
| Type I | Serping-1(AD) | C1-INH low |
| | | C1-INH function low |
| | | C4 low |
| | | C1q normal |
| Type II | Serping-1(AD) | C1-INH normal/raised |
| | | C1-INH function low |
| | | C4 low |
| | | C1q normal |
| Type III | Fac XII(XLD) | C1-INH normal |
| | | C1-INH function normal |
| | | C4 normal |
| Acquired | Secondary to lymphoma/SLE | C1-INH low |
| | | C4 low |
| | | C1q low |

AD, autosomal dominant; XLD, X-linked dominant; SLE, systemic lupus erythematosus.
Lesions often localize to scratch marks. If lesions occur in the scalp they may cause a scarring alopecia.

Mucosal involvement is common. The mouth is the most commonly affected but the anogenital region can be involved. It can present as lacy white streaks, white plaques or as ulceration. The prominent mucosal symptom is of severe pain rather than itch. Nails may be dystrophic and can be lost altogether (with scarring and ‘wing’ formation) in severe disease.

**Prognosis**

The condition often clears by 18 months but can recur at intervals. The hypertrophic and atrophic variants and mucosal disease are more persistent, lasting for years. Ulcerative mucosal disease is pre-malignant.

**Treatment**

This requires the use of potent topical steroids (0.05% clobetasol propionate) and occasionally oral prednisolone (30 mg daily for 2–4 weeks). Occlusion of topical treatments can be helpful. Oral lesions also require high potency steroids given as an ointment, gel or mouthwash. Resistant cases may respond to PUVA, oral retinoids (0.5 mg/kg per day) or azathioprine (1–2 mg/kg daily). Topical 0.1% tacrolimus ointment or pimecrolimus has proved a very useful therapy for painful oral disease unresponsive to steroids.

**Granuloma annulare**

Granuloma annulare is a dermatosis predominantly of children and young adults. It is characterized by clusters of small dermal papules (with no surface change) that often form into rings or part of a ring. They are common on the dorsal surface of the hands and feet. They are flesh coloured or slightly erythematous and are usually asymptomatic. As they heal, the centre becomes dusky and altered in texture. A deep form, which is tender, exists in children. Diffuse granuloma annulare may be associated with diabetes mellitus. The pathology shows a granulomatous dermal infiltrate with foci of degeneration of collagen (necrobiosis). Spontaneous resolution often occurs after months to years but cryotherapy or triamcinolone injection may help localize the disease.

**Lichen sclerosus**

Lichen sclerosus is a common inflammatory dermatosis that occurs in all age groups and particularly affects the anogenital region. It is more common in post-menopausal females. The underlying cause is unknown but HLA associations and studies showing antibodies to extracellular matrix protein-1 suggest an autoimmune aetiology. It presents with atrophic ivory-white patches with a well-defined edge on the vulva, glans penis, foreskin or perianal skin. Telangiectasia may be seen over the surface. Occasionally lesions involve the shaft of the penis and the urethral meatus. Lesions are often itchy but may be sore at times. Longstanding vulval lesions may be associated with fissuring and a marked loss of architecture, especially of the clitoral hood and the labia minora, which may become fused. Early lesions in young girls may present as haemorrhagic blisters and these are occasionally mistaken as signs of sexual abuse. Involvement of the foreskin can cause phimosis and dyspareunia, and urethral disease may interfere with micturition. Perianal lesions may fissure and cause constipation.

Rarely lichen sclerosus can affect non-genital skin. This is most common in females and clinically it may show rather more hyperkeratosis and follicular plugging than is seen in the anogenital region.

**Diagnosis**

Diagnosis is usually clinical without the need for biopsy.

**Treatment**

Treatment with very potent topical steroids helps control the symptoms. Hydroxychloroquine (200 mg twice daily) is used in resistant cases. The condition may burn itself out after many years, especially in children. There is a risk of developing squamous cell carcinoma in longstanding lesions. Male patients may require circumcision if phimosis does not respond to medical therapy.

**FACIAL RASHES**

Facial rashes often cause diagnostic confusion but a close examination of the clinical signs should help differentiate the underlying cause (Table 24.6). All facial rashes, by virtue of their visibility, can cause significant distress to the patient.

**Acne vulgaris**

Acne is a very common facial rash occurring in over 85% of adolescents and frequently continuing into early and mid-adult life. Occasionally it can cause profound psychological disturbance and depression, even suicide. The cause is multifactorial but follicular epidermal hyperproliferation, blockage of pilosebaceous units with surrounding inflammation, increased sebum production are critical factors in the pathological process (Fig. 24.20a) as is infection with *Propionibacterium acnes*.

*Propionibacterium acnes* induced inflammation has recently been shown to occur via activation of Toll-like
Retinoids are used for inflammatory acne. All topical agents can cause problems with irritation. Regular washing with acne soaps to remove excess grease is helpful (normal soaps can be comedogenic). ‘Picking’ should be discouraged.

**Clinical features**

Acne presents in areas rich in sebaceous glands such as the face, back and sternum area. The three cardinal features are:

1. Open comedones (blackheads) or closed comedones (whiteheads)
2. Inflammatory papules
3. Pustules (Fig. 24.20b).

The skin may be very greasy (seborrhoea). Rupture of the inflamed lesions may lead to deep-seated dermal inflammation and nodulocystic lesions, which are more likely to cause facial scarring. A premenstrual exacerbation of acne is sometimes noticed. There is a tendency for spontaneous improvement over a number of years but acne can persist unabated into adult life.

A number of clinical variants exist:

- **Infantile acne.** Facial acne is occasionally seen in infants and is sometimes cystic. It is thought to be due to the influence of maternal androgens and resolves spontaneously.
- **Steroid acne.** Acne may occur secondary to corticosteroid therapy or Cushing’s syndrome. Clinically the rash often appears as a pustular folliculitis on the trunk without comedones.
- **Oil acne.** This is an industrial disease seen in workers who have prolonged contact with oils or other hydrocarbons and is common on the legs and other exposed sites.
- **Acne fulminans.** This is a rare variant seen most commonly in young male adolescents. Severe necrotic and crusted acne lesions appear associated with malaise, pyrexia, arthralgia and bone pain (due to sterile bone cysts). It requires urgent treatment with oral prednisolone (30–40 mg daily) and analgesics followed by a course of oral isotretinoin (see below).
- **‘Acne conglobata’.** Cystic acne with abscesses and interconnecting sinuses.
- **‘Acne excoriée’.** Deeply excoriated and picked acne with associated scarring. It is much more common in females.
- **‘Follicular occlusion triad’.** This is a rare disorder most commonly seen in black Africans. It is characterized by the presence of severe nodulocystic acne, dissecting cellulitis of the scalp (p. 1233) and hidradenitis suppurativa (p. 1198). This may be caused by a problem of follicular occlusion.

**Treatment**

This is aimed at decreasing sebum production, decreasing bacteria, normalizing duct keratinization and decreasing inflammation.

Regular washing with acne soaps to remove excess grease is helpful (normal soaps can be comedogenic). ‘Picking’ should be discouraged.

- **First-line therapy**
  - Mild acne can respond to a variety of topical agents, e.g. keratolytics (benzoyl peroxide, azelaic acid) or topical retinoids (tretinoin or isotretinoin) or retinoid-like agents (adapalene). Topical antibiotics, e.g. erythromycin or clindamycin, are used for inflammatory acne. All topical agents can cause problems with irritation.
  - **Low-dose oral antibiotic therapy** often helps but must be given for at least 3–4 months. Oxytetracycline 500 mg twice daily is often used first. Minocycline 100 mg daily, erythromycin 500 mg twice daily or trimethoprim 100 mg twice daily are also used.
  - An extra treatment, cyproterone acetate 2 mg/ethinylestradiol 35 μg (co-cyprindol), is of value in females if there is no contraindication to oral contraception. This acts as a normal combined contraceptive but has antiandrogen activity. It may take 6–8 months to have its maximum effect. There is an increased incidence of DVT.

- **Second-line therapy**
  - **Third-line therapy** Third-line treatment with an oral retinoid drug (isotretinoin) should be given if:
    - the above measures fail
    - there is nodulocystic acne with scarring
    - there is severe psychological disturbance.

- **Use of retinoids (isotretinoin or acitretin).** Retinoids are synthetic vitamin A analogues that affect cell growth and differentiation. They are very teratogenic. Isotretinoin is a ‘hospital-only drug’ in most countries due to its teratogenicity and is restricted to the use of dermatologists and a few trained family doctors. A pregnancy test, contraceptive...
advice and signed consent are mandatory prior to its use in fertile women, and pregnancy testing must be repeated monthly during therapy. It is given as a 4-month course at a dose of 0.5–1 mg/kg per day. Over 90% of individuals will respond to this therapy and 65% of people will obtain a long-term ‘cure’.

Patients must avoid pregnancy during therapy and for 1 month after stopping isotretinoin (but for 2 years after stopping acitretin used only in psoriasis) as it is very lipophilic. Both drugs cause drying of the skin, especially of the lips and nasal mucosa. Hair thinning and exercise-induced myalgia are not uncommon. Blood count, liver biochemistry and fasting lipids need to be monitored during therapy. In a few individuals retinoids may cause depression but it should also be remembered that acne itself has been a cause of suicide.

A number of physical techniques are currently under assessment (e.g. lasers, blue light, microdermabrasion) but they are not as effective as isotretinoin and can be very expensive as repeat treatments are often needed.

**Rosacea**

Rosacea (Fig. 24.21) is a common inflammatory rash predominantly affecting the face. The onset is usually in middle age and it is commoner in women. It often causes significant psychological distress.

The cause is unknown. Theories have suggested an underlying problem in vasomotor stability of blood vessels or a possible role of the skin mite *Demodex*.

**Clinical features**

The cardinal features are of facial flushing and inflammatory papules and pustules affecting the nose, forehead and cheeks. The flushing may precede the other signs by some years. There are no comedones. Additional features include dilated blood vessels (telangiectasia), inflammation of the eyelid margins (blepharitis), keratitis and sebaceous gland hypertrophy, especially of the nose. The latter is commoner in men and can cause a disfiguring enlargement of the nose called rhinophyma. The flushing may be exacerbated by alcohol, hot drinks, sunlight and changes in ambient temperature. Prolonged use of topical steroids can exacerbate or trigger the condition. As the disease progresses the flushing may be replaced by a permanent erythema.

**Treatment**

This is suppressive rather than curative. Long-term use of topical 0.075% metronidazole or topical 15% azelaic acid may help. Avoid topical steroids. A 3-month course of oral tetracycline (500 mg twice daily) is also helpful. Oral metronidazole (400 mg twice daily) or oral isotretinoin (0.5 mg/kg per day) is occasionally given in resistant cases (p. 1213). The papules and pustules tend to respond best to therapy but repeat courses may be necessary. The flushing and erythema are often resistant to treatment but cosmetic camouflage can be helpful for these features. Intense pulse light or pulsed dye laser therapy can help the erythema and telangiectasia but often needs to be repeated as rosacea tends to recur. Rhinophyma can be treated with plastic surgery or by carbon dioxide laser.

**Perioral dermatitis**

Perioral dermatitis is a common rash found around the mouth, especially in young females. The exact cause is unknown but it often has an iatrogenic component as topical steroids often exacerbate the condition in the long term.

**Clinical features**

It presents with erythema, scaling, papules and occasionally pustules around the mouth. It usually spares a halo of skin immediately adjacent to the lips. Rarely there is involvement around the eyes.

**Treatment**

Treatment involves stopping topical steroids although they may have to be withdrawn slowly to prevent too severe a rebound after withdrawal. The mainstay of treatment is with a 3–4-month course of low-dose oxytetracycline or erythromycin (both 500 mg twice daily) and topical metronidazole.

**Blushing**

Facial flushing in response to emotional stimuli is a normal physiological response that can be debilitating if it becomes sufficiently frequent to interfere with work and social interaction. Causes may be both psychological and physiological. Non-emotional causes should be excluded, e.g. postmenopause, drugs, and carcinoid syndrome.

**Treatment** includes cognitive behavioural therapy, cosmetic camouflage, beta-blockers and clonidine. Selective serotonin reuptake inhibitors may help associated depression and anxiety. Botulinum toxin and surgical sympathectomy, advocated by some, are not universally accepted treatments.

**PHOTODERMATOLOGY**

**Sunlight.** Light in the ultraviolet (UV) part of the spectrum combines short, medium and long wavelengths (UVC, UVB and UVA, respectively). Both UVB and UVA can penetrate the atmosphere and reach the skin. This light energy is potentially mutagenic and carcinogenic but it can also suppress cutaneous inflammation.

**Photosensitive rashes** usually appear on sites exposed to the sun’s rays, such as the face, the anterior ‘V’ of the chest, the ears and the backs of the hands. Certain ‘protected’ areas are characteristically spared such as under the chin or the upper eyelid and between the finger webs. Porphyria, drug sensitivity and lupus erythematosus should be excluded in all photosensitive patients.

Photosensitive rashes may be divided into photoexacerbated/provoked rashes and the idiopathic photodermatoses (Table 24.7). The former are discussed on pages 535 (SLE), 210 (pellagra) and 1043 (porphyria).
Phototherapy and photoprotection

**Phototherapy**

UVB and UVA both have a suppressive effect on cutaneous inflammation and there is increasing evidence that they can suppress systemic immunoreactivity to some degree. However, both types can cause skin ageing and predispose to skin malignancy if excessive doses are used. This is more of a problem in white-skinned individuals. Unaffected regions of skin or high-risk areas like the scrotum can be screened during phototherapy. UVB is less carcinogenic than UVA.

Narrow-band UVB (311 nm) is used therapeutically in the treatment of eczema and psoriasis (especially in children) and is usually given three times per week for 6–10 weeks. Eye protection needs to be worn during therapy.

Narrow-band UVB is usually used in preference to PUVA. UVA is relatively ineffective on its own so is used in conjunction with a photosensitizer (‘psoralen’), hence the term ‘PUVA’. PUVA is given twice a week and eye protection must be worn for the whole of the treatment day as the psoralen sensitizes the retina. Its use is limited by its carcinogenic potential (especially induction of squamous cell carcinoma of the skin). A maximum dose is given over a lifetime (1000 joules or 200 sessions approximately).

Sunbeds are used for tanning and consist of predominantly UVA light and are therefore rarely effective in treating skin disease. If used frequently there is an increased risk of skin cancer and premature ageing.

**Photoprotection**

There are two broad classes of sunblock cream: they either absorb UV light (e.g. aminobenzoic acid or methoxycinnamate) or reflect it (e.g. titanium dioxide). Most modern creams protect against UVB and UVA to varying degrees. UVB protection is graded by the ‘sun protection factor’ (SPF); an SPF of 15 implies you can spend 15 times longer in the sun before burning providing it is applied correctly. SPFs above 15 confer little extra protection. There is no standardized way of assessing efficiency against UVA. Some sunscreens (especially aminobenzoates) may rarely cause photosensitization. This can be proven by photopatch testing.

**Polymeroid light eruption (PLE)**

This is the most common photosensitive eruption in temperate regions, affecting up to 10–20% of the population. It is most common in young women. In many it is mild and often goes undiagnosed. An itchy rash appears some hours after sun exposure which is strictly confined to the exposed sites. Lesions may be papules, vesicles or plaques. They can last for several hours or several days. The condition starts in spring and often improves during the summer because of skin ‘hardening’.

**Treatment**

Avoidance of sunlight and the use of sunblocks are helpful in mild cases. Topical steroids help treat an attack. In those individuals who only get PLE after very intense sun exposure (e.g. on sunny holidays) a short course of oral prednisolone (30 mg daily for 7–10 days) will often prevent or treat an attack. For resistant cases ‘desensitization’ with low-dose PUVA (or narrow-band UVB) in the springtime may be required but patients will need to ‘top up’ their sun exposure from natural sunlight during the summer to keep their skin desensitized.

**Chronic actinic dermatitis (photosensitive eczema, actinic reticuloid)**

This is a relatively rare type of eczema occurring in a photosensitive distribution over the face, neck and hands. It typically affects middle-aged or elderly males. There may be a pre-existing eczema so the subsequent development of photosensitivity is often missed. This is further confounded by the fact that the eczema usually will spread to affect skin not exposed to sunlight, and the patient can become erythrodermic. The skin has typical features of eczema but is often atypical and can look almost lymphoma-like. The diagnosis can be confirmed by specialist monochromator light-testing. The most severe cases can be exacerbated by even artificial lighting as these patients can become exquisitely photosensitive.

**Treatment**

This consists of strict avoidance of sunlight including high-factor sunblocks and screening of house and car windows. Topical steroids and emollients are useful in milder cases. Oral prednisolone may be needed and azathioprine (30 mg daily for 7–10 days) will often prevent or treat an attack. In those individuals who only get PLE after very intense sun exposure (e.g. on sunny holidays) a short course of oral prednisolone (1–2 mg/kg daily) is used for long-term suppression. Low-dose phototherapy under steroid cover may help with ‘desensitization’.

**Solar urticaria**

This is extremely rare. Itchy urticarial lesions occur within minutes of sun exposure and characteristically settle within 1–2 hours. Sun avoidance, sunblocks, H1 antihistamines and low-dose phototherapy are all used in treatment.

**ERYTHRODERMA**

Erythroderma, meaning ‘red skin’, refers to the clinical state of inflammation or redness of all (or nearly all) of the skin. It is sometimes called exfoliative dermatitis, but dermatitis is not always present.
Skin disease

Aetiology
There are a number of underlying causes (Table 24.8); previous skin disease and drugs are the most common.

Clinical features
It is commoner in males and later in life. Patients often complain of their skin feeling ‘tight’ as well as itchy. Longstanding erythroderma is often associated with hair loss, ectropion of the eyelids and even nail shedding. Systemic symptoms are common such as malaise, pyrexia, widespread lymphadenopathy and other complications (see below). Erythroderma can occasionally lead to death so it should be regarded as a medical ‘emergency’.

Examination should specifically look for pustules and nail changes suggestive of psoriasis.

A skin biopsy may further help to elucidate the cause, especially of cutaneous lymphoma. T cell receptor gene rearrangement studies (looking for evidence of clonal T cell expansion in the skin and blood) are also useful in the diagnosis of lymphoma. Lymph node biopsy is also useful in lymphoma. In non-malignant disease lymph nodes normally show nonspecific, reactive (dermatopathic) changes. A number of cases defy an exact diagnosis.

Complications
The skin is one of the largest organs of the body, so perhaps it is no surprise that inflammation of the whole organ can cause metabolic and haemodynamic problems. Examples are:

- High-output cardiac failure from increased blood flow
- Hypothermia from heat loss
- Fluid loss by transpiration
- Hypoaalbuminaemia
- Increased basal metabolic rate
- ‘Capillary leak syndrome’.

Capillary leak syndrome is the most severe complication and has been responsible for a fatal outcome in some cases of psoriasis, although this is extremely rare. It is thought that the inflamed skin releases large quantities of cytokines that cause a generalized vascular leakage. This can cause cutaneous oedema and acute lung injury (p. 883).

Treatment
Treatment of erythroderma is best initiated in hospital. Patients must be kept very warm (with space blankets and heaters). Their vital signs should be monitored regularly, particularly fluid balance. Changes in serum electrolytes and albumin, as well as circulatory status, should be corrected. Swabs should be taken to detect any secondary skin infection.

The skin condition is treated with bed rest and either a bland emollient or a mild topical steroid. All non-essential drugs should be stopped. Where known, the underlying cause should be treated. The blanket use of systemic steroid therapy for erythroderma remains controversial in view of possible side-effects.

Capillary leak syndrome will often require specialized haemodynamic management in an intensive care unit.

CUTANEOUS SIGNS OF SYSTEMIC DISEASE

Some dermatoses are associated with a variety of underlying systemic diseases. Furthermore, some medical conditions may present with cutaneous features.

Erythema nodosum
Erythema nodosum has a number of underlying causes (Table 24.9). It presents as painful or tender dusky blue-red nodules, commonly over the shins or lower limbs, which fade over 2–3 weeks leaving a bruised appearance (see Fig. 24.39). It is most common in young adults, especially females. It may be associated with arthralgia, malaise and fever. Inflammation occurs in the dermis and the subcutaneous layer (panniculitis).

Treatment is of the symptoms with non-steroidal anti-inflammatory drugs (avoid in pregnancy), light compression bandaging and bed rest, as the condition resolves spontaneously. The underlying cause should be treated. In very persistent cases dapsone (100 mg daily), colchicine (500 μg twice daily) or prednisolone (up to 30 mg daily) can be useful.

Erythema multiforme
Erythema multiforme (EM) is a hypersensitivity rash of acute onset frequently caused by infection or drugs. A cell-mediated cutaneous lymphocytotoxic response is present.

In 50% of cases, the cause is not found but the following should be considered:

- Herpes simplex virus (the most common identifiable cause)
- Other viral infections (e.g. Epstein–Barr virus (EBV), orf)
- Drugs (e.g. sulphonamide, anticonvulsants)
- Mycoplasma infection
- Autoimmune rheumatic disease (e.g. SLE, polyarteritis nodosa)
- HIV infection

Figure 24.22 Erythema multiforme major. (a) Target lesions of the palm. (b) Mucosal involvement around the mouth.

- Wegener’s granulomatosis
- Carcinoma, lymphoma.

Clinically the lesions can be erythematous, polycyclic, annular or show concentric rings (‘target lesions’) (Fig. 24.22). Frank blistering is not uncommon. The rash tends to be symmetrical and commonly affects the limbs, especially the hands and feet where palms and soles may be involved. Occasionally, there is severe mucosal involvement leading to necrotic ulcers of the mouth and genitalia, and a conjunctivitis (‘EM major’ – not to be confused with Stevens–Johnson syndrome – see Table 24.10).

The term ‘EM minor’ is used for cases without mucosal involvement.

Erythema multiforme usually resolves in 2–4 weeks. Rarely, recurrent erythema multiforme can occur and this is triggered by herpes simplex infection in 80% of cases.

Treatment

This is symptomatic and involves treating the underlying cause. Some advocate the use of oral steroids in severe mucosal disease but this remains controversial.

Recurrent erythema multiforme can be treated with prophylactic oral aciclovir (200 mg twice daily) even if no cause has been found, as 80% of cases appear to be driven by herpes simplex virus. In resistant cases, azathioprine (1–2 mg/kg daily) is used.

Pyoderma gangrenosum

Pyoderma gangrenosum is a condition of unknown aetiology that presents with erythematous nodules or pustules which frequently ulcerate (Fig. 24.23). The ulcers can be large and grow at an alarming speed. The ulcer has a typical bluish black (‘gangrenous’) undermined edge and a purulent surface (‘pyoderma’). There may be an associated pyrexia and malaise. Biopsy through the ulcer edge shows an intense neutrophilic infiltrate and occasionally a vasculitis but the diagnosis depends mostly on the clinical appearance. The main causes are:

- Inflammatory bowel disease
- Rheumatoid arthritis
- Myeloma, monoclonal gammopathy, leukaemia, lymphoma
- Liver disease (e.g. primary biliary cirrhosis)
- Idiopathic (~20% in some series).

Treatment

This is with very potent topical steroids or 0.1% tacrolimus ointment. High-dose oral steroids may be needed to prevent rapidly progressive ulceration. Oral dapsone and minocycline are also used. Other immunosuppressants, such as ciclosporin, are useful in resistant cases. The underlying cause should be treated.

Acanthosis nigricans

Acanthosis nigricans presents as thickened, hyperpigmented skin predominantly of the flexures (Fig. 24.24). It can appear warty or velvety when advanced. In early life it is seen in obese individuals who have very high levels of insulin owing to insulin resistance (and this is sometimes termed ‘pseudo-acanthosis nigricans’). In older people it normally reflects an underlying malignancy (especially gastrointestinal tumours). Rarely it is associated with hyperandrogenism in females.
Skin disease

and then central white atrophy. A linear variant exists in childhood which is more severe as it can cause atrophy of underlying deep tissues and thus cause unequal limb growth or scarring alopecia. Rarely sclerodermatous skin changes may be seen in Lyme disease (acrodermatitis chronica atrophicans), chronic graft-versus-host disease, polyvinyl chloride disease, eosinophilic myalgia syndrome (due to tryptophan therapy) and bleomycin therapy.

Lupus erythematosus (LE)

There are three clinical variants to this disease but some patients may show features of more than one type.

- Chronic discoid lupus erythematosus (CDLE)
- Subacute cutaneous lupus erythematosus (SCLE)
- Systemic lupus erythematosus (SLE).

The aetiology is unknown but variable autoantibodies may be found in all types, suggesting that it is an autoimmune disorder. Very rarely it can be induced by certain drugs such as phenothiazines, hydralazine, methyldopa, isoniazid, tetracycline, mesalazine and penicillin.

**Chronic discoid lupus erythematosus (CDLE)**

CDLE is the most common type of LE seen by dermatologists and more frequently affects females. Clinically it presents with fixed erythema and a magenta-coloured rash around the eyes with associated oedema are usually present. Bluish red nodules or plaques may be present over the knuckles (Gottron’s papules) and extensor surfaces. The nail folds are frequently ragged with dilated capillaries. The diagnosis is made from the clinical appearance, muscle biopsy, electromyography (EMG) and a serum creatine phosphokinase. Skin biopsy is not diagnostic.

There is a childhood form, which usually occurs before the age of 10 and which eventually resolves. This type is associated with calcinosis in the skin, weak muscles and contractures. Life-threatening bowel infarction can also occur in the childhood form. The adult form usually occurs after the age of 40. Some cases are associated with an underlying malignancy whereas some are associated with other autoimmune rheumatic diseases. This latter group may overlap with scleroderma and lupus erythematosus.

**Treatment**

Skin disease may respond to sunscreens and hydroxychloroquine (200 mg twice daily) as well as immunosuppressants, e.g. prednisolone, azathioprine or ciclosporin.

**Dermatomyositis** (see also p. 543)

The rash is distinctive and often photosensitive. Facial erythema and a magenta-coloured rash around the eyes with associated oedema are usually present. Bluish red nodules or plaques may be present over the knuckles (Gottron’s papules) and extensor surfaces. The nail folds are frequently ragged with dilated capillaries. The diagnosis is made from the clinical appearance, muscle biopsy, electromyography (EMG) and a serum creatine phosphokinase. Skin biopsy is not diagnostic.

There is a childhood form, which usually occurs before the age of 10 and which eventually resolves. This type is associated with calcinosis in the skin, weak muscles and contractures. Life-threatening bowel infarction can also occur in the childhood form. The adult form usually occurs after the age of 40. Some cases are associated with an underlying malignancy whereas some are associated with other autoimmune rheumatic diseases. This latter group may overlap with scleroderma and lupus erythematosus.

**Treatment**

Skin disease may respond to sunscreens and hydroxychloroquine (200 mg twice daily) as well as immunosuppressants, e.g. prednisolone, azathioprine or ciclosporin.

**Scleroderma**

The term scleroderma (see also p. 538) refers to a thickening or hardening of the skin owing to abnormal dermal collagen. It is not a diagnostic entity in itself. Systemic sclerosis and morphea both show sclerodermatous changes but are separate conditions.

**Systemic sclerosis** (often called scleroderma) has cutaneous and systemic features and is discussed fully on page 538.

**Morphea** is confined to the skin and usually presents in children or young adults. It is commoner in females and the cause is unknown. Lesions are usually on the trunk and appear as bluish red plaques which progress to induration and then central white atrophy. A linear variant exists in childhood which is more severe as it can cause atrophy of underlying deep tissues and thus cause unequal limb growth or scarring alopecia. Rarely sclerodermatous skin changes may be seen in Lyme disease (acrodermatitis chronica atrophicans), chronic graft-versus-host disease, polyvinyl chloride disease, eosinophilic myalgia syndrome (due to tryptophan therapy) and bleomycin therapy.

**Lupus erythematosus (LE)**

There are three clinical variants to this disease but some patients may show features of more than one type.

- Chronic discoid lupus erythematosus (CDLE)
- Subacute cutaneous lupus erythematosus (SCLE)
- Systemic lupus erythematosus (SLE).

The aetiology is unknown but variable autoantibodies may be found in all types, suggesting that it is an autoimmune disorder. Very rarely it can be induced by certain drugs such as phenothiazines, hydralazine, methyldopa, isoniazid, tetracycline, mesalazine and penicillin.

**Chronic discoid lupus erythematosus (CDLE)**

CDLE is the most common type of LE seen by dermatologists and more frequently affects females. Clinically it presents with fixed erythematous, scaly, atrophic plaques with telangiectasia, especially on the face or other sun-exposed sites (Fig. 24.25). Hypopigmentation is common and follicular plugging may be apparent. Scalp involvement may lead to a scarring alopecia. Oral involvement (erythematous patches or ulceration) occurs in 25% of cases.

CDLE may be triggered and exacerbated by UV exposure. A few patients may also suffer with Raynaud’s phenomenon or unusual chilblain-like lesions (chilblain lupus). Only 5% of cases will go on to develop SLE but this is more common in children. Serum anti-nuclear factor (ANF) is positive in 30% of cases.

Skin biopsy shows a dense patchy, dermal cellular infiltrate (mostly T cells) which often is centred on appendages. Epidermal basal layer damage, follicular plugging and hyperkeratosis may be present. Direct immunofluorescence studies of lesional skin may show the presence of IgM and C3 in a granular band at the dermoepidermal junction (‘lupus band’).
Treatment
First-line therapy is with sunscreens and potent topical steroids. Certain oral antimarials (hydroxychloroquine 100–200 mg twice daily and mepacrine 100 mg daily) can prove very useful and are generally safe for long-term intermittent use. Oral prednisolone is beneficial but its use is limited by its side-effect profile. Azathioprine, retinoids, ciclosporin and thalidomide can be useful in resistant cases.

Prognosis
The disease is usually chronic although it often fluctuates in severity. CDLE remains confined to the skin in most patients and it will eventually go into remission in up to 50% of cases (after many years).

Subacute lupus erythematosus (SCLE)
SCLE is a rare cutaneous variant of LE. It presents with widespread indurated, sometimes urticated erythematous lesions, often on the upper trunk. The lesions can also be annular. Photosensitivity is often a prominent feature. Complications, such as arthralgia and mouth ulceration, are seen but significant organ involvement is rare. ANF and extractable nuclear antibodies (anti-Ro and anti-La) are usually positive (see p. 537).

Treatment is with oral dapsone, antimarials or systemic immunosuppression (prednisolone and ciclosporin).

Systemic lupus erythematosus (SLE)
(see also p. 535)
The cutaneous involvement of SLE is one of the minor problems of the disease but it may be the presenting feature.

Features include macular erythema over the cheeks, nose and forehead (‘butterfly rash’ – Fig. 24.26). Palmar erythema, dilated nail-fold capillaries, splinter haemorrhages and digital infarcts of the finger tips may also be seen but are not always noticed by the patient. Joint swellings, livedo reticularis and purpura are occasionally seen. Rarely SLE can be complicated by an atypical erythema multiforme-like rash (‘Rowell’s syndrome’).

Treatment (p. 537) is usually managed by a rheumatologist.

Pruritus
The pathophysiology of pruritus (itch) is poorly understood but may be due to peripheral mechanisms (as in skin disease), central or neuropathic mechanisms (as in multiple sclerosis), neurogenic (as in cholestasis/μ-opioid receptor stimulation) or psychogenic mechanisms (e.g. parasitophobia). Evidence suggests that low stimulation of unmyelinated C-fibres in the skin is associated with the sensation of itch (high stimulation produces pain). Histamine, tachykinins (e.g. substance P) and cytokines (e.g. interleukin-2) may also play a role peripherally in the skin. The major nerve pathways for itch and the influence of the central nervous system are not well characterized but opioid μ-receptor-dependent processes can regulate the perception and intensity of itch.

Pruritus (see also p. 1207, lichen simplex, nodular prurigo/neurodermatitis) in the absence of a demonstrable rash can be caused by a number of different medical problems (Table 24.11).

Asteatotic eczema and cholinergic urticaria are common causes of pruritus where the rash is often missed. The term idiopathic pruritus or ‘senile’ pruritus probably overlaps with asthenic eczema and this is common in the elderly.

Treatment involves avoiding soaps and symptomatic measures (as for asthenic eczema). Phototherapy, low-dose amitriptyline or gabapentin may help intractable cases. Underlying medical problems should be treated.

Sarcoidosis
Sarcoidosis (see also p. 845) is a multisystem granulomatous disorder of unknown aetiology. It may present as reddish brown dermal papules and nodules, especially around the eyelid margins and the rim of the nostrils. More polymorphic lesions (papules, nodules and plaques) may appear on the body. It is most common in black Africans where it is often accompanied by hypo- or hyperpigmentation. Rarely it presents with a bluish red infiltrate or swelling, especially of the nose or ears, called lupus pernio. Both these types of lesion are to be seen anywhere on the body but are common on the face. Erythema nodosum (p. 1216) of the shins is sometimes seen in acute-onset sarcoidosis. Erythema nodosum is an immunological reaction and not due to sarcoid tissue infiltration. Swollen fingers from a dacrytis may also be present. Whilst sarcoidosis may be confined to the skin, all patients should be investigated for evidence of systemic disease (p. 847).

Treatment of cutaneous lesions includes very potent topical steroids (0.05% clobetasol propionate), intralesional steroids, oral steroids and occasionally metotrexate or antimarials.

Neurofibromatosis type 1 (von Recklinghausen’s disease)
Type 1 neurofibromatosis is an autosomal dominant condition with high levels of penetrance. It often presents in childhood with a variety of cutaneous features. Many cases are new mutations in the NF1 gene. Early signs include...
café-au-lait spots (brown macules, >2.5 cm in diameter and more than five lesions) and axillary freckling. Lisch nodules (hyperpigmented iris hamartomas) may be seen in the eyes by slit lamp examination. Learning difficulties and skeletal dysplasia occur. Later on, fleshy skin tags and deeper soft tumours (neurofibromas) appear and they can progress to completely cover the skin causing significant cosmetic disability. A number of endocrine disorders are rarely associated including phaeochromocytoma, acromegaly and Addison’s disease.

**Tuberous sclerosis (epiloia)**

The tuberous sclerosis complex (TSC) is an autosomal dominant condition of variable severity which may not present until later childhood. It is characterized by a variety of hamartomatous growths. The three cardinal features are (1) mental retardation, (2) epilepsy and (3) cutaneous abnormalities – but not all have to be present. In most cases, it is due to a mutation in either the TSC1 gene (encodes hamartin) or the TSC2 gene (encodes tuberin). Genetic testing is available but the diagnosis still remains clinical, requiring two major features or one major and two minor features. The skin signs include:

- Adenoma sebaceum (reddish papules/fibromas around the nose)
- Periungual fibroma (nodules arising from the nail bed)
- Shagreen patches (firm, flesh-coloured plaques on the trunk)
- Ash-leaf hypopigmentation (pale macules best seen with UV light)
- Forehead plaque (indurated flesh-coloured patch)
- Café-au-lait patches
- Pitting of dental enamel.

Internal hamartomas can arise in the heart, lung, kidney, retina and CNS. Parents of a suspected case should be carefully examined (under UV light) as they may have a ‘forme fruste’ of the condition, which can manifest just as hypopigmented patches. This and gonadal mosaicism can have genetic implications for future offspring. A large contiguous gene defect may involve TSC2 and PKD1 genes causing tuberous sclerosis and polycystic kidney disease together in the same patient.

**Diabetes mellitus**

Diabetes mellitus (see also p. 1001) can have a number of cutaneous features. Complications of diabetes itself include:

- Fungal infection (e.g. Candidiasis)
- Bacterial infections (e.g. recurrent boils)
- Xanthomas
- Arterial disease (ulcers, gangrene)
- Neuropathic ulcers.

Specific dermatoses of diabetes include:

- Necrobiosis lipoidica (a patch of spreading erythema over the shin which becomes yellowish and atrophic in the centre and may ulcerate)
- Diffuse granuloma annulare (p. 1212)
- Diabetic dermopathy (red-brown flat-topped papules)
- Blisters (usually on the feet or hands)
- Diabetic stiff skin (tight waxy skin over the fingers with limitation of joint movement owing to thickened collagen – also called cheiroarthropathy).

**Chronic liver disease**

Chronic liver disease may present with jaundice, palmar erythema, spider naevi, white nails, hyperpigmentation and pruritus.

**Porphyria cutanea tarda** (PCT, p. 1045) is a rare genetic disorder associated with liver disease usually due to hepatic damage from excessive alcohol consumption or hepatitis C infection. Some 75% of cases are sporadic, 25% familial. Overall, 20% of cases have underlying hereditary haemochromatosis (p. 303). PCT presents clinically on exposed skin with sun-induced blisters, skin fragility, scarring, milia and hypertrichosis. Treatment of the cutaneous features is with repeated venesection and/or very low-dose chloroquine plus avoidance of alcohol. There is anecdotal evidence that specific treatment of hepatitis C will also help the skin, presumably by improving liver function. All people with PCT are at risk of hepatic carcinoma.

**Chronic kidney disease (CKD)**

Chronic kidney disease (see also p. 320) is commonly associated with intractable pruritus. Pallor, hyperpigmentation and ecchymoses are commonly seen. Rarely it is associated with non-inflammatory blisters, pseudo-porphyria cutanea tarda and cutaneous calcification. Longstanding renal transplant patients often suffer with recurrent viral warts and squamous cell carcinomas due to the immunosuppression. ‘Nephrogenic fibrosing dermopathy’ (also known as ‘nephrogenic systemic fibrosis’) is a newly described severe scleroderma-like skin disease in a subset of patients who have CKD (usually on dialysis). The disease is rapid in onset (days to weeks) with skin discoloration and thickening, joint contractures, muscle weakness and generalized pain. Widespread tissue fibrosis may ensue, causing severe morbidity. Patients may rapidly become wheelchair-bound. The condition is strongly associated with the contrast medium gadoxetate disodium used in MRI scans, and such contrast agents are best avoided in people with low GFRs. There is no accepted treatment but some advocate PUVA and extracorporeal photopheresis. No spontaneous remissions have been recorded. Rapid correction of renal function generally stops the condition progressing.

**Calciphylaxis** is discussed in Chapter 12.

**Thyroid disease** (see also p. 937)

Hypothyroidism may cause dry firm gelatinous (myxoelematous) skin with diffuse hair thinning and loss of the outer third of the eyebrows. Hyperthyroidism may be associated with warm sweaty skin and a diffuse alopecia. Graves’ disease is rarely associated with thyroid acropachy (‘clubbing’ with underlying bone changes) and pretibial myxoedema (a red-brown mucinous infiltration of the shins which can become lumpy and tender).

**Cushing’s syndrome** (see also p. 957)

This may cause hirsutism, a moon face, a buffalo hump, stretchmarks (striae) and a postural folliculitis (often called steroid acne) of the skin.

**Hyperlipidaemias**

Hyperlipidaemias (see also p. 1034) can present with xanthomas, which are abnormal collections of lipid in the skin. All people with xanthomas should be investigated for hyperlipidaemia although the most common type, called xanthelasmas (yellow plaques around the eyes), are usually associated

---

**FURTHER READING**

**FURTHER READING**

with normal lipids. There are a number of other clinical variants of xanthomas such as (1) tuberous xanthoma (firm orange-yellow nodules and plaques on extensor surfaces); (2) tendon xanthoma (firm subcutaneous swellings attached to tendons); (3) plane xanthoma (orange-yellow macules often affecting palmar creases); (4) eruptive xanthoma (numerous small yellowish papules commonly on the buttocks).

**Amyloidosis**

**Macular amyloid** is a common purely cutaneous variant seen in Asians. It is characterized by itchy brown rippled macules on the upper back.

**Systemic amyloid** may be associated with reddish brown papules, nodules or plaques especially around the eyes, the flexural areas and mucosal surfaces. Distinctive periorbital bruising and macroglossia may also be present.

**Systemic malignant disease**

Certain rashes may be a non-metastatic manifestation of an underlying malignancy: paraneoplastic dermatoses (Table 24.12). Rarely tumours can metastasize to the skin (Fig. 24.27). The level of blistering determines the clinical picture as well as the prognosis. Therefore skin biopsy for light and electron microscopy together with immunofluorescence (IFM) studies is paramount in diagnosis. However, remember that the commonest causes of skin blistering are chickenpox, herpes, impetigo, pemphigus foliaceus (characterized by anti-desmoglein 1 IgG autoantibodies), the development of autoantibodies, e.g. IgG, against the desmosomal protein desmoglein 1 and 3 is pathogenic in this disease and the autoantibodies can be measured as markers of disease activity. Desmoglein 1 and 3, an adhesion molecule, is expressed in skin and mucosal surfaces, so both will blister. Rarely the disease can be drug induced (e.g. penicillamine or captopril).

Skin biopsy shows a superficial intraepidermal split just above the basal layer with acantholysis (separation of individual cells). In the rarer variant, pemphigus foliaceus may proceed to ulcerate.

**BULLOUS DISEASE**

Primary blistering diseases of the skin are rare. A variety of skin proteins hold the skin together. Inherited abnormalities or immune damage of these proteins cause abnormal cell separation, inflammation, fluid accumulation and blistering (Fig. 24.27). The level of blistering determines the clinical picture as well as the prognosis. Therefore skin biopsy for light and electron microscopy together with immunofluorescence (IMF) studies is paramount in diagnosis. However, remember that the commonest causes of skin blistering are chickenpox, herpes, impetigo, pemphigus foliaceus and insect bite reactions, although the latter are often localized.

**Immunobullous disease**

**Pemphigus vulgaris**

Pemphigus vulgaris is a potentially fatal blistering disease occurring in all races but commoner in Ashkenazi Jews and possibly in people from the Indian subcontinent. Onset is usually in middle age and both sexes are affected equally. The development of autoantibodies, e.g. IgG, against the desmosomal protein desmoglein 1 and 3 is pathogenic in this disease and the autoantibodies can be measured as markers of disease activity. Desmoglein 1 and 3, an adhesion molecule, is expressed in skin and mucosal surfaces, so both will blister. Rarely the disease can be drug induced (e.g. penicillamine or captopril).

Skin biopsy shows a superficial intraepidermal split just above the basal layer with acantholysis (separation of individual cells). In the rarer variant, pemphigus foliaceus (characterized by anti-desmoglein 1 IgG autoantibodies),

**FURTHER READING**

Bullous pemphigoid
- life-threatening blistering.

Clinical features
Mucosal involvement (especially oral ulceration) is common and is the presenting sign in up to 50% of cases. This may then be followed by the appearance of non-itchy flaccid blisters, particularly involving the trunk. Blistering usually becomes widespread but they rapidly denude; thus pemphigus often presents with erythematous, weeping erosions. Blisters can be extended with gentle sliding pressure (Nikolsky’s sign). Flexural lesions often have a vegetative appearance. In pemphigus foliaceus the blisters and erosions often start in a seborrhoic distribution (scalp, face and upper chest) before becoming more widespread.

Treatment
This is with very high-dose oral prednisolone (60–100 mg daily) or pulsed methylprednisolone and is often needed lifelong. Therefore other immunosuppressants such as azathioprine or mycophenolate mofetil (or occasionally cyclophosphamide or ciclosporin) are used as steroid-sparing agents. Intravenous immunoglobulin infusions help gain quick control whilst waiting for these other drugs to work. The anti-B cell drug rituximab (anti-CD20 monoclonal antibody) is useful in multidrug-resistant cases.

Whilst treatment is normally effective, perhaps up to 10% of patients may die either due to complications of the disease or more commonly from side-effects of the treatment.

Bullous pemphigoid
Bullous pemphigoid is more common than pemphigus. It presents in later life (usually over 60) and mucosal involvement is rarer. Autoantibodies against a 230 kDa or 180 kDa hemidesmosomal protein (‘bullous pemphigoid antigen 1’ and ‘type XVII collagen’) play an aetiological role.

Skin biopsy shows a deeper blister (than in pemphigus) due to a subepidermal split through the basement membrane. Direct and indirect IMF studies show linear staining of IgG along the basement membrane.

Clinical features
Large tense bullae appear anywhere on the skin but often involve limbs (Fig. 24.28), hands and feet. The bullae may be centred on an erythematous or urticated background and they can be haemorrhagic. Pemphigoid can be very itchy. Mucosal ulceration is uncommon but a variant of pemphigoid exists which predominantly affects mucosal surfaces with scarring (mucous membrane pemphigoid).

Treatment
This is with high-dose oral prednisolone (30–60 mg daily) and steroid-sparing agents such as azathioprine or mycophenolate mofetil. Weekly methotrexate is also occasionally used. In general, disease control is easier than with pemphigus. Often treatment can be withdrawn after 2–3 years. Treatment often causes side-effects, especially as most patients are elderly. Occasionally localized or mild disease can be controlled with superpotent topical steroids, oral dapsone or high-dose oral minocycline.

Dermatitis herpetiformis
Dermatitis herpetiformis (DH) (see also p. 266) is a rare blistering disorder associated with gluten-sensitive enteropathy (coeliac disease). DH and coeliac disease are associated with other organ-specific autoimmune disorders. The HLA associations (B8, DR3, DQ2 in 80–90% of cases) and immunological findings (endomysial, tissue transglutaminase, reticulin and gliadin autoantibodies present in serum) are similar to coeliac disease.

Skin biopsy shows a subepidermal blister with neutrophil microabscesses in the dermal papillae. Direct immunofluorescent studies of uninvolved skin show IgA in the dermal papillae and patchy granular IgA along the basement membrane. The jejunum mucosa shows a partial villous atrophy.

Clinical features
Dermatitis herpetiformis is commoner in males and can present at any age but is most likely to appear for the first time in young adult life. It presents with small, intensely itchy blisters of the skin. The lesions have a predilection for the elbows, extensor forearms, scalp and buttocks. The tops of the blisters are usually scratched off; thus crusted erosions become widespread but they rapidly denude; thus pemphigus often presents with erythematous, weeping erosions.

Treatment
This should always be with a gluten-free diet (GFD, p. 266). Control of the skin disease can be obtained with oral dapsone (50–200 mg daily) or sulphonamides. If a strict GFD is adhered to, oral medication can often be withdrawn after 2 years.

Use of dapsone. Dapsone frequently causes a mild dose-related haemolytic anaemia (which is usually well tolerated) but the haemolysis can be devastating if there is G6PD deficiency. Liver damage, peripheral neuropathy and aplastic anaemia can also rarely occur so regular monitoring of a blood count and liver function is needed.

Linear IgA disease (chronic bullous dermatosis of childhood)
Linear IgA disease is a subepidermal blistering disorder of adults and children. Pathogenic IgA autoantibodies bind to a variety of basement membrane proteins including type XVII collagen and laminin-332 (see Fig. 24.27). It is the most common immunobullous disease seen in children. Rarely it is induced by vancomycin.

Clinical features
Linear IgA disease can present with circular clusters of large blisters, a pemphigoid type of blistering or a dermatitis herpetiformis picture. Mucosal involvement of the mouth, vulva...
and eyes is not uncommon and can cause scarring. Direct IMF studies of skin show linear IgA deposition along the basement membrane.

**Treatment**

This is with oral dapsone (50–200 mg daily) or sulphamides. Occasionally, immunosuppression is needed. Many patients show spontaneous resolution after 3–6 years.

**Mechanobullous disease (epidermolysis bullosa, ‘EB’)**

These are due to inherited abnormalities in structural skin proteins which lead to ‘skin fragility’. The resultant blistering tends to arise secondary to trauma and often appears at or shortly after birth. These conditions can be a mild inconvenience, severely disabling or fatal but fortunately are very rare. There are three groups of disorders in which the fundamental gene/protein abnormalities have been characterized.

- **Epidermolysis bullosa simplex** is a group of autosomal dominant genodermatoses characterized by ‘superficial’ blistering owing to mutations of cytoskeleton proteins within the basal layer of the epidermis, e.g. keratin 5 (chromosome 12q) or keratin 14 (chromosome 17q). Most forms of EB simplex show mild disease with intermittent blistering of the hands and feet, especially in hot weather. The teeth and nails are normal and scarring is absent.

- **Epidermolysis bullosa dystrophica** is a group of genodermatoses characterized by ‘deeper’ blistering associated with scarring and milia formation. The level of split is deep within the basement membrane and is due to a mutation in the COL-7A1 gene (locus at chromosome 3p21.1) which causes a loss of collagen VII in the anchoring fibrils. Nails, mucosae and even the larynx are often involved. The autosomal dominant variety is milder but the autosomal recessive type produces severe disease with painful disabling scarring, fusion of digits, joint contractures and dysphagia. Life expectancy is significantly reduced. Repeated scarring results in the development of multiple squamous cell carcinomas and most die from this complication in early adult life. The average life expectancy after the appearance of the first squamous cell carcinoma is 5 years. Stem cell transplantation is being used.

- **Junctional epidermolysis bullosa** is the most severe form. It is characterized by a split in the lamina lucida of the basement membrane and is due to mutations in various proteins, mainly laminin-332 but also α6β4 integrin or type XVII collagen. It presents at birth with widespread blistering and areas of absent skin. Erosions of the central face and hoarseness from laryngeal involvement are common. Nail and teeth abnormalities are also common. Both a lethal and a rarer non-lethal form of junctional EB exist and they show an autosomal recessive inheritance. The lethal form causes death in infancy or early childhood.

**Investigation and treatment**

Investigation and treatment of EB should be carried out in a specialist centre. Exact diagnosis depends on ultrastructural analysis of induced blisters in the skin and immunohistochemistry, and these investigations can be further confirmed with genetic testing. Only then can prognosis and genetic counselling be given accurately to parents. Prenatal diagnosis and preimplantation diagnosis is available for the more severe forms of EB. Gene therapy and bone marrow transplantation are two new approaches that are currently under assessment.

**SKIN TUMOURS**

**Benign cutaneous tumours**

**Melanocytic naevi (moles)**

Moles are a benign overgrowth of melanocytes that are common in white-skinned people. They appear in childhood and increase in number and size during adolescence and early adult life. They often start as flat brown macules with proliferation of melanocytes at the dermoepidermal junction (junctional naevi). The melanocytes continue to proliferate and grow down into the dermis (compound naevi) which causes an elevation of the mole above the skin surface. The pigmentation is usually even and the border regular. They eventually mature into a dermal naevus (cellular naevus), often with a loss of pigment.

**Blue naevus** is an acquired asymptomatic blue-looking mole. It is due to a proliferation of melanocytes deep in the mid-dermis.

**Basal cell papilloma (seborrheic wart)**

This is a common benign overgrowth of the basal cell layer of the epidermis. The lesion can be flesh coloured, brown or even black and often has a greasy appearance. The surface is irregular and warty and the lesions appear very superficial as though stuck on to the skin (Fig. 24.29). Tiny keratin cysts may be seen on the surface. They can be treated with cryotherapy or curettage.

**Dermatofibroma (histiocytoma)**

Dermatofibromas appear as firm, elevated pigmented nodules which may feel like a button in the skin. A peripheral ring of pigmentation is sometimes seen. They are often found on the leg and are commoner in females. There may be a preceding history of trauma or insect bite. The lesion consists of histiocytes, blood vessels and varying degrees of fibrosis. If symptomatic, excision is required.

**Epidermoid cyst (previously ‘sebaceous cyst’)**

Epidermoid cysts present as cystic swellings of the skin with a central punctum. They contain ‘cheesy’ keratin. These cysts occasionally rupture causing significant dermal inflammation.

**Pilar cyst (trichilemmal cyst)**

Pilar cysts are smooth cysts without a punctum usually found on the scalp. They may be multiple and familial.

**Figure 24.29 Seborrheic warts (basal cell papillomas).**

**Further reading**

Keratoacanthoma
Keratoacanthomas are rapidly growing epidermal tumours which develop central necrosis and ulceration (Fig. 24.30). They occur on sun-exposed skin in later life and can grow up to 2–3 cm across. Whilst they may resolve spontaneously over a few months, they are best excised both to exclude a squamous cell carcinoma (which they can mimic) and to improve the cosmetic outcome.

Pyogenic granuloma (granuloma telangiectaticum)
Pyogenic granulomas are a benign overgrowth of blood vessels. They present as rapidly growing pinkish red nodules which are friable and readily bleed. They may follow trauma and are often found on the fingers and lips. They are best excised to exclude an amelanotic malignant melanoma.

Cherry angioma (Campbell de Morgan spots)
These are benign angiokeratomas that appear as tiny pin-point red papules, especially on the trunk, and increase with age. No treatment is required.

Potentially pre-malignant cutaneous tumours
Solar keratoses (actinic keratoses)
These frequently develop later in life in white-skinned people who have had significant sun exposure. They appear on exposed skin as erythematous silver-scaly papules or patches with a conical surface and a red base (Fig. 24.31). The background skin is often inelastic, wrinkled and may show flat brown macules (solar lentigos) reflecting diffuse solar damage. A small proportion of these keratoses can transform into squamous cell carcinoma but only after many years.

Treatment of lesions is with cryotherapy, topical 5-fluorouracil cream, 5% imiquimod cream or diclofenac gel.

Bowen’s disease
This is a form of intraepidermal carcinoma-in-situ which rarely can become invasive. It is thought to be due to long-term sun exposure. It presents on exposed skin, most commonly women’s legs, as an isolated scaly red patch or plaque looking rather like psoriasis although it has a rather irregular edge. The lesions do not clear but slowly increase in size with time.

A variant which can show partial or full-thickness dysplasia can involve the epidermis of the mucosa or neighbouring skin. This can affect the vulva, the glans penis and perianal skin and is termed vulval (penile, or anal) intraepithelial neoplasia. Clinically, it can present as nonspecific erythema or as a warty thickening. These diseases have a stronger link with HPV and probably have a higher pre-malignant potential than Bowen’s disease. They are commoner in immunosuppressed individuals. The anal form is increasingly reported in HIV-positive patients (as indeed is anal carcinoma) and extension into the rectum may occur.

Treatment is with topical 5-fluorouracil, 5% imiquimod cream, cryotherapy, curettage, photodynamic therapy or a tissue-destructive laser.

Atypical mole syndrome (dysplastic naevus syndrome)
This is often familial. A large number of melanocytic naevi begin to appear in childhood even on unexposed sites. Individual lesions may be large with irregular pigmentation and border, and histologically they may show cytological and architectural atypia but no frank malignant change. Individuals with this condition have an increased risk of developing malignant melanoma. They should have their moles photographed and be regularly reviewed. Suspicious lesions should be excised.

Giant congenital melanocytic naevi
These are very large moles present at birth. Very large lesions (>20 cm across) show an increased risk of developing malignant melanoma (up to 5%). Excision may be considered but is rarely possible without multiple operations and marked disfigurement so regular monitoring is advised. There have been a number of reports showing that a few of these lesions improve spontaneously and partially resolve during childhood.

Lentigo maligna
This is a slow-growing macular area of pigmentation seen in elderly people, commonly on the face. The border and pigmentation are often irregular. Some people regard this lesion as a melanoma-in-situ. There is an increased risk of developing invasive malignant melanoma. Treatment is by excision if possible but 5% imiquimod cream is currently being tried in the very large lesions where surgery would be disfiguring.

Malignant cutaneous tumours
Basal cell carcinoma (rodent ulcer)
Basal cell carcinomas (BCC) are the most common malignant skin tumour but their relationship to excessive sun exposure is complex. Genotype and phenotype of the patient is also involved in pathogenesis. Multiple BCCs are seen in Gorlin’s syndrome due to mutations in the PTCH1 gene and mutations in this gene have also been described in the sporadic form of BCC.
Skin tumours

Malignant melanoma is the most serious form of skin cancer as metastasis can occur early and it causes a number of deaths even in young people. As with other types of skin cancer the incidence is continuing to increase, probably due to excessive exposure to sunlight. The history of childhood sun exposure and intermittent intense sun exposure appears to be necessary for the development of malignant melanoma. Other risk factors include pale skin, multiple melanocytic naevi (>50), sun sensitivity, immunosuppression, atypical mole syndrome, giant congenital melanocytic naevi, lentigo maligna and a positive family history of malignant melanoma. Malignant melanoma is commoner in later life but many young adults are also affected. A number of oncogenes and tumour suppressor proteins (CDK4, CDKN2a, B-RAF, PTEN, Ras, Rb, p53, p16) have been implicated in the pathogenesis of melanoma. Some 60% of human melanomas have an activating mutation (V600E) in the serine protein kinase B-RAF which has now become a target for ‘personalized’ therapy (p. 1226).

Diagnosis of melanoma is not always easy but the clinical signs listed in Table 24.13 help distinguish malignant from benign moles. Examination with a dermatoscope (a handheld polarized light source with magnification) can further help in detecting malignant lesions.

**Malignant melanoma**

Malignant melanoma is the most serious form of skin cancer as metastasis can occur early and it causes a number of deaths even in young people. As with other types of skin cancer the incidence is continuing to increase, probably due to excessive exposure to sunlight. The history of childhood sun exposure and intermittent intense sun exposure appears to be necessary for the development of malignant melanoma. Other risk factors include pale skin, multiple melanocytic naevi (>50), sun sensitivity, immunosuppression, atypical mole syndrome, giant congenital melanocytic naevi, lentigo maligna and a positive family history of malignant melanoma. Malignant melanoma is commoner in later life but many young adults are also affected. A number of oncogenes and tumour suppressor proteins (CDK4, CDKN2a, B-RAF, PTEN, Ras, Rb, p53, p16) have been implicated in the pathogenesis of melanoma. Some 60% of human melanomas have an activating mutation (V600E) in the serine protein kinase B-RAF which has now become a target for ‘personalized’ therapy (p. 1226).

Diagnosis of melanoma is not always easy but the clinical signs listed in Table 24.13 help distinguish malignant from benign moles. Examination with a dermatoscope (a handheld polarized light source with magnification) can further help in detecting malignant lesions.

**FURTHER READING**

**FURTHER READING**

Lesions may come and go or remain persistent over many years. Patients may well die of unrelated causes. Skin biopsy confirms the diagnosis, showing invasion by atypical lymphocytes. T cell receptor gene rearrangement studies show that there is often a monoclonal expansion of lymphocytes in the skin.

Occasionally the disease can progress to a cutaneous nodular or tumour stage, which may be accompanied by systemic organ involvement. In elderly males the disease may progress rarely to an erythrodermic variant accompanied by lymphadenopathy and peripheral blood involvement (‘Sézary’s syndrome’). All patients should be staged at the time of diagnosis to assess for any systemic involvement.

### Treatment

Early cutaneous disease can be left untreated or treated with topical steroids or PUVA. More advanced disease of the skin, or systemic involvement, may require radiotherapy, oral retinoids (bexarotene), chemotherapy (e.g. methotrexate), immunotherapy or electron beam therapy. AntiCD4 and antiCD25 monoclonal antibodies are currently under assessment in advanced disease.

### Kaposi’s sarcoma

This is a tumour of vascular and lymphatic endothelium that presents as purplish nodules and plaques. There are three types:

- **The ‘classic’ or ‘sporadic’ form** (as described by Kaposi) occurs in elderly males, especially Jewish people from Eastern Europe. It presents as slow-growing purple tumours in the foot and lower leg which rarely cause any significant problem.

- **The ‘endemic’ form** occurs in males from central Africa and shows more widespread cutaneous involvement as well as lymph node (or occasionally systemic) involvement. Oedema is a prominent feature.

- **The immunosuppression-related form** is more severe and is most common in HIV-positive men who have sex with men. Lesions are widespread and often affect the skin, bowel, oral cavity and lungs.

All three types have a strong association with herpes virus type 8 but other factors must be involved as herpes type 8 seroprevalence is up to 10% in the USA and 50% in some African countries. HAART (p. 171) has significantly reduced the incidence of Kaposi’s sarcoma in HIV infection although the prevalence has started to increase again over the last few years for as yet unexplained reasons.

### Treatment

Treatment of advanced Kaposi’s sarcoma is with radiotherapy, immunotherapy or chemotherapy.

### Arterial ulcers

Arterial ulcers present as punched-out, painful ulcers higher up the leg or on the feet. There may be a history of claudication, hypertension, angina or smoking. Clinically, the leg is cold and pale. Absent peripheral pulses, arterial bruits and loss of hair may be present. Doppler ultrasound studies will confirm arterial disease.

**Treatment** depends on keeping the ulcer clean and covered, adequate analgesia and vascular reconstruction if appropriate. Compression bandaging must not be used.

### Neuropathic ulcers

Neuropathic ulcers tend to be seen over pressure areas of the foot, such as the metatarsal heads, owing to repeated trauma. These are most commonly seen in diabetics due to peripheral neuropathy. In some developing countries leprosy is a common cause.

**Treatment** depends on keeping the ulcer clean and removing pressure or trauma from the affected area. Diabetics should pay particular attention to foot care and correctly fitting shoes with the help of a specialist podiatrist (p. 1009).

### Pressure sores (decubitus ulcers, bedsores)

These occur in the elderly, immobile, unconscious or paralysed patients. They are due to skin ischaemia from sustained pressure over a bony prominence, most commonly the heel and sacrum. Normal individuals feel the pain of continued pressure, and even during sleep movement takes place to change position continually. Pressure sores may be graded:

- **Stage I:** non-blanchable erythema of intact skin
- **Stage II:** partial-thickness skin loss of epidermis/dermis (blister or shallow ulcer)
- **Stage III:** full-thickness skin loss involving subcutaneous tissue but not fascia
- **Stage IV:** full-thickness skin loss with involvement of muscle/bone/tendon/joint capsule.

There are numerous risk factors for development of pressure sores (Table 24.15). The majority of pressure sores occur in hospital. Some 70% appear in the first 2 weeks of hospitalization, and 70% are in orthopaedic patients, especially those on traction. Between 20% and 30% of pressure sores occur in the community. Some 80% of patients who have deep ulcers involving the subcutaneous tissue die in the first 4 months.

**Management**

**Prevention**

Prevention is better than cure. Specialist ‘tissue-viability nurses’ help identify at-risk patients and train other clinical staff. Several risk assessment tools have been devised for...
the immobile patient based on the known risk factors. The ‘Norton scale’ and Waterlow Pressure Sore Risk Assessment (Box 24.4) are two such validated systems, which produce a numerical score, enabling staff to identify those at most risk. Braden, Walsall and Maelor scales are also used.

**Treatment**

- Bed rest with pillows and fleeces to keep pressure off bony areas (e.g. sacrum and heels) and prevent friction
- Air-filled cushions for patients in wheelchairs
- Special pressure-relieving mattresses and beds
- Regular turning but avoid pressure on hips
- Ensure adequate nutrition
- Non-irritant occlusive moist dressings (e.g. hydrocolloid)
- Adequate analgesia (may need opiates)
- Plastic surgery (debridement and grafting in selected cases)
- Treatment of underlying condition.

### Vasculitis

Vasculitis (see also p. 542) is the term applied to an inflammatory disorder of blood vessels which causes endothelial damage. Cutaneous vasculitis (confirmed by skin biopsy) may be an isolated problem but occasionally is associated with vasculitis in other organs. The most commonly used classification is based on the size of blood vessel involved (see Tables 11.19 and 11.20).

The cutaneous features are of haemorrhagic papules, pustules, nodules or plaques which may erode and ulcerate. These purpuric lesions do not blanch with pressure from a glass slide (‘diascopy’). Occasionally, a fixed livedo reticularis pattern may appear which does not disappear on warming. Pyrexia and arthralgia are common associations even in the absence of significant systemic involvement. Other clinical features depend on the underlying cause.

**Leucocytoclastic vasculitis** (LCV) or angiitis is the most common cutaneous vasculitis affecting small vessels. This

usually appears on the lower legs as a symmetrical palpable purpura. It is rarely associated with systemic involvement. It can be caused by drugs (15%), infection (15%), inflammatory disease (10%) or malignant disease (<5%) but often no cause is found (55–60%). Investigations are only necessary with persistent lesions or associated signs and symptoms. Whilst LCV often settles spontaneously, treatment with analgesia, support stockings, dapsone or prednisolone may be needed to control the pain and to heal up any ulceration. Urticarial vasculitis is discussed on page 1211.

Calciphylaxis (calcific uraemic arteriopathy) is described in Chapter 12.

**Lymphatics**

**Lymphoedema**

Lymphoedema refers to a chronic non-pitting oedema due to lymphatic insufficiency. It is most commonly seen affecting the legs and tends to progress with age. The legs can become enormous and prevent wearing of normal shoes. Chronic disease may cause a secondary ‘cobblestone’ thickening of the skin. Lymphoedema can be primary (and present early in life) due to an inherited deficiency of lymphatic vessels (e.g. Milroy’s disease) or can be secondary due to obstruction of lymphatic vessels (e.g. filarial infection or malignant disease).

*Treatment* is with compression stockings and physical massage. If there is recurrent cellulitis, long-term antibiotics are advisable as each episode of cellulitis will further damage the lymph vessels. Surgery should be avoided.

**Lymphangioma circumscriptum**

This is a rare hamartoma of lymphatic tissue. It usually presents in childhood with multiple small vesicles in the skin which weep lymphatic fluid and sometimes blood. They reflect deep vessel involvement so surgery should be avoided. Cryotherapy or CO2 laser treatment may help the superficial lesions.

**DISORDERS OF COLLAGEN AND ELASTIC TISSUE**

**Ehlers–Danlos syndrome** (see also p. 559)

Ehlers–Danlos syndrome (EDS) can be subdivided into at least 10 variants. They are all inherited disorders causing abnormalities in collagen of the skin, joints and blood vessels. Clinically this causes increased elasticity of the skin, hypermobile joints (6–9 on the Beighton scale; see Box 11.19) and fragile blood vessels causing easy bruising or in some cases internal haemorrhage. The skin is hyperextensible but recoils normally after stretching. It is easily injured and heals slowly with scarring like tissue paper. Pseudotumours may occur at the sites of scarring (such as elbows and knees) consisting mainly of fat, but calcification can occur.

**Pseudoxanthoma elasticum**

Pseudoxanthoma elasticum is a rare disease characterized by abnormal mineralization of collagen and elastic tissue primarily affecting the skin, eye and blood vessels. It is caused by mutations in the cell transporter gene ABCC6. The phenotype can vary enormously and this may be dependent on the site of the mutation. The skin may be loose, lax and wrinkled. It can look yellowish and papular (‘plucked chicken skin’) and tends to lose its elastic recoil when stretched. Skin changes are best seen in the flexures, especially the sides of the neck. Non-cutaneous features are not always present but they include recurrent gastrointestinal bleeding, early myocardial infarction, claudication and angioid streaks on the retina reflecting disruption of vascular elastic tissue.

**Striae**

Striae are visible linear scars due to dermal collagen damage and stretching. Histologically a thinned epidermis overlies parallel bundles of fine collagen. They occur commonly over the abdomen and breasts in pregnancy but also occur on the thighs and trunk in rapidly growing adolescents as well as in some obese individuals. They are also seen in Cushing’s syndrome and corticosteroid therapy. They are also rarely seen in Marfan’s syndrome. Striae are initially reddish blue but fade to white atrophic marks. Puberty-related striae normally disappear completely.

**Keloid scars**

Keloid scars are characterized by smooth hard nodules (Fig. 24.36) due to excessive collagen production. They may occur spontaneously or follow skin trauma/surgery and they are often itchy. They tend to affect young adults and are much commoner in black Africans. Sites of predilection include the shoulders, upper back and chest, earlobes and chin. Unlike hypertrophic scars (which fade within 12 months) keloids are persistent and may continue to enlarge.

*Treatment* is with triamcinolone injection, compression with silica gels or surgery, but surgery must be followed by steroid injection or superficial radiotherapy or it may make the problem worse.

**DISORDERS OF PIGMENTATION**

**Hypopigmentation**

**Vitiligo**

Vitiligo is a common autoimmune disorder of depigmentation due to areas of melanocyte loss. Sufferers often have relatives with other organ-specific autoimmune disorders. It
Vitiligo

This occurs most commonly in black African people and is of unknown aetiology. It presents with small (2–4 mm) asymptomatic porcelain-white macules, often on skin exposed to sunlight. The borders are often sharply defined and angular. There is no effective treatment.

Leprosy (see also p. 130)

Both tuberculoid leprosy and indeterminate leprosy can present with anaesthetic patches of depigmentation and should always be considered in people from endemic regions. Loss of hair and decreased sweating may also be present in the lesions.

Hyperpigmentation

Freckles (ephelides)

These appear in childhood as small brown macules after sun exposure. They fade in the winter months.

Lentigos

These are more permanent macule of pigmentation similar to freckles but they tend to persist in the winter. Solar lentigos (also called ‘liver spots’) occur in older people on exposed skin due to actinic damage.

Chloasma (melasma)

These are brown macules often seen symmetrically over the cheeks and forehead and are most common in women. Chloasma can occur spontaneously but it is also associated with pregnancy and the oral contraceptive pill.

Metabolic/endocrine effects

A generalized skin darkening can occur with chronic liver disease, especially haemochromatosis. It also is seen sometimes in Cushing’s syndrome, Addison’s disease (more marked in palmar creases and buccal mucosa) and Nelson’s syndrome.

Peutz–Jeghers syndrome (p. 271)

This is an autosomal dominant condition which presents with brown macules of the lips and perioral region. It is associated with gastrointestinal polyposis.

Urticaria pigmentosa (cutaneous mastocytosis)

This presents most commonly with multiple pigmented macules in children. These lesions tend to become red, itchy and urticated if they are rubbed (Darier’s sign). Occasionally lesions may blister, and in the rare congenital, diffuse form of the disease the skin may become thickened and leathery. Occasionally systemic symptoms are present such as wheeze, flushing, syncope or diarrhoea, reflecting extensive mast cell degranulation from the skin. Anaphylaxis occurs very rarely and may be precipitated by mast cell degranulators such as aspirin or opiates. The condition spontaneously resolves after some years in children but is persistent in adults.

Skin biopsy shows an excess of mast cells in the skin. A mutation in the proto-oncogene c-kit often underlies the condition resulting in mast cell proliferation and mast cell apoptosis. Rarely there may be infiltration of internal organs with mast cells (systemic mastocytosis), especially in adult disease or neonatal disease. This can involve any organ but especially the bone (where it can cause severe pain), gastrointestinal tract, liver and spleen. There is a small risk of developing leukaemia if the bone marrow is heavily infiltrated.

Treatment of the skin, if required, is with antihistamines, sodium cromoglicate or PUVA as well as avoidance of opiates and NSAIDs.

Other conditions with pigmentation

Café-au-lait macules are seen in neurofibromatosis types 1 and 2, tuberous sclerosis, ataxia telangiectasia, Fanconi’s anaemia, multiple endocrine neoplasia type 1 and McCune–Albright syndrome.

Multiple lentigines are seen in Peutz–Jeghers syndrome, xeroderma pigmentosum, LEOPARD syndrome (Lentigines,
Electrocardiographic conduction abnormalities, Ocular hypertelorism, Pulmonary stenosis, Abnormalities of genitalia, Retardation of growth, Deafness) and Carney complex (lentiginosis, myxomas of heart and skin, endocrine overactivity).

**Acquired melanocytic naevi** are seen in Turner’s syndrome (p. 978) and atypical mole syndrome (dysplastic naevus syndrome, p. 1224).

## DRUG-INDUCED RASHES

Drugs can be toxic and teratogenic but they can also cause problems through allergic reactions. This frequently presents in the skin where just about any type of skin rash can arise (Table 24.16) although a widespread symmetrical maculopapular rash is the most common type (Fig. 24.38). ‘Fixed drug eruptions’ occur where a rash evolves and resolves at a specific site. The rash is reproduced at exactly the same site after a repeated exposure.

### Toxic epidermal necrolysis

This is characterized by widespread subepidermal blistering and sloughing of more than 30% of the skin and a high mortality (30–50%). A prodrome of cough, myalgia and anorexia may precede skin signs by 2–3 days. The skin may be itchy but typically takes on a burning quality. Fever and mucosal involvement are common. The internal epithelial surfaces (lung, bladder, gastrointestinal tract) are also involved. Multiorgan failure and sepsis often occur. Toxic epidermal necrolysis (TEN) can be fatal even after drug withdrawal and intensive care support. Patients should be managed in intensive care or a specialized burns unit. All drugs where possible should be withdrawn. Occlusive cutaneous dressings significantly reduce the pain, and an ophthalmological assessment and oral hygiene are necessary. Specific medical treatment with steroids or ciclosporin is controversial and rarely used. Intravenous immunoglobulin may be beneficial if given early in the disease and this is more commonly used.

A variant exists called Stevens–Johnson syndrome (SJS) where the damage is restricted to the mucosal surfaces with milder bullous involvement of the skin (<10%). Both SJS and...
TEN are commoner in slow acetylators and very much commoner in those with HIV infection.

**Drug-induced hypersensitivity syndrome (DHS)**

Also called ‘anticonvulsant hypersensitivity syndrome’, ‘drug reaction with eosinophilia and systemic symptoms’, this is a serious adverse systemic reaction to a drug typically occurring 2–6 weeks after initial exposure. It is characterized by a generalized mucocutaneous rash, fever and lymphadenopathy with variable arthralgia, pharyngitis, peri orbital oedema and hepatosplenomegalgy. Rarely postulation of the skin and conjunctivitis are present. The blood may show a peripheral eosinophilia, lymphocytosis with atypical lymphocytes, and a hepatic picture. It can progress to multiorgan failure.

The cause of DHS is unknown but it may in part be due to genetic deficiency of epoxide hydrolase, a hepatic enzyme that detoxifies the arene oxide metabolites of antiepileptic drugs. There have been a number of reports about reactivation of various herpes family viruses (HHV 6 and 7, CMV, EBV) associating with DHS, the significance of which remains unclear. DHS can occur with any drug but a common culprit is one of the aromatic anticonvulsants (carbamazepine, phenytoin, phenobarbital, primidone and clonazepam) as they can cross-react all these drugs must be avoided in the future. Sodium valproate is a suitable alternative. There is also potential for cross-reaction with the newer anticonvulsants vigabatrin and lamotrigine. Treatment is with drug withdrawal, systemic steroids and supportive care.

**DISORDERS OF NAILS**

Psoriasis and fungal nail infection are the commonest causes of nail dystrophy and are discussed above.

- **Nail pitting** can be caused by psoriasis, alopecia areata and atopic eczema. A few pits can be present due to trauma.
- **Onycholysis** (distal nail plate separation) is caused by psoriasis, thyrotoxicosis, following trauma and rarely due to a photosensitive reaction to drugs such as tetracyclines.
- **Koilonychia** (thick spoon-shaped nails) can be caused by iron deficiency anaemia or rarely be congenital.
- **Leuconydia** (white nails) is seen in hypobalbuminaemia. A striate congenital leuconychia exists.
- **Beau's lines** (transverse lines) appear as solitary depressions which grow out slowly over many months. They arise due to a severe illness or shock which causes a temporary arrest in nail growth.
- **Yellow-nail syndrome** is a rare disorder of lymphatic drainage. It presents with thickened, slow-growing, yellow nails which may be associated with pleural effusions, bronchiectasis and lymphoedema of the legs.
- **Onychogryphosis** is a gross thickening of the nail which is seen in later life, especially in the big toe-nail. There is often a history of preceding trauma. Both psoriasis and fungal infection can also cause nail thickening.
- **Nail-patella syndrome** is an autosomal dominant condition which presents with triangular rather than half-moon-shaped lunulae, especially of the thumb and forefingers. The nail plates may be small or dystrophic. The patellae are hypoplastic or absent. Other skeletal anomalies may be present and renal impairment (glomerulonephritis) occurs in up to 30% of individuals.

**DISORDERS OF HAIR**

**Hair loss**

Hair loss can be due to a disorder of the hair follicle in which the scalp skin looks normal (non-scarring alopecia) or due to a disorder within the scalp skin that causes permanent loss of the follicle (scarring or cicatricial alopecia). This latter form causes shiny atrophic bald areas in the scalp which are devoid of follicular openings. There are many causes of alopecia (Table 24.17).

**Androgenic alopecia**

Androgenic alopecia (male pattern baldness) is the most common type of non-scarring hair loss and depends on genetic factors and an abnormal sensitivity to androgens. It presents in young men with frontal receding followed by thinning of the crown, and there is often a positive family history. It also occurs in females but tends to occur at a later age, be milder and show little in the way of frontal recession. If acne and menstrual disturbance are also present, the cause may be polycystic ovary syndrome or another endocrine disorder of androgens.

**Treatment** may not be required. Topical 5% minoxidil lotion or oral finasteride (1 mg daily) can help arrest progression and may cause a small amount of regrowth, providing it is used early in disease, but the treatment needs to be continued possibly lifelong. Approximately one-third of patients will not respond to either therapy. Finasteride is a selective inhibitor of 5α-reductase type II and it can cause side-effects in 1% of patients such as loss of libido. It should not be used in females as it can affect the sexual development of a male fetus. However, antiandrogen therapy (e.g. cyproterone acetate or spironolactone) may help some women.

**Alopecia areata**

Alopecia areata may be regarded as an immune-mediated type of hair loss associated with other organ-specific autoimmune diseases. It presents in children or young adults with patches of baldness (Fig. 24.40). These may regrow to be followed by new patches of hair loss. The presence of broken
exclamation mark hairs (narrow at the scalp and wider and more pigmented at the tip) at the edge of a bald area is diagnostic. Regrowth may initially be with white hairs and often occurs slowly over months. Occasionally all of the scalp hair is lost (alopecia totalis) and rarely all body hair is lost (alopecia universalis). The nails may be pitted or roughened. Treatment has no effect on the long-term progression. Potent topical or injected steroids may be of limited use. Topical immunotherapy with diphencyprone, PUVA or topical 5% minoxidil is occasionally tried but often does not help. Wigs can be provided for severe cases and patient support groups are often beneficial.

Other disorders

Traction alopecia
This refers to the ‘mechanical damage’ type of hair loss that arises from pulling the hair back into a bun or tight plaiting. It is more common in black Africans.

Telogen effluvium
Telogen effluvium refers to the pattern of diffuse hair loss that occurs some 3 months after pregnancy or a severe illness. It occurs because ‘stress’ puts all the hairs into the telogen phase of hair shedding at the same time. The hair fully recovers and the normal staggered hair growth/hair shedding cycle resumes within a few months.

Dissecting cellulitis
This is a chronic folliculitis affecting predominantly young black males. It presents with papules and pustules over the occipital region of the scalp with hair loss. If severe, the back of the scalp becomes a boggy swelling (discharging pus) with areas of scarring alopecia. It can be complicated by keloid formation (‘acne keloidalis nuchae’). The nails may be pitted or roughened.

Treatment is difficult but prolonged courses of low-dose antibiotics are worth trying in early disease. Prolonged courses of isotretinoin can help a few individuals and deep surgical excision can be used in recalcitrant cases. Combined rifampicin and clindamycin (both 300 mg × 2) can be used in resistant cases.

Increased hair growth – hirsutism

Hirsutism (p. 979) refers to the male pattern of hair growth seen in females. The racial variation in hair growth must be considered. Certain races (e.g. Mediterranean and Asian) have more male pattern hair growth than northern European females. This is not due to excess androgens but may reflect a genetically determined altered sensitivity to them. If virilizing features (deep voice, clitoromegaly, dysmenorrhoea, acne) are present, a full endocrine assessment is necessary. Hirsutism can cause severe psychological distress in some individuals.

Treatment involves physical methods such as bleaching, waxing, electrolysis, photoepilation and laser therapy. Anti-androgen therapy is occasionally helpful.

Hypertrichosis

Hypertrichosis refers to the state of excessive hair growth at any site and occurs in both sexes. It can be seen in anorexia nervosa, porphyria cutanea tarda and underlying malignancy, and is caused by certain drugs (e.g. ciclosporin, minoxidil).

BIRTH MARKS/NEONATAL RASHES

Infantile haemangiomia (strawberry naevus, cavernous haemangiomia)

Infantile haemangiomia affects up to 1% of infants. It presents at, or shortly after birth as a single red lumpy nodule that grows rapidly for the first few months. Multiple lesions can be present. They will spontaneously resolve with good cosmesis but may take up to 7 years for complete resolution. Occasionally plastic surgery is needed after resolution to remove residual slack skin. Reassurance of parents is usually all that is required.

Urgent treatment is indicated if:

- the lesion interferes with feeding or vision
- the lesion ulcerates or bleeds frequently
- the lesion is associated with high-output cardiac failure from shunting of large volumes of blood
- the lesion consumes platelets and/or clotting factors causing potentially life-threatening haemorrhage (‘Kasabach–Merritt syndrome’).

The last two complications are very rare and only tend to occur in large lesions with significant deep vessel involvement.

Treatment has been revolutionized by the discovery in France that oral propranolol (2 mg/kg per day in 3 divided doses) rapidly shrinks these haemangiomas even the deep or sub-glottic lesions. High-dose systemic steroids, vincristine or embolization are rarely used for non-responding patients.

Port-wine stain (naevus flammaeus)

Port-wine stain is also called a capillary haemangiomia but strictly speaking it is not a haemangiomia, just an abnormal dilatation of dermal capillaries. It presents at birth as a flat red macular area and is commonly found on the face. It does not improve spontaneously and it may become thickened with time. If the lesion is found in the distribution of the first division of the trigeminal nerve it may be associated with ipsilateral meningeal vascular anomalies that can cause epilepsy and even hemiplegia (Sturge–Weber syndrome). If a port-wine stain involves the skin near the eye, glaucoma is a risk and ophthalmic assessment is mandatory.

Treatment of port-wine stains is ideally with the tunable dye (pulsed dye) laser. Facial lesions respond best but lesions can re-darken after some years.
Other conditions in the newborn

Milia

‘Milk spots’ are small follicular epidermal cysts. They are small pinhead white papules commonly found on the face of infants. They resolve spontaneously, unlike in adults.

Mongolian blue spot

This appears in infants as a deep blue-grey bruise-like area, usually over the sacrum or back. It is occasionally mistaken as a sign of child abuse. It is due to deep dermal melanocytes. It is very common in Oriental children, less common in black Africans and rare in Caucasians. It has usually disappeared by the age of 7 years.

Toxic erythema of the newborn (erythema neonatorum)

Toxic erythema of the newborn is a term used to describe a common transient blotchy maculopapular rash in newborns. The rash is occasionally pustular but the child is not toxic or unwell. It disappears spontaneously within a few days.

Nappy rash (‘diaper dermatitis’)

This is an irritant eczema caused by occlusion of faeces and urine against the skin. It is almost universal in babies. The flexures are usually spared, which is a useful differentiating feature from seborrhoeic and atopic eczema. If satellite lesions are present around the edge it may indicate a superimposed Candida infection. This rash can also occur in the elderly incontinent.

Treatment involves frequent changing of the nappy and regular application of a barrier cream.

Acrodermatitis enteropathica (p. 213)

This is due to a rare inherited deficiency of zinc absorption. It presents 4–6 weeks after weaning or earlier in bottle-fed babies. There is an erythematous, sometimes blistering, rash around the perineum, mouth, hands and feet. It may be associated with photophobia, diarrhoea and alopecia.

Treatment is with lifelong oral zinc, which seems to override the poor absorption. The response is rapid.

HUMAN IMMUNODEFICIENCY VIRUS AND THE SKIN

HIV infection (p. 171) commonly causes significant dermatological problems and a rash may even be the presenting feature of underlying HIV infection. These rashes can often be clinically atypical and difficult to diagnose, and skin biopsy and skin culture is sometimes required for diagnosis. Many of the skin problems are resistant to standard treatments, but HAART (p. 171) has decreased the prevalence.

Cutaneous infection and opportunistic infection are increased due to HIV-induced immune deficiency. Molluscum contagiosum is particularly common, especially on the face. Lesions are often multiple and of a ‘giant’ size measuring over 1 cm across. Molluscum is rarely seen in immunocompetent adults but can be the presenting feature of HIV. Other viral infections such as extensive ulcerative herpes or widespread viral warts are seen. Bacterial infections (e.g. staphylococcal boils) and fungal infections (e.g. ringworm and Candida) are also common. Recalcitrant and recurrent oropharyngeal candidiasis is a particular problem.

Opportunist infections such as cutaneous cytomegalovirus (pustules or necrotic ulcers), sporotrichosis (linear nodules) or Cryptococcus (red papules, psoriasiform or molluscum-like lesions) can pose diagnostic difficulties, stressing the need for skin biopsy and culture.

Inflammatory dermatoses show an increased incidence with HIV infection, probably due to an immune dysfunction or imbalance. Severe, extensive seborrhoeic eczema is very common and is often a presenting sign of HIV. Ichthyosis (dry scaly skin), nodular prurigo, pruritus and psoriasis are all more common in HIV infection and can be very severe. The treatment of these conditions can be difficult in patients who have low CD4 counts (<200/mm³), as oral immunosuppressive therapies (e.g. prednisolone, ciclosporin) are best avoided. Topical therapies and phototherapy seem relatively safe and oral retinoids are a safe option for psoriasis.

‘Autoimmune dermatoses’ such as bullous pemphigoid, thrombocytopenic purpura and vitiligo seem to be increased in incidence. The aetiology is related to polyclonal stimulation of B lymphocytes by HIV with a resulting abnormal antibody production. Erythrodema is sometimes seen in HIV disease where skin biopsy suggests a ‘graft-versus-host disease’ mechanism. This presumably reflects a severe underlying immune dysfunction of T lymphocyte control.

Adverse drug rashes are much commoner in HIV patients. Reactions to co-trimoxazole, dapsone (used in Pneumocystis prophylaxis) and antiretroviral drugs appear particularly common. Drug rashes may be severe (especially with nevirapine and efavirenz), resulting in erythrodema or toxic epidermal necrolysis. Other unusual rashes include a striking nail/mucosal pigmentation from zidovudine, paronychia from indinavir and facial lipodystrophy mostly from protease inhibitors.

Cutaneous tumours. Benign tumours such as extensive persistent viral warts and melanocytic naevi are more common with HIV infection. Pre-malignant conditions such as the intraepithelial dysplasias (cervix CIN, penis PIN, anal AIN) are all much increased possibly due to persistent HPV infection. The risk of malignant transformation in all these three sites is high and should be screened for.

Kaposi’s sarcoma (p. 1226) is much commoner in men who have sex with men with HIV than other groups. Basal and squamous cell carcinomas are also increased in incidence, presumably reflecting a loss of immune surveillance.

Interestingly, HAART has had little impact on reducing rates of anal, penile or cervical cancer and although Kaposi’s sarcoma seemed to almost disappear early on when CD4 counts rose it now has shown a resurgence recently even in those with high CD4 counts and fully suppressed virus.

‘Specific’ HIV dermatoses

‘Itchy folliculitis’ of HIV

Itchy folliculitis (also called papular pruritic eruption) is common in HIV as CD4 counts decline. Its aetiology is unknown. The previously described staphylococcal folliculitis, eosinophilic folliculitis, pityrosporum folliculitis, and demodex mite folliculitis are probably all part of a spectrum and the term ‘itchy folliculitis’ is useful to encompass these. It presents with intensely itchy papules centred on hair follicles and occurring most commonly over the upper trunk and upper arms (Fig. 24.41). The face is more commonly involved in black patients. Individual lesions frequently have the top scratched off, leaving a crateriform appearance. Treatment with oral minocycline, potent topical steroids and emollients help. Phototherapy or oral isotretinoin is useful in resistant cases.
Dermatoses of pregnancy

There are a number of minor skin changes during pregnancy. There is an increase in spider naevi, melanocytic naevi, skin tags and chloasma. The abdomen shows midline pigmentation (linea nigra) and striae (stretch marks). There are four less common skin problems associated with pregnancy.

Polymorphic eruption of pregnancy (PEP, also called ‘pruritic urticarial papules and plaques of pregnancy’)

This rash tends to appear in the last trimester of a first pregnancy in 1 in 160 cases. It is of unknown aetiology and recurs only rarely in subsequent pregnancies. It presents with very itchy urticated papules and plaques and occasionally small vesicles. Lesions usually start on the abdomen and striae but may spread to the upper arms and thighs. The umbilicus may be spared. PEP is commoner in twin pregnancies. The rash is not associated with any maternal or fetal risk. PEP has recently been shown to be associated with low maternal serum cortisol levels.

Treatment is with reassurance, bland emollients and mild topical steroids. The rash disappears after childbirth.

Prurigo of pregnancy

Prurigo of pregnancy affects 1 in 300 pregnancies. It usually starts on the abdomen in the 3rd trimester but may persist for some months after delivery. Clustered excoriated papules (prurigo-like lesions) occur on the abdomen and extensor surfaces of the limbs. The cause is unknown but pregnancy-related itch (pruritus gravidarum) may be due to cholestasis. Rarely liver biochemical tests are abnormal and urinary HCG levels may be elevated. It can recur in subsequent pregnancies. Some authors believe the condition is associated with an increase in fetal mortality but this remains controversial.

Treatment is with topical steroids and oral antihistamines.

Pruritic folliculitis of pregnancy

This occurs in the 2nd or 3rd trimester of pregnancy and is characterized by an itchy folliculitis which looks similar to steroid-induced ‘acne’. It is not associated with any increased maternal or fetal risk.

Treatment with topical benzoyl peroxide and hydrocortisone cream helps to relieve symptoms.

Pemphigoid gestationis (herpes gestationis)

This is the rarest of the pregnancy-related rashes (1 in 60 000). The immune changes of pregnancy appear to set off bullous pemphigoid. It is characterized by an itchy blistering eruption that starts on the abdomen but may become widespread. Large bullae may be present. Unlike PEP it can occur early, starting in the 2nd or even 1st trimester of pregnancy, and the umbilicus is often involved. It tends to recur in subsequent pregnancies and at an earlier stage. Diagnosis is confirmed by immunofluorescence studies.

A transient bullous eruption occurs in 5% of infants, presumably due to transplacental passage of the offending antibody. There is no increase in fetal mortality but there is an increased incidence of prematurity and low birth weight which is probably due to the autoantibody causing placental insufficiency.

Treatment of mild cases is with potent topical steroids but most cases will require oral corticosteroids. The steroid dose may need to be increased after delivery as there is often a postpartum flare-up of the disease. The rash can be set off again by the oral contraceptive pill and this should be avoided.

Principles of topical therapy

Dermatology is unique in having such direct accessibility to the affected organ. This allows the use of topical treatments which can avoid certain systemic side-effects.

A topical therapy consists of an active ingredient, an appropriate vehicle or base to deliver this, and often a preservative or stabilizer to maintain the product’s shelf-life. A cosmetically acceptable product is necessary and must be accompanied by instructions to the patients about correct usage as without this compliance tends to be poor. Perfumed or scented products should be avoided.

Bases and their uses

- **Creams.** A cream is a semisolid mixture of oil and water held together by an emulsifying agent. They need to have added preservatives such as parabens. They are ‘lighter’ and rub in more easily than ointments. They have a high cosmetic acceptability and are useful for topical treatments of the face and hands. Aqueous cream is particularly useful as a soap substitute.

- **Ointments.** These are semisolid and contain no water, being based usually on oils or greases such as...
Contact allergy to topical preparations is not uncommon and may be suspected by unusually resistant disease or by apparent worsening of a condition after application of a substance. It is more common with creams as it is often the result of allergy to the preservative or emulsifying agent. Allergy can also be due to the active ingredient itself (e.g. neomycin or hydrocortisone).

Folliculitis can occur due to blockage of hair follicles. Creams and ointments should be applied to the skin in the same direction as hair growth to try and prevent this blockage. It is a particular problem with the use of ointments in hot weather (especially if under occlusive bandages) and a lighter cream may be more appropriate at this time.

Safety of topical steroids

Providing that preparations of appropriate strength are used for the body site being treated, these compounds can be used safely on a long-term intermittent basis (p. 1205). If potent steroids are misused, they will cause skin atrophy manifest as striae, wrinkling, fragility and telangiectasia.

Problems with topical therapies

- **Systemic absorption** may occur but only if very large areas of inflamed skin are treated topically and especially if the treatment is occluded with bandages or polyurethane films. Neonates are particularly susceptible to this owing to the relative increase in body surface area to volume.
